Statistics indicate that approximately two thirds of the male partners of adolescent mothers are not teens themselves but are 20 years of age or older. In particular, teens in poorer, recently immigrant populations have considerably older partners (Males, 2004).

Adolescent males tend to become sexually active at an earlier age than females, and they have more sexual partners in their teenage years. When the father is an adolescent, he, too, generally has not yet completed the developmental tasks of his age group and is no better prepared psychologically to deal with the consequences of pregnancy than the adolescent mother. Research also suggests that, when compared to sons of older fathers, sons of adolescent fathers are at greater risk of becoming adolescent fathers themselves, creating an intergenerational cycle of adolescent fathering (Sipsma, Biello, Cole-Lewis, et al., 2010).

The adolescent who attempts to assume his responsibility as a father faces many of the same psychologic and sociologic risks as the adolescent mother. The mother and father are generally from similar socioeconomic backgrounds and have similar educational levels.

Although not married, many adolescent couples are involved in meaningful relationships. Adolescent fathers may be very involved in the pregnancy and may be present for the birth. Although relationships among fathers, teenage mothers, and their infants appear prone to deterioration over time, research suggests that many young fathers genuinely want to be involved with their children and would have more contact and input if they could. Issues such as conflicts with the teen mother or maternal grandparents and a lack of financial resources may act as additional barriers for the young father.

The lack of responsibility shown by some unwed fathers has caused a shift in cultural and community attitudes. Fathers are being included on birth certificates far more frequently today than in the past. This helps ensure the father's rights and encourages him to meet his responsibilities to his child. In addition, legal paternity gives children access to military and social security benefits and to medical information about their fathers.

In some situations, the pregnant adolescent may not want to identify or contact the father of the baby, and the father may not readily acknowledge paternity. Those situations include rape, exploitative sexual relations, incest, and casual sexual relations. If healthcare providers suspect any of the first three causes, further investigation into the situation is important for the well-being of the pregnant adolescent, and referral to other resources should be made as appropriate.

In situations in which the adolescent father wants to assume some responsibility, healthcare providers should support him in his decision. It is important, however, that the pregnant adolescent have the opportunity to decide whether she wants the father to participate in her health care.

If the adolescents perceive that they have a caring relationship, the adolescent father may want to be supportive and protective but probably does not understand the physical and psychologic changes that his partner is experiencing. The young man will need education regarding pregnancy, childbirth, child care, and parenting. Mentoring programs can be useful tools in helping teen fathers who do not have good role models to understand the role of a father and support their children.

Even if the adolescent father has been included in the health care of the young woman throughout the pregnancy, it is not unusual for her to want her mother as her primary support person during labor and birth. This is especially true with younger adolescents. It is important both to support her wishes and also to acknowledge and support the adolescent father's wishes as appropriate.

As a part of counseling, the nurse should assess the young man's stressors, his support systems, his plans for involvement in the pregnancy and childbearing, and his future plans. He should be referred to social services for an opportunity to be counseled regarding his educational and vocational future. When the father is involved in the pregnancy, the young mother feels less deserted, more confident in her decision making, and better able to discuss her future.

Reactions of Family and Social Supports to Adolescent Pregnancy

The reactions of family members and social supports to adolescent pregnancy are as varied as the motivation and cause of the pregnancy. In families who foster educational and career goals for their children, adolescent pregnancy is often a shock. Anger, shame, and sorrow are common reactions. The majority of pregnant adolescents from these families are most likely to use contraception or choose abortion, with the exception of those teens whose cultural and religious beliefs prevent them from seeking an abortion.

Some adolescent fathers also face negative reactions from people, including their own families and the families of their young partners. They may experience others' anger, shame, and disappointment. Their relationships with their peers may be altered as well.

In populations in which adolescent pregnancy is more prevalent and more socially acceptable, family and friends may be more supportive of the adolescent parents. In many cases, friends as well as the teen's mother are present at the birth. The expectant couple may also have friends who are already teen parents. For some male partners of these adolescent mothers, pregnancy and the birth of a baby are seen as a sign of adult status and increased sexual prowess—a sense of pride.

The mother of the pregnant adolescent is usually among the first to be told about the pregnancy. She typically becomes involved with decision making, especially with the younger adolescent, about issues such as maintaining the pregnancy, abortion, and dealing with the father-to-be and his family. As

discussed previously, the pregnant adolescent may not want to identify or contact the father of the baby, especially in situations where rape or other exploitative sex was involved, or with casual sexual relationships. Family input in these matters is important in the adolescent's decision making.

Once the decision about the pregnancy has been made, it is usually the mother who helps the teen access health care and accompanies her to her first visit. If the pregnancy is maintained, the mother may participate in prenatal care classes and can be an excellent support system for her daughter. She should be encouraged to participate if the mother-daughter relationship is positive. If the baby's father is involved in the pregnancy, he and the pregnant teen's mother may be able to work together to support the teenage mother. The nurse can update the pregnant teen's mother on childbearing practices to clarify any misconceptions she might have. During labor and birth, the mother may be a key figure for her daughter, offering reassurance and instilling confidence in the teen.

The younger the adolescent when she gives birth, the more she needs her mother's support. Children of adolescent parents experience more negative outcomes, including more aggressive behavior at a young age, when the adolescent is in constant conflict with her mother and becomes less involved in parenting.

> "Miranda left for college back East in September. She was just 18 and I thought she had the world in front of her. At Thanksgiving she came home to tell us she was 4 months pregnant and planned to keep the baby even though she and Tony had broken up and he wanted no part of fatherhood. She finished the semester, then moved back home and transferred to a state college near us. Tina was born 2 days after her mom finished the spring semester. Now Miranda's life is a juggling act—part-time job, part-time school, full-time mom. We help all we can. I am so sorry that my child has lost out on so much but I am proud of the woman she has become."

NURSING CARE MANAGEMENT

In working with adolescents, the nurse should remember that oftentimes the nurse is the first contact with the healthcare system that the adolescent has. Adolescents think differently than adults. Adolescents, especially younger adolescents, tend to be more concrete thinkers and may not plan ahead for more than a few days. As a result, nurses need to recognize that missed appointments are not unusual. Missed appointments may also be caused by other factors such as a lack of transportation, especially for those teens not old enough to drive. Teens may avoid health care because they are underinsured, uninsured, or lack the funds to pay for care. Many adolescents have never before accessed health care without a parent. They may fear that using their healthcare insurance for reproductive health visits will be discovered by their parents. If they are unable to share their concerns with a parent, they must be highly motivated to seek health care independently for purposes of contraception, treatment of sexually transmitted infections (STIs), diagnosis of pregnancy, or prenatal care.

Nursing Assessment and Diagnosis

The nurse begins her care of the pregnant adolescent by establishing a database to plan interventions for the adolescent mother and family. Areas of assessment include history of family health and personal physical health, developmental level and impact of pregnancy, and emotional and financial support. The nurse also assesses the family and social support network and the father's degree of involvement in the pregnancy. It is important for the nurse to demonstrate a sincere sense of caring for the young woman and the outcome of her pregnancy during early prenatal visits. Pregnant adolescents are different from other groups of pregnant women in their physical and psychologic response. Professionals need to equip themselves with awareness, knowledge, and skills to meet the needs of the pregnant teen (Tilghman, 2008). Listening more and talking less may be the best tool the nurse can use to develop an effective relationship with the pregnant adolescent.

As with all pregnant women, it is important to have information on the teen's general physical health. This may be the first time many adolescents have ever provided a health history. The nurse may find it helpful to ask very specific questions and give examples if the young woman appears confused about a question. The nurse may find that the teen's mother is best able to answer questions about family history because the adolescent is often unaware of this information.

The following areas should be assessed:

- Family and personal health history
- Medical history
- Menstrual history
- Obstetric and gynecologic history
- Substance abuse history

It is important to assess the maturational level of each individual. The adolescent's development level and the impact of pregnancy are reflected in the degree to which the teen recognizes the realities and responsibilities involved in pregnancy and parenting. The mother's self-concept (including body image), her relationship with the significant adults in her life, her attitude toward her pregnancy, and her coping methods in the situation are just a few of the significant factors that need to be assessed. It is important for the nurse to ask specifically about dating violence. Teens are not likely to reveal dating violence unless they are asked about it.

Adolescent lifestyles and support systems vary greatly. It is imperative that the interdisciplinary health team have information about the expectant adolescents' feelings and perceptions about themselves, their sexuality, and the coming baby; their knowledge of, attitude toward, and anticipated ability to care for and support the infant; their maturational level and needs; and the family, social, and financial support available to them.

The nursing diagnoses that are applicable to any pregnant woman apply to the pregnant adolescent. Other nursing diagnoses are influenced by the adolescent's age, support systems, socioeconomic situation, health, and maturity. Examples of

nursing diagnoses more specific to the pregnant adolescent may include the following:

- ***Imbalanced Nutrition: Less than Body Requirements*** related to poor eating habits
- ***Risk for Situational Low Self-Esteem*** related to unanticipated pregnancy

Nursing Plan and Implementation

Early, thorough prenatal care is the strongest and most critical determinant for reducing risk for the adolescent mother and her newborn. When an adolescent presents for health care, her needs must be met and she must be treated as an individual who can make decisions about her own health care. The pregnant adolescent may perceive the nurse who attempts to exert control over her health care as threatening to her independence and will terminate communication. The nurse needs to be vigilant to laying aside personal biases and assumptions when caring for the pregnant teen (King-Jones, 2008).

Community-Based Nursing Care

Many new and innovative community-based agencies have evolved to provide care for high-risk patients throughout the childbearing experience and beyond. Nurses in all community-based agencies can help adolescents access the healthcare system as well as social services and other support services (i.e., food banks and the Special Supplemental Food Program for Women, Infants, and Children [WIC]). Best practice research shows that teaching adolescents in groups according to their ages may be more effective for learning, because younger adolescent mothers may lack parenting skills and have different emotional needs than older adolescent mothers. Soliciting ideas from the teens themselves and identifying their values may also contribute to better education and success of programs for pregnant teens (Broussard & Broussard, 2009). In addition, many teens prefer teaching aids that are visual and that they can handle, such as realistic fetal models. Pregnant teens with low reading levels tend to prefer handouts and posters that have visual interest, short sentences, bulleted lists, and white space (Broussard & Broussard, 2010).

PROFESSIONALISM IN PRACTICE

Avoiding Stereotypical Assumptions

Nurses occasionally make comments regarding the age and immaturity of adolescent mothers, questioning their readiness to become parents. King-Jones (2008) emphasized that nurses need to provide individualized care that is free from "stereotypical assumptions" (p. 117), which stigmatize adolescent mothers. Discussions about patients with other nurses to brainstorm and problem solve in order to improve care are appropriate, but discussions without the patient's best interest in mind are inappropriate in the professional setting. Nurses should serve as role models if they find themselves in this situation. Comments such as "I wonder what we could do to help increase her confidence with her baby?" or "Perhaps she would benefit from talking about her concerns" may help to steer nonproductive conversations in a professional direction.

Nurses working with pregnant adolescents are also involved extensively in counseling and patient teaching. During their interactions, several challenges typically arise, including safeguarding the patient's confidentiality, winning her trust, and helping to build her sense of self-esteem. These and other challenges of adolescent prenatal care are discussed here.

Issues of Confidentiality and Consent to Care

Most states in the United States have passed legislation that confirms the right of some minors to assume the rights of adults. These adolescents are referred to as **emancipated minors**. An adolescent may be considered emancipated if he or she is self-supporting and living away from home, married, pregnant, a parent, or in the military. Even if a minor has not become formally emancipated, all 50 states have passed legislation that enables teens to consent to care without a parent's knowledge for certain "medically emancipated" conditions. These conditions vary from state to state. For example, all 50 states permit minors to consent to STI services but just over half (26) of the states explicitly permit minors (12 and older) to consent to contraception without a parent's knowledge or consent. Currently 32 states allow minors to consent to prenatal care; 4 states specify that "mature" minors can consent; 13 states have no relevant law or policy. All states either explicitly allow minors to give consent for their children's medical care or have no explicit policy about it (AGI, 2010b).

PROFESSIONALISM IN PRACTICE

Emancipated Minors

It is important to remember that if a pregnant minor is considered emancipated, she has the right and responsibility to consent to health care for herself and later for her child. She is entitled to respect and confidentiality in her dealings with healthcare providers. Only with her consent can other adults, including her parents, be included in communication.

Development of a Trusting Relationship with the Pregnant Adolescent

The first visit to the clinic or office may cause anxiety for the young woman. She may be nervous not only because of her situation, but also because this may be her first exposure to the healthcare system since early childhood. Making this experience as positive as possible for the young woman will encourage a favorable attitude toward health care and increase the likelihood that she will return for follow-up visits, whether she chooses to terminate or maintain the pregnancy.

Depending on how young the adolescent is, this may be her first pelvic examination, an anxiety-provoking experience for any woman. The nurse can help provide a thorough explanation of the procedure. A gentle and thoughtful examination technique will help the young woman to relax.

CLINICAL TIP

During the initial pelvic examination, with the consent of the examiner, offer the teen the opportunity to visualize her external genitalia and cervix with a handheld mirror. A mirror is helpful in enabling the young woman to see her cervix, thus educating her about her anatomy. It also gives her an active role in the exam if she so desires.

Developing a trusting relationship with the pregnant adolescent is essential. Honesty and respect for the individual and a caring attitude promote self-esteem. As the nurse develops a trusting relationship with the young woman, the nurse's attitudes about self-care and responsibility affect the adolescent's maturation process. Building a partnership with the adolescent, respecting her unique situation, and appreciating her values will assist the young mother to care for herself and her baby (Broussard & Broussard, 2009).

Promotion of Self-Esteem and Problem-Solving Skills

The nurse assists the adolescent in her decision-making and problem-solving skills so that she can proceed with her developmental tasks and begin to assume responsibility for her own as well as her newborn's life. An overview of what the young woman will experience over the prenatal course, along with thorough explanations and rationale for each procedure as it occurs, will foster the adolescent's understanding and give her some measure of control. Actively involving the young woman in her care gives her a sense of participation and responsibility (Figure 17-2 ■).

Adolescents tend to be egocentric, and even if they realize that their health-related behaviors affect their fetus, they might not feel that this is important. In light of this fact, it is often more helpful to emphasize the effects of these practices on the patient *herself.* Because of their immature cognitive development, they also need help in problem solving, in visualizing themselves in the future, and in imagining what the consequences of their actions might be.

Promotion of Physical Well-Being

Baseline weight and blood pressure measurements will be valuable in assessing weight gain and predisposition to preeclampsia-eclampsia. The adolescent may be encouraged to take part in her care by measuring and recording her weight. The nurse may use this time as an opportunity for assisting the young woman in problem solving: "Have I gained too much or too little weight?" "What influence does my diet have on my weight?" "How can I change my eating habits?"

Figure 17-2 ■ The nurse gives a young mother an opportunity to listen to her baby's heartbeat.

Source: Photographer, Elena Dorfman.

The nurse can also introduce the subject of nutrition during measurement of baseline and subsequent hemoglobin and hematocrit values. Because the adolescent is at risk for anemia, she will need education regarding the importance of iron in her diet. Indeed, basic education about nutrition is a critical component of care for pregnant teens.

Preeclampsia-eclampsia is one of the most common, serious complications of pregnancy in general. It also represents the most prevalent medical complication of pregnant adolescents. Preeclampsia-eclampsia is typically characterized by high blood pressure, proteinuria, and edema. In adult women, a blood pressure reading of 140/90 mmHg is often used as evidence of hypertension. However, it is sometimes difficult to recognize hypertension in adolescent females. Women ages 14 to 20 years without evidence of high blood pressure usually have diastolic readings between 50 and 66 mmHg. Gradual increases from the prepregnant diastolic readings, along with excessive weight gain, proteinuria, and sudden edema, must be evaluated as precursors to preeclampsia. Blood pressure readings of 140/90 mmHg are not acceptable as the determinant of preeclampsia in teens. This is one reason why early prenatal care is vital to the effective management of the adolescent.

Adolescents have an increased incidence of STIs. The initial prenatal examination should include gonococcal and chlamydial cultures and wet prep for *Candida, Trichomonas,* and *Gardnerella.* Tests for syphilis should also be done. Education about STIs is important, as is careful observation for herpetic lesions or other symptoms throughout the young woman's pregnancy. Although today's teens are knowledgeable about AIDS, they know much less about other STIs, especially with regard to symptoms and risk reduction. If the adolescent's history indicates that she is at increased risk for HIV, she should be given information about it and offered HIV screening.

The nurse should also discuss substance abuse with adolescents. It is important to review the risks associated with the use of tobacco, caffeine, drugs, and alcohol. The young woman should be aware of the effects of these substances on her development as well as on the development of the fetus.

Ongoing care includes the same assessments that the older woman receives. Special attention should be paid to evaluating fetal growth by determining when quickening occurs and by measuring fundal height, fetal heart tones, and fetal movement. Comparing the dates of auscultating fetal heart tones with the date of the last menstrual period and quickening can be helpful in determining correct estimates of time of birth. If, when measuring fundal height, there is a question of size-date discrepancy by 2 cm either way, an ultrasound is warranted to establish fetal age so that instances of intrauterine growth restriction (IUGR) may be diagnosed and treated early. To ensure the most accurate dating possible, an ultrasound is also warranted early in pregnancy if the date of the last menstrual period is not known.

Promotion of Family Adaptation

The nurse assesses the family situation during the first prenatal visit and ascertains the level of involvement the adolescent desires from each of her family members and the father of the child as well as her perception of their present support. A sen-

sitive approach to daughter-mother relationships helps motivate their communication. If the mother and daughter agree, the mother should be included in the patient's care. Pregnancy may change a teen's relationship with her mother from one of antagonism to one of understanding and empathy. The opportunity to renew or establish a positive relationship with their mothers is welcomed by most teens. It symbolizes approval, acceptance, and support from the individual who would serve as her role model for mothering.

The nurse should also help the mother assess her daughter's needs and assist her in meeting them. Some adolescents become more dependent during pregnancy, and some become more independent. The mother can ease and encourage her daughter's self-growth by understanding how best to respond and support the adolescent.

Finally, the father of the adolescent's infant can be included to promote the family's successful adaptation to the pregnancy. He may be asked to attend prenatal visits, classes, and health teaching and to be present at the birth itself and involved to the extent that he wishes and that is acceptable to the teenage mother. He should also have the opportunity to express his feelings and concerns and to have his questions answered.

Facilitation of Prenatal Education

Some school systems are currently attempting to meet prenatal education needs in a variety of ways. The most effective method appears to be mainstreaming the pregnant adolescent in academic classes with her peers and adding classes appropriate to her needs during pregnancy and initial parenting experiences. Classes about growth and development, beginning with the newborn and early infancy, can help teenage parents have more realistic expectations of their infants and may help decrease child abuse. Mainstreaming pregnant adolescents in school is also an ideal way to help them complete their education while learning the skills they need to cope with childbearing and parenting. Vocational guidance in this setting is also most beneficial to their future. Some schools provide infant and toddler child care facilities on their premises, which may allow the mother to continue her education without the added difficulty of finding appropriate child care.

As stated previously, early adolescents especially tend to be oriented to the present and to be concrete thinkers. As a result, teaching needs to be simple, direct, and responsive to their more immediate needs. Teens also responded positively when there were more hands-on experiences during childbirth preparation classes with less lecture and more one-on-one interaction (Broussard & Broussard, 2009).

For example, teaching about preparation for birth is most effective in the last weeks of pregnancy when this topic is of greater concern and teens are more motivated to practice breathing and relaxation techniques for labor. Although some childbirth educators believe that older couples can be role models for pregnant adolescents, most believe that prenatal classes with other teens are generally preferable even though these classes can be challenging to teach (Figure 17-3 ■). Attendance may be sporadic. The pregnant teen may be accompanied by her mother, her boyfriend, or her girlfriends. Those who bring girlfriends may bring a different one each time. In such cases, giggling and side conversations may occur. Such activity reflects the short attention span of the teen and is fairly typical. Thus, to keep the attention of the participants, it is important to use a variety of teaching strategies, including age-appropriate audiovisual aids, demonstrations, and games.

Figure 17-3 ■ Young adolescents may benefit from prenatal classes designed specifically for them.

Source: Jerry Thomas Photography.

Goals for prenatal classes may include some or all of the following:

- Providing anticipatory guidance about pregnancy.
- Preparing the participants for labor and birth.
- Helping participants identify the problems and conflicts of teenage pregnancy and parenting.
- Increasing self-esteem.
- Providing information about available community resources.
- Helping participants develop more adaptive coping skills.

During prenatal classes, nurses can also share information on breastfeeding, which has significant health benefits for both the adolescent mother and her infant. Adolescents often do not choose a feeding method until later in pregnancy, so early education can help ensure success for the adolescent who chooses to breastfeed her infant. As many infants of adolescents are born prematurely, it is important for the young mother to know that breast milk is the optimal nutrition for premature infants.

Topics on parenting, although sometimes included in prenatal classes for adolescents, tend to be less effective, again because adolescents tend to be oriented to the present. Parenting skills are crucial, but adolescents generally are not ready to learn about these skills until birth makes the newborn a reality.

Hospital-Based Nursing Care

The adolescent in labor has the same care needs as any pregnant woman. However, the importance of a sustained presence for her cannot be overemphasized. Adolescents want their care provider to be respectful, caring, and supportive. The nurse must be readily available and should answer questions simply and honestly, using lay terminology. Adolescents need their caregiver to provide education to guide their choices. The nurse can also help the

Case Study: Late Detection of Adolescent Pregnancy

Care Plan Activity: Adolescent's Response to Pregnancy

adolescent's support people understand their roles in assisting the teen. If the father is involved, the nurse can encourage him to work within his own level of comfort to play an active role in all phases of the birth process, perhaps by feeding ice chips to the mother, timing her contractions, and coaching her with her breathing. The nurse can also let the couple know that holding hands, backrubs, and supportive touching are acceptable and therapeutic. Chapter 24 ∞ provides further information on care of the adolescent during labor and birth.

During the postpartum period, most teens do not foresee that they will become sexually active in the near future and are often adamant about the fact that they will not become pregnant again for an extended period. However, the statistics demonstrate a different reality. Thus, contraception remains a critical part of the national effort to decrease adolescent pregnancy. Before discharge, it is important for the nurse to provide information about the resumption of ovulation and the importance of contraception. It is especially helpful to do this teaching with the sexual partner present.

Several safe and effective contraceptive options are available for adolescents. Condoms are by far the most common method of contraception among teens and, when used consistently and correctly, they offer the added advantage of protection against STIs. Healthcare providers often recommend a dual approach to prevent pregnancy and STIs—a condom combined with a second method of contraception, typically a hormonal method such as a combined oral contraceptive (Hillard, 2005). The American College of Obstetricians and Gynecologists (ACOG) (2007) supports the use of intrauterine devices (IUDs) as a safe, first-line contraceptive choice for adolescents, stating that the IUD does not increase the adolescent's risk of pelvic inflammatory disease (PID) or affect her fertility. The benefits and convenience of long-acting oral contraceptives also make them an appropriate choice for sexually active adolescents. In general, all methods used for healthy adults are potentially appropriate for adolescents providing they make educated decisions and understand what the use of various contraceptive methods entails.

Areas to discuss with the adolescent include the nature of her sexual relationship with her partner, the behaviors in which they are engaged, their ability to comply with the use of certain contraceptive devices, the costs of various methods, the teen's religious beliefs, and her partner's potential cooperation (Bearinger, Sieving, Ferguson, et al., 2007). As part of discharge planning, the nurse should ensure that the teen is aware of community resources available to assist her and her family. Postpartum classes and new-mother support groups, especially with peers, can be extremely beneficial. Such classes address a variety of topics, including postpartum adaptation, infant and child development, and parenting skills.

CLINICAL JUDGMENT

Case Study: Rachel Kalaras

Rachel Kalaras is an 18-year-old G1PO who is 16 weeks pregnant when she arrives for her prenatal visit. When discussing her plans for the pregnancy, Rachel indicates that she is considering adoption. She has not discussed this plan with anyone but is seeking information about the process of relinquishment.

Critical Thinking

What should you consider in discussing this issue with Rachel?
See www.nursing.pearsonhighered.com for possible responses.

Evaluation

Expected outcomes of nursing care include the following:

- A trusting relationship is established with the pregnant adolescent.
- The adolescent is able to use her problem-solving abilities to make appropriate choices.
- The adolescent follows the recommendations of the healthcare team and receives effective health care throughout her pregnancy, the birth, and the postpartum period.
- The adolescent, her partner (if he is involved), and their families are able to cope successfully with the effects of the pregnancy.
- The adolescent is able to discuss pregnancy, prenatal care, and childbirth.
- The adolescent demonstrates developmental and pregnancy progression within established normal parameters.
- The adolescent develops skill in child care and parenting.

Prevention of Adolescent Pregnancy

At the individual level, balanced, realistic sexuality education, which includes information on both abstinence and contraception, can delay teens' onset of sexual activity, increase the use of contraception by sexually active teens, and reduce the number of their sexual partners. The American Academy of Pediatrics (2007) has issued a policy statement on contraception and adolescents that addresses the role of healthcare providers in working with adolescents. The statement stresses the importance of encouraging abstinence while also providing counseling on risk-reduction approaches including the use of latex condoms for every act of sexual intercourse. It also emphasizes the need to ensure ready access to contraceptive services and appropriate follow-up.

Key strategies for prevention of unintended teen pregnancy and sexual health promotion that have been suggested include the provision of services that ensure accessible and high-quality reproductive health care; sex education programs that provide developmentally appropriate, evidence-based curricula; and youth development strategies to enhance life skills, connection to supportive adults, and educational and economic opportunities (Bearinger et al., 2007).

At the national level, the National Campaign to Prevent Teen and Unplanned Pregnancy (NCPTUP), a private, nonprofit organization made up of a broad spectrum of religious, political, social, human services, health, and academic organizations, is working to reduce teenage pregnancy by one third between 2006 and 2015 (NCPTUP, 2010). The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) is one of the many professional organizations that joined this group and made a commitment to focus on adolescent pregnancy prevention. Not surprisingly, the task forces have found

National Campaign to Prevent Teen Pregnancy

that adolescent pregnancy is a multifaceted problem with no easy answers. The best approach is local and is based on strong, community-wide involvement with a variety of programs directed at the multiple causes of the problem.

One of the major problems in local communities continues to be intense conflict among different groups about how to approach adolescent pregnancy prevention. Some parents and communities advocate abstinence-only programs, and, until recently, abstinence-only programs were funded by the government. Critics argue that these curricula are ineffective and insulting and tell teens what to think, not how to think for themselves (Taverner, 2007). Other parents advocate an "abstinence-plus" approach that stresses abstinence as the best approach but includes information on condoms and contraception for those teens who do not abstain.

Most Americans support providing education in junior and senior high schools with information about protection against unplanned pregnancy and sexually transmitted infections (STIs). Youth development programs that focus on meeting the needs of adolescents by building on young people's capacities, assisting them to cultivate their own talent and to increase their feelings of self-worth, ease their transition into adulthood and can reduce sexual risk behaviors and unintended teen pregnancy (Advocates for Youth, 2008).

The National Campaign's task forces have identified characteristics shared by all successful programs, regardless of the type of offering or community. Effective adolescent pregnancy prevention programs are long term and intensive. They also involve adolescents in program planning, include good role models from the same cultural and racial backgrounds, and focus on the adolescent male (Kirby, 2007). See Research Evidence in Practice for additional information on effective programs.

The National Campaign has identified a list of recommendations for parents that are designed to help teens avoid pregnancy. Nurses can use this information in working with parents (NCPTUP, 2008):

1. Parents should be clear about their own sexual attitudes and values in order to communicate clearly with children.
2. Parents need to talk with their children about sex early and often and be specific in the discussions.
3. Parents should supervise and monitor their children and teens with well-established rules, expectations, curfews, and standards of behavior.

CLINICAL QUESTION

What interventions are effective in preventing unintended pregnancy during the adolescent years?

RESEARCH EVIDENCE

Early childbearing carries significant health risks for both the teen mother and the baby. In addition, adolescents with unintended pregnancies face a number of challenges such as abandonment by their partners, peer social isolation, and an inability to complete their education, which has lifelong employment and economic consequences.

A review sponsored by the Cochrane Collaborative, one of the most rigorous sources of evidence reviews, appraised the results of more than 40 randomized controlled trials with more than 95,000 adolescent subjects. Some of the studies (11) were pooled into a meta-analysis that used statistical analysis to determine the clinical importance of the effects of treatments.

Interventions that are multifaceted have the strongest evidence for effectiveness. Specifically, a combination of educational and contraceptive interventions appears to reduce unintended pregnancy among adolescents. The education that was most effective did not focus solely on sexual factors, but rather included skills training and personal development as well. The most successful programs engaged stakeholders, including pregnant teens, parents, healthcare providers, schools, and churches, to design and implement programs that are practical, evidence based, and culturally appropriate. Involving teens in program design resulted in education that was more readily accepted by the target population.

Educational interventions were most effective when coupled with the promotion of the effective use of contraception. There was little evidence to show that either of these interventions alone was as effective as the integration of both education and contraception in preventing pregnancy.

WHAT QUESTIONS REMAIN UNANSWERED?

While these interventions have demonstrated effectiveness in reducing pregnancy, effects on other aspects of teen sexuality—timing of initial sexual intercourse, use of birth control, and sexually transmitted infections—was not conclusive. More research is needed to determine if there are successful interventions to prevent these additional adolescent risk behaviors.

WHAT IS BEST PRACTICE?

Multifaceted programs that educate teens about sexuality and personal skills development, coupled with promotion of appropriate contraceptive use, are most effective in preventing unintended pregnancies in adolescents.

CRITICAL THINKING

How can the nurse participate effectively in the design and development of effective pregnancy prevention programs for adolescents? How can the nurse apply these principles to the individual care and counseling of teens in preventing pregnancy?

4. Parents should know their children's friends and their families.
5. Parents need to clearly discourage early dating as well as frequent and steady dating.
6. Parents should take a strong stand against allowing a daughter to date a much older boy; similarly they should not allow a son to develop an intense relationship with a much younger girl.
7. Parents need to help children set goals for their future and have options that are more attractive than early pregnancy and childrearing.
8. Parents should show their children that they value education and take school performance seriously.
9. Parents need to monitor what their children are reading, listening to, and watching.
10. It is especially important that parents build a strong, loving relationship with their children from an early age by showing affection clearly and regularly, spending time with them doing age-appropriate activities, building children's self-esteem, and have meals together as a family often.

In summary, although it is sometimes difficult for adults, it is important to address topics related to healthy relationships, abstinence, birth control, responsible sexual behavior, and the possible consequences of unsafe practices honestly and in a way that reflects adolescents' knowledge level, perspectives, and personal experience. Discussion about teenage pregnancy needs to reflect an awareness of teens' priorities related to the costs and rewards of having a baby. All such discussions need to be honest, frank, and open and based on recognition of the developmental level of the teen (Herman, 2008).

FOCUS YOUR STUDY

- Birth rates for teens ages 15 to 19 have decreased from 61.8 per 1000 females in 1991 to 41.5 in 2008. Although this is a significant improvement, the U.S. teenage pregnancy rate is the highest of any industrialized nation.
- Many factors contribute to the high teenage pregnancy rate, including earlier age of first sexual intercourse, lack of knowledge about conception, lack of easy access to contraception, lessened stigma associated with adolescent pregnancy in some populations, poverty, early school failure, and early childhood sexual abuse.
- The major psychologic risk the pregnant adolescent faces is the interruption of her own developmental tasks.
- Physical risks of adolescent pregnancies include preterm births, low-birth-weight infants, cephalopelvic disproportion, iron deficiency anemia, and preeclampsia and its sequelae.
- Almost half of the fathers of infants of adolescent mothers are age 20 or older, but they are often similar to adolescent fathers psychosocially and are no more likely to be able to support the mother.
- Factors affecting an adolescent's response to pregnancy include her degree of achievement of the developmental tasks of adolescence (which can be closely associated with age) as well as cultural, religious, and socioeconomic factors.
- Nurses working with pregnant adolescents face many challenges, including safeguarding the patient's confidentiality, winning her trust, and helping to build her sense of self-esteem.
- Often the adolescent has little understanding of pregnancy, childbirth, or parenting. Consequently, education is a primary responsibility of the nurse.
- Adolescent pregnancy prevention programs should be multifaceted, target males as well as females, and involve community-wide approaches.

CRITICAL THINKING IN ACTION

Source: George Dodson/Pearson Education.

Sixteen-year-old Linda Perez and her mother present to you at the OB clinic for Linda's first prenatal visit. You determine that Linda is 20 weeks pregnant. Her weight is 135 lb, height 5′4″, T 98°F, P 80, R 14, BP 100/64. You assess that Linda's mother has type 2 diabetes, and that her siblings are healthy. Linda admits to having one sexual partner and says she has never been hospitalized. Her immunizations are up to date and she's never used tobacco or recreational drugs. To date, the father of the baby is not involved. Mrs. Perez is clearly upset that Linda's pregnancy is so far advanced without her knowledge. Linda is quiet and speaks only when questioned directly. You do your best to try to establish a trusting relationship with Linda and her mother by providing an atmosphere where issues can be discussed.

1. What psychologic factors contribute to teenage pregnancy?
2. Explore reasons why teenagers delay prenatal care.
3. Linda's mother asks you what factors facilitate adolescent pregnancies.
4. You assess that Linda has some anxiety concerning the birth process. She states she is not interested in prenatal classes because she is single and does not want to have natural childbirth. Your best response would be:

CHAPTER 18

Maternal Nutrition

I'm trying to be very careful about what I eat. I've had more salads and fresh fruit than I can remember. Sometimes, though, I get a "cookie attack" and indulge myself. My husband says I should eat oatmeal cookies so I could feel that my cravings were nutritionally sound!

LEARNING OUTCOMES

1. Identify the role of specific nutrients in the diet of the pregnant woman.
2. Compare nutritional needs during pregnancy, postpartum, and lactation with nonpregnant requirements.
3. Discuss effects of maternal nutrition on fetal outcomes.
4. Evaluate adequacy and pattern of weight gain during different stages of pregnancy.
5. Plan adequate prenatal vegetarian diets based on nutritional requirements of pregnancy.
6. Describe ways in which various physical, psychosocial, and cultural factors can affect nutritional intake and status.
7. Compare recommendations for weight gain and nutrient intakes in the pregnant adolescent with those for the mature pregnant adult.
8. Describe basic factors a nurse should consider when offering nutritional counseling to a pregnant adolescent.
9. Compare nutritional counseling issues for breastfeeding and formula-feeding mothers.
10. Formulate a nutritional care plan for pregnant women based on a diagnosis of nutritional problems.

Lactovegetarians *405*
Pica *408*
Recommended dietary allowance (RDA) *395*
Vegans *405*

A woman's nutritional status before and during pregnancy can significantly influence her own health and that of her unborn child. In most prenatal clinics and offices, nurses provide nutritional counseling directly or work closely with dietitians in providing any necessary nutritional assessment and teaching.

This chapter focuses on the nutritional needs of a normal pregnant woman. Special sections consider the nutritional needs of the pregnant adolescent and the woman after birth.

Many factors influence a woman's ability to achieve good prenatal nutrition, including the following:

- ***General nutritional status before pregnancy.*** Good prenatal nutrition is the result of proper eating throughout life, not just during pregnancy, although pregnancy may motivate a woman to improve poor eating habits. Nutritional deficits at conception and during the early prenatal period may influence the outcome of the pregnancy.
- ***Maternal age.*** An expectant adolescent must meet the nutritional needs for her own growth in addition to the nutritional needs of pregnancy.
- ***Maternal parity.*** A mother's nutritional needs and the outcome of her pregnancy are influenced by the number of pregnancies she has had and by the intervals between them.

A mother's nutritional status does affect her fetus. Factors influencing fetal well-being are interrelated, but nutrient deficiencies alone can produce measurable effects on cell and organ growth of the developing fetus. Fetal growth occurs in three overlapping stages: (1) growth by increase in cell number, (2) growth by increase in cell number and cell size, and (3) growth by increase in cell size alone. The nutritional problems that interfere with cell division may have permanent consequences. If the nutritional insult occurs when cells are mainly enlarging, the changes are usually reversible when normal nutrition resumes.

Growth of fetal and maternal tissues requires increased quantities of nutrients. These are listed in the **dietary reference intakes (DRIs)** as specific allowances for pregnant and lactating women (Table 18-1). The DRIs distinguish between pregnant women and pregnant adolescents because of the greater nutrient needs of the adolescent. The DRIs are subdivided into the **recommended dietary allowance (RDA)** and **adequate intake (AI)**. An RDA is the daily dietary intake that is considered sufficient to meet the nutritional requirements of nearly all individuals in a specific life stage and gender group. An AI is a value cited for a nutrient when the data are not sufficient to calculate an estimated average requirement.

Maternal Weight

Prepregnancy Weight

Prepregnancy weight is an important factor for both mothers and their babies. Women who are underweight before pregnancy, especially younger adolescents, have a higher risk of giving birth to a low-birth-weight infant than women who begin pregnancy at normal weight for height. Obesity during pregnancy is associated with many complications, including gestational diabetes, gestational hypertension, preeclampsia, birth defects, cesarean birth, fetal macrosomia, perinatal deaths, and postpartum anemia (Waller et al., 2007). Babies of obese women may be at a higher risk of becoming obese themselves as they age.

Maternal Weight Gain

Maternal weight gain is an important factor in fetal growth and in infant birth weight. An adequate weight gain over time indicates an adequate caloric intake. It does not, however, ensure that the woman has a sufficient nutrient intake. The diet may not be of high enough nutritional quality even though its caloric content supports the recommended weight gain. The pregnant woman must maintain the nutritional quality of her diet as her weight gain progresses.

Weight gain, even in women with a healthy pregnancy outcome, tends to be quite variable. Optimal weight gain depends on the woman's weight for height (body mass index [BMI]) and her prepregnant nutritional state. The Institute of Medicine (IOM) (2009) recommends weight gain in terms of optimum ranges based on prepregnant BMI (Table 18-2). Studies continue to show that weight gain within the IOM recommended weight ranges are associated with improved pregnancy outcomes, avoidance of excessive maternal postpartum weight retention, and reduction of risk of chronic disease later in life (American Dietetic Association [ADA], 2008).

The pattern of weight gain during pregnancy is also important. For example, inadequate prenatal weight gain during the second trimester is closely associated with reduced birth weight in the newborn. For women of normal weight, assuming a gain of 0.5 to 2 kg (1.1 to 4.4 lbs) during the first trimester, the recommended gain during the second and third trimesters is .45 kg (l lb) per week. The rate of weight gain in the second and third trimesters needs to be slightly higher for underweight women and slightly lower for overweight women (IOM, 2009). A maternal weight gain of 1.5 lb per week has been suggested for normal-weight women during the second half of a twin pregnancy. Underweight women should strive for a gain of 1.75 lb per week after 20 weeks' gestation.

The average maternal weight gain is distributed as follows:

5 kg (11 lb)	Fetus, placenta, amniotic fluid
0.9 kg (2 lb)	Uterus
1.8 kg (4 lb)	Increased blood volume
1.4 kg (3 lb)	Breast tissue
2.3 to 4.5 kg (5 to 10 lb)	Maternal stores

Obesity is becoming increasingly prevalent in the United States and in many developed countries. Because pregnant women who are obese are at risk for many pregnancy complications, it is recommended these women receive counseling on strategies to move toward and to remain at a healthful weight prior to conceiving (ADA & the American Society for Nutrition, 2009).

TABLE 18-1 Dietary Reference Intakes (DRIs) for Nonpregnant Females and for Pregnant and Lactating Females

	AGE	VITAMIN A (MCG/D)	VITAMIN D (MCG/D)	VITAMIN E (MG/Dα-TOCOPHEROL)	VITAMIN K (MCG/D)	VITAMIN C (MG/D)	THIAMINE (MG/D)	RIBOFLAVIN (MG/D)
Females	9–13 y	600	5*	11	60*	45	0.9	0.9
	14–18 y	700	5*	15	75*	65	1.0	1.0
	19–30 y	700	5*	15	90*	75	1.1	1.1
	31–50 y	700	5*	15	90*	75	1.1	1.1
	50–70 y	700	10*	15	90*	75	1.1	1.1
	Greater than 70 y	700	15*	15	90*	75	1.1	1.1
Pregnancy	Less than or equal to 18 y	750	5*	15	75*	80	1.4	1.4
	19–30 y	770	5*	15	90*	85	1.4	1.4
	31–50 y	770	5*	15	90*	85	1.4	1.4
Lactation	Less than or equal to 18 y	1200	5*	19	75*	115	1.4	1.6
	19–30 y	1300	5*	19	90*	120	1.4	1.6
	31–50 y	1300	5*	19	90*	120	1.4	1.6

*Values are adequate intakes (AIs) rather than recommended dietary allowances (RDAs). All other values on chart are RDAs.

Figure 18-1 ■ It is important to monitor a pregnant woman's weight over time.

Source: Michael Newman/Photo Edit Inc.

Because of the association between maternal weight gain and pregnancy outcome, most caregivers pay close attention to weight gain during pregnancy (Figure 18-1 ■). Weight gain charts can be useful in monitoring the rate of weight gain over time. If a significant deviation from the anticipated pattern occurs, the cause should be determined and appropriate interventions planned with the woman.

As mentioned earlier, weight gain alone does not guarantee adequate nutrition. A diet may be high in energy (calories) but low in vitamins, minerals, or complex carbohydrates and protein. Pregnancy is not a time to diet, and severe caloric restriction during pregnancy can result in maternal ketosis. Counseling the pregnant woman to eat a variety of nutrients from each of the food groups places less emphasis on the amount of her weight gain and more on the quality of her intake. MyPyramid offers users a colorful plan that emphasizes variety, proportions, moderation, and physical activity (Figure 18-2 ■). "MyPyramid for Moms" is also available through the U.S. Department of Agriculture's MyPyramid Web site to provide food plans that meet the energy needs of

NIACIN (MG/D)	VITAMIN B_6 (MG/D)	FOLATE (MCG/D)	VITAMIN B_{12} (MCG/D)	CALCIUM (MG/D)	PHOSPHORUS (MG/D)	MAGNESIUM (MG/D)	IRON (MG/D)	ZINC (MG/D)	IODINE (MCG/D)	SELENIUM (MCG/D)
12	1	300	1.8	1300*	1250	240	8	8	120	40
14	1.2	400	2.4	1300*	1250	360	15	9	150	55

17	2	500	2.8	1000*	700	320	9	12	290	70

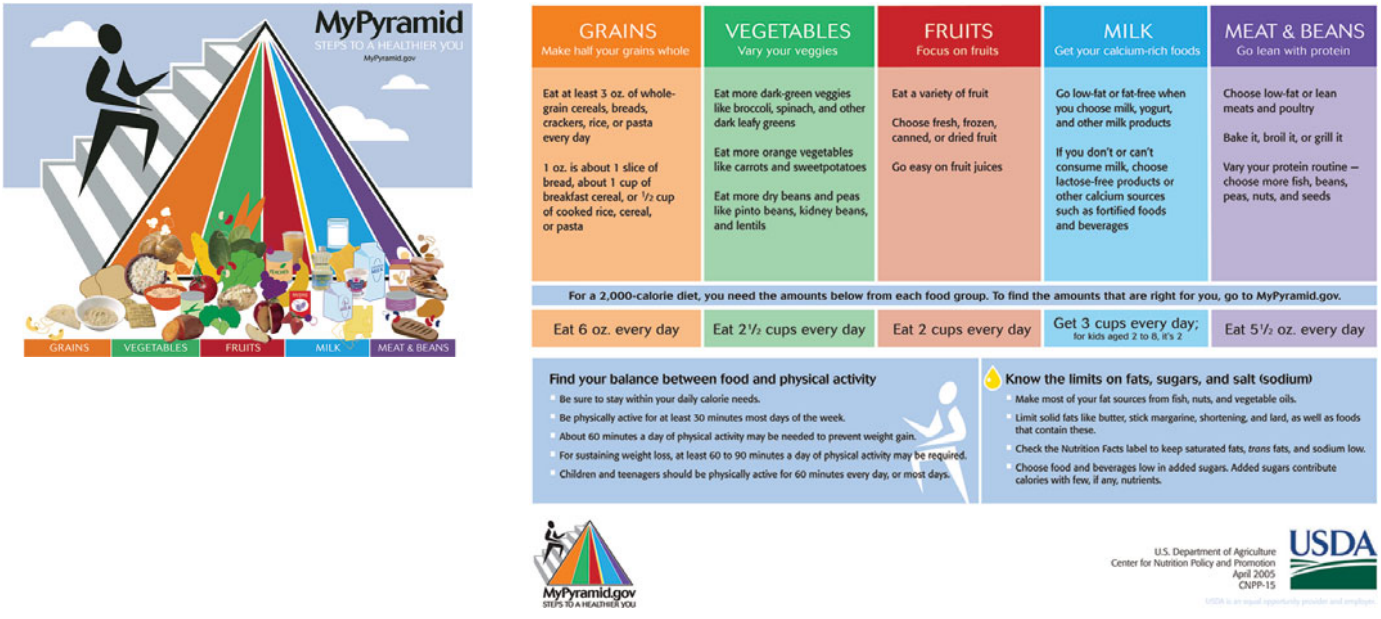

Figure 18-2 ■ MyPyramid: Steps to a Healthier You identifies the basic food groups and provides guidance about healthful eating. Grains, vegetables, fruits, and dairy products are emphasized with slightly less emphasis on protein. The narrow yellow bar is designated for fats, sugar, and salt. People are encouraged to have most of their fat intake come from fish, nuts, and vegetable oils while limiting solid fats like butter, margarine, shortening, and lard. The emphasis is also placed on limiting added sugars, which contribute calories but few, if any, nutrients.

Source: US Department of Agriculture; US Department of Health and Human Services.

pregnant women, as recommended by the dietary reference intakes, and promote healthier food choices (U.S. Department of Agriculture [USDA], 2009). The MyPyramid for Moms is a customized approach. At the Web site the pregnant woman answers a series of questions about her gestation, activity level, age, and so forth. Based on the information she provides, a specific plan is developed for her.

The pregnant woman can obtain most of the recommended nutrients by eating a well-balanced diet each day. The basic food groups and recommended amounts during pregnancy and lactation are presented in Table 18-3.

CLINICAL TIP

Consider factors that may cause variations in weight. Weight varies with time of day, amount of clothing, inaccurate scale adjustment, or weighing error. Consequently, do not overemphasize a single weight but pay attention to the pattern of weight gain.

TABLE 18-3 Daily Food Plan for Pregnancy and Lactation

FOOD GROUP	NUTRIENTS PROVIDED	FOOD SOURCE	RECOMMENDED DAILY AMOUNT DURING PREGNANCY	RECOMMENDED DAILY AMOUNT DURING LACTATION
Dairy products	Protein; riboflavin; vitamins A, D, and others; calcium; phosphorus; zinc; magnesium	Milk—whole, 2%, low-fat, skim, dry, buttermilk Cheeses—hard, semisoft, cottage Yogurt—plain, low-fat Soybean milk—canned, dry	Four (8 oz) cups (five for teenagers) used plain or with flavoring, in shakes, soups, puddings, custards, cocoa Calcium in 1 cup milk equivalent to 1 1/2 cups cottage cheese, 1 1/2 oz hard or semisoft cheese, 1 cup yogurt, 1 1/2 cups ice cream (high in fat and sugar)	Four (8 oz) cups (five for teenagers); equivalent amount of cheese, yogurt, and so forth
Meat and meat alternatives	Protein; iron; thiamine, niacin, and other vitamins; minerals	Beef, pork, veal, lamb, poultry, animal organ meats, fish, tofu; eggs; legumes; nuts, seeds, peanut butter, grains in proper vegetarian combination (vitamin B_{12} supplement needed)	Three servings (one serving = 2 oz), combination in amounts necessary for same nutrient equivalent (varies greatly)	Two servings
Grain products, whole grain or enriched	B vitamins; iron; whole grain also has zinc, magnesium, and other trace elements; provides fiber	Breads and bread products such as cornbread, muffins, waffles, hotcakes, biscuits, dumplings, cereals, pastas, rice	Six to 11 servings daily: one serving = one slice bread, 3/4 cup or 1 oz dry cereal, 1/2 cup rice or pasta	Same as for pregnancy
Fruits and fruit juices	Vitamins A and C; minerals; raw fruits for roughage	Citrus fruits and juices, melons, berries, all other fruits and juices	Two to four servings (one serving for vitamin C): one serving = one medium fruit, 1/2—1 cup fruit, 4 oz orange or grapefruit juice	Same as for pregnancy
Vegetables and vegetable juices	Vitamins A and C; minerals; provides roughage	Leafy green vegetables; deep yellow or orange vegetables such as carrots, sweet potatoes, squash, tomatoes; green vegetables such as peas, green beans, broccoli; other vegetables such as beets, cabbage, potatoes, corn, lima beans	Three to five servings (one serving of dark green or deep yellow vegetable for vitamin A): one serving = 1/2—1 cup vegetable, two tomatoes, one medium potato	Same as for pregnancy
Fats	Vitamins A and D; linoleic acid	Butter, cream cheese, fortified table spreads; cream, whipped cream, whipped toppings; avocado, mayonnaise, oil, nuts	As desired in moderation (high in calories): one serving = 1 tbsp butter or enriched margarine	Same as for pregnancy
Sugar and sweets		Sugar, brown sugar, honey, molasses	Occasionally, if desired	Same as for pregnancy
Desserts		Nutritious desserts such as puddings, custards, fruit whips, and crisps; other rich, sweet desserts and pastries	Occasionally, if desired	Same as for pregnancy
Beverages		Coffee, decaffeinated beverages, tea, bouillon, carbonated drinks	As desired, in moderation	Same as for pregnancy
Miscellaneous		Iodized salt, herbs, spices, condiments	As desired	Same as for pregnancy

Note: The pregnant woman should eat regularly, three meals a day, with nutritious snacks of fruit, cheese, milk, or other foods between meals if desired. (More frequent but smaller meals are also recommended.) Four to 6 (8 oz) glasses of water and a total of 8 to 10 (8 oz) cups total fluid intake should be consumed daily. Water is an essential nutrient.

Nutritional Requirements

The requirements for calories and almost all nutrients increase during pregnancy, although the amount of increase varies with each nutrient. These increases reflect the additional requirements of both the mother and the developing fetus (see Table 18-1).

Calories

The term **calorie (cal)** stands for the amount of heat required to raise the temperature of 1 gram of water 1 degree centigrade. The **kilocalorie (kcal)** is equivalent to 1000 cal and is the unit used to express the energy value of food.

The dietary reference intakes for total energy indicate energy requirements do not change during the first trimester. During the second and third trimesters, pregnant women should consume an extra 300 kcal per day (American College of Obstetricians and Gynecologists [ACOG], 2009). Weight gains should be monitored regularly, and dietary recommendations should be individualized to help the pregnant woman meet her caloric needs. Prepregnant weight, height, maternal age, activity, and health status all affect caloric requirements.

PATIENT TEACHING Helping the Pregnant Woman Add 300 kcal to Her Diet

PATIENT GOALS At the completion of the teaching, the woman will be able to:

1. Identify the MyPyramid for Moms categories and the foods included in each.
2. Cite the increase in kilocalories indicated during pregnancy.
3. Discuss the most nutritionally sound way to use the additional calories.
4. Use the information she has gained to plan a nutritionally sound sample menu.

TEACHING PLAN

Content	Teaching Method
Describe the basic food groups, which include the following: Grains: 6 to 11 servings (one serving = 1 slice bread, 1/2 hamburger roll, 1 oz dry cereal, 1 tortilla, 1/2 cup pasta, rice, grits) Fruits: Two to four servings; one should be a good source of vitamin C (one serving = 1 medium-sized piece of fruit, 1/2 cup juice) Vegetables: Three to five servings (one serving = 1 cup raw vegetable, 1 cup green leafy vegetable, 1/2 cup cooked vegetable) Dairy: Two to three servings (one serving = 1 cup milk or yogurt, 1.5 oz hard cheese, 2 cups cottage cheese, 1 cup pudding made with milk) Meats and alternatives: Two to three servings (one serving = 2 oz cooked lean meat, poultry, or fish; 2 eggs, 1/2 cup cottage cheese; 1 cup cooked legumes [kidney, lima, garbanzo, or soybeans, split peas]; 6 oz tofu; 2 oz nuts or seeds; 4 tbsp peanut butter)	Ask the woman if she has received nutritional information using this approach before. Discuss her understanding of it. Use that information to plan the amount of detail you will use. Use a chart or colorful handout to explain the basic food groups and to give examples of equivalent foods.
Point out that not all foods that are nutritionally equivalent have the same number of calories; it is important to consider that when making food choices.	Use a calorie-counting guide to compare the calories in a variety of foods that are equivalent, such as 2 oz beef and 2 oz fish or 1 cup low-fat milk and 1 cup whole milk.
Explain the design of MyPyramid for Moms. MyPyramid for Moms is designed to represent the food groups needed to make a balanced diet throughout pregnancy. The grain, fruit, vegetable, and dairy groups are the widest color bands of the pyramid and should account for the majority of the food selections. Fewer servings of meat or meat alternatives are required in the diet. Fats, oils, sweets, and sodium do not have a high nutritional value and should be used sparingly.	Use a similar approach to evaluate the calories in fats, oils, and sweets, but also evaluate their nutrient content, especially levels of nutrients such as vitamin C, iron, and calcium. Discuss the MyPyramid for Moms recommendations about the importance of regular exercise in controlling weight gain and maintaining good health.
Emphasize that a woman only has to add 300 kcal/day during pregnancy. This can be achieved by adding two milk servings and one serving of meat or alternative. Because of the varying caloric value, a woman needs to consider the advisability of using low-fat milk, lean cuts of meat, or fish broiled or baked instead of fried.	In planning the woman's diet to get optimum nutrition without too many additional calories, it is often helpful to ask her to plan and evaluate a sample menu.
Foods can be combined. For example, 1 cup spaghetti with a 2 oz meatball would count as 1 serving meat, 3/4 cup spaghetti = 1 grain, and 1/4 cup tomato sauce = 1/2 serving vegetable.	Provide handouts on which the woman can list the foods she has eaten and check off the corresponding nutrient categories. Have her bring her completed handouts to a subsequent visit.

Evaluation	Documentation
Evaluate the learning by providing time for discussion, questions, and practice using the calorie-counting guide. Teaching has been effective if all the identified goals are achieved and if the woman seems comfortable planning her diet to provide for the best nutrition possible.	Document the information given to the woman, including specifics on food groups, foods, and portion size. Specify if written instructions were provided in addition to verbal ones and describe the type of teaching method used. Document woman's verbalization of understanding and your clarification of any information.

See Patient Teaching: Helping the Pregnant Woman Add 300 kcal to Her Diet for basic nutritional information and suggestions for increasing caloric intake.

Carbohydrates

Carbohydrates provide the body's primary source of energy as well as fiber necessary for proper bowel functioning. If the carbohydrate intake is not adequate, the body uses protein for energy. Protein then becomes unavailable for growth needs. In addition, protein breakdown leads to ketosis. Ketosis can be a problem, especially in women with diabetes, because of glycosuria, reduced alkaline reserves, and lipidemia.

The carbohydrate and caloric needs of the pregnant woman increase, especially during the last two trimesters. Carbohydrate

intake promotes weight gain and growth of the fetus, placenta, and other maternal tissues. Dairy products, fruits, vegetables, and whole grain cereals and breads all contain carbohydrates.

Protein

During pregnancy, the woman needs increased amounts of protein to provide amino acids for fetal development, blood volume expansion, and growth of other maternal tissues, such as the breasts and uterus. Protein also contributes to the body's overall energy metabolism. The recommendation for protein during pregnancy is 60 g, an increase of about 14 g over nonpregnant levels. The quality of dietary protein is as important as the total amount consumed. The quality is determined by the complex of amino acids that makes up the protein. Plant proteins can meet a woman's protein needs; however, more of a given protein may be needed as animal proteins are of higher quality (see later discussion of vegetarianism).

To obtain high-quality protein in the diet, it is best to eat a variety of foods. Animal products, such as lean meats, fish, poultry, and eggs, are sources of high-quality protein. Dairy products are also important protein sources. A quart of milk supplies 32 g of protein, more than half the average daily protein requirement. Milk can be incorporated into the diet in a variety of dishes, including soups, puddings, custards, sauces, yogurt, and beverages such as hot chocolate and fruited milk drinks. Various kinds of hard and soft cheeses and cottage cheese are also excellent protein sources, although cream cheese is categorized as a fat source only. Table 18-4 provides information on the protein content of common foods.

TABLE 18-4 Amount of Protein in Common Foods

FOOD	PROTEIN (G)
Dairy Products	
Milk, 8 oz	8
Cheese: cheddar, Swiss, and so forth, 1 oz	7
Cottage cheese, 1/4 cup	7
Meat and Meat Alternatives	
Meat, fish, poultry, 1 oz	7
Egg, 1	7
Cooked dry beans and peas, 1/2 cup	7
Cooked soybeans, 1/2 cup	11
Tofu, raw, 1/2 cup	10
Peanut butter, 2 tbsp	7
Peanuts (3 tbsp), cashews/almonds (5 tbsp)	7
Breads and Cereals	
Bread, 1 slice	2
Buns, biscuits, muffins, 1	2
Cooked cereals and grains, 1/2 cup	2
Breakfast cereal, 1 oz	2
Vegetables and Fruits	
Vegetables, 1/2 cup	0.5–1
Fruits and juices, 1/2 cup	0.5
Miscellaneous	
Soy milk, 8 oz	6.6

Women who have allergies to milk, who have lactose intolerance, or who practice vegetarianism may find soy milk acceptable. It can be used in cooked dishes or as a beverage. Soy cheeses are also available.

Fat

Fats are valuable sources of energy for the body. Fats are more completely absorbed during pregnancy, resulting in a marked increase in serum lipids, lipoproteins, and cholesterol and decreased elimination of fat through the bowel. Fat deposits in the fetus increase from about 2% at midpregnancy to almost 12% at term. The U.S. Dietary Guidelines recommend that about 25% to 30% of total daily caloric intake should be from dietary fat, of which only 10% of fat calories should be saturated fat (U.S. Department of Health and Human Services & U.S. Department of Agriculture, 2005).

Essential fatty acids are important for the development of the central nervous system of the fetus. Of particular interest are the omega-3 fatty acids and their derivative, docosahexaenoic acid (DHA). Maternal dietary intake of DHA during pregnancy may be beneficial to both the mother and the fetus by reducing the risk of preterm birth, preeclampsia, and low birth weight, as well as enhancing the development of the fetal and infant brain (Innis, 2007). Although there are no current recommendations, studies indicate pregnant women may benefit from including 200 mg/day of DHA (Koletzko, Cetin, & Brenna, 2007). Dietary sources of DHA are naturally occuring in oily fish (see information on fish consumption under "Mercury in Fish" later in this chapter) and are also found in fortified dairy products and even some fortified soymilk. Plant sources of omega-3 fatty acids include soybean oil, canola oil, flaxseeds and their oil, and walnuts.

Minerals

The woman can increase minerals needed for the growth of new tissue during pregnancy by improving mineral absorption and increasing mineral intake.

Calcium and Phosphorus

Calcium and phosphorus are involved in the mineralization of fetal bones and teeth, energy and cell production, and acid–base buffering. Calcium is absorbed and used more efficiently during pregnancy. Some additional calcium and phosphorus are required early in pregnancy, but most of the fetus's bone calcification occurs during the last 2 or 3 months. Teeth begin to form at about 8 weeks' gestation and are formed by birth. The 6-year molars begin to calcify just before birth. Additional calcium is stored in the maternal skeleton as a reserve for lactation.

The identified adequate intake for calcium for the pregnant or lactating woman 19 years of age or older is 1000 mg per day. It is 1300 mg/day for pregnant women under 19. If calcium intake is not adequate, fetal needs will be met at the mother's expense by demineralization of maternal bone. Food is the preferred source of calcium because food provides other nutrients as well. A diet that includes 4 cups of milk or an equivalent dairy alternative (see Table 18-5) and a variety of other foods will provide sufficient calcium. Smaller amounts of calcium are supplied by legumes, nuts, dried fruits, and dark green leafy vegetables (such as kale, broccoli,

TABLE 18-5 Foods That Provide Comparable Amounts of Calcium

FOOD	AMOUNT
Dairy Products	
Milk	8 oz
Cheese, cheddar	1 1/2 oz
Pudding, vanilla	1 cup
Dairy Alternatives	
Soy milk*	8 oz
Fruits	
Figs	10
Raisins	2 cups
Vegetables	
Broccoli	2 1/2 cups
Collards	1 cup
Kale	3 cups
Mustard greens	3 1/2 cups
Turnip greens	1 1/2 cups
Fish	
Salmon, canned, with bones	2/3 cup
Sardines	6
Nuts	
Almonds	4 oz
Brazil nuts	1/2 cup
Miscellaneous	
Molasses, blackstrap	2 tbsp

Source: Data from Pennington, J. A. T. (1989). Bowes and Church's food values of portions commonly used *(15th ed.). Philadelphia, PA: Lippincott.*

*Amounts may vary with brand; be sure to check label.

collard greens, and beet greens). It is important to remember that some of the calcium in beet greens, spinach, and Swiss chard is bound with oxalic acid, which makes it less available to the body. Larger amounts of these foods need to be consumed if they are substituted for dairy sources of calcium (Table 18-5).

The recommended dietary allowance (RDA) for phosphorus does not change from that of a nonpregnant woman age 19 or older: 700 mg per day. Similarly, for females age 18 and younger it remains stable at 1250 mg per day. Phosphorus is readily supplied through calcium- and protein-rich foods, especially milk, eggs, and meat.

Iodine

Iodine is an essential part of the thyroid hormone thyroxine. Inorganic iodine is excreted in the urine during pregnancy. Enlargement of the thyroid gland may occur if iodine is not replaced by adequate dietary intake or additional supplement. Iodine deficiency is the most widespread nutritional cause of impaired brain development. This can result in cretinism and lesser degrees of intellectual disability (mental retardation).

A woman can meet the iodine requirement of 220 mcg per day by using iodized salt. Seafood is also a good source of iodine. Plant sources vary because they reflect the iodine content of the soil in which they grow. When sodium is restricted, the physician may prescribe an iodine supplement.

Sodium

The sodium ion is essential for proper metabolism and the regulation of fluid balance. Sodium intake in the form of salt is never entirely curtailed during pregnancy, even when hypertension or preeclampsia is present. The woman can obtain moderate sodium intake (2 to 3 g) by using fresh food lightly seasoned to taste during cooking. The use of extra salt at the table should be avoided. Salty foods, such as potato chips, ham, sausages, and sodium-based seasonings, can be eliminated to avoid excessive intake.

Zinc

Zinc is a part of numerous enzymes and is involved in protein metabolism and the synthesis of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). It is essential for normal fetal growth and development as well as milk production during lactation. The RDA during pregnancy for women age 19 and older is 11 mg per day. This increases to 12 mg during lactation. Best sources of zinc are meats, shellfish, and poultry. Good sources include whole grains and legumes.

Magnesium

Magnesium is essential for cellular metabolism and structural growth. The RDA for pregnancy is 320 mg. Good sources include milk, whole grains, dark green vegetables, nuts, and legumes.

Iron

Iron requirements increase during pregnancy because of the growth of the fetus and placenta and the expansion of maternal blood volume. Anemia in pregnancy is mainly caused by low iron stores, although it may also result from inadequate intake of other nutrients, such as vitamins B_6 and B_{12}, folic acid, ascorbic acid, copper, and zinc. Women with poor diet histories, frequent conceptions, or records of prior iron depletion are particularly at risk.

Iron deficiency anemia is generally defined as a decrease in the oxygen-carrying capacity of the blood. This significantly reduces the hemoglobin per deciliter of blood, the volume of packed red cells per deciliter of blood (hematocrit), or the number of erythrocytes. Iron deficiency anemia is associated with a higher incidence of low-birth-weight infants and preterm birth (Cunningham et al., 2010).

The normal hematocrit in the nonpregnant woman is 38% to 47%. In the pregnant woman, the level may drop to as low as 34%, even when nutrition is adequate. This condition is called the *physiologic anemia of pregnancy* (see chapter 14 ∞). Fetal demands for iron further contribute to symptoms of anemia in the pregnant woman. The fetal liver stores iron, especially during the third trimester. The infant will need this stored iron during the first 4 months of life to compensate for the normally inadequate levels of iron in breast milk and non–iron-fortified formulas. To prevent anemia, the woman must balance iron requirements and intake. Doing so is a problem for nonpregnant women and a greater one for pregnant women. Although the rate of absorption increases during pregnancy, it is still important to

select foods high in iron to increase the daily intake. Lean meats, dark green leafy vegetables, eggs, and whole grain and enriched breads and cereals are the foods usually depended on for their iron content. Other iron sources include dried fruits, legumes, shellfish, and molasses.

Iron absorption is generally higher for animal products than for vegetable products. However, the woman may enhance absorption of iron from nonmeat sources by combining them with meat or a food rich in vitamin C. In addition, the use of iron-fortified foods is a cost-effective and efficient way to increase iron intake.

The most iron that can reasonably be obtained from the average diet is about 15 to 18 mg per day. However, the recommended intake for iron during pregnancy is 27 mg per day. Thus during pregnancy a supplement of simple iron salt, such as ferrous gluconate, ferrous fumarate, or ferrous sulfate, is needed. This amount is available in most prenatal vitamins. Unfortunately iron supplements often cause gastrointestinal discomfort, especially if taken on an empty stomach. Consequently caregivers often begin iron supplementation in the second trimester after the incidence of nausea and vomiting subsides. Once the woman begins taking an iron supplement, absorption is increased if she takes it with a source of vitamin C such as orange juice. In addition, iron is often constipating, so it is important for the woman to consume sufficient fluids and roughage in her diet to combat this effect.

Vitamins

Vitamins are organic substances necessary for life and growth. They are found in small amounts in specific foods and generally cannot be synthesized by the body in adequate amounts.

Vitamins are grouped according to their solubility. Those that dissolve in fat are A, D, E, and K; those soluble in water include vitamin C and the B complex vitamins. An adequate intake of all vitamins is essential during pregnancy; however, several are required in larger than normal amounts to fulfill specific needs.

A balanced diet generally provides necessary vitamins without the need for supplementation. Despite this, many people who are concerned about nutrition have become involved in the practice of taking exceptionally large doses—megadoses—of vitamins. However, in vitamin therapy more is not necessarily better. Megadoses of vitamins, especially vitamins A, D, C, and B_6, have been documented to have a negative effect on the fetus. Furthermore, excessive intake of one vitamin may interfere with the body's use of another vitamin. For example, excessive intake of vitamin C may block the body's use of vitamin B_{12}. Consequently, although it is important to meet the recommended dietary allowances of vitamins during pregnancy, megadoses are best avoided.

Fat-Soluble Vitamins

The fat-soluble vitamins A, D, E, and K are stored in the liver and thus are available should the dietary intake become inadequate. They are not excreted in the urine, so excessive consumption of these vitamins, particularly vitamins A and D, can lead to toxicity. Symptoms of fat-soluble vitamin toxicity include nausea, gastrointestinal upset, dryness and cracking of the skin, and loss of hair.

VITAMIN A Vitamin A is involved in the growth of epithelial cells, which line the entire gastrointestinal tract and compose the skin. Vitamin A plays a role in the metabolism of carbohydrates and fats. The body cannot synthesize glycogen in the absence of vitamin A, and the body's ability to handle cholesterol is also affected. In addition, the protective layer of tissue surrounding nerve fibers does not form properly if vitamin A is lacking. Probably the best known function of vitamin A is its effect on vision in dim light. A person's ability to see in the dark depends on the eye's supply of retinol, a form of vitamin A. In this manner, vitamin A prevents night blindness. Vitamin A is associated with the formation and development of healthy eyes in the fetus.

If maternal stores of vitamin A are adequate, the overall effects of pregnancy on the woman's vitamin A requirements are not remarkable. The blood serum level of vitamin A decreases slightly in early pregnancy, rises in late pregnancy, and falls before the onset of labor. Thus the RDA for vitamin A is 770 mcg per day for pregnant women age 19 and older.

Deficiencies of vitamin A are not common in the United States. Among the poor of developing countries, vitamin A deficiency is a major cause of preventable childhood blindness and an important factor in morbidity and mortality from infection, especially among pregnant women and children (World Health Organizatioin, 2009). Although routine supplementation with vitamin A is not recommended, supplementation with 5000 international units is indicated for women whose dietary intake may be inadequate, specifically strict vegetarians and recent emigrants from countries where deficiency of vitamin A is endemic.

Rich plant sources of vitamin A include deep green and yellow or deep orange vegetables and some fruits; animal sources include liver, egg yolk, cream, butter, fortified margarine, and milk.

VITAMIN D Vitamin D is best known for its role in the absorption and utilization of calcium and phosphorus in skeletal development. To supply the needs of the developing fetus, the pregnant woman should have a vitamin D intake of 5 mcg per day.

Main food sources of vitamin D include fortified milk, margarine, butter, liver, and egg yolks. Drinking a quart of vitamin D–fortified milk daily provides the vitamin D needed during pregnancy. Vitamin D is also obtained through the synthesis of sunlight on the skin. During the winter months, however, women who live in northern latitudes are at risk for limited sun exposure. Foods that provide good sources of vitamin D should be encouraged.

Excessive intake of vitamin D is not usually a result of eating but of taking high-potency vitamin preparations. Overdoses during pregnancy can cause hypercalcemia or high blood calcium levels because of withdrawal of calcium from the skeletal tissue. Symptoms of toxicity include excessive thirst, loss of appetite, vomiting, weight loss, irritability, and high blood calcium levels.

VITAMIN E The major function of vitamin E, or tocopherol, is as an antioxidant. Vitamin E takes on oxygen, thus preventing other nutrients from undergoing chemical changes. For exam-

ple, vitamin E helps spare vitamin A by preventing its oxidation in the intestinal tract and the tissues. It decreases the oxidation of polyunsaturated fats, thus helping to retain the flexibility and health of the cell membrane. In protecting the cell membrane, vitamin E affects the health of all cells in the body.

Vitamin E is also involved in certain enzymatic and metabolic reactions. It is an essential nutrient for the synthesis of nucleic acids required in the formation of red blood cells in the bone marrow. Vitamin E is beneficial in treating certain types of muscular pain and intermittent claudication, in surface healing of wounds and burns, and in protecting lung tissue from the damaging effects of smog. These functions may help explain the abundant claims and cures attributed to vitamin E, many of which have not been scientifically proved.

The newborn's need for vitamin E has been widely recognized. Human milk provides adequate vitamin E, whereas cow's milk is lower in vitamin E content. Deficiency symptoms of vitamin E are related to long-term inability to absorb fats. In humans, malabsorption problems exist in cases of cystic fibrosis, liver cirrhosis, postgastrectomy, obstructive jaundice, pancreatic problems, and sprue.

The recommended intake of vitamin E is unchanged at 15 mg per day. Vitamin E is widely distributed in foodstuffs, especially vegetable fats and oils, whole grains, greens, and eggs.

Some pregnant women massage vitamin E oil on the abdominal skin to make it supple and possibly prevent permanent stretch marks. It is questionable whether taking high doses orally will accomplish this goal or satisfy any other claims related to vitamin E's role in reproduction or virility. In addition, excessive intake of vitamin E has been associated with abnormal coagulation in the newborn.

VITAMIN K Vitamin K, or menadione as used synthetically in medicine, is an essential factor for the synthesis of prothrombin; its function is thus related to normal blood clotting. Synthesis occurs in the intestinal tract by the *Escherichia coli* normally inhabiting the large intestine. However, the body's need for vitamin K is not totally met through synthesis. Green leafy vegetables and liver are excellent sources. The requirement for vitamin K does not increase during pregnancy. It is 90 mcg per day.

Intake of vitamin K is usually adequate in a well-balanced prenatal diet. Secondary problems may arise if an illness results in malabsorption of fats or if antibiotics are used for an extended period. Antibiotics inhibit vitamin K synthesis by destroying intestinal *E. coli.*

Water-Soluble Vitamins

Water-soluble vitamins are excreted in the urine. Only small amounts are stored, so there is little protection from dietary inadequacies. Thus adequate amounts must be ingested daily. During pregnancy, the concentration of water-soluble vitamins in the maternal serum falls, whereas high concentrations are found in the fetus.

VITAMIN C The requirement for vitamin C (ascorbic acid) is increased in pregnancy from 75 to 85 mg per day. The major function of vitamin C is to aid the formation and development of connective tissue and the vascular system. Ascorbic acid is essential to the formation of collagen. Collagen is like cement that binds cells together, just as mortar holds bricks together. If the collagen begins to disintegrate because of lack of ascorbic acid, cell functioning is disturbed, and cell structure breaks down, causing muscular weakness, capillary hemorrhage, and eventual death. These are symptoms of scurvy, the disease caused by vitamin C deficiency. Newborns of women who have taken megadoses of vitamin C may experience a rebound form of scurvy.

Maternal plasma levels of vitamin C progressively decline throughout pregnancy, with values at term being about half those at midpregnancy. It appears that ascorbic acid concentrates in the placenta; levels in the fetus are 50% or more above maternal levels.

A nutritious diet should meet the pregnant woman's needs for vitamin C without additional supplementation. Common food sources of vitamin C include citrus fruit, tomatoes, cantaloupe, strawberries, potatoes, broccoli, and other leafy green vegetables. Ascorbic acid is readily destroyed by water and oxidation. Therefore, foods containing vitamin C should have limited exposure to air, heat, and water during storage and cooking.

THE B VITAMINS The B vitamins include thiamine (B_1), riboflavin (B_2), niacin, folic acid, pantothenic acid, vitamin B_6, and vitamin B_{12}. These vitamins serve as vital coenzyme factors in many reactions, such as cell respiration, glucose oxidation, and energy metabolism. Consequently, the quantities needed invariably increase as caloric intake increases to meet the metabolic and growth needs of the pregnant woman.

The *thiamine* requirement increases from the prepregnant level of 1.1 mg per day to 1.4 mg per day. Sources include pork, liver, milk, potatoes, enriched breads, and cereals.

Riboflavin deficiency is manifested by *cheilosis* (fissures and cracks of the lips and the corners of the mouth) and other skin lesions. During pregnancy, women may excrete less riboflavin and still require more because of increased energy and protein needs. Thus the recommended intake of riboflavin increases by 0.3 mg per day, to 1.4 mg per day for pregnant women age 19 and older. Sources include milk, liver, eggs, enriched breads, and cereals.

Niacin requirements increase by 4 mg per day during pregnancy to 18 mg. Sources of niacin include meat, fish, poultry, liver, whole grains, enriched breads, cereals, and peanuts.

Folic acid, or folate, is required for normal growth, reproduction, and lactation and prevents the macrocytic, megaloblastic anemia of pregnancy. Megaloblastic anemia due to folic acid deficiency is seldom found in the United States, but those caring for pregnant women must be aware that it does occur.

Even more significantly, an inadequate intake of folic acid has been associated with neural tube defects (NTDs) (spina bifida, anencephaly). Although these defects are considered multifactorial (see chapter 12 ∞), research indicates that 50% to 70% of spina bifida and anencephaly could be prevented by adequate intake of folic acid (Centers for Disease Control and Prevention [CDC], 2009). Consequently experts recommend that all women of childbearing age (15 to 45 years) consume 400 mcg

RESEARCH EVIDENCE IN PRACTICE

Iron and Folic Acid Supplementation During Pregnancy

CLINICAL QUESTION

What is a safe, effective dosing regimen for iron and folic acid supplementation during pregnancy?

RESEARCH EVIDENCE

The effectiveness of iron supplementation in preventing maternal anemia has been well documented. Likewise, folic acid supplementation has been widely demonstrated to reduce the incidence of neural tube defects. However, there is a lack of clarity about the most effective dosage and regimen of both supplements.

The American College of Obstetricians and Gynecologists (ACOG) convened a study group to review the evidence and develop clinical guidelines for the use of folic acid supplements during pregnancy. Their recommendations are based on a systematic review of the literature and the opinions of an expert panel. The findings were confirmed by a large randomized controlled trial sponsored by the Canadian Society of Obstetricians and Gynaecologists.

Periconceptional folic acid supplementation is recommended because it has been shown to reduce the occurrence of neural tube defects. For low-risk women, the appropriate dosage is 400 mcg per day. For women at high risk or who have had a previous pregnancy that resulted in an infant with a neural tube defect, folic acid supplementation of 4 mg per day is recommended.

Two Cochrane Collaborative reviews of 89 trials involving more than 35,000 women support the safety and efficacy of iron supplementation during pregnancy. Daily iron supplementation was associated with increased maternal hemoglobin levels both pre- and post-birth. The risk of anemia was reduced in those mothers who took daily iron supplements. However, these benefits were seen both in women who took iron supplements daily and those who took the supplements intermittently. The women who took the iron supplements intermittently were less likely to have undesirable side effects and hemoconcentration. The risk of hemoconcentration among those women taking daily iron supplements was greater during the second and third trimesters.

While there are many foods that provide iron and folic acid naturally (spinach, lentils, broccoli, oranges, etc.) it is unlikely that diet alone can provide levels similar to folate-multivitamin supplementation.

WHAT QUESTIONS REMAIN UNANSWERED?

Intermittent folic acid therapy has not been tested. It is unclear whether the daily dosage of folic acid is required, but given the seriousness of neural tube defects, daily folic acid supplementation is recommended until further trials demonstrate the effectiveness of intermittent dosing.

WHAT IS BEST PRACTICE?

Universal prenatal supplementation with iron provided either daily or weekly is effective to prevent anemia at term. Women in the reproductive age group should be advised about the benefits of folic acid supplementation even before they become pregnant, during wellness visits, and especially if they are contemplating pregnancy. Daily dosages of 400 mcg of folic acid are effective for low-risk women; 4 mg should be taken by women in high-risk groups.

CRITICAL THINKING

For women who are contemplating pregnancy, what is the most effective way to ensure they will be compliant with a daily regimen of folic acid supplementation?

of folic acid daily, because half of all U.S. pregnancies are unplanned and NTDs occur very early in pregnancy (3 to 4 weeks after conception), before most women realize they are pregnant (CDC, 2009). See Research Evidence in Practice: Iron and Folic Acid Supplementation During Pregnancy.

The best food sources of folates are fresh green leafy vegetables, liver, peanuts, and whole-grain breads and cereals. Folic acid can be made inactive by oxidation, ultraviolet (UV) light, and heating. It can easily be lost during improper storage and cooking. To prevent unnecessary loss, foods should be stored covered to protect them from light, cooked with only a small amount of water, and not overcooked.

No allowance has been set for *pantothenic acid* in pregnancy but 5 mg per day is considered an adequate intake. Sources include meats, egg yolk, legumes, and whole grain cereals and breads.

Vitamin B_6 (pyridoxine) is associated with amino acid metabolism; thus a higher-than-average protein intake requires increased pyridoxine intake. The RDA for vitamin B_6 during pregnancy is 1.9 mg per day, an increase of 0.6 mg over the allowance for nonpregnant women. Generally the slightly increased need can be supplied by dietary sources, which include wheat germ, yeast, fish, liver, pork, potatoes, and lentils.

Vitamin B_{12}, or *cobalamin*, is the cobalt-containing vitamin found only in animal sources. Rarely is B_{12} deficiency found in women of reproductive age. Vegans (see later discussion of vegetarianism) can develop a deficiency, however, so it is essential that their dietary intake be supplemented with this vitamin. A deficiency may also be due to a congenital inability to absorb vitamin B_{12}, resulting in pernicious anemia; however, infertility is a complication of this type of anemia.

Occasionally, vitamin B_{12} levels decrease during pregnancy but increase again after birth. The RDA during pregnancy is 2.6 mcg per day, an increase of 0.2 mcg.

Folic acid and iron are the only nutritional supplements generally recommended during pregnancy. The increased need for other vitamins and minerals can usually be met with an adequate diet. To avoid possible deficiencies, however, many healthcare professionals still recommend a daily vitamin supplement.

CLINICAL TIP

In eliciting a pregnant woman's health history, keep in mind the fact that more women are consuming over-the-counter vitamin, mineral, and food supplements today than in the past. Thus it is important to ask about the use of any over-the-counter supplements to help avoid potentially harmful excess intakes.

Fluid

The nutrient water is essential for life and is found in all body tissues. It is necessary for many biochemical reactions. It also serves as a lubricant, acts as a medium of transport for carrying substances in and out of the body, and aids in the regulation of body temperature. A pregnant woman should consume at least 8 to 10 (8 oz) glasses of fluid each day, of which 4 to 6 glasses should be water. Other beverages such as juices and milk can contribute water as well as other nutrients to the diet. Sodas and diet sodas should be used in moderation because they do not contribute to the nutritional value of the diet.

Caffeine is found in beverages, foods, and medications. Its use during pregnancy remains controversial. High caffeine intake is associated with delayed conception, spontaneous miscarriage, and low birth weight but is not associated with birth defects (Higdon & Frei, 2006). Caffeinated beverages have a diuretic effect, which may be counterproductive to increasing fluid intake. In a position statement on maternal health, the American Dietetic Association states "pregnant women should avoid caffeine intakes above 300 mg" (ADA, 2008). The average 16 oz cup of coffee contains about 188 mg of caffeine, while carbonated sodas contain about 18–48 mg/12 oz, and energy drinks range from 33 to 75 mg per 8 oz (McCusker, Goldberger, & Cone, 2006).

Vegetarianism

Vegetarianism is the dietary choice of many people for religious, health, ethical, and economic reasons. Well-planned vegetarian diets are nutritionally adequate and appropriate for all stages of life, including pregnancy. Vegetarian diets are associated with many health benefits in the treatment and prevention of certain diseases (ADA, 2009). There are several types of vegetarians and dietary practices vary among the types. **Lacto-ovovegetarians** include milk, dairy products, and eggs in their diet. **Lacto-vegetarians** include dairy products but no eggs. **Vegans** are strict vegetarians who will not eat any food from animal sources.

The expectant woman who is lacto-ovovegetarian can obtain ample amounts of high-quality proteins from dairy products and eggs. Plant protein quality may be improved if consumed with these animal proteins. If the diet contains fewer than four servings of milk and dairy products, calcium supplementation may be necessary.

Appropriate meal planning for vegan diets ensures that a pregnant woman obtains necessary nutrients to promote the growth and development of the fetus. Protein needs increase slightly for vegans because of the lower quality protein sources ingested when animal proteins are excluded. Adequate dietary protein can be obtained by consuming a varied diet with adequate caloric intake and plant-based proteins. Consuming an assortment of plant proteins throughout the day such as beans and rice, peanut butter on whole grain bread, and whole grain cereal with soymilk, ensures the expectant mother obtains all essential amino acids. Protein and amino acid supplements are not recommended. Obtaining sufficient calories to achieve adequate weight gains can be difficult because vegan diets tend to be higher in fiber and, therefore, filling. Low prepregnancy weight and optimum pregnancy weight gains are often a problem. Supplementation with energy-dense foods helps provide increased energy intake to prevent the body from using protein for caloric needs.

Because vegans use no animal products, a daily supplement of 4 mg of vitamin B_{12} is necessary. If soy milk is used, only partial supplementation may be needed. If no soy milk is taken, daily supplements of 1200 mg of calcium and 10 mg of vitamin D are needed.

A vegan diet may be low in iron and zinc because the best sources of these minerals are found in animal products. In addition, a high-fiber intake may reduce mineral (calcium, iron, and zinc) bioavailability. The nurse should emphasize the use of foods containing these nutrients.

A guide to vegetarian food groups is provided in Table 18-6.

Factors Influencing Nutrition

It is important to consider the many factors that affect a patient's nutrition. What are the age, lifestyle, dietary practices, and culture of the pregnant woman? What food beliefs and habits does she have? What a person eats is also determined by availability, economics, and symbolism. These and other factors influence the expectant mother's acceptance of the nurse's intervention.

Common Discomforts of Pregnancy

Gastrointestinal functioning can be altered at times during pregnancy, resulting in discomforts such as nausea, vomiting, heartburn, and constipation. Although these changes can be

TABLE 18-6 Vegetarian Food Groups

FOOD GROUP	MIXED DIET	LACTO-OVOVEGETARIAN	LACTO-VEGETARIAN	VEGAN
Grain	Bread, cereal, rice, pasta	Bread, cereal, rice, pasta	Bread, cereal, rice, pasta	Bread, cereal, rice, pasta
Fruit	Fruit, fruit juices	Fruit, fruit juices	Fruit, fruit juices	Fruit, fruit juices
Vegetable	Vegetables, vegetable juices	Vegetables, vegetable juices	Vegetables, vegetable juices	Vegetables, vegetable juices
Dairy and dairy alternatives	Milk, yogurt, cheese	Milk, yogurt, cheese	Milk, yogurt, cheese	Fortified soy milk, rice milk
Meat and meat alternatives	Meat, fish, poultry, eggs, legumes, tofu, nuts, nut butters	Eggs, legumes, tofu, nuts, nut butters	Legumes, tofu, nuts, nut butters	Legumes, tofu, nuts, nut butters

uncomfortable for the woman, they are seldom a major problem. These discomforts and dietary modifications that may provide relief are discussed in chapter 16 ∞.

Herbal, Botanical, and Alternative Therapies

While the use of some herbal, botanical, and alternative therapies may seem like a natural and safe alternative to some individuals, the pregnant consumer should take caution. Very few clinical trials exist that have examined the safety of supplements and herbs during pregnancy. Pregnant women should be advised to avoid alternative therapies until further research can determine their safety. Herbal and botanical supplements may potentially cause complications during the pregnancy and should be discontinued immediately when a woman determines she is pregnant. (ADA, 2009)

Use of Artificial Sweeteners

Foods and beverages that contain artificial sweeteners are increasingly available. Sweeteners classified as Generally Recognized as Safe (GRAS) by the Food and Drug Administration (FDA) are acceptable for use during pregnancy and include acesulfame potassium (Sweet One), aspartame (NutraSweet, Equal), saccharin (Sweet N Low, Sugar Twin), and sucralose (Splenda). As with other foods, moderation should be exercised in using artificial sweeteners.

Stevia sweeteners (Truvia, PureVia, SunCrystals) are the newest low-calorie sweeteners to become available. Derived from leaves of the Stevia rebaudiana Bertoni plant, Rebaudioside A is FDA approved for safe consumption as a sweetener. While Stevia sweeteners are marketed as natural, at this time the sweeteners offer no additional clinical advantages over any other non-nutritive sweetener (International Food Information Council, 2009).

Mercury in Fish

Fish and shellfish are important parts of a healthy diet but nearly all contain traces of mercury. Although this is not a concern for most people, some fish and shellfish contain higher levels of mercury than others, and mercury can pose a threat to the unborn baby or a young child. The developing fetal brain is quite susceptible to the neurotoxic effects of mercury, which crosses the placenta and the blood-brain barrier. Mercury exposure can have a negative effect on cognitive functioning, resulting in deficiencies in language, attention, motor function, memory, and visual-spatial abilities (Huffling, 2006). Because of this, the U.S. government has issued the following guidelines for women who are pregnant or who may become pregnant, breastfeeding mothers, and young children (FDA, 2004):

- Do not eat swordfish, shark, tilefish, or king mackerel, because these fish contain high levels of mercury.
- Eat up to 12 oz/week (two average meals) of a variety of shellfish and fish that are lower in mercury. (Commonly eaten fish that are lower in mercury include canned light tuna, shrimp, salmon, catfish, and pollack. Albacore [white] tuna has more mercury than canned light tuna, so only 6 ounces/week of albacore tuna is recommended.)
- Check local advisories about the mercury content of fish caught locally by family and friends. If no information is available, limit fish caught in local areas to 6 oz/week and avoid consuming additional fish that week.

Salmonella and Listeria Infection

The pregnant woman's immune system is somewhat weakened during pregnancy, As a result, pregnant women and their fetuses are at high risk for foodborne illnesses, which can cause miscarriage, serious health problems, or even maternal death.

Because of the risk of *Salmonella* contamination in raw eggs, pregnant women are advised to avoid eating or tasting foods that may contain raw or lightly cooked eggs. These foods include, for example, cake batter, cookie dough made with raw eggs, homemade eggnog, sauces made with raw eggs such as Caesar salad dressing and hollandaise sauce, and homemade ice cream (FDA, 2009).

Listeria monocytogenes is another bacterium that poses a threat to an expectant mother and her fetus. Listeria is especially challenging because the organism can be found in refrigerated, ready-to-eat foods such as unpasteurized milk and dairy products, meat, poultry, and seafood. To prevent listeriosis, pregnant women should be advised to do the following (FDA, 2009):

- Maintain refrigerator temperature at 40°F (4°C) or below and the freezer at 0°F (−18°C).
- Refrigerate or freeze prepared foods, leftovers, and perishables within 2 hours after eating or preparation.
- Do not eat hot dogs and luncheon meats unless they are reheated until they are steaming hot.
- Avoid soft cheeses such as feta, brie, Camembert, blue veined cheeses, queso fresco, or queso blanco (a soft cheese often used by Hispanic women in their cooking) unless the label clearly states that they are made with pasteurized milk.
- Do not eat refrigerated patés or meat spreads or foods that contain raw (unpasteurized) milk or drink unpasteurized milk.
- Avoid eating refrigerated smoked seafood such as salmon, trout, cod, tuna, or mackerel unless it is in a cooked dish such as a casserole. Canned or shelf-stable patés, meat spreads, and smoked seafood are considered safe to eat.

Lactase Deficiency (Lactose Intolerance)

Some individuals have difficulty digesting milk and dairy products. This condition, known as **lactase deficiency**, or **lactose intolerance**, results from an inadequate amount of the enzyme lactase, which breaks down the milk sugar lactose into smaller digestible substances.

Lactase deficiency is a common condition affecting millions in the United States. Some ethnic and racial populations are more affected than others and include African Americans, Hispanic Americans, American Indians, and Asian Americans (National Digestive Diseases Information Clearinghouse, 2009). People who are not affected are mainly of Northern European heritage. Symptoms may include abdominal distention, discomfort, nausea, vomiting, loose stools, and cramps.

When counseling pregnant women who might be intolerant of milk and milk products, the nurse should be aware that tolerances vary between individuals and even a partial serving of milk or dairy products can produce symptoms. Lactase deficiency need not be a problem for pregnant women, because the enzyme is available over the counter in tablets or drops. In addition, specially treated cow's milk is now available in most large grocery stores.

Cultural, Ethnic, and Religious Influences

Cultural, ethnic, and, occasionally, religious backgrounds determine one's experiences with food and influence food preferences and habits (Figure 18-3 ■). People of different nationalities are accustomed to eating foodstuffs available in their country of origin and prepared in a manner consistent with the customs and traditions of their ethnic and cultural group. In addition, the laws of certain religions allow particular foods, prohibit others, and direct the preparation and serving of meals. (See Developing Cultural Competence: The Kosher Diet.)

In each culture, certain foods have symbolic significance. Generally, these symbolic foods are related to major life experiences such as birth, death, or developmental milestones. Although generalizations have been made about the food practices of ethnic and religious groups, there are many variations. Food customs will differ among groups in various regions of the same country, among families within local regions, and among individuals within the same family. The extent to which the use of traditional ethnic foods and customs is continued is affected by the recency of immigration; the extent of exposure to other cultures; and the availability, quality, and cost of the traditional foods.

When working with a pregnant woman from any ethnic background, the nurse needs to understand the cultural influences on the woman's eating habits and to identify beliefs she may have about foods and pregnancy. Talking with the patient can enable the nurse to determine the level of influence that traditional food customs exert. Only then can the nurse provide dietary advice in a manner that is meaningful to the woman.

Figure 18-3 ■ Cultural factors affect food preferences and habits.

DEVELOPING CULTURAL COMPETENCE

The Kosher Diet

The kosher diet followed by many Jewish people forbids the eating of pig products and shellfish. Certain cuts of meat from sheep and cattle are allowed as are fish with fins and scales. In addition, many Jews believe that meat and dairy products should not be mixed or eaten at the same meal.

Psychosocial Factors

The sharing of food has long been a symbol of friendliness, warmth, and social acceptance in many cultures. Food is also symbolic of motherliness; that is, taking care of the family and feeding them well is a part of the traditional mothering role. Some foods and food-related practices are associated with status. Certain items may be prepared "just for company." Other foods are served only on special occasions—holidays such as Thanksgiving, for example.

Socioeconomic level may be a determinant of nutritional status. Poverty-level families are unable to afford the same foods that higher income families can. Thus, pregnant women with low incomes are frequently at risk for inadequate intake of nutrients.

Knowledge about the basic components of a balanced diet is essential. Often educational level is related to economic status, but even people on very limited incomes can prepare well-balanced meals if their knowledge of nutrition is adequate.

The expectant woman's attitudes and feelings about her pregnancy may influence her nutritional status. For example, food may be used as a substitute for the expression of emotions such as anger or frustration, or as a way of expressing feelings of joy. The woman who is depressed or who does not wish to be pregnant may manifest these feelings by loss of appetite or by an overindulgence of certain foods.

Eating Disorders

Millions of men and women are affected by eating disorders each year, but eating disorders are most common in adolescent girls and young women. These psychologic disorders can have a major impact on a pregnant patient's physiologic and emotional well-being.

Anorexia nervosa is an eating disorder that is characterized by an extreme fear of weight gain and fat. People with this problem have distorted body images and perceive themselves as fat even when they are extremely underweight. Their dietary intake is very restrictive in both variety and quantity. They may also engage in excessive exercise to prevent weight gain.

Bulimia nervosa, another eating disorder, is characterized by bingeing (secretly consuming large quantities of food in a short period) and purging. Self-induced vomiting is the most common method of purging; laxatives and/or diuretics may also be used. Individuals with bulimia often maintain normal or near-normal weight for their height, so it is often difficult to know whether bingeing and purging occur.

Although pregnancies occur most often in women of normal weight, the underweight woman can conceive. The presence of an eating disorder can be difficult to detect because of the secretive nature of the behaviors. Many women will decrease or

UNICEF

TABLE 18-7 Abnormalities That May Indicate an Undisclosed Eating Disorder

Somatic

- Arrested growth
- Marked change or frequent fluctuation in weight
- Inability to gain weight
- Fatigue
- Constipation or diarrhea
- Susceptibility to fractures
- Delayed menarche
- Hypokalemia, hyperphosphatemia, metabolic acidosis or alkalosis, or high serum amylase levels

Behavioral

- Change in eating habits
- Difficulty eating in social settings
- Reluctance to be weighed
- Depression
- Social withdrawal
- Absence from school or work
- Deceptive or secretive behavior
- Stealing (e.g., to obtain food)
- Substance abuse
- Excessive exercise

discontinue their eating disorder behaviors during pregnancy, only to resume them postpartum. Table 18-7 identifies abnormalities that may indicate an eating disorder.

Women with eating disorders who become pregnant are at risk for a variety of complications. The consequences of the restricting, bingeing, and purging behaviors characteristic of eating disorders can result in a lack of nutrients available for the fetus. Women with eating disorders are at increased risk for miscarriage, low birth weight, premature birth, obstetric complications, perinatal mortality, and birth defects (Madsen, 2009). Pregnancy can be an especially difficult time for the woman with an eating disorder, even if she has long desired a child. For someone who already struggles with eating and body image, the consumption of additional food and the expectations that she will gain additional weight can result in feelings of fear, anxiety, depression, and guilt. Women with eating disorders also have high rates of depression postpartally (Astrachan-Fletcher, Veldhuis, Lively, et al., 2008). When working with a pregnant woman with an eating disorder, education and individualized meal plans can help the woman increase her dietary intake while maintaining a sense of control.

The treatment needs of a woman with an eating disorder can best be met by a team approach that includes medical, nutritional, and psychiatric practitioners who are familiar with eating disorders. The pregnant woman with an eating disorder needs to be closely monitored and supported throughout her pregnancy to help ensure the best possible outcome.

> *"I developed anorexia during my sophomore year in college. My parents were shocked when they saw me at Thanksgiving and, fortunately, they got me some help. For the past several years I have maintained my weight in the low normal range and feel OK about it. Now I am expecting my first child. It is so hard to think of gaining 25 to 30 pounds, but I am working very hard to eat properly for my baby. I have reconnected with my therapist so that I can be sure I keep my head on straight about the importance of good nutrition. I don't think people realize how tough eating disorders are to overcome but I will NOT jeopardize my child, I just won't!"*

Pica

Pica is the persistent craving and eating of substances such as ice, freezer frost, cornstarch, laundry starch, baby powder, clay, dirt, and other nonnutritive substances. Most women who eat such substances do so only during pregnancy.

Iron deficiency anemia is the most common concern with pica. The ingestion of laundry starch or certain types of clay may contribute to iron deficiency by replacing iron-containing foods from the diet or by interfering with iron absorption. Women with pica that involves eating ice or freezer frost often have poor weight gain because of lack of appetite, whereas the ingestion of starch may be associated with excessive weight gain. The ingestion of large quantities of clay could fill the intestine and cause fecal impaction.

Assessment for pica is an important part of a nutritional history. However, women may be embarrassed about their cravings or reluctant to discuss them for fear of criticism. It is helpful if the nurse uses a nonjudgmental approach and explains the possible harmful effects. Some women are able to switch to eating nonfat powdered milk instead of laundry starch and frozen fruit pops instead of ice. Others find that sucking on hard lemon or mint candies helps decrease the craving.

Nutritional Care of the Pregnant Adolescent

Nutritional care of the pregnant adolescent is of particular concern to healthcare professionals. Many adolescents are nutritionally at risk because of a variety of complex and interrelated emotional, social, and economic factors that may adversely affect dietary intake. Nutritional status is an important, modifiable variable in any pregnancy, but especially in adolescent pregnancy because teens are more likely than older women to be underweight at the onset of pregnancy and to gain less weight during pregnancy. For women who are underweight when they become pregnant, the greater the weight gain, the lower the incidence of perinatal mortality. Conversely, more adolescents are overweight or obese today than in the past. Overweight and obese teens are at increased risk for adult obesity and for developing diabetes and risk factors for coronary heart disease (Groth, 2006). Important nutrition-related factors

Application: Pica

to assess in pregnant adolescents include low prepregnant weight, low weight gain during pregnancy, younger age with regard to menarche, smoking, excessive prepregnant weight, anemia, unhealthy lifestyle (drugs, alcohol use), chronic disease, and history of an eating disorder.

Adolescent women generally are considered physiologically mature about 4 years after menarche because linear growth is usually completed by this time. Their nutritional needs would be similar to those of other "adult" women. Adolescents who become pregnant fewer than 4 years after menarche, however, are at a high biologic risk because of their physiologic and anatomic immaturity. They are most likely to be growing, which can impact the fetus's development. Nutritional needs for these young women will be higher than for those whose growth has been completed. Thus young adolescents (13 to 15 years) need to gain more weight than older adolescents (16 years or older) to produce babies of equal size. In determining the optimum weight gain for a pregnant adolescent, the nurse needs to add the recommended weight gain for a normal adult pregnancy to the amount of weight gain expected during the postmenarcheal year during which the pregnancy occurs. Young adolescents (2 years after menarche) should strive for a weight gain at the upper end of the range of weight gain for adults (see Table 18-2).

The nutritional needs of pregnant adolescents are generally estimated by using the dietary reference intake (DRI) for nonpregnant teenagers (ages 11 to 14 or 15 to 18) and adding nutrient amounts recommended for all pregnant women (see Table 18-1).

Specific Nutrient Concerns

Caloric needs of pregnant adolescents vary widely. Major factors in determining caloric needs include whether growth has been completed and the physical activity level of the individual. Figures as high as 50 kcal/kg have been suggested for young, growing teens who are very active physically. A satisfactory weight gain will confirm adequacy of caloric intake in most cases.

An inadequate iron intake is a major concern with the adolescent diet. Iron needs are high for the pregnant teen because of the requirement for iron by the enlarging maternal muscle mass and blood volume. Iron supplements—providing 30 to 60 mg of elemental iron—are indicated.

Calcium is another nutrient that demands special attention from pregnant adolescents. Inadequate intake of calcium is frequently a problem in this age group. Adequate calcium intake is needed to support normal growth and development of the fetus as well as growth and maintenance of calcium stores in the adolescent. Inadequate calcium has been associated with maternal hypertension and preeclampsia. Pregnant adolescents who consume adequate calcium have a lower incidence of hypertension, preterm birth, and low-birth-weight infants (Stang, Story, & Feldman, 2005). An extra serving of dairy products is usually recommended for teenagers. Calcium supplementation is indicated for teens with an aversion to or intolerance of milk unless other dairy products or significant calcium sources are consumed in sufficient amounts.

Because folic acid plays a role in cell reproduction, it is also an important nutrient for pregnant teens. As previously indicated, a supplement is often suggested for pregnant females, whether adult or adolescent.

Other nutrients and vitamins must be considered when evaluating the overall nutritional quality of the teenager's diet. Nutrients that have frequently been found to be deficient in this age group include zinc and vitamins A, D, E, and B_6. Eating a wide variety of foods—especially fresh and lightly processed foods—is helpful in obtaining adequate amounts of trace minerals, fiber, and other vitamins.

Dietary Patterns

Healthy adolescents often have irregular eating patterns. Many skip breakfast, and most tend to be frequent snackers. Teens rarely follow the traditional three-meals-a-day pattern; their day-to-day intake often varies drastically; and they eat food combinations that may seem bizarre to adults. Despite this, adolescents usually achieve a better nutritional balance than most adults would expect.

> "My mom is so cool. She has hung in with me throughout this pregnancy even though I know she feels bad about it—she thinks my life will be harder and I guess she is right. She is really working to make sure that I eat right so that I have a healthy baby but instead of nagging, she has turned this into something we are doing together. We have taken a couple of cooking classes and experimented with different recipes. Last week we made some great but healthy snacks and I brought them to my friend Cary's birthday party. Those snacks just disappeared!"

In assessing the diet of the pregnant adolescent, the nurse should consider the eating pattern over time, not simply a single day's intake. This pattern is critical because of the irregularity of most adolescent eating patterns. Once the pattern is identified, counseling can be directed toward correcting deficiencies.

Counseling Issues

A positive approach to nutritional counseling for the pregnant adolescent is more effective than a negative one. The nurse must be ready to suggest nutrient-dense foods that pregnant teens can choose in many places and at any time. If an adolescent's family member does most of the meal preparation, it may be useful to include that person in the discussion if the adolescent agrees. Involving the expectant father in counseling may be beneficial. The pregnant teenager will soon become a parent, and her understanding of nutrition will influence not only her well-being but also that of her child. However, teens tend to live in the present, and counseling that stresses long-term changes may be less effective than more concrete approaches. Messages should emphasize that the pregnant teen is eating for her own health and that of the baby and should focus on foods themselves rather than on nutrients. In many cases, classes with other teens are effective. In

a group atmosphere, adolescents often work together to plan adequate meals including foods that are their special favorites.

Postpartum Nutrition

Nutritional needs will change following the birth. Nutrient requirements will vary depending on whether the mother decides to breastfeed. An assessment of postpartal nutritional status is necessary before the nurse provides nutritional guidance.

Postpartum Nutritional Status

Postpartum nutritional status is determined primarily by assessing the new mother's weight, hemoglobin and hematocrit levels, clinical signs, and dietary history.

As previously discussed, an ideal weight gain for the normal-weight woman during pregnancy is between 11.5 and 16 kg (25 and 35 lb). (See Table 18-2.) After birth, there is a weight loss of approximately 10 to 12 lb. Additional weight loss will be most rapid during the first few weeks after birth as the uterus returns to normal size, tissue fluids are released, and maternal blood volume returns to normal. The mother's weight will then begin to stabilize. Weight loss may also be affected by lactation. Individual weight loss of women who breastfeed will vary but tends to be greater than that of women who do not if breastfeeding continues for at least 6 months.

The rate of postpartum weight loss is influenced by many factors. Some women approach their prepregnancy weight several weeks after birth; most approach this weight about 6 months later. The amount of weight gained during pregnancy is a major determinant of weight loss after childbirth. Generally, women who gain excessive weight during pregnancy are more likely to sustain a weight gain 1 year following childbirth, putting them at increased risk of long-term overweight or obesity.

It is important to evaluate the mother's current weight, ideal weight for her height, weight before pregnancy, and weight before the birth. Women who are interested in weight reduction should be referred to a dietitian. Hemoglobin and erythrocyte values vary after birth, but they should return to normal levels within 2 to 6 weeks. Hematocrit levels should rise gradually because of hemoconcentration as extracellular fluid is excreted. The hematocrit is usually checked at the postpartum visit to detect any anemia. Mothers can be encouraged to eat a diet high in iron. Iron supplements are generally prescribed for 2 to 3 months following birth to replenish supplies depleted by pregnancy.

The nurse assesses any clinical symptoms the new mother may be experiencing. Food cravings and aversions typically drop significantly during the postpartal period and do not usually pose a problem. However, constipation is a common problem following birth. The nurse can encourage the woman to maintain a high fluid intake to keep the stool soft. Dietary sources of fiber and physical exercise are also helpful in preventing constipation.

Care Plan Activity: Maternal Nutritional Requirements

The nurse obtains specific information on diet and eating habits directly from the woman. Visiting the mother during mealtimes provides an opportunity for unobtrusive nutritional assessment. Which foods has a woman selected? Has she avoided fruits and vegetables? Is her diet nutritionally sound? A comment focusing on a positive aspect of her meal selection may initiate a discussion of nutrition.

The dietitian should be informed about any woman whose cultural or religious beliefs require specific foods. Appropriate meals can then be prepared for her. The nurse may also refer women with unusual eating habits or numerous questions about food or nutrition to a dietitian. In all cases, the nurse should provide literature on nutrition so that the woman will have a source of appropriate information at home.

Nutritional Care of Formula-Feeding Mothers

After birth, the formula-feeding mother's dietary requirements return to prepregnancy levels (see Table 18-1). If the mother has a good understanding of nutritional principles, it is sufficient to advise her to reduce her daily caloric intake by about 300 kcal and to return to prepregnancy levels for other nutrients.

If the mother has a poor understanding of nutrition, this is an opportunity to teach her the basic principles and the importance of a well-balanced diet. Her eating habits and dietary practices will eventually be reflected in the diet of her child.

If the mother has gained excessive weight during pregnancy (or perhaps was overweight before pregnancy), referral to a dietitian is appropriate. The dietitian can design weight reduction diets to meet nutritional needs and food preferences. Weight loss goals of 1 to 2 lb per week are usually suggested.

In addition to learning how to meet her own nutritional needs, the new mother will usually be interested in learning how to provide for her infant's nutritional needs. A discussion of infant feeding, which includes topics such as selecting infant formulas, formula preparation, and vitamin and mineral supplementation, is appropriate and generally well received.

Nutritional Care of Breastfeeding Mothers

Nutrient needs increase during breastfeeding. Table 18-1 lists the dietary reference intakes (DRIs) during breastfeeding for specific nutrients. Table 18-3 includes a daily food guide for lactating women. A few key nutrients need further discussion.

Calories

One of the most important factors in the breastfeeding woman's diet is calories. An inadequate caloric intake can reduce milk volume. However, milk quality generally remains unaffected. The breastfeeding mother should increase her caloric intake by 200 kcal over the pregnancy requirements (that is, a 500-kcal increase from her prepregnancy requirement). This results in a total of about 2500 to 2700 kcal per day for most women.

Depending on her own dietary preferences, the breastfeeding mother can use the MyPyramid for Moms food guide to assess her dietary intake. She should strive to include a variety of foods from each food group. Her caloric intake needs to provide enough energy to sustain lactation. After her weight stabilizes several weeks following childbirth, weight loss should not exceed more than 1 lb per week.

Protein

An adequate protein intake is essential while breastfeeding because protein is an important component of breast milk. An intake of 65 g per day during the first 6 months of breastfeeding and 62 g per day thereafter is recommended. As in pregnancy, it is important that the woman consume adequate nonprotein calories to prevent the use of protein as an energy source.

Calcium

Calcium is also an important nutrient in milk production, and increases over nonpregnancy needs are expected. Requirements during breastfeeding remain the same as requirements during pregnancy: 1000 mg per day. An inadequate intake of calcium from food sources necessitates the use of calcium supplements.

Iron

Iron needs during lactation are not substantially different from those of nonpregnant women because iron is not a principal component of breast milk. However, as previously mentioned, continued supplementation of the mother for 2 to 3 months after parturition is advisable to replenish maternal stores depleted by pregnancy.

Fluids

Liquids are especially important during lactation because inadequate fluid intake may decrease milk volume. The recommended fluid intake of 8 to 10 (8 oz) glasses daily can be met by the consumption of water, juices, milk, and soups.

> "For me, the hardest part of breastfeeding was drinking enough fluid. I am not a big water person and they told me to go easy on caffeine beverages. Once I started adding a slice of lemon to my water, I found it a lot easier. My baby is 13 months old now and I have stopped breastfeeding, but I still drink the water with lemon. I think I have developed a good new habit!"

Counseling Issues

In addition to counseling mothers on how to meet their increased nutrient needs during breastfeeding, nurses should discuss a few issues related to infant feeding. For example, many mothers are concerned about how specific foods they eat will affect their babies during breastfeeding. Generally, there are no foods the nursing mother must avoid except those to which she might be allergic. Occasionally, however, some breastfeeding mothers find that their babies are affected by certain foods. Onions, turnips, cabbage, chocolate, spices, and seasonings are commonly listed as offenders. The best advice to give the breastfeeding mother is to avoid those foods she suspects cause distress in her infant. For the most part, however, she should be able to eat any nourishing food she wants without fear that her baby will be affected. For further discussion of successful infant feeding, see chapter 32 ∞.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse needs to assess nutritional status in order to plan an optimal diet with each woman. The nurse may gather data by consulting the woman's chart and by interviewing her. Information is obtained about the following:

- The woman's height and weight and her weight gain during pregnancy
- Pertinent laboratory values, especially hemoglobin and hematocrit
- Clinical signs that have possible nutritional implications, such as constipation, anorexia, or heartburn
- Diet history to determine the woman's views on nutrition as well as her specific nutrient intake

The nurse can obtain a diet history by asking the woman to complete a 24-hour diet recall, in which she lists everything consumed in the previous 24 hours, including foods, fluids, and any supplements. At least 3 days of diet recalls should be done to compensate for daily variations. Diet may also be evaluated using a food frequency questionnaire. The questionnaire lists common categories of foods and asks the woman how frequently in a day (or week) she consumes foods from the list. Common categories include vegetables, fruits, milk or cheese, meat or poultry, fish, desserts or sweets, coffee or tea, and alcoholic beverages. This method may be less reliable because it requires the individual to be accurate about her intake.

PROFESSIONALISM IN PRACTICE

Taking a Diet History

When completing a diet history, nurses who are effective communicators remember that it is as important to identify the foods a woman avoids as it is to determine which foods she eats.

During the data-gathering process, the nurse has an opportunity to discuss important aspects of nutrition in the context of the family's needs and lifestyle. The nurse also seeks information about psychologic, cultural, and socioeconomic factors that may influence food intake.

The nurse can use a nutritional questionnaire to gather and record important facts. This information provides a database that the nurse can use to develop an intervention plan to fit the woman's individual needs. The sample questionnaire shown in Figure 18-4 ■ has been filled in to demonstrate this process.

Once the data are obtained, the nurse begins to analyze the information, formulate appropriate nursing diagnoses, and develop patient goals. For a woman during the first trimester, for example, the diagnosis may be *Imbalanced Nutrition: Less than Body Requirements* related to nausea and vomiting. In many cases the diagnosis may be related to excessive weight gain. In such cases the diagnosis might be *Imbalanced Nutrition: More than Body Requirements* related to excessive calorie intake. Although these diagnoses are broad, the nurse must

2. **How many snacks per day?** 3 **when** 10:30 am 4:00 pm 10:00 pm
3. **What other foods are important to your usual diet?** chocolate and candy bars
4. **Amount per day** 4 bars/week
5. **Do you have any different food preferences now?** no
6. **Do you eat nonfoods such as:**

		Amount
laundry starch	no	NA
ice	yes	10 cubes/day
other (name)	no	NA

7. **What foods do you dislike or do not eat?** spinach and dried beans
8. **For added information complete a typical daily intake (24-hour recall is suggested).**

Do you have special problems in food preparation such as:

1. **Physical disability** yes _____ no ✔ **Explain** _____
2. **Cooking appliances** yes _____ no ✔ **Explain** _____
3. **Refrigeration of food** yes _____ no ✔ **Explain** _____

Who does the meal planning? I do. **shopping?** We both do.

cooking? I do most of the time but my husband likes to help.

Are there transportation problems? We have only one car but we go in the evening.

Financial situation: My husband is working and going to school. I am not working. **Food stamps** yes **WIC** no

Do you have any previous nutritional problems? No. I have never paid much attention to food before, but now I have lots of questions.

Are there any problems with this pregnancy? Nausea Yes, in the morning.

Constipation No **Other** NA

Assessment by the nurse following the completion of the questionnaire.

Basic estimated nutrient and caloric value of typical daily intake.

Please circle one of the following:

Protein intake was	low	(adequate)	high
Caloric intake was	low	adequate	(high)
Calcium intake was	(low)	adequate	high
Iron intake was	(low)	adequate	high
Vitamin C intake was	low	(adequate)	high

Figure 18-4 ■ Sample nutritional questionnaire used in nursing management of a pregnant woman.

be specific in addressing issues such as inadequate intake of nutrients such as iron, calcium, or folic acid; problems with nutrition because of a limited food budget; problems related to physiologic alterations, such as anorexia, heartburn, or nausea; and behavioral problems related to excessive dieting, anorexia nervosa, or bulimia. In some instances, the diagnosis *Readiness for Enhanced Knowledge* may seem most appropriate, especially if the woman asks for information about nutrition.

Nursing Plan and Implementation

After the nursing diagnosis is made, the nurse can plan an approach to correct any nutritional deficiencies or improve the overall quality of the diet.

Health Promotion Education

In counseling the pregnant woman, the nurse needs to avoid "talking down" to her or "preaching" to her. The nurse should present information in a clear, logical way, using appropriate language but avoiding jargon. Examples are often helpful in clarifying material. The nurse should also answer all questions appropriately and clearly.

When a person requires nutritional counseling, a dietary change usually is necessary. However, change is often difficult. Counseling will be more effective if the nurse understands the woman's values and explains the needed change in a way that is meaningful to the patient. Because the pregnant woman must follow the plan, it should be developed in cooperation with her; be suitable for her financial level and background; and be based on reasonable, achievable goals.

The following example demonstrates one way a nurse can implement a plan with a patient based on the nursing diagnosis.

Diagnosis: *Imbalanced Nutrition: Less than Body Requirements* related to low intake of calcium

Patient goal: The woman will increase her intake of calcium to the DRI level.

Implementation:

1. Plan with the woman additional milk or dairy products that she can reasonably add to the diet (specify amounts).
2. Encourage the use of other calcium sources, such as leafy green vegetables and legumes.
3. Plan for the addition of powdered milk in cooking and baking.
4. If none of the above is realistic or acceptable, consider the use of calcium supplements.

Most families can benefit from guidance about food purchasing and preparation. The nurse should advise women to plan food purchases thoughtfully by preparing menus and a grocery list before shopping. It is also helpful to advise patients to monitor sales, compare brands, and be selective when purchasing "convenience" foods, which tend to be expensive. Other techniques for keeping food costs down without jeopardizing quality include buying food in season, using bulk foods when appropriate, using whole grain or enriched products, buying lower grade eggs (grading has no relation to the egg's nutritional value but indicates color of the shell and delicacy of flavor), and avoiding fancy grades of food and foods in elaborate packaging.

Community-Based Nursing Care

Food is a significant portion of a family's budget, and meeting nutritional needs may be a challenge for families on limited incomes. Community-based services offered through clinics, local agencies, schools, and volunteer organizations are effective in addressing these needs. Increasingly, nurses play an important role in managing such community-based services, especially those services focusing on patient education. In addition, most communities offer special assistance to qualifying families to meet their nutritional needs. The Food Stamp Program provides stamps or coupons for participating households whose net monthly income is below a specified level. These stamps can be used to purchase food for the household each month.

The Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) is designed to assist low-income pregnant, postpartum, or breastfeeding women and their children under 5 years of age. To be eligible, applicants must meet income guidelines (income at or below 185% of the U.S. poverty level), state residency requirements, and be individually determined to be nutritionally at risk by a healthcare professional (Food and Nutrition Service, 2009). The program provides food assistance, nutrition education, and referrals to healthcare providers. The food distributed, including dried beans and peas, peanut butter, eggs, cheese, milk, fortified adult and infant cereals, juice, and iron-fortified infant formula, is designed to provide good sources of iron, protein, and certain vitamins for individuals with an inadequate diet. Participation in the WIC program during pregnancy and infancy is associated with a reduced risk of infant death. In addition, the WIC program is credited with helping reduce the incidence of low birth weight in infants and in decreasing the incidence of anemia in the infants and young children of low-income families.

Evaluation

Once a plan has been developed and implemented, the nurse and patient may wish to identify ways of evaluating its effectiveness. Evaluation may involve keeping a food journal, writing out weekly menus, returning weekly for weighing, and the like. If anemia is a special problem, periodic hematocrit assessments are also indicated.

Women with serious nutritional deficiencies are referred to a dietitian. The nurse can then work closely with the dietitian and the patient to improve the pregnant woman's health by modifying her diet.

FOCUS YOUR STUDY

- Maternal weight gains averaging 11.5 to 16 kg (25 to 35 lb) for a normal-weight woman are associated with the best reproductive outcomes.
- If the diet is adequate, folic acid and iron are the only supplements generally recommended during pregnancy.
- Women should not restrict caloric intake to reduce weight during pregnancy.
- Pregnant women should be encouraged to eat regularly and to eat a wide variety of foods, especially fresh and lightly processed foods.
- Taking megadoses of vitamins during pregnancy is unnecessary and potentially dangerous.
- Pregnant women who eat vegetarian diets should place special emphasis on obtaining ample proteins, calories, calcium, iron, vitamin D, vitamin B_{12}, and zinc through food sources or supplementation if necessary.
- Pregnant women should avoid eating fish such as swordfish, shark, tilefish, or king mackerel, which contain high levels of mercury, and should limit their intake of fish that are lower in mercury.
- Food safety and sanitation should be a priority when preparing and storing food; foods that are known to cause foodborne illness should be avoided during pregnancy.
- Evaluation of physical, psychosocial, and cultural factors that affect food intake is essential before the nurse can determine nutritional status and plan nutritional counseling.
- Adolescents who become pregnant less than 4 years after menarche have higher nutritional needs and are considered to be at high biologic risk.
- Weight gains during adolescent pregnancy must accommodate recommended gains for a normal pregnancy plus necessary gains due to growth.
- After childbirth, the formula-feeding mother's dietary requirements return to prepregnancy levels.
- Breastfeeding mothers require an additional 200 calories above pregnancy intake and increased fluid intake to maintain ample milk volume.

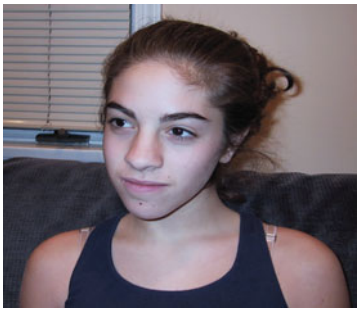
CRITICAL THINKING IN ACTION



Sandra Hill is a 17-year-old at 19 weeks' gestation with her first pregnancy. She presents to you accompanied by her mother. Her mother tells you that Sandra is an active teenager who plays sports and has been taking dance lessons for 5 years. She maintains a B+ average in school. Sandra voices concern about potential weight gain during pregnancy. She tells you that this was not a planned pregnancy and she has ambivalent feelings about it. You become concerned as she tells you that she has reduced her caloric intake over the last few months to try to keep her weight down and camouflage her pregnancy. You do a nutritional assessment and find that she is deficient in calcium, iron, and protein. Sandra seems to have irregular eating patterns and she admits to skipping breakfast often. She asks why she has to gain so much weight when you explain the nutritional needs of her baby during the pregnancy.

1. Discuss weight distribution in pregnancy.
2. Discuss foods that will increase calcium, protein, and iron in her diet.
3. Explain why folate supplementation is important.
4. What criteria will measure adequate caloric intake during pregnancy?

See www.nursing.pearsonhighered.com for possible responses.

CHAPTER 19

Pregnancy at Risk: Pregestational Problems

Today is the anniversary of my Julie's death. She died of a heroin overdose. During the years before her death, we tried everything to help her, but nothing worked. She would disappear, sometimes for weeks, and then reappear filled with good intentions to kick her habit—but she never could. She was 29 when I lost her, and 3 months pregnant with our grandchild. I miss her so. I don't know if my heart will ever mend.

LEARNING OUTCOMES

1. Summarize the effects of alcohol and illicit drugs on the childbearing woman and her fetus/newborn.
2. Discuss the pathology, treatment, and nursing care of pregnant women with diabetes.
3. Discriminate among the four major types of anemia associated with pregnancy with regard to signs, treatment, and implications for pregnancy.
4. Discuss AIDS, including care of the pregnant woman with HIV/AIDS, neonatal implications, and ramifications for the childbearing family.
5. Describe the effects of various heart disorders on pregnancy, including their implications for nursing care.
6. Compare the effects of selected gestational medical conditions on pregnancy.

KEY TERMS

AIDS *436*
Crack *419*
Gestational diabetes mellitus (GDM) *423*
HIV *436*
Macrosomia *424*

Pregnancy is biologically, physiologically, and psychologically stressful, even for healthy women. For women with preexisting (pregestational) conditions such as substance abuse, diabetes, HIV infection, and cardiac disease, it may be life threatening. For these women, pregestational counseling is especially important to identify early interventions designed to diminish the adverse effects of pregnancy on both the mother and fetus. In some cases, interventions before conception may be critical.

Prenatal care is aimed toward identification, assessment, and care management of women whose pregnancies are at risk because of potential or existing complications. This chapter focuses on women with pregestational medical disorders and their possible effects on the outcome of pregnancy. Chapter 20 ∞, in turn, focuses on medical disorders that develop during pregnancy.

Care of the Woman Practicing Substance Abuse

Substance abuse occurs when an individual experiences difficulties with work, family, social relations, and/or health as a result of alcohol or drug use. National survey data indicate that approximately 8% of people in the United States used illicit drugs in the month before the survey was taken (Substance Abuse and Mental Health Services Administration [SAMHSA], 2009). In general, the rate of illicit drug use among pregnant women is less than half the rate as among nonpregnant women (9.8%). Specifically, 5.1% of pregnant women reported using an illicit drug during pregnancy. However, illicit drug usage varies greatly by age, peaking at 21.6% of users in the 15- to 17-year-old age group for pregnant females, a much higher rate than nonpregnant females (12.9%) at the same age (SAMHSA, 2009). See Figure 19-1 ■.

Because women of childbearing age (15 to 44 years) make up a substantial proportion of the drug-using population, the problem has major significance for women and children. In testimony to these statistics is the increasing number of drug-exposed infants being born throughout the United States. Indiscriminate use of drugs during pregnancy, particularly in the first trimester, may adversely affect the health of the woman and the growth and development of her fetus. Drugs that are commonly misused include tobacco, alcohol, cocaine, marijuana, amphetamines, barbiturates, hallucinogens, club drugs, heroin, and other narcotics. Tobacco is discussed in chapter 16 ∞ as a teratogenic substance. Table 19-1 identifies common addictive drugs and their effects on the fetus and newborn.

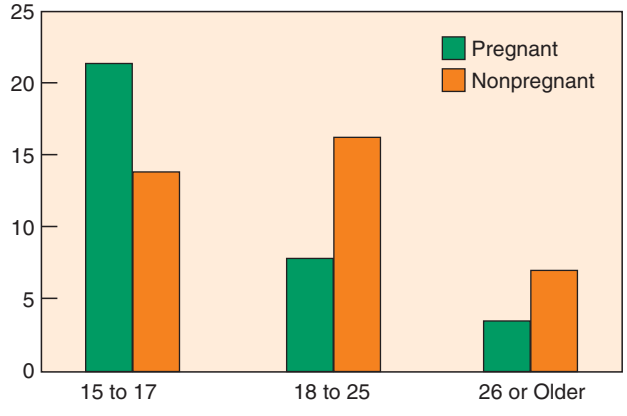

Figure 19-1 ■ Percentages of females ages 15 to 44 reporting past month use of any illicit drugs, by pregnancy status and age, 2008.

Source: Substance Abuse and Mental Health Services Administration. (2009). Results from the 2008 National Survey on Drug Use and Health: National Findings (Office of Applied Studies, NSDUH Series H-36, HHS Publication No. SMA 09-4434). Rockville, MD.

Drug use during pregnancy may be the most frequently missed diagnosis in all of maternity care. Substance-abusing women typically do not seek prenatal care until late in their pregnancy. They may be noncompliant or they may present in labor with no history of prenatal care. Even when they do seek care early, physicians and nurses may fail to ask the woman about drug and alcohol use because of their own lack of knowledge, discomfort, or biases. When asked, women may deny use of illegal substances out of fear, shame, or a reluctance to be confronted with the need to stop using the substance in question. Although some clinics perform routine or random drug screens, the patient should be informed that a drug screen is being performed and how the results will be provided to them.

CLINICAL TIP

Keep in mind that approximately 1 of 10 women in the United States, regardless of socioeconomic status or ethnic background, is currently abusing a substance. If you consider that possibility with every woman, you will ask the important questions about drug use and be alert for signs of substance abuse.

Providing prenatal care to chemically dependent women presents multiple dilemmas and challenges to clinicians. However, pregnancy represents a period in most women's lives when they recognize the need for and are receptive to caring and responsive interventions. By optimizing the prenatal experience of chemically dependent women, maternal-fetal outcomes can be improved and the groundwork laid for the ongoing therapeutic services that are needed to maintain the health and well-being of the mother and child (Amato et al., 2008).

The substance-abusing woman who seeks prenatal care may not voluntarily reveal her addiction, so caregivers should be alert for a history or physical signs that suggest substance abuse (Table 19-2). Because substance abuse has increased rapidly in the past decade, it is helpful to discuss the specific substances that are abused to increase understanding of this serious problem.

Substances Commonly Abused During Pregnancy

The substances most commonly abused during pregnancy are alcohol, nonmedical use of pain relievers and tranquilizers, inhalants, cocaine/crack, marijuana, phencyclidine (PCP),

TABLE 19-1 Possible Effects of Selected Drugs of Abuse/Addiction on Fetus and Newborn

MATERNAL DRUG	EFFECT ON FETUS/NEWBORN
Depressants	
Alcohol	Mental retardation, microcephaly, midfacial hypoplasia, cardiac anomalies, intrauterine growth restriction (IUGR), potential teratogenic effects, fetal alcohol syndrome (FAS), fetal alcohol effects (FAE).
Narcotics	
Heroin	Withdrawal symptoms, known as neonatal abstinence syndrome (NAS), include tremors, irritability, sneezing, vomiting, fever, diarrhea, abnormal respiratory function, and potential seizure activity.
Methadone	With abrupt maternal termination of the drug, severe withdrawal symptoms can include preterm labor, rapid labor, abruption, nonreassuring fetal status, and meconium aspiration. Neonates may present with NAS and be small for gestational age.
Barbiturates	Withdrawal symptoms.
Phenobarbital	Withdrawal symptoms. Fetal growth restriction.
Tranquilizers	
Diazepam (Valium)	Withdrawal symptoms (Gidai, Acs, Bánhidy, et al., 2008).
Antianxiety Drugs	
Lithium	Congenital anomalies.
Stimulants	
Amphetamines	
Amphetamines sulfate (Benzedrine)	Low birth weight, withdrawal symptoms (Thompson, Levitt, & Stanwood, 2009).
Cocaine	Cerebral infarctions, microcephaly, learning disabilities, poor state organization, decreased interactive behavior, central nervous system (CNS) anomalies, cardiac anomalies, genitourinary anomalies, sudden infant death syndrome (SIDS).
Nicotine (half to one pack cigarettes/day)	Increased rate of spontaneous abortion, increased incidence of placental abruption, small for gestational age (SGA), small head circumference, decreased length, SIDS, attention deficit hyperactivity disorder (ADHD) in school-age children.
Psychotropics	
PCP ("angel dust")	Withdrawal symptoms. Newborn behavioral and developmental abnormalities.
Marijuana	Possible association with structural and neurobehavioral defects (Hurt et al., 2009).

TABLE 19-2 Possible Signs of Substance Abuse

History
- History of vague or unusual medical complaints
- Family history of alcoholism or other addiction
- History of childhood physical, sexual, or emotional abuse
- History of cirrhosis, pancreatitis, hepatitis, gastritis, sexually transmitted infections, or unusual infections such as cellulitis or endocarditis
- History of high-risk sexual behavior
- Psychiatric history of treatment and/or hospitalization

Physical Signs
- Dilated or constricted pupils
- Inflamed nasal mucosa
- Evidence of needle "track marks" or abscesses
- Poor nutritional status
- Slurred speech or staggering gait
- Odor of alcohol on breath

Behavioral Signs
- Memory lapses, mood swings, hallucinations
- Pattern of frequently missed appointments
- Frequent accidents, falls
- Signs of depression, agitation, euphoria
- Suicidal gestures

MDMA (Ecstasy), and heroin (SAMHSA, 2009). For a discussion of the nonmedical abuse of pain relievers and tranquilizers, readers are referred to pharmacology textbooks. This chapter addresses alcohol use because of the profound, long-term effects it can have on a child and illicit substances to ensure that readers are aware of their implications.

Alcohol

Alcohol abuse has increased dramatically among women in the United States. An estimated 10.6% of pregnant women age 15 to 44 use alcohol in a given month, with 10.3% reporting binge drinking in the first trimester (SAMHSA, 2009). This figure is of concern because birth defects that are related to prenatal fetal exposure to alcohol can occur in the first 3 to 8 weeks' gestation, often before the woman even knows that she is pregnant.

Chronic abuse of alcohol can undermine maternal health by causing malnutrition (especially folic acid and thiamine deficiencies), bone marrow suppression, increased incidence of infections, and liver disease. As a result of alcohol dependence, the woman may have withdrawal seizures in the intrapartal period as early as 12 to 48 hours after she stops drinking. Delirium tremens may occur in the postpartal period, and the newborn may suffer withdrawal syndrome.

The effects of alcohol on the fetus may result in a group of signs referred to as fetal alcohol spectrum disorders (FASD). The syndrome has characteristic physical and mental abnormalities that vary in severity and combination. (See discussion in chapter 33 ∞.) There is no definitive answer as to how much alcohol a woman can safely consume during pregnancy. Consequently, the expectant woman should "play it safe" by avoiding alcohol completely. *Even low levels of alcohol should be avoided* (March of Dimes [MOD], 2008; O'Leary et al., 2009).

The nursing staff in the maternal-newborn unit must be aware of the manifestations of alcohol abuse so that they can prepare for the patient's special needs. The care regimen includes sedation to decrease irritability and tremors. Oral benzodiazepines such as lorazepam (Ativan) or diazepam (Valium) are most commonly used (Wisner et al., 2007). Seizure precautions, intravenous fluid therapy for hydration, and preparation for an addicted newborn are also part of care. Although high doses of sedatives and analgesics may be necessary for the woman, caution is advised because these can cause fetal depression.

Breastfeeding generally is not contraindicated, although alcohol is excreted in breast milk. Excessive alcohol consumption may intoxicate the infant and inhibit maternal let-down reflex. Discharge planning for the alcohol-addicted mother and newborn should be correlated with the social service department of the hospital.

Cocaine/Crack

Cocaine use appears to have reached its peak during the 1990s, but it continues to be of concern for the childbearing family (Bessaa et al., 2009). Cocaine acts at the nerve terminals to prevent the reuptake of dopamine and norepinephrine, which in turn results in vasoconstriction, tachycardia, and hypertension. Placental vasoconstriction decreases blood flow to the fetus.

Cocaine is usually taken in three ways: snorting, smoking, and intravenous (IV) injection. **Crack** is a form of freebase cocaine that is made up of baking soda, water, and cocaine mixed into a paste and microwaved to form a rock. The rock can then be smoked. Many women, especially those in low-income areas, favor this form of the drug over other forms because it is cheaper and readily available. In addition, smoking crack leads to a quicker, more intense high because the drug is absorbed through the large surface area of the lungs.

The onset of effects of cocaine occurs rapidly, but the euphoria lasts only about 30 minutes. Irritability, depression, pessimism, fatigue, and a strong desire for more cocaine usually follow this profound euphoria and excitement. This pattern often

RESEARCH EVIDENCE IN PRACTICE

Nonpharmacologic Treatment for Alcoholism in Pregnancy

CLINICAL QUESTION

What are effective treatments for preexisting alcoholism in women who become pregnant?

RESEARCH EVIDENCE

Women who abuse alcohol during pregnancy increase the risk of problems for their children, both in the immediate postpartum period and in later childhood (e.g., fetal alcohol syndrome, developmental delays, and/or behavioral changes). Experts have long recommended that alcohol intake be avoided during pregnancy. However, pregnant women with acute alcohol addiction may find it difficult to abstain. Thus, women who are addicted to alcohol should have early treatment for their substance abuse to promote a normal pregnancy and birth.

Three randomized controlled trials involving more than 7000 women focused on nonpharmacologic treatments for alcoholism during pregnancy. A Cochrane Collaborative review summarized another four studies involving more than 700 women into a practice guideline for management of prenatal alcoholism.

The ideal treatment is to offer maternal abstinence and alcohol withdrawal programs when women are contemplating pregnancy but have not yet conceived. These programs may also be initiated during pregnancy with close medical monitoring. These studies showed that educational and counseling interventions initiated during pregnancy can be effective in supporting maternal abstinence from alcohol. The most effective is the provision of an educational session and a self-help manual, followed by reinforcement at each prenatal visit.

WHAT QUESTIONS REMAIN UNANSWERED?

There was substantial variation in the content and type of educational and psychosocial interventions in all of these studies. A standard approach to nonpharmacologic interventions for alcohol withdrawal and abstinence has yet to be developed and remains a question.

WHAT IS BEST PRACTICE?

Women who suffer alcohol addiction or abuse and who are contemplating pregnancy should be encouraged to undergo withdrawal prior to conception. However, alcohol withdrawal during pregnancy can still result in a normal pregnancy if abstinence is practiced. An initial educational session with educational materials, followed by periodic reinforcement and psychologic support, can help women remain alcohol-free during pregnancy.

CRITICAL THINKING

What elements of an educational intervention could form the basis for a standard approach? What psychologic support is needed by women who are withdrawing from alcohol addiction?

leads the user to take repeated doses to sustain the effect. Cocaine metabolites may be present in the urine of a pregnant woman for up to 4 to 7 days following use.

The cocaine user is difficult to identify prenatally. Because cocaine is an illegal substance, many women are reluctant to volunteer information about their drug use. The nurse who is familiar with the woman may recognize subtle signs of cocaine use, including mood swings and appetite changes, and withdrawal symptoms such as depression, irritability, nausea, lack of motivation, and psychomotor changes.

Major adverse maternal effects of cocaine use include seizures and hallucinations, pulmonary edema, respiratory failure, and cardiac problems. Women who use cocaine have an increased incidence of spontaneous first trimester abortion, abruptio placentae, intrauterine growth restriction (IUGR), preterm birth, and stillbirth (Walton-Moss, McIntosh, Conrad, et al., 2009).

Exposure of the fetus to cocaine in utero seems to be associated with increased incidence of neonatal complications, especially decreased birth weight and head circumference (Singer et al., 2008). See chapter 33 ∞ for further discussion. A recent large, prospective randomized study demonstrated more autonomic nervous system dysfunction (irritability, jitteriness, tremors, high-pitched cry, and excessive suck) in exposed newborns (Richardson, Goldschmidt, & Willford, 2008). The study's authors note that often these women also use alcohol, tobacco, and marijuana as well as other drugs, so fetal exposure to multiple drugs may contribute to an increased incidence of congenital anomalies.

Exposed infants are found to have more feeding difficulties than nonexposed infants. These difficulties may be related to some extent to the infant's behaviors but have also been found to be related to maternal behaviors. Cocaine-using mothers were found to be less flexible, less engaged, and less responsive to their infants' feeding cues. Nursing interventions that help mothers interpret infant feeding cues and optimize the mother-infant relationship should be emphasized. In a longitudinal study of the effects of prenatal cocaine exposure, investigators continued to find changes in neurobehavioral function at 1 year and beyond (Richardson et al., 2008).

Cocaine does cross into the breast milk and may cause such symptoms in the breastfeeding infant as extreme irritability, vomiting, diarrhea, dilated pupils, and apnea. Thus women who continue to use cocaine following childbirth should avoid breastfeeding.

Marijuana

Typically, pregnant women use marijuana in conjunction with alcohol and tobacco. Men who smoke marijuana may have decreased sperm counts and may develop gynecomastia (enlarged breasts); women may experience menstrual cycle irregularities. To date, however, there is no evidence that marijuana has any teratogenic effects on the fetus (Cunningham et al., 2010; Wisner et al., 2007). The impact of heavy marijuana use on pregnancy is difficult to evaluate because of the variety of social factors that may influence the results. Nevertheless, smoking of any type—be it tobacco or marijuana—poses a risk during pregnancy and is best avoided (Wisner et al., 2007).

Phencyclidine (PCP)

Phencyclidine (PCP) is a popular hallucinogen that can be smoked, taken orally, or injected intravenously. The onset of effects occurs in 2 to 4 minutes and lasts about 4 to 6 hours with no withdrawal state. The drug causes confusion, delirium, and hallucinations and may produce feelings of euphoria. Signs of PCP use include constricted pupils, ataxia, nystagmus, double vision (diplopia), dizziness, and diaphoresis. The greatest risk for the pregnant woman is overdose or a psychotic response. Signs of overdose include hypertension, hyperthermia, diaphoresis, and possible coma, which may jeopardize fetal well-being (Rayburn & Bogenschutz, 2004).

MDMA (Ecstasy)

MDMA (methylenedioxymethamphetamine), a derivative of amphetamine better known as Ecstasy, is the most commonly used of a group of drugs referred to as *club drugs,* so called because they have become popular among adolescents and young adults who frequent dance clubs and "raves." Other club drugs include flunitrazepam (Rohypnol), gamma hydroxybutyrate (GHB), and ketamine hydrochloride. PCPs and lysergic acid diethylamide (LSD) are sometimes classified as club drugs as well. MDMA is the third most widely used illicit drug after marijuana and amphetamines.

Ecstasy has been widely perceived as "safe" because of a relatively low incidence of adverse reactions. However, adverse responses are very unpredictable and the incidence is growing (Gamma, Jerome, Liechti, et al., 2005). MDMA is taken by mouth usually in tablet form. Its effects last for about 4 to 6 hours. MDMA use is appealing because it produces euphoria and feelings of empathy for others (thus it is also called the "hug drug"). Short-term adverse effects include clouded thinking, agitation, disturbed behavior, sweating, dry mouth, increased heart rate, muscle spasms including jaw clenching, and hyperthermia (elevated temperature). The most common significant adverse effects occur when people take multiple doses in one night (called "stacking"). These effects include hyperthermia, hyponatremia (low blood sodium), hypertension, cardiac arrhythmias, and kidney failure (National Institute on Drug Abuse [NIDA], 2009). Deaths have occurred among users. Repeated use of Ecstasy is associated with mood, sleep, and anxiety disorders; memory deficits; increased impulsiveness; and attention problems, which may last for up to 2 years following cessation of use. In addition, because MDMA may deplete levels of serotonin, users may increase their risk of neurologic and psychiatric problems (O'Malley, 2005).

Little is yet known about the effects of MDMA on pregnancy. Preliminary research using rats suggests that prenatal use of MDMA may be associated with long-term impaired memory and learning in the child. However, the impact of the timing of Ecstasy exposure during brain development may be a critical issue (Thompson, Heiman, Chambers, et al., 2009).

Heroin

Heroin is an illicit central nervous system (CNS) depressant narcotic that alters perception and produces euphoria. It is an addictive drug that is generally administered intravenously

although it may also be sniffed/snorted or smoked. Pregnancy in women who use heroin is considered high risk because of the associated increased incidence of poor nutrition, iron deficiency anemia, and preeclampsia-eclampsia (see chapter 20 ∞). There is also an increased rate of breech position, abnormal placental implantation, abruptio placentae, preterm labor, premature rupture of the membranes (PROM), and meconium staining. Heroin users also have a higher incidence of sexually transmitted infection because many must rely on prostitution to support their drug habits. They also are at increased risk of HIV infection because they may use nonsterile needles or share needles when administering the drug.

The fetus of a heroin-addicted woman is at increased risk for preterm birth, IUGR, and withdrawal symptoms after birth, such as restlessness; lack of habituation; shrill, high-pitched cry; irritability; fist sucking; vomiting; and seizures. Signs of withdrawal usually appear within 72 hours and may last for several days. These behaviors may interfere with successful maternal-infant attachment and increase the potential for parenting problems or abuse in an already high-risk mother (Vucinovic et al., 2009).

Methadone is the most commonly used drug in the treatment of women who are dependent on opioids such as heroin. Methadone blocks withdrawal symptoms and the craving for street drugs. Dosage should be individualized to achieve the most therapeutic level for the mother during pregnancy. Methadone does cross the placenta, and fetal exposure in utero may result in neonatal abstinence syndrome (NAS) in the newborn. Preliminary evidence indicates that buprenorphine, a partial opioid agonist, is safe and effective during pregnancy and may decrease the severity of NAS. Because it has been authorized for use in physician offices it provides addicted patients with another treatment option (NIDA, 2010). (See chapter 33 ∞ and Table 33-7 ∞, Neonatal Abstinence Score Sheet on page 932, for more information about NAS.) In either case, there currently does not seem to be a clear dose-related effect on the newborn (Jansson, Velez, & Harrow, 2009). The most important goal is to help the mother recover from illicit drug abuse to optimize the long-term health of both the mother and baby.

Clinical Therapy

Antepartum care of the substance-abusing woman involves medical, socioeconomic, and legal considerations. The use of a team approach allows for the comprehensive management necessary to provide safe labor and childbirth for the woman and her fetus.

The management of drug addiction may include hospitalization as necessary to initiate detoxification. "Cold turkey" withdrawal is not advisable during pregnancy because of potential risk to the fetus. Maintenance and support therapy are best individualized to the woman's history and condition.

Urine screening may also be done regularly throughout pregnancy if the woman is known or suspected to be abusing drugs. This testing is helpful in identifying the type and amount of drug being abused and in providing objective feedback to the woman. Screening strategies should include maternal informed consent before screening. Healthcare providers need to stay abreast of their state laws requiring consent for screening in pregnancy to ensure they are in compliance (Hulsey, 2005).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Nurses and other healthcare providers should make it a practice to screen all pregnant women for substance abuse. Because illicit drug users seldom use only one drug, it is necessary to complete a thorough drug and alcohol abuse history (Amato et al., 2008). Several simple screening tools are available. In addition, the nurse should be alert for clues in the history or appearance of the woman that suggest substance abuse (refer to Table 19-2). If abuse is suspected, the nurse needs to ask direct questions, beginning with less threatening questions about the use of tobacco, caffeine, and over-the-counter medications. The nurse can then progress to questions about alcohol consumption and finally to questions focusing on past and current use of illicit drugs. The nurse who is matter-of-fact and nonjudgmental in approach is more likely to elicit honest responses.

Nursing assessment of the woman who is known to abuse substances focuses on her general health status, with specific attention to nutritional status, susceptibility to infections, and evaluation of all body systems. The nurse also assesses the woman's understanding of the impact of substance abuse on herself and her pregnancy. Some women are reluctant to discuss their substance abuse; others are quite open about it. Once the nurse establishes a relationship of trust, the nurse can gain information to use in planning the woman's ongoing care.

Nursing diagnoses that may apply to the woman practicing substance abuse include the following:

- ***Imbalanced Nutrition: Less Than Body Requirements*** related to inadequate food intake secondary to substance abuse
- ***Risk for Infection*** related to use of inadequately cleaned syringes and needles secondary to IV drug use
- ***Ineffective Health Maintenance*** related to a lack of information about the impact of substance abuse on the fetus

Nursing Plan and Implementation

Preventing substance abuse during pregnancy is the ideal nursing goal and is best accomplished through education. Unfortunately, many women who abuse substances do not receive regular health care and may not seek care until far along in their pregnancies or at the onset of labor.

The nurse's role in providing prenatal care for the woman who is practicing substance abuse focuses on ongoing assessment and patient teaching. It is essential that nurses caring for childbearing families develop the knowledge and skill necessary to identify pregnant women who abuse substances. To provide care that is truly effective, it is equally important that nurses develop and maintain a nonjudgmental, nonpunitive, positive attitude when caring for these women. It is also useful for nurses to be aware of substances that are commonly abused in their communities and the signs and symptoms that characterize these substances.

When the nurse encounters a pregnant woman who screens positive for substance abuse, the nurse should review with the

woman what the screen revealed and express concern for the health of the mother and infant. The nurse can then go on to state the belief that the mother is concerned about the baby's health and stress the need for the woman to stop using drugs or alcohol during pregnancy. The nurse can then discuss possible strategies to help the woman quit (addiction treatment programs, 12-step programs, individual counseling) and suggest a referral for more in-depth assessment by a specialist. If feasible, the nurse can make an appointment while the woman is in the office or clinic. Nurses should also be aware of treatment options available for women who lack financial resources. Finally the nurse should make a follow-up appointment to see the woman again after her drug or alcohol assessment. The knowledgeable nurse can provide information about the relationship between substance abuse and existing health problems and the implications for the woman's unborn child. By establishing a relationship of trust and support, the nurse may foster the woman's cooperation.

Preparation for labor and birth should be part of the prenatal planning. Fear, tension, or discomfort may be relieved through psychologic support and careful explanation of the labor process. If pain medication is necessary, it should not be withheld, however, because the notion that it will contribute to further addiction is not correct. Preferred methods of pain relief include the use of psychoprophylaxis and regional or local anesthetics, such as pudendal block and local infiltration. These techniques decrease the risk of additional fetal respiratory depression. Immediate intensive care should be available for the newborn who may have respiratory depression, be small for gestational age (SGA), and be premature. For care of the addicted newborn, see chapter 33 ∞.

Postpartum follow-up and referral is essential and may include home visits. Follow-up requires careful coordination with community agencies and may involve public health nurses and social workers.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to describe the impact of substance abuse on herself and her unborn child.
- The woman successfully gives birth to a healthy infant.
- The woman agrees to cooperate with referral to social services (or other appropriate community agency) for follow-up care after discharge.

Care of the Woman with Diabetes Mellitus

Diabetes mellitus, an endocrine disorder of carbohydrate metabolism, results from inadequate production or utilization of insulin.

Normal Glucose Homeostasis

After consumption of a meal, the body metabolizes carbohydrates into glucose. Insulin, produced by the beta cells of the islets of Langerhans in the pancreas, lowers blood glucose levels by enabling the glucose to move from the blood into muscle and liver cells, where it is stored as glycogen. When several hours have passed since a meal, falling blood glucose levels stimulate the pancreas to release glucagon, which in turn stimulates breakdown of liver glycogen stores into glucose, which is returned to the bloodstream. Glucagon can also stimulate the synthesis of glucose directly from amino acids in stored body proteins.

Carbohydrate Metabolism in Normal Pregnancy

Carbohydrate metabolism is affected early in pregnancy by a rise in serum levels of estrogen, progesterone, and other hormones. These hormones stimulate maternal insulin production and increase tissue response to insulin; therefore, anabolism (building up) of glycogen stores in the liver and other tissues occurs.

In the second half of pregnancy, the woman demonstrates prolonged hyperglycemia and hyperinsulinemia (increased secretion of insulin) following a meal. Although the mother is producing more insulin, placental secretion of human placental lactogen (hPL) and prolactin (from the decidua), as well as elevated levels of cortisol (an adrenal hormone) and glycogen, cause increased maternal peripheral resistance to insulin. This resistance helps ensure that there is a sustained supply of glucose available for the fetus. This glucose is transported across the placenta to the fetus, who uses it as a major source of fuel. Maternal amino acids are also actively transported by the placenta from the mother to her fetus. These amino acids are used by the fetus for protein synthesis and as a source of energy. In addition to ensuring that glucose is available to the fetus, the increased maternal resistance to insulin also means that the pregnant woman has a lower peripheral uptake of glucose to meet her own needs. This results in a catabolic (destructive) state during fasting periods (e.g., during the night and after meal absorption). Because increasing amounts of circulating maternal glucose are being diverted to the fetus, maternal fat is metabolized (lipolysis) during fasting periods much more readily than in a nonpregnant person. This process is called *accelerated starvation.* Ketones may be present in the urine as a result of lipolysis.

The delicate system of checks and balances that exists between glucose production and glucose use is stressed by the growing fetus, who derives energy from glucose taken from the mother and by maternal resistance to the insulin her body produces. This stress is referred to as the diabetogenic effect of pregnancy. Thus any preexisting disruption in carbohydrate metabolism is augmented by pregnancy, and any diabetic potential may precipitate gestational diabetes mellitus.

Pathophysiology of Diabetes Mellitus

In diabetes mellitus, the pancreas does not produce sufficient amounts of insulin to allow necessary carbohydrate metabolism. With inadequate amounts of insulin, glucose cannot enter the cells but remains circulating in the blood. The body cells become energy depleted while the blood glucose level remains elevated. Fats and proteins in the body tissues are then oxidized by the cells as a source of energy. This results in wasting of fat and muscle tissue of the body, negative nitrogen balance due to

protein breakdown, and ketosis due to fat metabolism. The strong osmotic force of the glucose concentration in the blood pulls water from the cells into the blood, which results in cellular dehydration. The high level of glucose in the blood eventually spills over into the urine, producing glycosuria. Osmotic pressure of the glucose in the urine prevents reabsorption of water into the kidney tubules, causing extracellular dehydration.

These pathologic developments cause the four cardinal signs and symptoms of diabetes mellitus: polyuria, polydipsia, weight loss, and polyphagia. *Polyuria* (frequent urination) results because water is not reabsorbed by the renal tubules because of the osmotic activity of glucose. *Polydipsia* (excessive thirst) is caused by dehydration from polyuria. *Weight loss* (seen in insulin-dependent diabetes, also called type 1 diabetes) is due to the use of fat and muscle tissue for energy. *Polyphagia* (excessive hunger) is caused by tissue loss and a state of starvation, which results from the inability of the cells to utilize the blood glucose. Diagnosis of diabetes is based on the presence of clinical symptoms and laboratory tests showing elevated glucose levels in the blood, glycosuria, and ketoacidosis.

Classification of Diabetes Mellitus

The primary classification of diabetes is based on cause and includes four main categories (ADA, 2010):

- Type 1 diabetes develops because of β-cell destruction and generally results in an absolute insulin deficiency.
- Type 2 diabetes, the most common form, results from a combination of an insulin secretory defect and insulin resistance.
- Other specific types, of which there are eight subcategories, including, for example, genetic defects, drug-induced diabetes, and endocrine disorders. (Note: the detailed list can be found in medical-surgical texts and through the ADA original source.)
- Gestational diabetes mellitus

Table 19-3 shows White's classification of diabetes in pregnancy. This classification is useful for describing the extent of the disease.

Gestational diabetes mellitus (GDM) is defined as carbohydrate intolerance of variable severity with onset or first recognition during pregnancy. It results from (1) an unidentified preexistent disease, (2) the unmasking of a compensated metabolic abnormality by the added stress of pregnancy, or (3) a direct consequence of the altered maternal metabolism stemming from changing hormonal levels. Diagnosis of GDM is important because even mild diabetes increases the risk of perinatal morbidity and mortality. (See discussion in Fetal-Neonatal Risks.) Although GDM incidence rates vary, it has been estimated that 15% to 50% of these individuals will progress to overt type 2 diabetes mellitus in the decades following the affected pregnancy (American College of Obstetricians and Gynecologists [ACOG], 2009).

Influence of Pregnancy on Diabetes

Pregnancy can affect diabetes significantly. First, the physiologic changes of pregnancy can drastically alter insulin requirements. Second, pregnancy may accelerate the progress of vascular disease secondary to diabetes.

The disease may be more difficult to control during pregnancy because insulin requirements are changeable. Insulin need frequently decreases early in the first trimester. Levels of hPL, an insulin antagonist, are low; energy demands of the embryo are minimal; and the woman may be consuming less food because of nausea and vomiting. Nausea and vomiting may also cause dietary fluctuations, which can increase the risk of hypoglycemia or insulin shock. Insulin requirements usually begin to rise late in the first trimester as glucose use and glycogen storage by the woman and fetus increase. As a result of placental maturation and production of hPL and other hormones, insulin requirements may double or quadruple by the end of pregnancy.

Increased energy needs during labor may require more insulin to balance intravenous glucose. After delivery of the placenta, insulin requirements usually decrease abruptly with loss of hPL in the maternal circulation.

Other factors contribute to the difficulty in controlling the disease. As pregnancy progresses, the renal threshold for glucose decreases. There is an increased risk of ketoacidosis, which may occur at lower serum glucose levels in the pregnant woman with diabetes than in the nonpregnant woman with diabetes. The vascular disease that accompanies diabetes may progress during pregnancy. Hypertension may occur. Nephropathy may result from renal blood vessel impairment, and retinopathy may develop (from occlusion of the microscopic blood vessels of the eye).

TABLE 19-3 White's Classification of Diabetes in Pregnancy

CLASS	CRITERION
A	Chemical diabetes
B	Maturity onset (age over 20 years), duration under 10 years, no vascular lesions
C_1	Age 10 to 19 years at onset
C_2	10 to 19 years' duration
D_1	Under 10 years at onset
D_2	Over 20 years' duration
D_3	Benign retinopathy
D_4	Calcified vessels of legs
D_5	Hypertension
E	No longer sought
F	Nephropathy
G	Many failures
H	Cardiopathy
R	Proliferating retinopathy
T	Renal transplant (added by Tagatz and colleagues of the University of Minnesota)

The primary concern for the pregnant woman who has diabetes is control of circulating blood glucose levels. If control can be achieved and maintained, diabetes generally does not worsen during pregnancy. The woman's health status may even improve because of close medical supervision.

Influence of Diabetes on Pregnancy Outcome

The pregnancy of a woman who has diabetes carries a higher risk of complications, especially perinatal mortality and congenital anomalies. The risk has been reduced by the recent recognition of the importance of tight metabolic control (fasting blood glucose less than 95 mg/dl and 2-hour postprandial less than 120 mg/dl). New techniques for monitoring blood glucose, delivering insulin, and monitoring the fetus have also reduced perinatal mortality (ACOG, 2005).

Maternal Risks

Maternal health problems in diabetic pregnancy have been greatly reduced by the team approach to preconception planning and early prenatal care and by the increased emphasis on maintaining tight control of blood glucose levels. The prognosis for the pregnant woman with gestational, type 1, or type 2 diabetes that has not resulted in significant vascular damage is positive. However, diabetic pregnancy still carries higher risks for complications than normal pregnancy.

Hydramnios, or an increase in the volume of amniotic fluid, occurs in 10% to 20% of pregnant women with diabetes. It is thought to be a result of excessive fetal urination because of fetal hyperglycemia (Rinala, Dryfhout, & Lambers, 2009). *Preeclampsia-eclampsia* occurs more often in diabetic pregnancies, especially when diabetes-related vascular changes already exist.

Hyperglycemia due to insufficient amounts of insulin can lead to *ketoacidosis* as a result of the increase in ketone bodies (which are acidic) in the blood released when fatty acids are metabolized. Ketoacidosis usually develops slowly, but it may develop more rapidly in the pregnant woman because of the hyperketonemia associated with accelerated starvation in the fasting state. The tendency for higher postprandial glucose levels because of decreased gastric motility and the contrainsulin effects of hPL also predispose the woman to ketoacidosis. If the ketoacidosis is not treated, it can lead to coma and death of both mother and fetus.

Another risk to the pregnant woman with diabetes is a difficult labor (*dystocia*), caused by fetopelvic disproportion if fetal macrosomia exists. The pregnant woman with diabetes is also at increased risk for recurrent monilial vaginitis and urinary tract infections because of increased glycosuria, which contributes to a favorable environment for bacterial growth. If untreated, asymptomatic bacteriuria can lead to pyelonephritis, a serious kidney infection.

Several studies have demonstrated that pregnancy worsens *retinopathy* in women with diabetes. Most investigators agree that during a diabetic pregnancy, good control of blood glucose levels and the use of laser photocoagulation (a treatment used to prevent retinal hemorrhage when the retina shows changes in the blood vessels) when indicated minimize the risk of the negative effects of pregnancy. Hence, women with preexisting diabetes should be referred to an ophthalmologist for evaluation during pregnancy (ACOG, 2005).

Fetal-Neonatal Risks

Many of the problems of the newborn result directly from high maternal plasma glucose levels. In the presence of severe maternal ketoacidosis, the risk of fetal death has ranged from 35% to a decrease more recently of 10% (ACOG, 2005). Fetal enzyme systems cease functioning in an acidic environment.

The incidence of *congenital anomalies* in diabetic pregnancies is 5% to 10% and is the major cause of death for infants of mothers with diabetes. Research suggests that this increased incidence of congenital anomalies is related to multiple factors including high glucose levels in early pregnancy (Eriksson, 2009). The anomalies often involve the heart, central nervous system (CNS), and skeletal system. Septal defects, coarctation of the aorta, and transposition of the great vessels are the most common heart lesions seen. CNS anomalies include hydrocephalus, meningomyelocele, and anencephaly. One anomaly, *sacral agenesis,* appears only in infants of mothers with diabetes. In sacral agenesis, the sacrum and lumbar spine fail to develop and the lower extremities develop incompletely. To reduce the incidence of congenital anomalies, preconception counseling and strict diabetes control before conception and in the early weeks of pregnancy are indicated.

Characteristically, infants of mothers with diabetes in White's classes A, B, and C (see Table 19-3) are large for gestational age (LGA) as a result of high levels of fetal insulin production stimulated by the high levels of glucose crossing the placenta from the mother. Sustained fetal hyperinsulinism and hyperglycemia ultimately lead to excessive growth, called **macrosomia**, and deposition of fat. If born vaginally, the macrosomic infant is at increased risk for birth trauma such as fractured clavicle or brachial plexus injuries due to shoulder dystocia. To prevent such injuries, cesarean birth may be indicated if birth weight is expected to exceed 4500 g (ACOG, 2005).

After birth, the umbilical cord is severed, and, thus, the generous maternal blood glucose supply is eliminated. However, continued islet cell hyperactivity leads to excessive insulin levels and depleted blood glucose (hypoglycemia) in 2 to 4 hours in the neonate. Macrosomia can be significantly reduced by tight maternal blood glucose control.

Infants of mothers with diabetes with vascular involvement may demonstrate intrauterine growth restriction (IUGR). This occurs because vascular changes in the mother decrease the efficiency of placental perfusion, and the fetus is not as well sustained in utero.

Respiratory distress syndrome appears to result from inhibition, by high levels of fetal insulin, of some fetal enzymes necessary for surfactant production. Polycythemia in the newborn is due primarily to the diminished ability of glycosylated hemoglobin in the mother's blood to release oxygen. *Hyperbilirubinemia* is a result of the inability of immature liver enzymes to metabolize the increased bilirubin resulting from the polycythemia. Hypocalcemia, characterized by signs of irritability or even

tetany, may occur. The cause of these low calcium levels in infants of mothers with diabetes is not known.

Clinical Therapy

Detection and Diagnosis of Gestational Diabetes

Gestational diabetes is more common than pregestational diabetes. It is estimated to range from 2% to 10% of pregnancies, depending on the population studied (ACOG, 2009). Therefore, screening for its detection is a standard part of prenatal care. If diabetes is suspected, further testing is undertaken for diagnosis.

All pregnant women should have their risk of diabetes assessed at the first prenatal visit. Women at high risk (prior history of GDM or birth of an LGA infant, marked obesity, diagnosis of polycystic ovarian syndrome, presence of glycosuria, or a strong family history of type 2 diabetes mellitus [DM]) should be screened for diabetes as soon as possible. Various screening approaches may be used. HA1c equal to or greater than 6.5% would be considered diagnostic as would a fasting plasma glucose level equal to or greater than 126 mg/dl (ADA, 2010a).

Differences of opinion exist about screening low-risk women. The ADA (2010a) identifies women at low risk as those who meet *all* of the following criteria:

- Age less than 25 years
- Normal weight prior to pregnancy
- Caucasian (i.e., member of an ethnic group with a low incidence of DM)
- No history of an abnormal glucose tolerance
- No known DM in a first-degree relative

In January 2010, it was the position of the ADA that women at low risk do not require screening. However, the ADA stated that it is planning to work with U.S. obstetric organizations to consider adopting a recommendation that "all women not known to have prior diabetes undergo a 75-g OGTT at 24-28 weeks of gestation" (2010a, p. S15) based on work being done by the International Association of Diabetes and Pregnancy Study Groups (IADPSG). In March 2010, the IADPSG recommended that at 24–28 weeks' gestation, a 2-hr 75-g oral glucose tolerance test (OGTT) be done for all women not previously diagnosed with overt diabetes. For the 75-g test the following values are used to diagnose GDM (IADPSG, 2010):

Fasting	92 mg/dl
1 hour	180 mg/dl
2 hours	153 mg/dl

It remains to be determined whether healthcare professionals in the United States will adopt the recommendations of the IADPSG.

Current practice dictates that women at average risk (those who meet any of the criteria identified as excluded for low-risk women) should be tested toward the end of the second trimester (24 to 28 weeks) using a 1-hour, 50-gram oral glucose challenge test (GCT).The oral glucose load is administered without regard to time of day or time of last meal, and venous plasma glucose is measured 1 hour later. A plasma level that is equal to or greater than 130 to 140 mg/dl (depending on the laboratory used) indicates a need for further diagnostic testing (ADA, 2010a). Because women who meet the low-risk criteria comprise only about 10% of the population, it is not unusual to find that some busy clinics and offices are using the 50-g GCT to screen all women who are not considered high risk (Landon, Catalano, & Gabbe, 2007).

During pregnancy, if the 1-hour oral glucose screen indicates that a woman might have gestational diabetes, diagnosis is made using a 100-gram 3-hour oral glucose tolerance test (OGTT). To do this test, the woman eats an unrestricted diet, consuming at least 150 grams of carbohydrates per day for at least 3 days before her scheduled test. She then ingests 100-gram oral glucose solution in the morning after an overnight fast. Plasma glucose is measured fasting and at 1, 2, and 3 hours. The woman should remain seated and not smoke throughout the test. Gestational diabetes is diagnosed if two or more of the following values are met or exceeded:

Fasting	95 mg/dl
1 hour	180 mg/dl
2 hours	155 mg/dl
3 hours	140 mg/dl

Case Study: Patient with Gestational Diabetes

Laboratory Assessment of Long-Term Glucose Control

Glycosylated hemoglobin (HbA_{1c}) is a laboratory test that loosely reflects glucose control over the previous 4 to 8 weeks. It measures the percentage of glycohemoglobin in the blood. Glycohemoglobin, or HbA_{1c}, is the hemoglobin to which a glucose molecule is attached. The test is not reliable for screening for gestational diabetes and is not recommended at this time (Gandhia, Brown, Simmb, et al., 2008).

In women with known pregestational diabetes, however, abnormal HbA_{1c} values correlate directly with the frequency of spontaneous abortion and fetal congenital anomalies. A value greater than 10% is associated with a fetal anomaly rate of 20% to 25% (ACOG, 2005). Consequently, women with preexisting diabetes who plan to become pregnant should work to achieve HbA_{1c} levels at target levels (less than 6%) without significant hypoglycemia. Once pregnancy is achieved, HbA_{1c} levels should be tested at the initial prenatal visit and every 2 to 3 months if target levels have been achieved (Kitzmiller et al., 2008).

Antepartum Management of Diabetes

The major goals of medical care for a pregnant woman with diabetes—whether gestational or pregestational—are (1) to maintain a physiologic equilibrium of insulin availability and glucose utilization during pregnancy and (2) to ensure an optimally healthy mother and newborn. To achieve these goals, good prenatal care using a team approach is a top priority. The team consists of an obstetrician; an endocrinologist; a perinatologist; a diabetes nurse-educator; a perinatal nurse; a dietitian; a social worker; and, most important, the woman with diabetes and her partner if the partner is involved in the pregnancy. Education of the couple and their active involvement in managing her care are essential for a good outcome.

For the woman with gestational diabetes, the diagnosis may be a shock, leaving her frightened and anxious. This anxiety may lead to an inability to adhere to important treatment regimens. She needs clear explanation and teaching to enlist her participation in ensuring a good outcome. The diabetes

nurse-educator plays a major role in this counseling (Jones, Roche, & Appel, 2009).

Diet therapy and regular exercise form the cornerstone of intervention for GDM. Insulin therapy is indicated when dietary management is unable to achieve a 1-hour postprandial blood glucose value less than 130 to 140 mg/dl, a 2-hour postprandial level less than 120 mg/dl, or a fasting glucose less than 95 mg/dl. In most instances, the overt diabetic manifestation disappears postpartum, though subtle manifestations of impaired insulin secretory capacity may remain.

Oral hypoglycemics are rarely used during pregnancy because they cross the placenta and have not been well studied. However, glyburide, a second-generation sulfonylurea, may not cross the placenta and has been found to be comparable to insulin without evidence of adverse effects in the mother or fetus. This oral agent is a viable alternative for treating women with gestational diabetes mellitus (Serlin & Lash, 2009).

The woman with pregestational diabetes needs to understand changes she can expect during pregnancy; thus she should receive such teaching in preconception counseling. At the initial prenatal visit, height, weight, and vital signs are assessed along with a thorough assessment of thyroid and cardiac function. Special attention is given to dating the pregnancy. Laboratory data are obtained, and the diabetes is classified using White's criteria. Women should be screened for diabetic neuropathy, and a funduscopic examination is done to detect any retinopathy. In some cases, the woman may be referred to an ophthalmologist for further evaluation (ACOG, 2005).

Care Plan Activity: Antepartum Patient at Risk

Dietary Regulation

The pregnant woman requires about 300 kilocalories (kcal) per day more than she does when she is not pregnant to meet increased metabolic demands. In general, women need approximately 30 kcal/kg of ideal body weight (IBW) during the first trimester and 35 to 36 kcal/kg IBW during the second and third trimesters. If ketonuria develops or the woman complains of hunger, the number of calories may be increased. Dietary guidelines are similar for women with gestational and pregestational diabetes. Approximately 40% to 50% of the kcal should come from complex carbohydrates, 15% to 20% from protein, and 20% to 30% from fats. This caloric intake is divided among three meals and three snacks. A prebedtime snack may be indicated to prevent hypoglycemia at night. Management should focus on food choices for appropriate weight gain, normoglycemia, and absence of ketones. Although weight loss is not recommended during pregnancy, modest carbohydrate and calorie restriction may be appropriate for overweight and obese woman to improve glycemic control and reduce weight gain (ADA, 2008).

Because it is so important that the pregnant woman follow these guidelines, a dietitian works out meal plans based on the woman's lifestyle, culture, and food preferences and teaches her food exchanges so she can vary and plan her own meals. Daily food records, weekly weight checks, and regular ketone testing can assist in identifying an individual's energy requirements in order to help avoid the need for insulin therapy (ADA, 2008).

Glucose Monitoring

Glucose monitoring is an essential part of diabetes management for determining the need for insulin and assessing glucose control. Many physicians have the woman come in for a weekly assessment of her fasting glucose levels and one or two postprandial levels. In addition, frequent self-monitoring of glucose levels is paramount in maintaining good glucose control. Self-monitoring is discussed beginning on page 428.

Insulin Administration

Whether the woman with gestational diabetes needs additional insulin (over her own body production) depends on how well her blood glucose levels can be maintained by diet alone. Individuals with pregestational diabetes usually have type 1 diabetes, requiring insulin administration. Whether the patient has gestational or pregestational diabetes, human insulin should be used because it is the least likely to cause an allergic response. If the woman has previously used bovine or porcine insulin, she may require smaller doses of human insulin to achieve the same pharmacologic effect. Insulin is given either in multiple injections or by continuous subcutaneous infusion. Multiple injections are used more commonly and with excellent results. Most women will need a mixture of intermediate and regular insulin. Some clinicians have moved away from the use of regular insulin, replacing it with a fast-acting human analog called lispro. Lispro is associated with better glucose control (ACOG, 2005). Often a 4-dose approach is used, with regular insulin or lispro taken before each meal and NPH or Lente insulin added at bedtime (ACOG, 2005). Other clinicians vary the NPH and regular insulin patterns slightly but still prefer a 4-dose approach. It is important to remember that the amount of insulin needed usually increases during each trimester of pregnancy.

Evaluation of Fetal Status

Information about the well-being, maturation, and size of the fetus is important for planning the course of the pregnancy and the timing of birth. Because pregnancies complicated by diabetes are at increased risk of neural tube defects, a quadruple screen, which includes testing for maternal serum α-*fetoprotein AFP*, is offered at weeks 16 to 20 of gestation (see chapter 15 ∞ and chapter 21 ∞).

Daily maternal evaluation of *fetal activity,* begun at about 28 weeks, is effective and simple to do. The woman is taught a particular method for counting fetal movements (see chapter 16 ∞). She records the results on a special card, and brings the card to each subsequent office visit.

Nonstress testing (NST) may be started at about 28 weeks. If evidence of IUGR, preeclampsia, oligohydramnios, or poorly controlled blood glucose exists, testing may begin as early as 26 weeks and may be done more often. NSTs are increased to twice weekly at 32 weeks' gestation. If the NST is nonreactive, a fetal biophysical profile or *contraction stress test* is performed. If the woman requires hospitalization (for example, to control glycemia or for complications), NSTs may be done daily. See chapter 21 ∞ for a further discussion of nonstress testing.

Ultrasound at 18 weeks confirms gestational age and diagnoses multiple pregnancy or congenital anomalies. It is repeated at 28 weeks to monitor fetal growth for IUGR or

macrosomia. Some physicians order *fetal biophysical profiles* (ultrasound evaluation of fetal well-being in which fetal breathing movements, fetal activity, reactivity, muscle tone, and amniotic fluid volume are assessed) as part of an ongoing evaluation of fetal status.

Intrapartum Management of Diabetes Mellitus

During the intrapartum period, medical therapy includes the following:

- ***Timing of birth.*** Most diabetic pregnancies are allowed to go to term, with spontaneous labor, thereby decreasing the risk of respiratory distress in the newborn. Some clinicians do opt to induce labor in a woman at term to avoid problems related to decreased perfusion as the placenta ages. Cesarean birth may be indicated if evidence of nonreassuring fetal status exists. Birth before term may be indicated for women with diabetes who have vascular changes and worsening hypertension or if evidence of IUGR exists (ACOG, 2005). In pregnancies in which there is evidence of fetal macrosomia, fetal compromise, or elevated maternal HbA_{1c}, amniocentesis for fetal lung maturity may be indicated. Below is a list of available tests that help determine fetal lung maturity. No test has been proven to be superior, but recent modifications to performing the fluorescence polarization has increased its use in the clinical setting (ACOG, 2008c).

Test	Lung Maturity Value
Fluorescence Polarization (TDx-FLM II)	55 mg/g or greater of albumin
Lecithin/Sphingomyelin (L/S) ratio	2.0–3.5
Phosphatidylglycerol	Present or between 0.5–2.0

Fetal lung maturity must be weighed against other considerations when deciding time of childbirth. If preterm labor occurs, tocolytic therapy (use of medications in an attempt to halt preterm labor) (see chapter 20 ∞) and β-sympathomimetic drugs should not be administered because they may worsen maternal glucose control (ACOG, 2003a).

- ***Labor management.*** The degree of prenatal maintenance of normal maternal glucose levels (euglycemia) and the maintenance of maternal euglycemia during labor are important in preventing neonatal hypoglycemia. Maternal insulin requirements often decrease dramatically during labor. Consequently, maternal glucose levels are measured hourly to determine insulin need (Figure 19-2 ■). The primary goal in controlling maternal glucose levels intrapartally is to prevent neonatal hypoglycemia (ACOG, 2005). During active labor, insulin may not be needed. Long-acting insulin should be reduced or stopped and regular insulin should be used to meet most or all of the woman's identified needs. Often two intravenous lines are used, one with a 5% dextrose solution and one with a saline solution. The saline solution is then available if a bolus is needed or for piggybacking insulin. Insulin clings to the plastic intravenous bag and tubing. To ensure that the woman receives the desired dose, the intravenous tubing must be flushed with insulin before the prescribed amount is added. During the second stage of labor and the immediate postpartum period, the woman may not need additional insulin. The intravenous insulin is discontinued with the completion of the third stage of labor.

Figure 19-2 ■ During labor the nurse closely monitors the blood glucose levels of the woman with diabetes mellitus.

Source: Vicky Flanagan, RN, BSN/Pearson Education.

Postpartum Management of Diabetes Mellitus

Maternal insulin requirements fall significantly postpartally because the levels of hPL, progesterone, and estrogen fall after placental separation, and their anti-insulin effect ceases, resulting in decreased blood glucose levels. The mother with diabetes may require no insulin for the first 24 hours or only one fourth to one half her previous dose. Then, reestablishment of insulin needs based on blood glucose testing is necessary. Diet and exercise levels must also be redetermined. Consequently, the woman with diabetes that is not controlled by diet alone may need insulin for a period of time (ACOG, 2005).

Women with GDM who did not require insulin during pregnancy generally do not need it during the postpartum period. Clinicians routinely discontinue insulin for women with GDM following childbirth and then monitor blood glucose levels. If elevated glucose levels develop, oral antihyperglycemic agents may be tried if the woman is not breastfeeding (ACOG, 2005). Antihyperglycemics are contraindicated during breastfeeding.

The woman should be reassessed 6 weeks postpartum to determine whether her glucose levels are normal. If her levels are normal, she should be reassessed at a minimum of 3-year intervals (ACOG, 2009).

Diabetic control and the establishment of parent-child relationships in light of neonatal needs are the priorities of this period. If her newborn must be cared for in a special care nursery, the mother needs support and information about the baby's condition. Every effort must be made to provide as much contact as possible between the parents and their newborn.

Breastfeeding is encouraged as beneficial to both mother and baby. The composition of breast milk is not altered by diabetes, and infants of mothers with diabetes gain weight appropriately. The lactating mother with diabetes often has a sense of well-being and diminished insulin needs even while increasing caloric intake. Blood glucose levels may be lower because glucose is transferred from serum to breast to be converted to lactose, and energy is expended in milk production. Caloric needs increase during lactation to 500 to 800 kcal above prepregnant requirements. Insulin must be adjusted according to individual needs. Home blood glucose monitoring should continue for the person with insulin-dependent diabetes.

The woman and her partner, if involved, should receive information on family planning. Barrier methods of contraception (diaphragm and condom) used with spermicide are safe, effective, and inexpensive and are the method of choice for women with insulin-dependent diabetes. The use of combined oral contraceptives (COCs) by women with diabetes is controversial because of the risk of vascular disease (Cunningham et al., 2010). Many physicians who prescribe low-dose COCs to women with diabetes restrict them to women who have no vascular disease and who do not smoke. The progesterone-only pill may also be used as may Depo-Provera. Many couples who have completed their families choose elective sterilization.

> "It's hard to realize that I have gestational diabetes and to know that it increases my chances of getting diabetes later. My grandmother had diabetes, so I always thought of it as an old person's disease. All the fingersticks, watching my diet, and keeping track has taken some getting used to. I'll be glad when our baby is born and I can put this behind me, at least for now."

NURSING CARE MANAGEMENT

The Nursing Care Plan for a woman with diabetes mellitus summarizes nursing management.

Nursing Assessment and Diagnosis

Whether diabetes has been diagnosed before pregnancy occurs or the diagnosis is made during pregnancy (GDM), careful assessment of the disease process and the woman's understanding of diabetes is important. Thorough physical examination, including assessment for vascular complications, any signs of infectious conditions, and urine and blood testing for glucose, is essential at the first prenatal visit. Follow-up visits are usually scheduled twice a month during the first two trimesters and weekly during the last trimester.

Assessment also yields vital information about the woman's ability to cope with the combined stress of pregnancy and diabetes and her ability to follow a recommended regimen of care. It is necessary to determine the woman's knowledge about diabetes and self-care before formulating a teaching plan.

Nursing diagnoses that may apply to the pregnant woman with diabetes mellitus include the following:

- ***Risk for Imbalanced Nutrition: More Than Body Requirements*** related to imbalance between intake and available insulin
- ***Risk for Injury*** related to possible complications secondary to hypoglycemia or hyperglycemia
- ***Interrupted Family Processes*** related to the need for hospitalization secondary to GDM

Nursing Plan and Implementation

Prepregnancy counseling may be provided by a nurse and a physician, using a team approach. Ideally, the couple is seen before pregnancy so that the diabetes can be assessed by ophthalmologic evaluation, electrocardiographic study, and a 24-hour urine collection for creatinine clearance and protein excretion. Prepregnancy counseling about the importance of tight glucose control is cost effective in preventing congenital anomalies. If the diabetes is of recent onset without vascular complications, the outcome of pregnancy should be good, provided that glucose levels are controlled.

Community-Based Nursing Care

In many cases, women with GDM are stabilized in the hospital, and necessary teaching for self-care is begun. Women with preexisting diabetes may also require hospitalization for stabilization of their diabetes. In either case, the majority of ongoing teaching and supervision of pregnant women with diabetes is then carried out by nurses in clinics, community agencies, and the women's homes.

Effective Insulin Use

The nurse ensures that the couple understands the purpose of the insulin, the types of insulin the woman is to use, the number of doses she is to receive daily, and the correct procedure for its administration. The woman's partner is also instructed about insulin administration in case it should be necessary for the partner to give it. For some highly motivated women whose glucose levels are not well controlled with multiple injections, the continuous insulin infusion pump may improve glucose control.

The nurse teaches the patient how and when to monitor her blood sugar, the desired range of blood sugar levels, and the

NURSING CARE PLAN The Woman with Diabetes Mellitus

INTERVENTION	RATIONALE
1. Nursing Diagnosis: Imbalanced Nutrition: Less than body requirements related to poor carbohydrate metabolism **Goal:** Patient will maintain adequate nutrition throughout pregnancy.	
■ Emphasize importance of regular prenatal visits for assessment of *weight gain, controlled blood sugar,* heart tones, urine ketones, and fundal height measurement.	■ Regular follow-up and assessment of weight, blood sugar levels, fetal heart tones, urine ketones, and fundal height will promote a healthy pregnancy and outcome as well as allow for modifications in the treatment regimen if necessary.
■ Coordinate care with a dietitian to assist patient in meal planning and educate patient on the daily caloric needs of pregnancy.	■ A daily intake of high-quality foods promotes fetal growth and controls maternal glucose levels.
■ Instruct patient on signs and symptoms of hyperglycemia: polyphagia, nausea, hot flushes, polydipsia, polyuria, fruity breath, abdominal cramps, rapid deep breathing, headache, weakness, drowsiness, and general malaise. Instruct patient on signs and symptoms of hypoglycemia: hunger; clammy skin; irritability; slurred speech; seizures; tachycardia; headache; pallor; sweating; disorientation; shakiness; blurred vision; and, if untreated, coma or convulsions.	■ Maintaining a euglycemic state throughout pregnancy aids in preventing diabetic complications and promotes a positive pregnancy outcome.
■ Instruct patient on management of hyperglycemia and hypoglycemia.	
■ Include family members in meal.	■ Gives the family member a sense of involvement and an understanding of the importance of adequate nutrition in pregnancy.
EXPECTED OUTCOME:	The patient will maintain adequate nutrition as evidenced by adequate weight gain, normal blood sugar levels, fetal heart rate, verbalization of understanding of personal treatment regimen, and appropriate fetal growth and development during pregnancy.
2. Nursing Diagnosis: Risk for Injury to the fetus related to possible complications associated with altered tissue perfusion secondary to maternal diagnosis of diabetes mellitus **Goal:** Uncomplicated birth of a healthy newborn.	
■ Assess fetal heart tones for reassuring variability and accelerations.	■ Reassuring fetal heart rate variability and accelerations are interpreted as adequate placental oxygenation.
■ Instruct mother on how to lie in a left recumbent position after eating and record how many fetal movements she feels in an hour.	■ More than five fetal kicks in an hour are indicative of fetal well-being.
■ Collaborative: Perform oxytocin challenge test (OCT)/contraction stress test (CST) and nonstress tests as determined by physician.	■ Fetal surveillance testing assesses fetal well-being and adequate placental perfusion.
■ Prepare patient for frequent ultrasound assessments.	■ Ultrasonography is indicated at 7–9 weeks to confirm gestational age and then every 4–6 weeks to evaluate fetal well-being per physician's orders.
■ Prepare patient for possible amniocentesis procedure.	■ A sample of amniotic fluid that can be used to detect fetal lung maturity and enables medical personnel to prepare for a potential preterm birth.
■ Assist physician with biophysical profile assessment.	■ Helps ensure fetal well-being and a positive fetal outcome.
EXPECTED OUTCOME:	The fetus will not exhibit signs and symptoms of altered tissue perfusion as evidenced by positive fetal activity, reassuring fetal heart rate patterns, a biophysical profile score between 8 and 10, negative CST, L/S ratio indicating fetal lung maturity, and a reactive nonstress test.
3. Nursing Diagnosis: Readiness for Enhanced Knowledge about the effects of blood sugar on pregnancy related to an expressed desire to maintain stable blood glucose levels **Goal:** The patient and her family will verbalize the importance of maintaining blood sugar within prescribed ranges during pregnancy.	
■ Assess the patient and family's cognitive level and develop a teaching strategy that will facilitate learning at that level.	■ Behavior changes occur when teaching strategies are appropriate for the patient and family's cognitive level.

(continued)

NURSING CARE PLAN **The Woman with Diabetes Mellitus** continued

INTERVENTION	RATIONALE
■ Teach blood glucose monitoring, insulin administration, and predicted insulin needs throughout pregnancy, and then have patient and family members repeat the discussion.	■ Basic understanding of the relationship between blood sugar levels and how insulin needs change throughout pregnancy will foster compliance with prescribed regimen.
■ Emphasize the importance of maintaining a healthy diet and exercise program during pregnancy. Encourage patient and family to develop a sample diabetic diet and exercise regimen that is appropriate for pregnancy while present in the clinic or hospital and evaluate for appropriateness.	■ Involves the patient and her family members in the planning of her care, and the evaluation process promotes cooperation, positive reinforcement, and a time for modifications of regimen if necessary.
■ Emphasize the importance of prenatal care for the purpose of maternal and fetal surveillance.	■ Frequent prenatal visits allow for modifications in regimen and promote a healthy pregnancy outcome.

EXPECTED OUTCOME: The patient and family members will verbalize understanding of the effects of blood sugar fluctuations on pregnancy as evidenced by asking questions and seeking health information when necessary. The patient adheres to personal treatment regimen throughout pregnancy.

4. Nursing Diagnosis: Risk for Infection related to increased levels of glucose in urine
Goal: The patient will have no urinary tract infections (UTIs) during pregnancy.

■ Encourage patient to utilize preventive measures to prevent UTIs: increasing intake of water and cranberry juice, wearing cotton underwear, wiping perineum from front to back, voiding frequently, and voiding before and immediately after sexual intercourse.	■ Utilizing preventive measures decreases the likelihood of patient acquiring a UTI.
■ Instruct patient on the signs and symptoms of UTIs: urinary frequency, dysuria, cloudy urine, hematuria, lower back pain, and foul-smelling urine.	■ Patient will be aware of signs and symptoms of UTIs and report to physician for immediate intervention.
Collaborative:	
■ Instruct patient on how to obtain a clean-catch urine sample and send to laboratory for culture and sensitivity per physician's orders.	■ A clean-catch urine sample will contain bacteria if a UTI is present.
■ Administer prescribed antibiotic therapy and teach patient about medication, adverse effects, and appropriate dosage.	■ Antibiotic therapy is the appropriate treatment for a UTI. Compliance increases when a patient fully understands medication regimen.
■ Encourage patient to drink 8–10 glasses of water each day.	■ Increased fluid intake assists in flushing bacteria out of the urinary tract system.

EXPECTED OUTCOME: Patient will remain free of UTIs during pregnancy as evidenced by verbalizing and complying with appropriate preventive measures, increasing fluid intake, and identifying negative urine samples during prenatal visits.

5. Nursing Diagnosis: Anxiety related to unfamiliarity with diagnosis
Goal: The patient expresses less anxiety.

■ Assess patient's level of anxiety (mild-1, moderate-2, or severe-3) and have patient verbalize causes of anxiety.	■ Verbalization of anxiety provokers encourages expression of feelings and questions.
■ Share information on diabetes care such as nutrition, exercise, and glucose control in a clear and concise manner.	■ Accurate information gives the patient a sense of control and comfort.
■ Instruct patient on anxiety-reducing techniques such as imagery, breathing exercises, and massage used in pregnancy.	■ Gives patient the tools necessary for decreasing anxiety.
■ Refer patient to a diabetes support group.	■ A support group allows patients with similar problems to express concerns and share information with each other.

EXPECTED OUTCOME: The patient demonstrates appropriate coping strategies as evidenced by utilizing resources efficiently and verbalizing feelings of anxiety and the ways to deal with them.

Figure 19-3 ■ The nurse teaches the pregnant woman with gestational diabetes mellitus how to do home glucose monitoring.

Source: Jenny Thomas Photography.

importance of good glycemic control (Figure 19-3 ■). Most women use a glucose meter because it provides a more accurate reading. The nurse teaches the patient to follow the manufacturer's directions exactly; to wash hands thoroughly before puncturing her finger; and to touch the blood droplet, not her finger, to the test pad on the strip.

With a blood glucose meter, an electronic eye measures the blood sugar, and a digital reading is given. The blood droplet should cover the test pad because uncovered portions are read as low sugar. The glucose meter is a portable pocket-sized device that is more accurate than the visual, color comparison method. Some meters are able to store and recall a specified number of readings, which helps ensure the accuracy of recorded results.

CLINICAL TIP

When teaching a pregnant woman to do her own blood glucose testing, have gloves available and put them on if it becomes necessary to help the woman obtain a blood sample. The woman does not need to wear gloves during the procedure.

Also be sure to wear gloves when doing fingersticks for blood glucose levels, when testing the urine for ketones, when starting an IV for insulin therapy, or when drawing blood for other laboratory tests.

The nurse may offer the patient the following tips about finger puncture:

- Various spring-loaded devices are available that make puncturing easier.
- Hanging the arm down for 30 seconds increases blood flow to the fingers.
- Warming the hands under running water increases blood flow to them.
- The sides of fingers should be punctured instead of the ends because the ends contain more pain-sensitive nerves.

Patients with diabetes need to keep a record of each blood sugar reading as a guide for management. Specific record sheets are available for this purpose and should be brought to each visit.

Planned Exercise Program

Exercise is encouraged for the woman's overall well-being. If she is used to a regular exercise program, she is encouraged to continue. She is advised to exercise after meals (when blood sugar levels are high), to wear diabetic identification, to carry a simple sugar such as hard candy (because of the possibility of exercise-induced hypoglycemia), to monitor her blood glucose levels regularly, and to avoid injecting insulin into an extremity that will soon be used during exercise.

If she has not been following a regular exercise plan, she is encouraged to begin gradually. Because exercise can alter metabolism, the woman's blood glucose should be well controlled before she begins an exercise program. Women with GDM should not use unusual, strenuous, and excessive exercise in an attempt to reduce glucose levels.

Health Promotion Education

Using the information gained during the nursing assessment of the pregnant woman with diabetes, the nurse provides appropriate teaching to the woman and her family so that the woman can meet her own healthcare needs as much as possible.

- ***Glucose monitoring.*** Home blood glucose monitoring is the most accurate and convenient way to determine insulin dose and assess control. It should be taught at the first visit after the diagnosis of gestational diabetes has been established. The woman with pregestational diabetes may already be monitoring her own blood sugar. Women with GDM typically measure their blood glucose 4 times a day (fasting and 1 to 2 hours after meals), while women with preexisting diabetes monitor their blood 5 to 7 times each day (Reece & Homko, 2008). Women are encouraged to maintain blood sugars in the normal ranges as follows: fasting (before eating or taking insulin), less than 95 mg/dl; 2 hours after each meal less than 120 mg/dl (Cleveland Clinic, 2007). New technology that is capable of automatically and painlessly monitoring blood glucose levels is currently being investigated and shows great promise.
- ***Symptoms of abnormal blood glucose levels.*** The pregnant woman with diabetes must recognize symptoms of changing glucose levels—whether hypoglycemia or hyperglycemia accompanied by ketoacidosis—and take appropriate action by immediately checking her capillary blood glucose level. Hypoglycemia may develop fairly rapidly. Symptoms include sweating, periodic tingling, disorientation, shakiness, pallor, clammy skin, irritability, hunger, headache, and blurred vision. If the pregnant woman is hypoglycemic with a mild blood glucose level less than 65 to 70 mg/dl, 1 cup of milk (8 oz, 14 grams of sugar) or 3–5 glucose tablets should be effective and prevent marked rebound hyperglycemia from excess glucose consumption. More severe hypoglycemia (less than 50 mg/dl) should be treated with 1 cup orange juice or 22 grams sugar (Kitzmiller et al., 2008). Many people overtreat their symptoms by continuing to eat, which can cause rebound hyperglycemia.

The woman should carry a snack at all times and should have other fast sources of glucose (simple carbohydrates such as hard candy) at hand so that she can treat an insulin

reaction when milk is not available. Family members are also taught how to inject glucagon in the event that food does not work or is not feasible, for instance, in the presence of severe morning sickness.

Hyperglycemia and ketoacidosis typically develop more slowly and tend to occur more commonly during the second half of pregnancy. Because most problems for the fetus are related to maternal hyperglycemia, this is a serious situation. Symptoms include polyuria, polydipsia, dry mouth, fatigue, nausea, hot flushed skin, rapid deep breathing, abdominal cramps, acetone breath, headache, drowsiness, depressed reflexes, oliguria or anuria, stupor, or coma. Hyperglycemia is treated with insulin.

- ***Smoking.*** Smoking has harmful effects on the maternal vascular system and the developing fetus and is contraindicated for both pregnancy and diabetes.
- ***Travel.*** Insulin can be kept at room temperature while traveling. Insulin supplies should be kept with the traveler and not packed in the baggage. Most airlines can supply special meals if notified a few days before departure. The woman should wear a diabetic identification bracelet or necklace. In addition, the woman should check with her physician for any instructions or advice before leaving.
- ***Support groups.*** Many communities have diabetes support groups or education classes, which can be helpful to women with newly diagnosed diabetes.
- ***Cesarean birth.*** Chances for a cesarean birth increase if the pregnant woman has diabetes because of the risk of fetal macrosomia and shoulder dystocia. This possibility should be anticipated—enrollment in cesarean birth preparation classes may be suggested. Many hospitals offer classes, and information is available through other organizations. The couple may prefer simply to discuss cesarean birth with the nurse and their obstetrician and read some books on the topic.

Hospital-Based Nursing Care

Hospitalization may become necessary during the pregnancy to evaluate blood glucose levels and adjust insulin dosages. In such cases, nurses monitor the woman's status and continue to provide teaching so that the woman is knowledgeable about her condition and its management. During the intrapartum period, the nurse must have a clear understanding about the impact of labor on the condition. The nurse carefully monitors the woman's status, maintains her intravenous fluids, is alert for signs of hypoglycemia, and provides the care indicated for any woman in labor. If a cesarean birth is indicated, the nurse provides appropriate care as described in chapter 28 ∞.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to discuss her condition and its possible impact on her pregnancy, labor and birth, and postpartum period.
- The woman participates in developing a healthcare regimen to meet her needs and follows it throughout her pregnancy.
- The woman avoids developing hypoglycemia or hyperglycemia.
- The woman gives birth to a healthy newborn.
- The woman is able to care for her newborn.

Care of the Woman with Anemia

Anemia indicates inadequate levels of hemoglobin (Hb) in the blood. *Anemia* is defined as hemoglobin less than 12 g/dl in nonpregnant women and less than 11 g/dl in pregnant women (ACOG, 2008a). Race, altitude, smoking, nutrition, and medications can affect the normal limits of hemoglobin. The lower limit of normal tends to be higher for women who smoke and those who live at higher altitudes because their bodies require a greater quantity of red blood cells to maintain their tissue oxygen levels. For example, a pregnant woman who lives in Denver, Colorado (elevation 5280 feet), would be considered anemic if her hemoglobin dropped below 10.5 g/dl. Similarly, a pregnant African American woman or a smoker should be considered anemic at 10.2g/dl or below (ACOG, 2008a).

The common anemias of pregnancy are due either to insufficient hemoglobin production related to nutritional deficiency in iron or folic acid during pregnancy, or to hemoglobin destruction in inherited disorders, specifically sickle cell anemia and thalassemia.

Iron Deficiency Anemia

Dietary iron is needed to synthesize hemoglobin. Because hemoglobin is necessary to transport oxygen, a deficiency of iron may affect the body's transport of oxygen.

Iron deficiency anemia is the most common medical complication of pregnancy, primarily as a consequence of expansion of plasma volume without normal expansion of maternal hemoglobin mass (ACOG, 2008a). Approximately 200 mg of iron will be conserved because of the functional amenorrhea of pregnancy, but a pregnant woman needs approximately 1000 mg more iron intake during the pregnancy. Between 300 and 400 mg of iron is transferred to the fetus; 500 mg is needed for the increased red blood cell mass in the woman's own increased circulating blood volume; another 100 mg is needed for the placenta; and about 280 mg is needed to replace the 1 mg of iron lost daily through feces, urine, and sweat.

The greatest need for increased iron intake occurs in the second half of pregnancy. When the iron needs of pregnancy are not met, maternal hemoglobin falls below 11 g/dl. Serum ferritin levels, indicating iron stores, are below 12 mg/L.

Many women begin pregnancy in a slightly anemic state. In pregnancy, mild anemia can rapidly become more severe; therefore, it needs immediate treatment.

Maternal Risks

The woman with iron deficiency anemia may be asymptomatic, but she is more susceptible to infection, may tire easily, has an increased chance of preeclampsia and postpartal hemorrhage, and tolerates poorly even minimal blood loss during birth. Healing of an episiotomy or an incision may be delayed. If the anemia is severe (Hb less than 6 g/dl), cardiac failure may ensue.

Fetal-Neonatal Risks

There is evidence of increased risk of low birth weight, prematurity, stillbirth, and neonatal death in infants of women with severe iron deficiency (maternal Hb less than 6 g/dl). The infant is not iron deficient at birth because of active transport of iron across the placenta, even when maternal iron stores are low. However, these babies do have lower iron stores and are at increased risk for developing iron deficiency during infancy.

Clinical Therapy

The first goal of health care is to prevent iron deficiency anemia. If it occurs, the goal is to return low iron and hemoglobin levels to normal. To prevent anemia, the American Academy of Pediatrics (AAP) and ACOG (2008) recommend that pregnant women take at least 27 mg supplements of iron daily. This amount is contained in most prenatal vitamins. In addition, the woman should be encouraged to eat an iron-rich diet. To prevent constipation, the most common side effect of iron supplementation, a stool softener may be necessary.

If anemia is diagnosed, the dosage should be increased to 60 to 120 mg per day of iron. If the woman remains anemic after 1 month of therapy, further evaluation is indicated. With a twin pregnancy, a larger dose is needed. If a large dose of oral iron causes vomiting, diarrhea, or constipation, or if the anemia is discovered late in pregnancy, parenteral iron may be needed.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The main presenting symptom of iron deficiency anemia may be fatigue. Nutritional history usually gives evidence of poor dietary intake of iron. The nurse should also determine whether there was a history of anemia in a prior pregnancy. Physical examination reveals pallor of skin and conjunctiva. Laboratory studies show hemoglobin values below 10 g/dl, serum ferritin levels below 12 mg/L, and possibly microcytic and hypochromic red blood cells (a late finding).

Nursing diagnoses that may apply to a pregnant woman with iron deficiency anemia include the following:

- ***Risk for Imbalanced Nutrition: Less Than Body Requirements*** related to inadequate intake of iron-containing foods
- ***Constipation*** related to daily intake of iron supplements

Nursing Plan and Implementation

The nurse stresses the importance of an iron-rich diet and of iron supplements during pregnancy. Supplements are indicated because dietary sources cannot meet the extra requirements. The woman is taught to take iron tablets with vitamin C (e.g., orange juice) to increase absorption. Iron absorption is reduced by 40% to 50% if the tablets are taken with meals. However, gastrointestinal upset is more likely if they are taken on an empty stomach. The patient may tolerate the iron better if she starts with small doses and gradually increases the dosage over several days. She is informed that her stool will turn black and may be more formed. She is also advised to keep the tablets out of the reach of children because ingestion may be fatal to a young child.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to identify the risks associated with iron deficiency anemia during pregnancy.
- The woman takes her iron supplements as recommended.
- The woman's Hb levels remain normal or return to normal during her pregnancy.

Folic Acid Deficiency Anemia

Folate deficiency is the most common cause of megaloblastic anemia during pregnancy, affecting between 1% and 4% of pregnant women in the United States. It is more prevalent with twin pregnancies.

Folic acid is needed for deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) synthesis and cell duplication. In its absence, immature red blood cells fail to divide, become enlarged (megaloblastic), and are fewer in number. Even more significantly, an inadequate intake of folic acid has been associated with neural tube defects (NTDs) (spina bifida, anencephaly, meningomyelocele) in the fetus or newborn. With the tremendous cell multiplication that occurs in pregnancy, an adequate amount of folic acid is crucial. However, increased urinary excretion of folic acid and fetal uptake can rapidly result in folic acid deficiency.

Clinical Therapy

Diagnosis of folic acid deficiency anemia may be difficult, and it is usually not detected until late in pregnancy or the early puerperium. This is because serum folate levels normally fall as pregnancy progresses. Even though folate levels are lower with deficiency, they will fluctuate with diet. Measurement of erythrocyte folate status is more reliable but indicates folate status of several weeks previously. Women with true folic acid deficiency anemia often present with nausea, vomiting, and anorexia. Hemoglobin levels as low as 3 to 5 g/dl may be found. Typically the blood smear reveals that the newly formed erythrocytes are macrocytic.

Folic acid deficiency during pregnancy is prevented by a daily supplement of 0.4 mg of folate. Treatment of deficiency consists of 1-mg folic acid supplement. Because iron deficiency anemia almost always coexists with folic acid deficiency, the woman also needs iron supplements.

NURSING CARE MANAGEMENT

The nurse can help the pregnant woman avoid folate deficiency by teaching her food sources of folic acid and cooking methods for preserving folic acid. The best sources are fresh leafy green vegetables, orange juice, other citrus fruits and juices, red meats, fish, poultry, and legumes. As much as 50% to 90% of folic acid can be lost by cooking in large volumes of water. Microwave cooking destroys more folic acid than conventional cooking.

The Food and Drug Administration (FDA) requires the addition of folic acid for all foods labeled "enriched." Even with this addition, the U.S. Public Health Service recommends that all women of childbearing age (15 to 45 years) consume 0.4 mg of folic acid daily. This recommendation is important because half of all U.S. pregnancies are unplanned and NTDs occur very early in pregnancy (3 to 4 weeks after conception), before most women realize they are pregnant (AAP/ACOG, 2008). Nurses can play a crucial role in helping young women become aware of this important recommendation.

Sickle Cell Disease

Sickle cell disease (SCD) is a recessive autosomal disorder in which the normal adult hemoglobin, hemoglobin A (HbA), is abnormally formed. This abnormal hemoglobin is called hemoglobin S (HbS). It occurs primarily in people of African descent and occasionally in people of Southeast Asian or Mediterranean origin (i.e., Greeks, Italians, Arabs, and Turks) (ACOG, 2007). The abnormal red cells break down, causing anemia, which is characterized by acute, recurring episodes of tissue, abdominal, and joint pain. Individuals with the disorder are homozygous for the sickle cell gene. They inherit from each parent an allele causing an amino acid substitution in the two beta protein chains in the hemoglobin molecule. Heterozygous individuals are carriers for sickle cell trait (SCT) but are usually asymptomatic. One of the beta protein chains formed in their hemoglobin is normal; the other has the amino acid substitution. Approximately 1 in 12 African Americans has sickle cell trait and 1 in every 300 African American newborns has some form of sickle cell disease (ACOG, 2007).

Hemoglobin S (HbS) causes the red blood cells to be sickle or crescent shaped. In conditions of low oxygenation, normal hemoglobin is soluble, but HbS becomes semisolid and distorts the red blood cell shape. These erythrocytes easily interlock and clog capillaries, particularly in organs characterized by slow flow and high oxygen extraction, such as the spleen, bone marrow, and placenta. This phenomenon, called *sickling,* varies in frequency depending on the amount of the HbS in the red blood cells (there is seldom a crisis with levels below 40%) and other hemoglobin factors. Diagnosis is confirmed by hemoglobin electrophoresis or a test to induce sickling in a blood sample. Prenatal diagnosis and newborn screening for sickle cell disease are important components of perinatal care (ACOG, 2007).

Maternal Risks

Women with sickle cell trait have a good prognosis for pregnancy if they have adequate nutrition and prenatal care. They are, however, at increased risk for nephritis, bacteriuria, and hematuria, and tend to become anemic.

Women with sickle cell disease have considerably more risk during pregnancy. Low oxygen pressure—caused by high temperature, dehydration, infection, or acidosis, for example—may precipitate a vaso-occlusive crisis. The crisis produces sudden attacks of pain that may be general or localized in bones or joints, lungs, abdominal organs, or the spinal cord. The pain is due to ischemia in the tissues from occluded capillaries. Vaso-occlusive crises occur more often in the second half of pregnancy.

Maternal mortality due to sickle cell disease is rare. However, sickle cell crisis occurred in 47% of patients in one cohort study (Yu, Stasiowska, Stephens, et al., 2009). Other complications included anemia requiring blood transfusion (32%), infections (28%), and emergency cesarean sections (30%). Acute chest syndrome, congestive heart failure, or acute renal failure may also occur.

Fetal-Neonatal Risks

The incidence of fetal death during and immediately following an attack has decreased greatly in recent years (Creary, Williamson, & Kulkarni, 2007). Prematurity and intrauterine growth restriction (IUGR) are also associated with sickle cell disease. Fetal death is believed to be due to sickling attacks in the placenta.

Clinical Therapy

Because the woman with sickle cell disease maintains her hemoglobin levels by intense erythropoiesis, additional folic acid supplements (4 mg/day) are required. Maternal infection should be treated promptly because dehydration and fever can trigger sickling and crisis. Vaso-occlusive crisis is best treated by a perinatal team in a medical center. Proper management requires close observation and evaluation of all symptoms. The term *sickle cell crisis* should be applied only after all other possible causes for the pain are excluded (Creary et al., 2007).

Rehydration with intravenous fluids; administration of oxygen, antibiotics, and analgesics; and monitoring of fetal heart rate are important aspects of therapy. Antiembolism stockings may be used postpartum.

If vaso-occlusive crisis occurs during labor, the previous therapies are instituted and the woman is kept in a left lateral position. Oxytocics may be used if needed to promote labor. Episiotomy and outlet forceps may be recommended to shorten the second stage of labor.

Several antisickling agents are being researched, and in the future sickle cell crisis may be prevented.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The woman with sickle cell disease usually relates a history of frequent illnesses and recurrent abdominal and joint pains and is found to be extremely anemic. The woman may appear undernourished and have long, thin extremities. Ulcers are often present on her ankles. Anemia may be severe.

A diagnosis of sickle cell disease is confirmed by hemoglobin electrophoresis or a test to induce sickling in a blood sample. The woman is assessed for infection, which is associated with one third of sickle cell crises in adults. Infections most often seen during pregnancy or postpartum are pneumonia, urinary tract infections, puerperal endomyometritis, and osteomyelitis.

Fetal status is assessed during a crisis by electronic fetal monitoring. During labor, the woman's vital signs are assessed frequently and continuous fetal heart rate monitoring is initi-

Figure 19-4 ■ Health teaching is an important part of nursing care for the pregnant woman with sickle cell anemia.

Source: Mark Richards/PhotoEdit, Inc.

ated. Compatible blood should be available for transfusion. Oxygen is administered if necessary. The woman is assessed for joint pains and other signs of sickle cell crisis.

Nursing diagnoses that might apply to the pregnant woman with sickle cell disease include the following:

- ***Acute Pain*** related to the effects of sickle cell crisis
- ***Readiness for Enhanced Knowledge*** about the need to avoid exposure to infection related to the risk of triggering a sickle cell crisis

Nursing Plan and Implementation

The nursing goal for a pregnant woman with sickle cell disease is to provide effective health teaching to help prevent a sickle cell crisis, improve the anemia, and prevent infection. The nurse teaches the woman to increase hydration, use good hygiene, avoid people with infections, seek immediate treatment for infection, and take folic acid supplements (Figure 19-4 ■). As stated earlier, folic acid is important because of its role in red blood cell production; therefore, folic acid supplements are essential. Bed rest is sometimes recommended to decrease the chance of preterm labor. Other nursing interventions are aimed at facilitating the medical therapy and alleviating anxiety through support and education.

Partners should be screened to evaluate their sickle cell status. If both partners have either sickle cell trait or sickle cell disease, genetic counseling is warranted.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to describe her condition and identify its possible impact on her pregnancy, labor and childbirth, and postpartum period.
- The woman takes appropriate healthcare measures to avoid a sickle cell crisis.
- The woman gives birth to a healthy infant.
- The woman and her caregivers quickly identify and successfully manage any complications that arise.

Thalassemia

The thalassemias are a group of autosomal recessive disorders characterized by a defect in the synthesis of the alpha or beta chains in the hemoglobin molecule. The one most frequently encountered in the United States is β-thalassemia. Symptoms are caused by the shortened lifespan of the red blood cells, which result in active erythropoiesis in the liver, spleen, and bones. This produces hepatosplenomegaly and, sometimes, bony malformations. The thalassemias are seen most often in persons from Greece, Italy, or southern China and are also known as Mediterranean anemia and Cooley anemia. Early identification of thalassemia and preventive management avoids missed diagnosis and unnecessary treatment for iron deficiency anemia (ACOG, 2007). Prenatal genetic diagnosis is now available for this disorder.

If the woman is heterozygous for β-thalassemia, half of the beta chains are formed normally. This is β-thalassemia minor, or β-thalassemia trait. Mild anemia is usually the only symptom.

Persons born homozygous for the disease have β-thalassemia major. Because newborns have fetal hemoglobin (HbF), which does not have beta chains, no symptoms are present for several months. Once infants with β-thalassemia major start producing adult-type hemoglobin (HbA), they develop severe anemia and are dependent on transfusions from which they eventually develop iron overload. Iron chelation therapy must be instituted soon after chronic transfusions are begun because excess iron damages the liver and heart (Cunningham et al., 2010). Without chelation therapy, these children do not live past the second or third decade. Girls with the disorder are often amenorrheic and infertile.

Maternal-Fetal-Neonatal Risks

The woman with β-thalassemia minor has mild anemia with small (microcytic) red cells. This mild anemia must be distinguished from iron deficiency anemia because a woman with β-thalassemia minor should not receive iron therapy unless she is also deficient in iron. A woman with iron deficiency anemia typically has low serum iron and serum ferritin levels, whereas the woman with β-thalassemia minor has normal levels. β-thalassemia minor varies in degree of severity from extremely mild (minima) anemia, which results in a relatively smooth pregnancy, to a more symptomatic form (intermedia).

Pregnancy is rare in women with β-thalassemia major. If it does occur, the woman generally has severe anemia, needs transfusion therapy, and is at risk for congestive heart failure. These women are generally cared for by a perinatologist in a facility that can accommodate high-risk pregnancies.

Clinical Therapy

Folic acid supplements are indicated for women with thalassemia, but iron supplements are not given. Those with thalassemia intermedia and thalassemia major may need transfusion and chelation therapy. They should avoid exposure to infections and seek treatment promptly if an infection develops. Their care is similar to that of women with sickle cell anemia.

NURSING CARE MANAGEMENT

The woman with thalassemia needs to understand her disease and the possibility of transmitting it to her offspring. Thus genetic counseling may be helpful. These patients have lived with thalassemia since childhood but may have questions about its effect on pregnancy outcome and their own prognosis.

Care of the Woman with AIDS

AIDS (acquired immune deficiency syndrome), caused by the virus known as **HIV** (human immunodeficiency virus), is one of today's major health concerns. By the end of 2007, an estimated 551,932 persons in the United States were living with HIV/AIDS (Centers for Disease Control and Prevention [CDC], 2009). Male adults and adolescents are still the largest group of infected individuals (73%). Of this group, infection occurred as follows: male-to-male sexual contact (64%), intravenous (IV) drug use (16%), high-risk heterosexual contact (12%), and 7% through both male-to-male sexual contact and IV drug use. Among females with HIV/AIDS, 72% were infected through high-risk heterosexual contact and 26% were infected because of IV drug use (CDC, 2009).

Of the estimated 7181 children living with HIV/AIDS in the United States, 91% were exposed perinatally (CDC, 2009). Fortunately, the number of new pediatric AIDS cases is declining rapidly. The decline is associated with new CDC and ACOG guidelines (2008d) that emphasize:

1. Universal counseling about the risks of HIV transmission from mother to fetus
2. Recommended opt-out HIV screening of all pregnant women during each pregnancy
3. Repeat HIV testing in the third trimester in areas with high HIV prevalence rates; HIV negative individuals with high-risk behaviors; individuals with unknown HIV status at the time of labor
4. Immediate antiretroviral prophylaxis for HIV-positive pregnant women in labor and their infants following birth

In a review of the successes and challenges of preventing HIV transmission from mother-to-child internationally, Paintsil and Andiman (2009) highlight the disparities between resource-rich and poor countries. The authors maintain that prevention of transmission at a rate of less than 2% should be the goal and "resource-rich countries should be unrelenting in their efforts to provide access to HIV testing for all women . . . including antiretroviral treatment for HIV-infected women and children."

DEVELOPING CULTURAL COMPETENCE

Variations in the Prevalence Rates of New HIV Infections

The prevalence rates of individuals with HIV/AIDS infection vary significantly among races and ethnic groups: 83.7 per 100,000 in the black/African American population, 29.3 per 100,000 in the Hispanic/Latino population, and 11.5 per 100,000 in the white population (CDC, 2009).

Pathophysiology of HIV/AIDS

HIV found in blood, semen, vaginal fluid, and breast milk has been implicated in disease transmission, although the virus has been isolated in urine, tears, cerebrospinal fluid, lymph nodes, brain tissue, and bone marrow. HIV shedding has also been detected in the genital tract of women.

Once infected with the virus, the individual develops antibodies that can be detected with a reactive enzyme immunoassay (EIA) and confirmed with the Western blot test or immunofluorescence assay (IFA). A confirmed case is then categorized into one of four HIV infection stages for adults and adolescents over age 13. See Table 19-4.

TABLE 19-4 HIV Infection Stages for Adults and Adolescents over Age 13

STAGE	AIDS-DEFINING CONDITION	AND ONE OF THE FOLLOWING CD4+ T-LYMPHOCYTE FINDINGS
1	None	CD4+ T-lymphocyte count greater than or equal to 500 cells/mm^3 or CD4+ T-lymphocyte percentage of total lymphocytes greater than or equal to 29
2	None	CD4+ T-lymphocyte count 200–499 cells/mm^3 or CD4+ T-lymphocyte percentage of total lymphocytes of 14–28
3 (AIDS)	Documentation of an AIDS-defining condition supersedes CD4 count or %	CD4+ T-lymphocyte count less than 200 cells/mm^3 (without AIDS-defining condition) or CD4+ T-lymphocyte percentage of total lymphocytes of less than 14 (without AIDS-defining condition)
HIV test positive but other criteria unknown	No information available	No information available

Note: These infection stages are intended for public health surveillance only and not as a guide for clinical diagnosis. There are 24 AIDS-defining conditions ranging from multiple bacterial infections to HIV encephalopathy, Kaposi's sarcoma, and wasting syndrome.

Source: Adapted from Revised surveillance case definitions for HIV infection among adults, adolescents, and children aged less than 18 months and for HIV infection and AIDs among children aged 18 months to less than 13 years —United States, 2008. (2008, December 5). Morbidity and Weekly Report, 57*(RR10), 1–8.*

For children aged 18 months to under 13 years, laboratory-confirmed evidence of HIV and AIDS is now required. Diagnostic confirmation of AIDS-defining conditions is no longer sufficient to confirm a case. A child less than18 months of age is categorized as definitively HIV infected if born to a mother who is HIV positive and if the child has two HIV-positive results from separate specimens (not including the umbilical cord) (Schneider et al., 2008).

Maternal Risks

Recent advances and availability of antiretroviral therapy (ART) have led HIV-positive women who adhere to their ART to consider pregnancy because of their increased life expectancy. If pregnancy is considered, priorities should focus on maintaining the health of the mother before, during, and after the pregnancy, preventing transmission to a potentially seronegative father, and preventing mother-to-child transmission. Reproductive assisted technology is one possibility along with further interventions including cesarean birth to reduce the risk of transmission to the fetus (Matthews & Mukherjee, 2009).

For women who have not had access to ART or who are noncompliant, AIDS-defining symptoms that are more common in women than men include wasting syndrome, esophageal candidiasis, and herpes simplex virus disease. Kaposi's sarcoma is rare in women. Non-AIDS-defining gynecologic conditions, such as vaginal *Candida* infections and cervical pathology, are prevalent among women at all stages of HIV infection.

Fetal-Neonatal Risks

HIV transmission can occur during pregnancy and through breast milk; however, it is believed that the majority of all infections occur during labor and birth. For HIV-infected pregnant women who receive no prophylactic medication, the rate of transmission to the newborn is about 25%. However, for HIV-infected pregnant women who receive prophylactic antiretroviral therapy, give birth by elective cesarean at 38 weeks, before rupture of membranes, and avoid breastfeeding, the rate of transmission drops to 2% or less (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2010). These decreases in transmission are dramatic and impressive.

Clinical Therapy

Treatment of the HIV-Infected Mother

Early knowledge of a woman's HIV status is important for her well-being and that of her child. Thus the revised CDC screening guidelines for pregnant women state that HIV screening should be emphasized as a routine part of all prenatal care. To this end, the recommendation that all pregnant women should be tested for HIV has been strengthened while continuing to ensure that testing of pregnant women and their infants is voluntary and informed (Panel on Treatment of HIV-Infected Women, 2010). Initial testing is done using an enzyme-linked immunosorbent assay (ELISA) and confirmed with the Western blot test or immunofluorescence assay (IFA). A woman who tests positive should be counseled about the implications of the diagnosis for herself and her fetus to ensure an informed reproductive choice. The care of the woman who chooses to continue her pregnancy should focus on stabilizing the disease, preventing opportunistic infections and transmission of the virus from mother to fetus, and providing psychosocial and educational support.

Antiretroviral therapy should be recommended to all infected pregnant women regardless of whether they are symptomatic to reduce the rate of perinatal transmission. Women receiving highly active antiretroviral therapy (HAART) during pregnancy, whether for treatment or for prophylaxis, should be given a combination regimen that contains at least three drugs, and should include ZDV (Retrovir or zidovudine). Longer duration therapy is preferable to shorter duration approaches. Thus, it is best to start prophylaxis after the first trimester and no later than 28 weeks' gestation in women who do not require immediate therapy for their own health (Panel on Treatment of HIV-Infected Women, 2010). Treatment recommendations have also been developed for the mother and infant for the intrapartum and postpartum periods and take into account the therapeutic regimen they had been on prenatally. The decision about which regimen is most appropriate should be determined following discussion with the woman about the risks and benefits based on her individual HIV status.

HIV-infected women should be evaluated and treated for other sexually transmitted infections and for conditions occurring more commonly in women with HIV, such as tuberculosis, cytomegalovirus, toxoplasmosis, and cervical dysplasia. HIV-infected women with no history of hepatitis B should receive the hepatitis vaccine, which is not contraindicated prenatally, as well as the pneumococcal vaccine and an annual flu shot. In addition to routine prenatal laboratory tests, a platelet count and a complete blood count with differential should be obtained at the first prenatal visit and repeated each trimester to identify anemia, thrombocytopenia, and leukopenia, which are associated both with HIV infection and with antiviral therapy.

The woman with HIV also should be assessed regularly for serologic changes that indicate the disease is progressing. This is determined by the absolute $CD4^+$ T-lymphocyte count, which provides the number of helper T4 cells. When $CD4^+$ counts fall to 200/mm^3 or lower, opportunistic infections such as *Pneumocystis carinii* pneumonia are more likely to develop, and prophylaxis may need to be instituted (Panel on Treatment of HIV-Infected Pregnant Women, 2010).

At each prenatal visit, asymptomatic HIV-infected women are monitored for early signs of complications, such as weight loss in the second or third trimester or fever. The woman is asked about signs of vaginal infection. Her mouth is inspected for signs of infections such as thrush (candidiasis) or hairy leukoplakia; her lungs are auscultated for signs of pneumonia; and her lymph nodes, liver, and spleen are palpated for signs of enlargement. Each trimester the woman should have a visual examination and a funduscopic examination to detect such complications as toxoplasmosis retinitis. Further discussion of therapy for the pregnant woman can be found at www.nursing.pearsonhighered.com.

A pregnancy complicated by HIV infection, even if asymptomatic, is considered high risk, and the fetus is monitored

closely. Weekly nonstress testing (NST) is begun at 32 weeks' gestation, and serial ultrasounds are done to detect IUGR. Biophysical profiles are also indicated (see chapter 21 ∞). Invasive procedures such as amniocentesis are avoided when possible to prevent the contamination of a noninfected infant.

Scheduled cesarean birth is indicated for women with HIV RNA levels greater than 1000 copies/ml and for women with unknown HIV RNA levels near the time of birth whether they are on antiretroviral therapy or not. Data about the potential benefits of cesarean birth for women on combination antiretroviral therapy or prophylaxis and viral levels less than 1000 are not clear and women should be told about the risks associated with cesarean birth and the potential complications, especially because the use of combined antiretroviral therapy reduces the risk of vertical transmission of infection significantly (Panel on Treatment of HIV-Infected Women, 2010). The cesarean may be done as early as 38 weeks' gestation to decrease the risk of rupture of the membranes or onset of labor. Intrapartum care is similar to that for all pregnant women, although strict adherence to universal precautions is crucial to avoid nosocomial infection. To prevent exposure of an uninfected infant to HIV during labor and birth, invasive procedures such as vaginal examinations following rupture of the membranes, fetal scalp electrode monitoring, fetal scalp sampling, and vacuum extraction should be done only after carefully evaluating the risks and benefits.

Women who are HIV positive are at increased risk for complications such as intrapartal or postpartal hemorrhage, postpartal infection, poor wound healing, and infections of the genitourinary tract. Thus they need careful monitoring and appropriate therapy as indicated.

Following childbirth, the HIV-positive woman should be referred to a physician knowledgeable about treating individuals with HIV infection. Because of the profound implications of HIV infection for the woman, her family, the fetus/newborn, and her healthcare providers, screening is recommended for all pregnant women, and those at increased risk should be rescreened in the third trimester. These women include the following: prostitutes; women with multiple sexual partners; women whose current or previous sex partners have been bisexual, have abused IV drugs, had hemophilia, or tested positive for HIV; women who are or have been IV drug users; and women from countries where heterosexual transmission is common. In addition, clinics located in areas with a large HIV-positive population may require routine HIV screening of all prenatal patients.

Treatment of the Neonate

Following birth, all HIV-exposed infants should complete a 6-week regimen of oral zidovudine prophylactically (Panel on Treatment of HIV-Infected Pregnant Women, 2010). Testing for HIV in infants with known perinatal HIV exposure is best done at 14–21 days, 1–2 months, and 4–6 months using the HIV DNA polymerase chain reaction (PCR) or HIV RNA virologic assay. Some experts also test within 48 hours of birth because up to 30% to 40% of infected infants can be identified at that time (Working Group on Antiretroviral Therapy and Medical Management of HIV-Infected Children, 2009). If the results of the HIV DNA PCR are positive, prophylaxis should be discontinued and the newborn should be immediately referred to an HIV specialist for confirmation of the diagnosis and initiation of combination antiretroviral therapy (Panel on the Treatment of HIV-Infected Women, 2010).

In cases in which the woman does not begin antiretroviral therapy until she is in labor, prophylaxis for the newborn is provided by giving the mother an intravenous drug such as zidovudine, which crosses the placenta rapidly. The infant is also given zidovudine orally for 6 weeks to reduce the risk of transmission (Panel on the Treatment of HIV-Infected Pregnant Women, 2010). An HIV antibody positive test in the infant up to 18 months of age may indicate the presence of maternal antibodies, and so follow-up testing is required to confirm the infant's HIV status.

Progression of HIV to AIDS in infants and small children is associated with severe immune suppression (i.e., CD4 cell count less than 15%) and typically manifests as failure to thrive, hepatosplenomegaly, interstitial lymphocytic pneumonia, recurrent infections, cell-mediated immunodeficiency, evidence of Epstein-Barr virus, and neurologic abnormalities. Recurrent bacterial infections are common in children with AIDS; Kaposi's sarcoma is rare. Encephalopathy, characterized by delayed developmental milestones or the loss of acquired skills, including cognitive abilities, is found in 50% to 90% of children with AIDS. Treatments that prevent the central nervous system (CNS) effects of HIV have yet to be identified. The prognosis for an infected child remains poor (Working Group on Antiretroviral Therapy and Medical Management of HIV-Infected Children, 2009).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

A woman who tests positive for HIV may be asymptomatic or may present with any of the following signs or symptoms: fatigue, anemia, malaise, progressive weight loss, lymphadenopathy, night sweats, diarrhea, fever, neurologic dysfunction, cell-mediated immunodeficiency, or evidence of Kaposi's sarcoma (purplish, reddish brown lesions, either externally or internally).

If a woman tests HIV positive or is involved in a relationship or an activity that places her at high risk, the nurse should assess the woman's knowledge level about the disease, its implications for her and her fetus, and self-care measures the woman can take.

Examples of nursing diagnoses that might apply for an HIV-positive pregnant woman include the following:

- ***Readiness for Enhanced Knowledge:*** Information About HIV/AIDS related to its long-term implications for the woman and her unborn child
- ***Risk for Infection*** related to altered immunity secondary to HIV/AIDS
- ***Compromised Family Coping*** related to the implications of a positive HIV test in one of the family members

> "I've been a nurse for 35 years now, and I've never seen anything change nursing practice more than HIV/AIDS has. Nursing students today will take universal precautions for granted because they won't know any other way, but I can remember when we could touch more freely. I remember drying a newly born infant and stroking him—my hands warm against his skin. I remember a time when people didn't think twice before trying to stop bleeding or give other first aid at an accident scene. I know this way is safer, but a part of me mourns what we have lost."

Nursing Plan and Implementation

Community-Based Nursing Care

Nurses need to help women understand that HIV/AIDS is a fatal disease. HIV infection can be avoided if women avoid sharing IV drug needles and practice safe sex, including insisting that their sex partners wear a latex condom for each act of intercourse.

Women at risk for AIDS should be offered premarital and prepregnancy screening for HIV antibodies (ACOG, 2008d). They should be given clear information about the implications of a diagnosis of HIV and the importance of receiving and adhering to antiretroviral therapy, as well as living the healthiest lifestyle possible. Access to information about the disease and about the test results empowers women by enabling them to make informed decisions about their sexual activities and about becoming pregnant.

A detailed drug and sexual history of each prenatal patient is the first step in perinatal HIV/AIDS prevention. All women should be offered HIV counseling. The following are counseling guidelines for HIV testing:

- The nurse should discuss HIV testing during the normal prenatal assessment, explaining that HIV testing is recommended for all pregnant women and that they will receive an HIV test as part of the routine panel unless the woman declines (opt-out testing). No woman should be tested without her knowledge, but no written consent is required (ACOG 2008c).
- The nurse should assure the woman of confidentiality, explaining the difference between anonymity and confidentiality.
- The nurse should provide an environment that is private, comfortable, and nonjudgmental.
- The nurse should provide the woman with information about AIDS, including pathophysiology, mode of transmission of HIV, high-risk behaviors, and methods of decreasing transmission, such as practicing safe sex and not sharing needles.
- Post-test counseling should be provided. A negative test means that no HIV antibodies were found; it does not ensure that the woman has not been infected with the virus, because antibodies may not be detected for 6 weeks to 6 months after exposure.
- If test results are positive, supportive follow-up is necessary. This includes an explanation of the implications for the woman and her unborn child as well as the value of antiretroviral therapy, recommended medical therapy, follow-up of sex partners, transmission prevention, discussion of immediate posttest plans, and referral to appropriate psychologic and educational services. The nurse should tell the woman not to donate blood or blood products and not to share toothbrushes, razors, and other implements that could be contaminated with blood.

This information can be overwhelming to the woman who is HIV positive and should be provided orally and in writing. She will need more than one counseling session to absorb the information. The initial reaction may be one of shock or denial, so it is important for the nurse to allow her a little time to think and to give her empathy and support. The nurse needs to stress that being HIV positive does not mean that the woman has AIDS but that she can transmit the virus to others (by sexual contact, sharing IV drug needles, and donating blood) and to her fetus during pregnancy or childbirth or by breastfeeding. Antiretroviral therapy is now able to prolong life expectancy for HIV-positive individuals who adhere to their treatment plans and maintain as healthy a lifestyle as possible (CDC, 2008).

In monitoring the asymptomatic HIV-positive pregnant woman, the nurse should be alert for nonspecific symptoms such as fever, weight loss, fatigue, persistent candidiasis, diarrhea, cough, skin lesions, and behavior changes. Laboratory findings—such as decreased hemoglobin, hematocrit, and T4 lymphocytes; elevated erythrocyte sedimentation rate (ESR); and abnormal complete blood count, differential, and platelets—may indicate complications or progression of the disease.

Education about optimal nutrition and maintenance of wellness are important and should be reviewed frequently with the woman.

Hospital-Based Nursing Care

The Nursing Care Plan for the Woman with HIV Infection beginning on page 440 summarizes essential nursing management during the antepartum, intrapartum, and postpartum periods.

In community and hospital settings, the nurse faces the important task of taking the precautions necessary to protect staff, other patients, and families from exposure to HIV while meeting the needs of the childbearing woman with this infection.

In 1987 the CDC stated that the prevalence of AIDS and the risk of exposure faced by healthcare workers is significant enough that *precautions should be taken with all patients* (not only those with known HIV infection), especially in dealing with blood and body fluids. These practices are now called *standard precautions.*

Nurses who deal with childbearing families are exposed to blood and body fluids and should pay careful attention to the CDC guidelines, which are addressed in introductory nursing courses in preparation for clinical practice. Protocols have been established for postexposure treatment of caregivers who experience a needle stick or exposure to the body fluids of a person with HIV or a person whose HIV status is not known. The effectiveness of such therapy, using a combined drug approach, depends on starting therapy rapidly. Thus such exposure should be reported immediately.

NURSING CARE PLAN The Woman with HIV Infection

INTERVENTION	RATIONALE
1. Nursing Diagnosis: Risk for Infection related to inadequate defenses (leukopenia, suppressed inflammatory response) secondary to HIV-positive status **Goal:** Patient will remain free of opportunistic infection during the course of pregnancy.	
■ Obtain a complete health history and physical examination during first prenatal visit.	■ A complete health history will help determine risk factors for the development of opportunistic infections, and a physical examination will assist in identifying any underlying problem symptoms or illnesses that may compromise the pregnancy or complicate the treatment of HIV.
■ Educate the woman as to the signs and symptoms of infection.	■ Early recognition of signs and symptoms of infection will allow for immediate treatment, which may decrease the severity of the infection. Signs and symptoms of infections include fever, weight loss, fatigue, persistent candidiasis, diarrhea, cough, and skin lesions (Kaposi's sarcoma and hairy leukoplakia in the mouth).
■ Obtain nutritional history and monitor weight gain at each prenatal visit.	■ The HIV-infected woman needs to maintain optimal nutritional intake. A compromised nutritional status may affect maternal and fetal well-being. Depleted reserves of protein and iron may decrease the patient's ability to fight infection, thereby making her more susceptible to opportunistic infections.
Collaborative: Monitor the absolute $CD4^+$ T-lymphocyte count, erythrocyte sedimentation rate (ESR), complete blood count (CBC) with differential, and hemoglobin and hematocrit (H & H) at each prenatal visit.	■ Laboratory results provide information about the woman's immune system and the potential for disease progression. Opportunistic infections are more likely to occur when the $CD4^+$ T-lymphocyte count drops below a level of $200/mm^3$. ESR can rise above 20 mm/hr with anemia and with acute and chronic inflammation. CBC with differential and platelet count helps identify anemia, thrombocytopenia, and leukopenia. H & H can also identify anemia.
EXPECTED OUTCOME: Patient will remain free of opportunistic infection as evidenced by $CD4^+$ T-lymphocyte count within normal limits; no complaints of chills, fever, or sore throat; normal weight gain throughout pregnancy.	
2. Nursing Diagnosis: Readiness for Enhanced Therapeutic Regimen Management related to an expressed desire for information a about HIV/AIDS and its long-term implications for the woman, her unborn child, and her family **Goal:** The patient and her family will verbalize the importance of following her medication regimen and of regular prenatal care.	
■ Assess the patient's and family's level of understanding of HIV infection, its modes of transmission, and the long-term implications.	■ Knowledge of the woman's (and her family's) level of understanding about her HIV infection forms a starting point for further health teaching.
■ Explain the risks of mother-to-child transmission of HIV infection.	■ In untreated women the risk of transmission is 25%. That risk can be reduced to less than 2% with the availability of antiretroviral therapy, the use of cesarean birth when indicated, and formula-feeding rather than breastfeeding.
■ Describe antiretroviral therapy (ART). Include the regimen prescribed, its purposes, and the procedures for taking it.	■ ART therapy approaches vary based on the health status of the individual woman and whether she is currently on ART therapy. Generally it includes oral Zidovudine (ZDV) daily, IV ZDV during labor and until birth, and ZDV therapy for the infant for 6 weeks following birth.
■ Discuss signs the woman should be alert for, including fever, fatigue, weight loss, cough, skin lesions, and behavior changes.	■ These symptoms may indicate that the woman is developing symptomatic loss, persistent candidiasis, diarrhea, HIV infection.
EXPECTED OUTCOME: Woman will actively seek information about her condition, her treatment regimen, and her pregnancy and will cooperate with her caregivers.	

NURSING CARE PLAN The Woman with HIV Infection continued

INTERVENTION	RATIONALE
3. Diagnosis: Compromised Family Coping related to the implications of positive maternal HIV status on fetal/neonatal well-being and long-term family functioning **Goal:** Family is able to manage stressors related to the maternal diagnosis.	
■ Assess ability and readiness of family to learn about HIV and its long-term implications.	■ Readiness is a key element in the teaching-learning process.
■ Provide woman and her family with accurate, reliable information about her diagnosis, its prognosis for her and for her baby, and the immediate and long-term implications for her care.	■ Fear and anxiety will lessen when the woman and her family understand her health status and the implications of the HIV diagnosis and can then plan for the future.
■ Assess interactions between the woman and her family. Be alert for potentially destructive behaviors.	■ If the HIV diagnosis was not expected, the couple may have to deal with issues of blame, concerns about mortality, and worries about the status of the baby. If the HIV diagnosis was known, concerns may focus on fetal/neonatal well-being. In either case, negative responses can lead to destructive behaviors.
■ Assist family in realistically identifying the needs of the woman and family unit.	■ Once needs are identified realistically, it is possible to plan interventions to meet the needs.
Collaborative: Explore available community resources and family support systems.	■ Because HIV is a long-term condition, the family may require ongoing assistance.
EXPECTED OUTCOME:	Family members actively participate in the treatment plan, are involved in planning for labor and birth in light of a positive HIV status, and are able to express unresolved feelings about the diagnosis.

Health Promotion Education

The psychologic implications of HIV/AIDS for the childbearing family are staggering. The woman is faced with the knowledge that she and her newborn, if infected, may have a decreased life expectancy, although, as noted earlier, women who adhere to antiretroviral therapy are living longer, healthier lives. If her infant is not infected, the mother may face the possibility that others will raise her child. She may have feelings of fear, helplessness, anger, and isolation. If she shares her diagnosis with others, she may face rejection and condemnation. The couple must deal with the impact of the illness on the partner, who may or may not be infected, and on other children. Dealing with the tasks and responsibilities of a newborn may be especially difficult if the woman is physically depleted or if she is trying to come to grips with the long-term implications of her condition.

The nonjudgmental, supportive nurse plays an essential role in preserving confidentiality and the patient's right to privacy. In addition, the nurse can help ensure that the woman receives complete, accurate information about her condition and ways she might cope. This usually involves a referral to social services for follow-up care.

Evaluation

Expected outcomes of nursing care include the following:

- The woman discusses the implications of her positive HIV antibody screen (or diagnosis of AIDS), its implications for herself and her unborn child, the method of transmission, and treatment options.
- The woman uses information about referral to social services (or other agency) for follow-up assistance and counseling.
- The woman begins to verbalize her feelings about her condition and its implications in an atmosphere she finds supportive.

Care of the Woman with Heart Disease

A healthy woman with a normal heart has adequate cardiac reserve to adjust easily to the demands of pregnancy. The woman with heart disease, however, has decreased cardiac reserve, making it more difficult for her heart to accommodate the higher workload of pregnancy.

Heart disease ranks fourth after hypertension, hemorrhage, and infection as a cause of maternal mortality. Currently, cardiac disease complicates about 1% of pregnancies. Although rheumatic heart disease used to predominate, at least half of all cases of heart disease currently encountered during pregnancy are caused by congenital heart defects (Curry, Swan, & Steer, 2009). Other less common causes of heart disease in pregnancy include Marfan syndrome, peripartum cardiomyopathy, and Eisenmenger syndrome. All can cause significant maternal mortality. Mitral valve prolapse is usually asymptomatic but is addressed here because of its frequent occurrence during pregnancy.

Congenital Heart Defects

Congenital heart defects have become a more common finding in pregnant women as improved surgical techniques enable females

born with heart defects to live to childbearing age. The exact pathology depends on the specific defect. Congenital defects most often seen in pregnant women include tetralogy of Fallot, atrial septal defect, ventricular septal defect, patent ductus arteriosus, and coarctation of the aorta. When surgical repair can be accomplished with no remaining evidence of organic heart disease, pregnancy may be undertaken with confidence. In such cases, antibiotic prophylaxis is recommended to prevent subacute bacterial endocarditis at the time of birth. When congenital heart disease is associated with cyanosis, whether the defect was originally uncorrected or the correction failed to relieve the cyanosis, the woman should be counseled that the risk to both her and the fetus would be higher than in the general population. She also needs to know that there is an increased risk that the baby will inherit the disorder.

Rheumatic Heart Disease

Rheumatic heart disease has declined rapidly in the last four decades because of prompt identification of pharyngeal infections caused by group A β-hemolytic streptococcus and the availability of penicillin for treatment. Rheumatic fever, which may develop in untreated streptococcal infections, is an inflammatory connective tissue disease that can involve the heart, joints, central nervous system (CNS), skin, and subcutaneous tissue. When the heart is affected, mitral valve stenosis is the most common and serious lesion. Aortic valve involvement, manifested by aortic insufficiency, is the second most common problem. The tricuspid and pulmonic valves are rarely affected.

The increased blood volume of pregnancy, coupled with the pregnant woman's need for increased cardiac output, stresses the heart of a woman with mitral valve stenosis. She may develop dyspnea, orthopnea, and pulmonary edema and is at increased risk for congestive heart failure (CHF). Even the woman who has no symptoms at the onset of pregnancy is at risk for CHF.

Marfan Syndrome

Marfan syndrome is an autosomal dominant disorder of connective tissue in which there may be serious cardiovascular involvement—usually dissection or rupture of the aorta. Because there may be a fivefold increase in morbidity during pregnancy, a pregnant woman with Marfan syndrome needs very careful cardiovascular assessment and counseling about her prognosis for pregnancy (Pacini et al., 2009). Because of its inheritance pattern, there is a 50% chance that the disease will be passed on to offspring.

Peripartum Cardiomyopathy

Peripartum cardiomyopathy is a dysfunction of the left ventricle that occurs in the last month of pregnancy or the first 5 months postpartum in a woman with no previous history of heart disease. This is a relatively rare but serious condition, which occurs in 1 in 3000 to 4000 live births. Early reports suggested a mortality rate of nearly 50%, but more recent studies indicate a 0%–5% rate in the United States (Ramaraj & Sorrell, 2009). The symptoms are related to CHF: dyspnea, orthopnea, chest pain, palpitations, weakness, and edema. The cause is unknown, although symptoms are often attributable to chronic hypertension, mitral stenosis, obesity, or viral myocarditis. The condition usually presents with anemia and infection; consequently, treatment focuses on underlying abnormalities. Digitalis, diuretics, vasodilators, anticoagulants, sodium restriction, and strict bed rest are often part of the treatment. Peripartum cardiomyopathy may resolve with bed rest as the heart gradually returns to normal size. Subsequent pregnancy is strongly discouraged because the disease tends to recur during pregnancy.

Eisenmenger Syndrome

Eisenmenger syndrome is not a single congenital defect, but a complication that can develop as a result of other cardiac lesions causing left-to-right shunting (as with atrial septal defects or ventricular septal defects). This shunting can result in progressive pulmonary hypertension. As pulmonary vascular resistance increases, the shunting becomes bidirectional or reverses to right-to-left shunting. This condition cannot be corrected surgically, and the maternal mortality rate remains as high as 40%, unchanged for the past 50 years (Makaryus, Forouzesh, & Johnson, 2006).

Mitral Valve Prolapse

Mitral valve prolapse (MVP) is a usually asymptomatic condition commonly found in women of childbearing age. The condition is more common in women than in men and seems to be inherited. In MVP, the mitral valve leaflets tend to prolapse into the left atrium during ventricular systole because the chordae tendineae that support them are long and thin. As a result, some mitral regurgitation may occur. On auscultation a midsystolic click and a late systolic murmur are heard.

Women with MVP usually tolerate pregnancy well, and the prognosis is excellent. Most women require assurance that they can continue with normal activities. A few women experience symptoms such as palpitations, chest pain, and dyspnea, which are usually due to arrhythmias. They are often treated with propranolol hydrochloride (Inderal). Limiting caffeine intake also helps decrease palpitations. Antibiotic prophylaxis is no longer recommended (Bonow et al., 2008).

Clinical Therapy

The primary goal of medical management is early diagnosis and ongoing treatment of the woman with cardiac disease. Auscultation of heart sounds along with a good history and physical are the first steps to diagnosis. Echocardiogram, chest x-ray, electrocardiogram, and sometimes cardiac catheterization may be necessary for establishing the type and severity of the heart disease. The severity of heart disease can also be determined by the individual's ability to perform ordinary physical activity. The following classification of functional capacity for those with cardiac disease has been standardized by the Criteria Committee of the New York Heart Association (1994):

- ***Class I.*** Individuals with cardiac disease but with no resulting limitation of physical activity and no symptoms of cardiac insufficiency. Ordinary physical activity causes no undue fatigue, dyspnea, or palpitations; anginal pain is not present.
- ***Class II.*** Individuals with cardiac disease that results in slight limitation of physical activity. They are comfortable at

rest but ordinary physical activity causes fatigue, dyspnea, palpitation, or anginal pain.

- ***Class III.*** Individuals with cardiac disease that results in marked limitation of physical activity. They are comfortable at rest but less than ordinary physical activity results in fatigue, dyspnea, palpitation, or anginal pain.
- ***Class IV.*** Individuals with cardiac disease that results in the inability to carry on any physical activity without experiencing discomfort. Even at rest, they may experience symptoms of cardiac insufficiency or anginal pain; discomfort increases with any physical activity.

Women in classes I and II usually experience a normal pregnancy and have few complications, whereas those in classes III and IV are at risk for more severe complications, which may affect both maternal and fetal outcomes. Preconception counseling is important for these women to optimize maternal and fetal outcomes.

Because anemia increases the work of the heart, it should be diagnosed early and treated. Infection also increases the cardiac workload, so even minor infections should be treated thoroughly. To reduce the risk of pyelonephritis, monthly screening for asymptomatic bacteriuria is indicated, with antibiotic therapy as needed.

As pregnancy progresses, it is important to minimize cardiac workload and promote tissue perfusion. Depending on the specific lesion, the woman's activity and weight gain may need to be limited (Bonow et al., 2008).

Drug Therapy

Besides the iron and vitamin supplements prescribed during pregnancy, the pregnant woman with heart disease may need additional drug therapy to maintain health. Antibiotic prophylaxis is not indicated for uncomplicated vaginal or cesarean birth unless infection is suspected. If the woman develops coagulation problems, the anticoagulant heparin may be used. Heparin offers the greatest safety to the fetus because it does not cross the placenta. The thiazide diuretics and furosemide (Lasix) may be used to treat congestive heart failure if it develops. Digitalis glycosides and common antiarrhythmic drugs may be used to treat cardiac failure and arrhythmias. These agents do cross the placenta but have no reported teratogenic effect; however, they have not been adequately studied to establish their safety in pregnancy (Bonow et al., 2008).

Labor and Childbirth

Spontaneous natural labor with adequate pain relief is usually recommended for patients in classes I and II. Special attention should be given to the prompt recognition and treatment of any signs of heart failure (Figure 19-5 ■). Those in classes III and IV may need to be hospitalized before onset of labor for cardiovascular stabilization. They may also require invasive cardiac monitoring during labor.

Vaginal birth with low-dose regional analgesia (epidural) is recommended with the use of forceps or vacuum assistance if necessary to limit maternal pushing. The regional analgesia helps decrease maternal cardiac output and oxygen demand by reducing pain and related maternal anxiety (Burt & Durbridge, 2009). Cesarean birth is usually used only if fetal or maternal indications exist, not on the basis of heart disease alone.

Figure 19-5 ■ When a woman with heart disease begins labor, the nursing students and instructor caring for her monitor her closely for signs of congestive heart failure.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse assesses the stress of pregnancy on the functional capacity of the heart during every antepartal visit. The nurse notes the category of functional capacity assigned to the woman; takes the woman's pulse, respirations, and blood pressure; and compares them to the normal values expected during pregnancy and to the woman's previous values. The nurse then determines the woman's activity level, including rest, and any changes in the pulse and respirations that have occurred since previous visits. The nurse also identifies and evaluates other factors that would increase strain on the heart. These might include anemia, infection, anxiety, lack of support system, and household and career demands.

The following symptoms, if they are progressive, are indicative of CHF, the heart's signal of its decreased ability to meet the demands of pregnancy:

- Cough (frequent, with or without hemoptysis)
- Dyspnea (progressive, upon exertion)
- Edema (progressive, generalized, including extremities, face, eyelids)

- Heart murmurs (heard on auscultation)
- Palpitations
- Rales (auscultated in lung bases)

Progressiveness of the cycle is the critical factor, because some of these same symptoms are seen to a minor degree in a pregnancy without cardiac problems.

Nursing diagnoses that might apply to the pregnant woman with heart disease include the following:

- ***Decreased Cardiac Output:*** Easy fatigability
- ***Impaired Gas Exchange*** related to pulmonary edema secondary to cardiac decompensation
- ***Fear*** related to the effects of the maternal cardiac condition on fetal well-being

Nursing Plan and Implementation

Nursing care is directed toward maintaining a balance between cardiac reserve and cardiac workload.

Antepartum Period

Nursing actions are designed to meet the physiologic and psychosocial needs of the pregnant woman with heart disease. The priority of nursing actions varies according to the severity of the disease process and the individual needs of the woman as determined by nursing assessment.

The woman and her family should thoroughly understand her condition and its management and should recognize signs of potential complications. This will increase their understanding and decrease anxiety. When the nurse provides explanations, uses printed material, and offers frequent opportunities to ask questions and discuss concerns, the woman is better able to meet her own healthcare needs and seek assistance appropriately.

As part of health teaching, the nurse explains the purposes of the dietary and activity changes that are required. A diet is instituted that is high in iron, protein, and essential nutrients but low in sodium, with adequate calories to ensure normal weight gain. Such a diet best meets the nutrition needs of the patient with cardiac disease. Excessive weight gain is avoided because it taxes the heart. To help preserve her cardiac reserves, the woman may need to restrict her activities. In addition, 8 to 10 hours of sleep and frequent daily rest periods are essential. The nurse can encourage the woman to rest in the side-lying position to promote optimal placental perfusion. Because upper respiratory infections may tax the heart and lead to decompensation, the woman must avoid contact with sources of infection and report symptoms of infection immediately.

During the first half of pregnancy, the woman is seen approximately every 2 weeks to assess cardiac status. During the second half of pregnancy, the woman is seen weekly. These assessments are especially important between weeks 28 and 30, when the blood volume reaches maximum amounts. If symptoms of cardiac decompensation occur, prompt medical intervention is indicated to correct the cardiac problem.

Intrapartum Period

Labor and birth exert tremendous stress on the woman and her fetus. This stress could be fatal to the fetus of a woman with cardiac disease because the fetus may be receiving an inadequate oxygen and blood supply. Thus the intrapartum care of a woman with cardiac disease is aimed at reducing the amount of physical exertion and accompanying fatigue.

The nurse evaluates maternal vital signs frequently to determine the woman's response to labor. A pulse rate greater than 100 beats per minute or respirations greater than 24 per minute may indicate beginning cardiac decompensation, especially if accompanied by dyspnea, and require further evaluation. The nurse also auscultates the woman's lungs frequently for rales and carefully observes for other signs of developing decompensation.

To ensure cardiac emptying and adequate oxygenation, the nurse encourages the laboring woman to assume either a semi-Fowler's position with lateral tilt or side-lying position with her head and shoulders elevated. Oxygen by mask, diuretics to reduce fluid retention, sedatives and analgesics, prophylactic antibiotics, and digitalis may also be used as indicated by the woman's status.

The nurse remains with the woman to support her. It is essential that the nurse keep the woman and her family informed of labor progress and management plans, collaborating with them to fulfill their wishes for the birth experience as much as possible. The nurse needs to maintain an atmosphere of calm to lessen the anxiety of the woman and her family.

Continuous electronic fetal monitoring is used to provide ongoing assessment of the fetus's response to labor. To prevent overexertion and the accompanying fatigue, the nurse encourages the woman to sleep and relax between contractions and provides her with emotional support and encouragement. During pushing, the nurse encourages the woman to use shorter, more moderate open glottis pushing (see chapter 24 ∞), with complete relaxation between pushes. The nurse monitors vital signs closely during the second stage.

Postpartum Period

The postpartum period is a significant time for the woman with cardiac disease. After birth, the intra-abdominal pressure and the venous pressure are reduced, the splanchnic vessels engorge, and blood flow to the heart increases. As extravascular fluid returns to the bloodstream for excretion, cardiac output and blood volume increase. This physiologic adaptation places great strain on the heart and may lead to decompensation, especially in the first 48 hours postpartum.

So that the healthcare team can detect any possible problems, the woman may remain in the hospital longer than the low-risk woman postpartally. Her vital signs are monitored frequently, and she is assessed for signs of decompensation. She stays in the semi-Fowler's or side-lying position, with her head and shoulders elevated, and begins a gradual, progressive activity program. Appropriate diet and stool softeners facilitate bowel movement without undue strain.

The postpartum nurse gives the woman opportunities to discuss her birth experience and helps her deal with any feelings or concerns that cause her distress. The nurse also encourages

maternal-infant attachment by providing frequent opportunities for the mother to interact with her child.

Because there is no evidence that cardiac output is compromised during lactation, the only concern about breastfeeding for women with cardiovascular disease is related to medications that the mother may be taking. These must be evaluated for their ability to pass into the milk and for any effect of the drug on lactation. The nurse can assist the breastfeeding mother to a comfortable side-lying position with her head moderately elevated or to a semi-Fowler's position. To conserve the mother's energy, the nurse should position the newborn at the breast and be available to burp the baby and reposition him or her at the other breast. The nurse can also encourage family members to provide the new mother with support and assistance as needed to help her avoid becoming fatigued.

In addition to providing the normal postpartum discharge teaching, the nurse stresses that follow-up for the new mother is imperative. Moreover, the nurse should ensure that the woman and her family understand the signs of possible problems resulting from her heart disease or from other postpartum complications. For women with heart disease, postpartum complications such as hemorrhage, thromboembolism, anemia, and infection pose a real threat and may even precipitate heart failure.

The nurse plans with the woman an activity schedule that is gradual, progressive, and appropriate to her needs and home environment. The nurse provides appropriate health teaching, including information about resumption of sexual activity and contraception. Visiting nurse or homemaker assistance referrals may be necessary, depending on the woman's status.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to discuss her condition and its possible impact on her pregnancy, labor and birth, and the postpartum period.
- The woman participates in developing an appropriate healthcare regimen and follows it throughout her pregnancy.
- The woman gives birth to a healthy infant.
- The woman does not develop congestive heart failure, thromboembolism, or infection.
- The woman is able to identify signs and symptoms of possible postpartum complications.
- The woman is able to care effectively for her newborn infant.

Other Medical Conditions and Pregnancy

A woman with a preexisting medical condition should be aware of the possible impact of pregnancy on her condition, as well as the impact of her condition on the outcome of her pregnancy. Table 19-5 discusses some of the less common medical conditions vis-à-vis pregnancy.

TABLE 19-5 Less Common Medical Conditions and Pregnancy

BRIEF DESCRIPTION	MATERNAL IMPLICATIONS	FETAL/NEONATAL IMPLICATIONS
Asthma		
Asthma, an obstructive lung condition, is the most common respiratory disease found in pregnancy, complicating approximately 8% of all pregnancies (Schatz & Dombrowski, 2009). Typical symptoms include wheezing, dyspnea, and episodic coughing. A severe asthmatic attack may require hospitalization. It is managed by long-term comprehensive drug therapy to prevent airway inflammation, combined with drug treatment to manage attacks or exacerbations. Patient education focuses on triggers (such as cold air, dust, smoke, exercise, food additives), methods of prevention, and treatment options.	The severity of asthma may improve, worsen, or remain unchanged during pregnancy. The mechanisms associated with these variations remain undefined; however, poor asthma control is associated with increased maternal and neonatal complications, most likely from poor adherence to the treatment regime. Maternal complications include preeclampsia, growth restriction, and preterm birth. Asthma management during labor and delivery focuses on maintenance of adequate hydration and analgesia as well as continuing asthma medications (ACOG, 2008b).	Prematurity and low birth weights are more common among the infants of women who have asthma (Schatz & Dombrowski, 2009). The goal of therapy is to prevent maternal exacerbations because even a mild exacerbation can cause severe hypoxia-related complications in the fetus. If an exacerbation occurs, it should be managed in the same way as for a nonpregnant woman because the asthma drugs used are less of a threat to the fetus than a serious asthma attack (ACOG, 2008b).
Epilepsy		
Chronic disorder characterized by seizures; may be idiopathic or secondary to other conditions, such as head injury, metabolic and nutritional disorders such as phenylketonuria (PKU) or vitamin B_6 deficiency, encephalitis, neoplasms, or circulatory interferences. Treated with anticonvulsants.	Vast majority of pregnancies in women with seizure disorders are uneventful and have an excellent outcome. Women with more frequent seizures before pregnancy may have exacerbations during pregnancy, but this may be related to nausea and vomiting, lack of cooperation with drug regimen, or sleep deprivation. During pregnancy the woman should continue to be treated with the medication that best controls her seizures. Folic acid therapy should be started prior to conception if possible. Folic acid and vitamin D are indicated throughout pregnancy (Tomson & Battino, 2009).	Certain anticonvulsant medications are associated with increased incidence of congenital anomalies, especially cleft lip and heart defects, although the incidence has decreased in recent years. The lowest dose of a single effective medication is the goal of treatment to decrease the potential for fetal anomalies. Multiple medications and valproic acid should also be avoided for women planning pregnancy when possible (Tomson & Battino, 2009).

(continued)

TABLE 19-5 Less Common Medical Conditions and Pregnancy continued

BRIEF DESCRIPTION	MATERNAL IMPLICATIONS	FETAL/NEONATAL IMPLICATIONS
Hepatitis B		
Hepatitis B, caused by the hepatitis B virus (HBV), is a major, growing health problem. Groups at risk include those from areas with a high incidence (primarily developing countries), illegal intravenous (IV) drug users, prostitutes, homosexuals, those with multiple sex partners, or occupational exposure to blood, although many infected people have no identifiable source of infection. HBV transmission is blood borne, primarily sexually and perinatally transmitted. Because of the dramatic increase and the difficulty of vaccinating high-risk individuals before they become infected, the CDC now recommends (1) testing all pregnant women for the presence of hepatitis B surface antigen and prophylactic treatment for all infants born to women who are HBsAG-positive or whose status is unknown; (2) routine infant vaccination; (3) vaccination of children and adolescents through age 18 years who have not been vaccinated; (4) vaccination of unvaccinated adults who are at risk for hepatitis B (Libbus & Phillips, 2009).	Hepatitis B does not usually affect the course of pregnancy. However, chronic HBV carriers have a great potential for infecting others when exposure to blood and body fluids occurs. In addition, chronic carriers may develop long-term sequelae, such as chronic liver disease and liver cancer. Approximately 4000 to 5000 deaths are caused annually by liver disease associated with chronic HBV infection. It is now recommended that all pregnant women be tested for the presence of hepatitis B surface antigen (HBsAg). A woman who is negative may be given the hepatitis vaccine.	Perinatal transmission most often occurs at or near the time of childbirth. More important, the risk of becoming a chronic carrier of the HBV is inversely related to the age of the individual at the time of initial infection. Therefore, infants infected perinatally have the highest risk of becoming chronically infected if not treated. Recommendations now include routine vaccination of all neonates born to HBsAg-negative women and immunoprophylaxis to all newborns of HBsAg-positive women (Libbus & Phillips, 2009).
Hyperthyroidism (thyrotoxicosis)		
Enlarged, overactive thyroid gland; increased T_4: thyroxine-binding globulin (TBG) ratio and increased basal metabolic rate (BMR). Symptoms include muscle wasting, tachycardia, excessive sweating, and exophthalmos. Treatment by antithyroid drug propylthiouracil (PTU) while monitoring free T_4 levels. Surgery used only if drug intolerance exists.	Mild hyperthyroidism is not dangerous. Increased incidence of preeclampsia and postpartum hemorrhage if not well controlled. Serious risk related to thyroid storm characterized by high fever, tachycardia, sweating, and congestive heart failure. Now occurs rarely. When diagnosed during pregnancy, may be transient or permanent.	Neonatal thyrotoxicosis is rare. Even low doses of antithyroid drug in mother may produce a mild fetal/neonatal hypothyroidism; higher dose may produce a goiter or mental deficiencies. Fetal loss not increased in euthyroid women. If untreated, rates of abortion, intrauterine death, and stillbirth increase. Breastfeeding contraindicated for women on antithyroid medication because it is excreted in the milk (may be tried by woman on low dose if neonatal T_4 levels are monitored).
Hypothyroidism		
Characterized by inadequate thyroid secretions (decreased T_4: TBG ratio), elevated thyroid-stimulating hormone (TSH), lowered BMR, and enlarged thyroid gland (goiter). Symptoms include lack of energy, excessive weight gain, cold intolerance, dry skin, and constipation. Treated by thyroxine replacement therapy.	Long-term replacement therapy usually continues at same dosage during pregnancy as before. Weekly nonstress test (NST) after 35 weeks' gestation.	If mother untreated, fetal loss 50%; high risk of congenital goiter or true cretinism. Therefore, newborns are screened for T_4 level. Mild TSH elevations present little risk because TSH does not cross the placenta.
Maternal Phenylketonuria (PKU) (hyperphenylalaninemia)		
Inherited recessive single gene anomaly causing a deficiency of the liver enzyme needed to convert the amino acid phenylalanine to tyrosine, resulting in high serum levels of phenylalanine. Brain damage and intellectual disability (mental retardation) occur if not treated early.	Low phenylalanine diet is mandatory before conception and during pregnancy. The woman should be counseled that her children will either inherit the disease or be carriers, depending on the zygosity of the father for the disease. Treatment at a PKU center is recommended.	Risk to fetus if maternal treatment not begun preconception. In untreated women increased incidence of fetal mental retardation, microcephaly, congenital heart defects, and growth retardation. Fetal phenylalanine levels are approximately 50% higher than maternal levels.
Multiple Sclerosis		
Neurologic disorder characterized by destruction of the myelin sheath of nerve fibers. The condition occurs primarily in young adults, more commonly in females, and is marked by periods of remission; progresses to marked physical disability in 10 to 20 years.	Exacerbation rate is reduced during the second and third trimester but increased during the 3 months following birth. Exclusive breastfeeding has recently been reported to reduce postpartum exacerbation (Franklin & Tremlett, 2009). Rest is important; help with child care should be planned. Uterine contraction strength is not diminished, but because sensation is frequently lessened, labor may be almost painless.	Some evidence for slightly lower birth weight infants (3%–4%). Increased evidence of a genetic predisposition. Therefore, reproductive counseling is recommended.
Rheumatoid Arthritis		
Chronic inflammatory disease believed to be caused by a genetically influenced antigen-antibody reaction. Symptoms include fatigue, low-grade fever, pain and swelling of joints, morning stiffness, pain on movement. Treated with salicylates, physical therapy, and rest. Corticosteroids used cautiously if not responsive to above.	Usually there is remission of rheumatoid arthritis symptoms during pregnancy, often with a relapse postpartum. Anemia may be present due to blood loss from salicylate therapy. Mother needs extra rest, particularly to relieve weight-bearing joints, but needs to continue range-of-motion exercises. If in remission, may stop medication during pregnancy.	Woman taking prednisone during pregnancy give birth slightly earlier (38 weeks vs. 39 weeks) and have corresponding lower birth weights (de Man et al., 2009).

TABLE 19-5 Less Common Medical Conditions and Pregnancy continued

BRIEF DESCRIPTION	MATERNAL IMPLICATIONS	FETAL/NEONATAL IMPLICATIONS
Systemic Lupus Erythematosus (SLE)		
Chronic autoimmune collagen disease, characterized by exacerbations and remissions; symptoms range from characteristic rash to inflammation and pain in joints, fever, nephritis, depression, cranial nerve disorders, and peripheral neuropathies.	SLE during pregnancy needs to be actively managed with careful surveillance of blood pressure, proteinuria, and placental blood flow. SLE medications may be necessary to control exacerbations and lupus flare. Preeclampsia, prematurity, and fetal growth restriction are common complications. Women with severe disease may be counseled to avoid pregnancy (Ruiz-Irastorza & Khamashta, 2009).	Increased incidence of spontaneous abortion, stillbirth, prematurity, intrauterine growth restriction (IUGR), and neonatal lupus. Neonatal lupus is characterized by a photosensitive skin rash, thrombocytopenia, neutropenia, or anemia, all of which resolve by about 6 months of age. Complete congenital heart block is the most serious complication of SLE, typically diagnosed in utero. When diagnosed, the mother is given corticosteroids that cross the placenta and decrease fetal heart inflammation. The prognosis for these infants varies based on the extent of the cardiac damage. An increased rate of learning disabilities is reported in these children (Tincani et al., 2006).
Tuberculosis (TB)		
Tuberculosis (TB) is a major health problem. Two billion people (approximately one third of the population of the world) carry the TB bacteria. Worldwide more women die from TB than from any other infection (Nhan-Chang & Jones, 2010). Infection is caused by *Mycobacterium tuberculosis;* inflammatory process causes destruction of lung tissue, increased sputum, and coughing. Associated primarily with poverty and malnutrition, 80% of new cases are found in developing countries primarily in Asia and Africa. In the United States the majority of cases occur in foreign-born people (Nhan-Chang & Jones, 2010).Treated with isoniazid and either ethambutol or rifampin, or both.	The incidence of pregnancy complications may be higher in women with TB. TB skin test screening is recommended for women in high-risk groups (healthcare workers; foreign-born women from countries with a high TB risk; women who have had known contact with infectious person, those who are HIV infected, alcoholics, or illicit drug users; women living or working in homeless shelters; prisoners and detainees [Cunningham et al., 2010]). If TB is inactive due to prior treatment, isoniazid therapy is delayed until the postpartum period unless the woman is HIV positive, has close contact with a person with active TB, or has had a skin test convert to positive within the last 2 years. For those women, isoniazid is started during pregnancy (Nhan-Chang & Jones, 2010). Women with active TB are treated with isoniazid, rifampin, and ethambutol during pregnancy (Cunningham et al., 2010). Extra rest and limited contact with others is required until disease becomes inactive.	If maternal TB is inactive, mother may breastfeed and care for her infant. If TB is active, newborn should not have direct contact with mother until she is noninfectious. Isoniazid crosses the placenta, but most studies show no teratogenic effects. Rifampin crosses the placenta. Possibility of harmful effects is still being studied.

FOCUS YOUR STUDY

- Almost any health problem that a person can have when not pregnant can coexist with pregnancy. Some problems, such as anemias, may be exacerbated by pregnancy. Others, such as collagen disease, may go into temporary remission with pregnancy. Regardless of the health problem, careful health care is needed throughout pregnancy to improve the outcome for mother and fetus.
- The diagnosis of high-risk pregnancy can shock an expectant couple. Providing emotional support, teaching about the condition and prognosis, and educating for self-care are important nursing measures that help the patient cope.
- Substance abuse (either drugs or alcohol) not only is detrimental to the mother's health but also may have profound lasting effects on the fetus.
- The key point in the care of the pregnant woman with diabetes is scrupulous maternal plasma glucose control. This is best achieved by home blood glucose monitoring, multiple daily insulin injections, regular exercise, and a

careful diet. To reduce incidence of congenital anomalies and other problems in the newborn, the woman should be euglycemic (have a normal blood glucose) throughout the pregnancy. Women with diabetes, even more than most other patients, need to be educated about their conditions and involved with their own care.

- Anemia indicates inadequate levels of hemoglobin (Hb) in the blood. Anemia is defined as hemoglobin less than 12 g/dl in nonpregnant women and less than 11 g/dl in pregnant and postpartum women. Iron deficiency anemia is the most common form of anemia. Other anemias include folic acid deficiency, sickle cell anemia, and thalassemia.
- HIV infection, which is transmitted via blood and body fluids, may also be transmitted transplacentally to the fetus. Currently, there is no definitive therapy for HIV/AIDS. Nurses should employ blood and body fluid precautions (standard precautions) in caring for all women to avoid potential spread of infection.
- Cardiac disease during pregnancy requires careful assessment, limitation of activity, and knowing and reporting signs of impending cardiac decompensation by both patient and nurse.
- Worldwide, more women die from TB than from any other infection. Most cases are concentrated in developing countries.

CRITICAL THINKING IN ACTION

Jane Adams, a 23-year-old, G3 P2, at 37 weeks' gestation, presents to you in the birthing unit complaining of "vaginal pressure" but no contractions. You assess her and find that her history includes being HIV positive for 2 years, second-trimester cocaine and marijuana use, missed appointments, anemia (HCT 28%), and a positive syphilis serology. Jane tells you that she has other children and that they are being cared for by her mother, who has legal custody of them. You admit Jane and place her on the fetal monitor for evaluation of fetal well-being and contraction patterns. The monitor shows you that the fetal heart rate baseline is 120 to 130 with no decelerations; contractions are mild and irregular, lasting 20 to 30 seconds. You obtain vital signs of BP 130/88, temperature 97.0°F, P 88, R 14. A vaginal exam determines that Jane is 7 cm dilated at +1 station with intact membranes. She asks you if being HIV positive will affect her labor.

1. Discuss the prophylactic regimen for the prevention of HIV transmission to the fetus during labor.
2. Discuss the transmission of HIV to the fetus during pregnancy and birth.
3. Identify the emotional impact of HIV infection or other STIs on the woman.
4. On postpartum day 2 you inform Jane that her infant is HIV antibody positive. How would you clarify the results?

CHAPTER 20

Pregnancy at Risk: Gestational Onset

I had taken more than a year to conceive and was so excited when my home pregnancy test turned positive. My husband was with me when I called my family. I could hardly breathe with the excitement of the moment. Five weeks later, I was in an ambulance speeding to a medical center equipped to save my life. My ectopic pregnancy had not yet been diagnosed when it ruptured at home. I underwent surgery to remove my tube and the pregnancy that was contained within. Afterward, I was dazed and debilitated. For weeks I focused on my recovery rather than my loss. How ironic that I was fully confronted with the reality of my loss on what would have been my due date when in the mail I received a package of samples congratulating me on the birth of my new baby.

—Kristin, R.N.

LEARNING OUTCOMES

1. Delineate the bleeding problems associated with pregnancy.
2. Contrast the etiology, medical therapy, and nursing interventions for the various bleeding problems associated with pregnancy.
3. Discuss the medical therapy and nursing care of a woman with hyperemesis gravidarum.
4. Describe the development and course of hypertensive disorders associated with pregnancy.
5. Explain the cause and prevention of hemolytic disease of the newborn secondary to Rh incompatibility.
6. Compare Rh incompatibility to ABO incompatibility with regard to occurrence, treatment, and implications for the fetus/newborn.
7. Summarize the effects of surgical procedures on pregnancy, and explain ways in which pregnancy may complicate diagnosis of conditions that require surgery.
8. Discuss the implications of trauma due to accidents or battering for the pregnant woman and her fetus.
9. Describe the effects of infections on the woman and her unborn child.

KEY TERMS

Abortion *451*
Eclampsia *460*
Ectopic pregnancy *454*
Erythroblastosis fetalis *478*
Gestational trophoblastic disease (GTD) *456*
HELLP syndrome *463*
Hydatidiform mole *456*
Hydrops fetalis *478*
Hyperemesis gravidarum *459*
Miscarriage *451*
Preeclampsia *460*
Rh immune globulin *476*

Pregnancy is usually a normal, uncomplicated experience. In some cases, however, problems arise during the pregnancy that place the woman and her unborn child at risk. Regular prenatal care serves to detect these potential complications quickly so that effective care can be provided. This chapter focuses on problems that primarily occur during pregnancy, those with a gestational onset.

Care of the Woman at Risk Because of Bleeding During Pregnancy

During the first and second trimesters of pregnancy the major cause of bleeding is abortion. Broadly, this is the expulsion of the fetus before viability. This definition is imprecise, however, because the definition of viability changes. **Abortion** is often defined as "pregnancy termination prior to 20 weeks' gestation or with a fetus weighing less than 500 g" (Cunningham et al., 2010, p. 215). Abortions are either spontaneous, occurring naturally, or induced, occurring as a result of medical or surgical interruption. **Miscarriage** is a lay term applied to spontaneous abortion.

Other complications that can cause bleeding in the first half of pregnancy are ectopic pregnancy and gestational trophoblastic disease. In the second half of pregnancy, particularly in the third trimester, the two major causes of bleeding are placenta previa and abruptio placentae.

General Principles of Nursing Intervention

Vaginal bleeding is relatively common during pregnancy. Bleeding can arise following sexual intercourse or exercise as a result of trauma to the highly vascular cervix, from cervical or vaginal lesions, implantation of the pregnancy, or threatened or impending miscarriage. However, the woman is advised to report any spotting or bleeding that occurs during pregnancy so that it can be evaluated.

It is often the nurse's responsibility to make the initial assessment of bleeding. In general, the following nursing measures should be implemented for pregnant women being evaluated for bleeding during pregnancy:

- Monitor blood pressure and pulse frequently. The frequency is determined by the extent of the bleeding and the stability of the woman's condition.
- Observe the woman for indications of shock, such as pallor, clammy skin, perspiration, dyspnea, or restlessness.
- Count and weigh pads to assess amount of bleeding over a given time period; save any tissue or clots expelled.
- If pregnancy is of 12 weeks' gestation or beyond, assess fetal heart tones with a Doppler.
- Prepare for intravenous (IV) therapy. There may be standing orders to start IV therapy on bleeding patients.
- Prepare equipment for examination.
- Have oxygen therapy available.
- Collect and organize all data, including antepartum history, onset of bleeding episode, any associated pain, laboratory studies (hemoglobin, hematocrit, Rh status, and hormonal assays).
- Obtain an order to type and cross-match for blood if there is evidence of significant blood loss.
- Assess coping mechanisms and support system of the woman in crisis. Give emotional support to enhance her coping abilities by continuous, sustained presence, by clear explanation of procedures, and by communicating her status to her family. Most important, prepare the woman for possible fetal loss. Assess her expressions of anger, denial, guilt, depression, or self-blame.
- Assess the family's response to the situation.

Spontaneous Abortion (Miscarriage)

Many pregnancies end in the first trimester as a result of spontaneous abortion. Pregnancy loss during the early weeks of gestation, when the pregnancy may not yet be recognized, may be seen as a heavy menstrual period. However, when only clinically recognized pregnancies are considered, the incidence is at least 15% (Porter, Branch, & Scott, 2008). In healthy women, advanced maternal age is the most significant risk factor for spontaneous miscarriage. Women younger than age 20 have a 12% risk while the risk is greater than 50% for women over age 45 (Porter et al., 2008).

Over half of first trimester spontaneous abortions are related to chromosomal abnormalities (Calleja-Agius, 2008; Cunningham et al., 2010). Other causes include teratogenic drugs, faulty implantation due to abnormalities of the female reproductive tract, a weakened cervix, placental abnormalities, chronic maternal diseases, endocrine imbalances, and maternal infections. Women who use hot tubs or jacuzzis are twice as likely to have miscarriages as nonusers (Centers for Disease Control and Prevention [CDC], 2005). Fever may also increase the risk of miscarriage although research results about this hypothesis are contradictory. The major malformations most commonly associated with febrile illnesses in women are neural tube defects (American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2007a).

The pathophysiology of spontaneous abortion differs according to the cause. Chromosomal defects are generally seen as spontaneous abortions during weeks 4 to 8. Insufficient or excessive hormonal levels usually will result in loss by 10 weeks' gestation. Infectious and environmental factors may also be seen in first trimester pregnancy loss. In late spontaneous abortion, the cause is usually a maternal factor, for example, cervical insufficiency or maternal disease, and fetal death may not precede the onset of abortion (Valley, Jackson-Williams, & Fly, 2006). See chapter 26 ∞ for discussion of cervical insufficiency.

Spontaneous abortion can be extremely distressing to the couple desiring a child. Chances for carrying the next pregnancy to term after one spontaneous abortion are as good as they are for the general population. Thereafter, however, chances of successful pregnancy decrease with each succeeding abortion. Following two to three consecutive losses, a

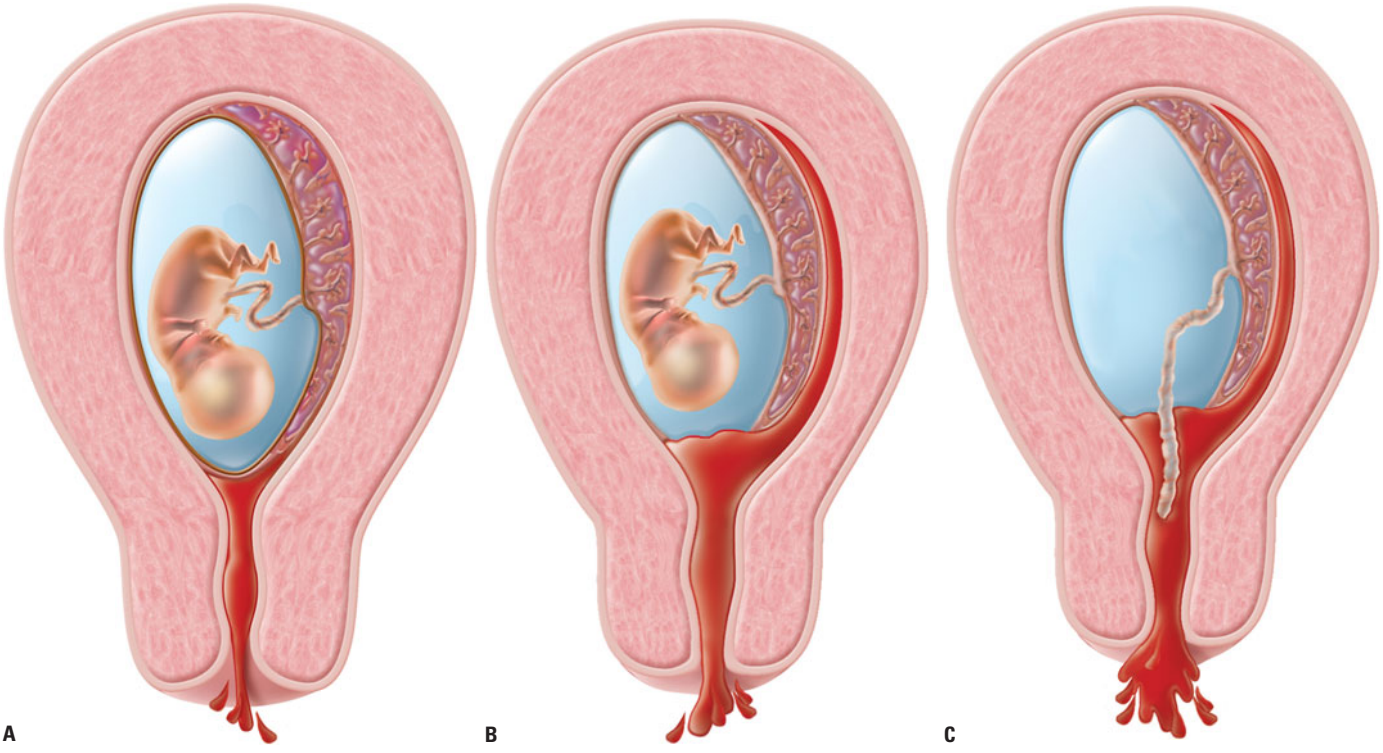

Figure 20-1 ■ Types of spontaneous abortion. A. Threatened. The cervix is not dilated, and the placenta is still attached to the uterine wall, but some bleeding occurs. B. Imminent. The placenta has separated from the uterine wall, the cervix has dilated, and the amount of bleeding has increased. C. Incomplete. The embryo/fetus has passed out of the uterus; however, the placenta remains.

woman and her partner should be evaluated and are candidates for genetic counseling.

Classification

Spontaneous abortions are subdivided into the following categories so that they can be differentiated clinically:

- ***Threatened abortion*** (Figure 20-1A ■). Unexplained bleeding, cramping, or backache indicate that the fetus may be in jeopardy. Bleeding may persist for days. The cervix is closed. It may be followed by partial or complete expulsion of pregnancy, or it may resolve without threatening the fetus. Evaluation for hydatidiform mole or ectopic pregnancy (discussed shortly) is advisable.
- ***Imminent abortion*** (Figure 20-1B ■). Bleeding and cramping increase. The internal cervical os dilates. Membranes may rupture. The term *inevitable abortion* also applies.
- ***Incomplete abortion*** (Figure 20-1C ■). Part of the products of conception are retained, most often the placenta. The internal cervical os is dilated.
- ***Complete abortion.*** All the products of conception are expelled. The uterus is contracted and the cervical os may be closed.
- ***Missed abortion.*** The fetus dies in utero but is not expelled. Uterine growth ceases, breast changes regress, and the woman may report a brownish vaginal discharge. The cervix is closed. Diagnosis is made based on history, pelvic examination, and a drop in hCG levels or a negative pregnancy test and may be confirmed by ultrasound if necessary. If the fetus is retained beyond 4 weeks, fetal autolysis (breakdown of cells or tissue) results in the release of thromboplastin, and disseminated intravascular coagulation (DIC) may develop.
- ***Recurrent pregnancy loss, formerly called habitual abortion.*** Abortion occurs consecutively in three or more pregnancies.
- ***Septic abortion.*** There is presence of infection; may occur with prolonged, unrecognized rupture of the membranes, pregnancy with intrauterine device (IUD) in utero, or attempts by inadequately prepared individuals to terminate a pregnancy. Septic abortion is less common since the availability of legal abortion.

Clinical Therapy

One of the more reliable indicators of potential spontaneous abortion is the presence of pelvic cramping and backache. These symptoms are usually absent in bleeding caused by polyps, ruptured cervical blood vessels, or cervical erosion.

Vaginal bleeding occurs in 20% to 25% of first trimester pregnancies. Of these, approximately half will result in subsequent miscarriage (Cunningham et al., 2010). Several days of spotting or light bleeding associated with pain may also increase the chance of miscarriage. Painless spotting or light bleeding for a day or two did not increase the risk of miscarriage above the risk for women with no bleeding.

Evaluations to help determine the cause of vaginal bleeding include speculum examination to determine the presence of cervical polyps or cervical erosion, ultrasound scanning for the presence of cardiac activity and a gestational sac, or crown-rump length that is small for gestational age. Presence of a fetal heartbeat on ultrasound provides a high likelihood of the pregnancy

continuing. Laboratory determination of hCG level can confirm a pregnancy, but because the hCG level falls slowly after fetal death, it cannot confirm a live embryo/fetus. Hemoglobin and hematocrit levels are obtained to assess blood loss. Blood is typed and cross-matched for possible replacement needs.

Although there is no evidence that supports the value of restricting physical activity, the therapy prescribed for the pregnant woman with bleeding often includes bed rest, abstinence from coitus, and, perhaps, sedation. If bleeding persists and abortion is imminent or incomplete, the woman may be hospitalized, IV therapy or blood transfusions may be started to replace fluid, and dilation and curettage (D&C) or suction evacuation is performed to remove the remainder of the products of conception. If the woman is Rh negative and not sensitized, and there has been prior ultrasound documentation of fetal cardiac activity, Rh immune globulin (RhoGAM) is given within 72 hours (Moise, 2008a). (See discussion of Rh sensitization later in this chapter.)

In missed abortions, the products of conception eventually are expelled spontaneously. If this does not occur within 1 month to 6 weeks after fetal death, hospitalization is necessary. Suction evacuation, or D&C, is done if the pregnancy is in the first trimester. Beyond 12 weeks' gestation, induction of labor by IV oxytocin and intra-amniotic prostaglandin $F_{2\alpha}$, intravaginal prostaglandin E_2, or intravaginal misoprostol (a synthetic prostaglandin E_1 analog) may be used to expel the dead fetus.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse assesses the amount and appearance of any vaginal bleeding and monitors the woman's vital signs and degree of discomfort. The woman's blood type and antibody status should be identified to determine the need for Rh immune globulin (see page 482). If the pregnancy is 10 to 12 weeks or more, fetal heart rate should be assessed by Doppler. The nurse also assesses the responses of the woman and her family to this crisis and evaluates their coping mechanisms and ability to comfort each other.

Nursing diagnoses that may apply include the following:

- ***Fear*** related to the risk of pregnancy loss
- ***Acute Pain*** related to abdominal cramping secondary to threatened abortion
- ***Grieving*** related to expected loss of unborn child

Nursing Plan and Implementation

Community-Based Nursing Care

If a woman in her first trimester of pregnancy begins cramping or spotting, she may be evaluated on an outpatient basis if the bleeding is not heavy. Providing emotional support is an important task for nurses caring for women who have spontaneously aborted. Couples who approached the pregnancy with feelings of joy and a sense of expectancy now feel grief, sadness, and possibly anger.

Because many women, even with planned pregnancies, feel some ambivalence initially, guilt is a common emotion. The woman may harbor negative feelings about herself, ranging from lowered self-esteem resulting from a belief that she is lacking or abnormal in some way, to a notion that the abortion may be a punishment for some wrongdoing.

DEVELOPING CULTURAL COMPETENCE

Culture and Response to Fetal Loss

Remember that individual responses to fetal loss following miscarriage may vary greatly and may be influenced by ethnic or cultural norms.

- Miscarriage may be viewed in many ways. For example, it may be seen as a punishment from God, as the result of the evil eye or of a hex or curse by an enemy, or as a natural part of life.
- When grieving over a pregnancy loss, women from some cultures and ethnic groups may show their emotions freely, crying and wailing, whereas other women may hide their feelings behind a mask of stoicism.
- In some cultures the woman's partner is her primary source of support and comfort. In others, the woman turns to her mother or close female relatives for comfort.
- Avoid stereotyping women according to culture. Individual responses are influenced by many factors, including the degree of assimilation into the dominant culture.

The nurse can offer invaluable psychologic support to the woman and her family by encouraging them to verbalize their feelings. Reflective listening gives the woman an opportunity to express and explore her feelings. The nurse can take cues from questions the woman asks, discuss the grief cycle, and provide resources. Referrals can help the woman and her family find ways to deal with their loss. If the woman has older children, she may need guidance in how to help them understand and cope with what has occurred. Commemorating the pregnancy and baby is helpful in validating the significance of the loss. The grieving period following a spontaneous abortion usually lasts 6 to 24 months. Many couples can be helped during this period by an organization or support group established for parents who have lost a fetus or newborn. Nurses may benefit from education to help them understand the impact of early pregnancy loss through programs such as those available through Bereavement Services of LaCrosse, WI. See chapter 37 ∞ for further discussion.

> "I was stunned by the depth of loss I felt following my miscarriage when I was 2 1/2 months along. It didn't seem possible that I had already become so emotionally attached to the baby I carried. Afterward I was surprised by the number of women I knew who shared stories of their own miscarriages and confirmed that the emotions I was feeling were normal, if painful."

The physical pain of the cramps and the amount of bleeding may be more severe than a couple anticipates, even when they are prepared for the possibility of an abortion. Nurses need to be aware that couples feel unprepared for their first experience of spontaneous abortion. Nurses should offer support in dealing with

the physical experience by explaining why the discomfort is occurring and by offering analgesics for pain relief.

Hospital-Based Nursing Care

A suction D&C is performed if the woman experiences an incomplete or missed abortion. This can be performed on an outpatient basis, and, barring any complications, the woman can return home a few hours after the procedure with instructions for self-care. An Rh-negative woman with a negative antibody screen should be given Rh immune globulin before discharge.

Throughout the procedure the nurse monitors the woman's physical status and provides emotional support. The nurse also answers any questions the woman or her partner may have and provides referrals to community agencies as needed.

Health Promotion Education

If the woman had a D&C, someone should remain with her for the first 12 to 24 hours. The woman is instructed to report all episodes of heavy bleeding, fever, chills, foul-smelling vaginal discharge, or abdominal tenderness to her healthcare provider. The woman who experiences a pregnancy loss requires information about possible causes of the loss and the chances of recurrence with a future pregnancy. She may also require information about the grief process so she is prepared for it when she goes home. In addition, she should receive information about available resources, including support groups to help her cope with her feelings related to the loss of the pregnancy. The woman's partner or a family member should be included in the educational process when possible to assist him or her in personal grief work as well as to provide tools to help support the woman through the loss.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to explain spontaneous abortion, the treatment measures employed in her care, and long-term implications for future pregnancies.
- The woman suffers no complications.
- The woman and her partner are able to begin verbalizing their grief and to recognize that the grieving process usually lasts several months.

Ectopic Pregnancy

Ectopic pregnancy is an implantation of a fertilized ovum in a site other than the endometrial lining of the uterus. It may result from a number of different causes. Risk factors for ectopic pregnancy include tubal damage caused by pelvic inflammatory disease; previous pelvic or tubal surgery; endometriosis; previous ectopic pregnancy; presence of an IUD; high levels of progesterone, which can alter the motility of the egg in the fallopian tube; congenital anomalies of the tube; use of ovulation-inducing drugs; primary infertility; smoking; and advanced maternal age.

Ectopic pregnancy occurs in 1.5% to 2.0% of pregnancies. In recent years, the mortality rate has declined to 0.5 deaths per 1000 in the United States. This decrease can be credited to improved recognition of early signs and symptoms and better diagnostic methods, which allow detection before tubal rupture. Nevertheless, ectopic pregnancy accounts for 6% of all maternal deaths in the United States. The recurrence risk of ectopic pregnancy in a woman with one previous ectopic pregnancy is 10% and in women with two or more, the risk is at least 25% (Barnhart, 2009).

The actual pathogenesis of ectopic pregnancy occurs when the fertilized ovum is prevented or slowed in its progress down the tube. The fertilized ovum implants in either the fallopian tube or the ovary, peritoneal cavity, cervix, or uterine cornua (Figure 20-2 ■). The most common location for implantation of an ectopic pregnancy is the ampulla of the tube. The occurrence of ectopic pregnancy in women who have used assisted reproductive technology is 4%. A heterotopic pregnancy (one conceptus is ectopic and one is intrauterine) is extremely rare

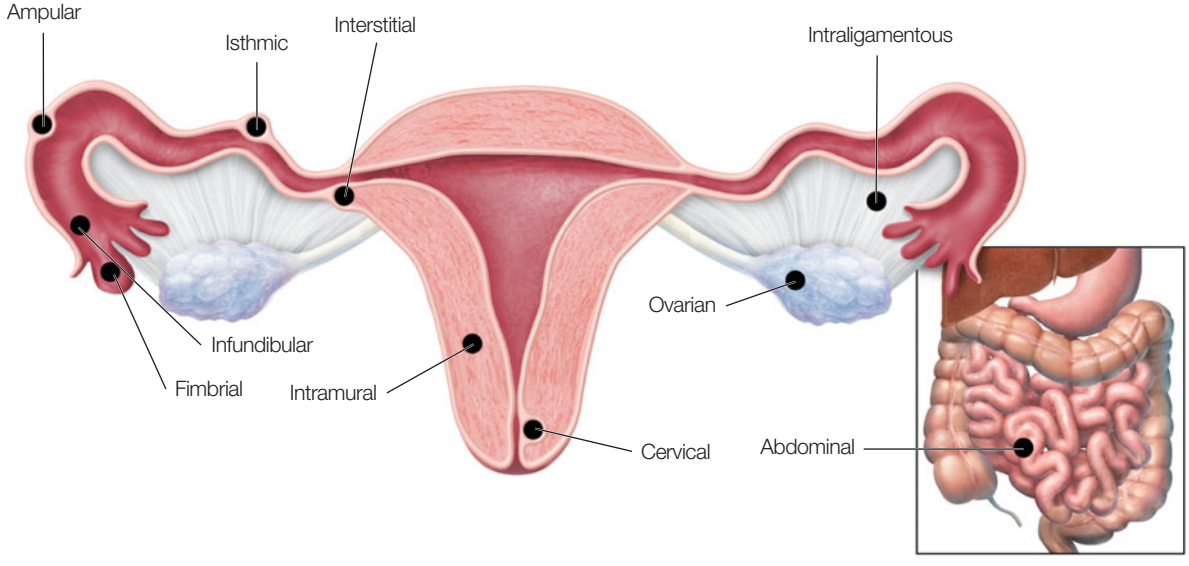

Figure 20-2 ■ Various implantation sites in ectopic pregnancy. The most common site is within the fallopian tube, hence the name "tubal pregnancy."

in spontaneously occurring pregnancies but may be as high as 1% in assisted conception (Barnhart, 2009).

Initially, the normal symptoms of pregnancy may be present, specifically, amenorrhea, breast tenderness, and nausea. The normal clinical signs of early pregnancy such as the bluish discoloration of the cervix (Chadwick's sign) and the softening of the isthmus (Hegar's sign) may be noted on physical exam. The hormone hCG is present in the blood and urine. With an ectopic implantation, the trophoblastic cells grow into the adjacent tissue, often the tubal wall, and arterial vessels. This results in internal hemorrhage. The faulty implantation of the placenta causes fluctuation of hormone levels. Hormones first stimulate the endometrial lining of the uterus to grow, but fluctuation in levels cannot support the endometrium, and vaginal bleeding ensues. The implanted ovum quickly begins to rupture the fallopian tube if it is implanted there. The woman may experience one-sided lower abdominal pain or diffuse lower abdominal pain and vasomotor disturbances such as fainting or dizziness. In about 50% of cases, referred right shoulder pain occurs from blood irritating the subdiaphragmatic phrenic nerve.

In many instances, the symptoms are not obvious. One fourth of ectopic pregnancies may involve uterine enlargement. Physical examination usually reveals adnexal tenderness; an adnexal mass is palpable in approximately one half of the cases.

If internal hemorrhage is profuse, the woman rapidly develops signs of hypovolemic shock. More commonly, the bleeding is slow (chronic), and the abdomen gradually becomes rigid and very tender. If bleeding into the pelvic cavity has been extensive, vaginal examination causes extreme pain, and a mass of blood may be palpated in the cul-de-sac of Douglas.

Laboratory tests may reveal low hemoglobin and hematocrit levels and rising leukocyte levels. In a normal pregnancy β-hCG titers double every 48 hours from 3 to 6 weeks' gestation. Ectopic pregnancies are associated with β-hCG titers that increase more slowly.

Clinical Therapy

It is important to differentiate an ectopic pregnancy from other disorders with similar clinical presenting pictures. Consideration must be given to possible spontaneous abortion, ruptured corpus luteum cyst, appendicitis, salpingitis, torsion of the ovary, ovarian cysts, and urinary tract infection.

The following measures are used to establish the diagnosis of ectopic pregnancy and assess the woman's status:

- A careful assessment of menstrual history, particularly the last menstrual period (LMP).
- Careful pelvic exam to identify any abnormal pelvic masses and tenderness.
- Laboratory testing as described previously.
- Ultrasonography. In a normal pregnancy, transvaginal ultrasound should detect an intrauterine pregnancy with almost 100% accuracy at greater than 5.5 weeks gestation and an intrauterine gestational sac when the β-hCG is greater than 1500 milli–International Unit/ml. If there is failure to determine the location of a pregnancy on the initial ultrasound, repeat ultrasound examination 2 to 7 days later may provide a diagnosis (Barnhart, 2009). Confirming an intrauterine pregnancy nearly eliminates the diagnosis of ectopic pregnancy.
- Serial measurements of serum hCG values should increase a minimum of 53% in 2 days. Seventy-one percent of women with an ectopic pregnancy have serial serum hCG values that increase more slowly than expected with a viable intrauterine pregnancy (Barnhart, 2009).
- Laparoscopy. If the presence or absence of an ectopic pregnancy cannot be confirmed by other measures, laparoscopic intervention may be necessary for both diagnosis and treatment.

Once an ectopic pregnancy is confirmed, therapy options are reviewed with the woman. Medical management using methotrexate is indicated for the woman who desires future pregnancy if her ectopic pregnancy is unruptured and of 3.5 cm size or less and if her condition is stable. In addition, there must be no fetal cardiac motion and no evidence of maternal thrombocytopenia, leukopenia, kidney disease, or liver disease.

Methotrexate is a folic acid antagonist that interferes with the proliferation of trophoblastic cells. The medication is administered intramuscularly using either a single-dose, two-dose, or multiple-dose regimen. As an outpatient, the woman is monitored for increasing abdominal pain. β-hCG titers are monitored regularly. β-hCG titers increase for 1 to 4 days and then decrease. If hCG levels do not decrease by at least 15% from day 4 to day 7 after the initial injection but the patient is clinically stable, an additional dose of methotrexate on day 7 is generally recommended (Thurman, Cornelius, Korte, et al., 2010). If the patient is not clinically stable, surgical intervention may be required. The single-dose regimen is useful in patients with a low initial hCG level and requires fewer patient visits, but is associated with higher treatment failures. The multidose regimen, which includes methotrexate and leucovorin administered on alternate days, is preferred for women with presenting hCG levels greater than 5000 miU/ml. The two-dose regimen was designed to address the failure rate associated with the single dose approach but has not yet been well studied (Barnhart, 2009).

If surgery is indicated and the woman desires future pregnancies, a laparoscopic linear salpingostomy will be performed to gently evacuate the ectopic pregnancy and preserve the tube. If the tube is ruptured or if future childbearing is not an issue, laparoscopic salpingectomy (removal of the tube) is performed. If the woman is in shock and unstable, an abdominal incision will be made. During surgery, the most important risk to be considered is potential hemorrhage. Bleeding must be controlled, and replacement therapy should be on hand. The Rh-negative nonsensitized woman is given Rh immune globulin to prevent sensitization.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

When the woman with a suspected ectopic pregnancy is admitted to the hospital, the nurse assesses the appearance and amount of vaginal bleeding. The nurse monitors vital signs, particularly blood pressure and pulse, for evidence of developing shock.

It is also the nurse's responsibility to assess the woman's emotional status and coping abilities and to evaluate the couple's informational needs. If surgery is necessary, the nurse performs the ongoing assessments appropriate for any patient postoperatively.

Nursing diagnoses that may apply for a woman with an ectopic pregnancy include the following:

- ***Grieving*** related to the loss of the pregnancy
- ***Acute Pain*** related to abdominal bleeding secondary to tubal rupture
- ***Deficient Fluid Volume*** related to hypovolemia secondary to maternal blood loss
- ***Readiness for Enhanced Knowledge (Treatment of Ectopic Pregnancy)*** related to an expressed desire to gain better understanding of the condition and its long-term implications

Nursing Plan and Implementation

Community-Based Nursing Care

Women with ectopic pregnancy are often seen initially in a clinic or office setting. Nurses need to be alert to the possibility of ectopic pregnancy if a woman presents with complaints of abdominal pain and lack of menses for 1 to 2 months. Once an initial evaluation is complete, if no ultrasound is available, the woman should be referred to another facility where ultrasound is available. The nurse plays an important role in monitoring the woman's condition and in providing her with information.

A woman with a confirmed ectopic pregnancy who meets the criteria for methotrexate administration is followed as an outpatient. The nurse should advise the woman that some abdominal pain is common following the injection but it is generally mild and lasts only 24 to 48 hours. More severe pain might indicate treatment failure and should be evaluated. The woman should also report heavy vaginal bleeding, dizziness, or tachycardia. In addition, the nurse should stress the need to return for follow-up β-hCG testing.

For all women treated for ectopic pregnancy, a follow-up phone call by the nurse may be especially welcome. It gives the woman the opportunity to ask any questions she may have. In addition, the nurse can use the opportunity to assist the woman in dealing with her grief.

Hospital-Based Nursing Care

Once a diagnosis of ectopic pregnancy is made and surgery is scheduled, the nurse starts an IV as ordered and begins preoperative teaching. The nurse should report signs of developing shock to the physician immediately and initiate interventions. If the woman is experiencing severe abdominal pain, the nurse can administer appropriate analgesics and evaluate their effectiveness.

Health Promotion Education

Teaching is an important part of nursing care. The woman may want her condition and various procedures explained. She may need instruction about measures to prevent infection, symptoms to report (pain, bleeding, fever, chills), and her follow-up visit. The woman needs to understand that she is at increased risk of ectopic pregnancy with a subsequent pregnancy. Thus it is important for her to seek early pregnancy confirmation and access to prenatal care.

The woman and her family will need emotional support during this difficult time. Their feelings and responses to this crisis will probably be similar to those that occur in cases of spontaneous abortion. As a result, similar nursing actions are required.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to explain ectopic pregnancy, treatment alternatives, and implications for future childbearing.
- The woman and her caregivers detect possible complications early and manage them appropriately.
- The woman and her partner are able to begin verbalizing their loss and recognize that the grieving process usually lasts several months.

Gestational Trophoblastic Disease

As discussed in chapter 11 ∞, the trophoblast is the outermost layer of embryonic cells and gives rise to the chorion. **Gestational trophoblastic disease (GTD)** is the pathologic proliferation of trophoblastic cells, and includes partial or complete hydatidiform mole, invasive mole (chorioadenoma destruens), and choriocarcinoma.

Hydatidiform mole (molar pregnancy) is a condition in which a proliferation of trophoblastic cells results in the formation of a placenta characterized by *hydropic* (fluid-filled) grapelike clusters. The significance of this disease for the woman who has it is the loss of the pregnancy and the possibility, though remote, of developing choriocarcinoma, a form of cancer, from the trophoblastic tissue. Molar pregnancies are classified into two types, complete and partial, both of which meet the preceding criteria. Little is known about the cause of either type, but some of the pathophysiology has been clarified. The *complete mole* develops from an anuclear ovum that contains no maternal genetic material, an "empty" egg. In most cases, a haploid sperm, 23X, fertilizes this anuclear egg and duplicates before the first cell division (diploidy). The conceptus then contains in its cells a 46XX chromosomal set of totally paternal origin (Berkowitz & Goldstein, 2009). A 46XY chromosomal set is far less common and occurs when an empty egg is fertilized by two sperm. The hydropic vesicles that form from the chorionic villi are avascular in the complete mole. No embryonic or fetal tissue or membranes are found. Choriocarcinoma seems to be associated primarily with the complete mole (ACOG, 2008c).

In contrast to the complete mole, the *partial mole* usually has a triploid karyotype, that is, 69 chromosomes. Most often, a normal ovum with 23 chromosomes is fertilized by two sperm (dispermy) or by a sperm that has failed to undergo the first meiosis and therefore contains 46 chromosomes (Berkowitz & Goldstein, 2009). In partial molar pregnancy, the villi are often vascularized and may be hydropic only in sections of the placenta rather than universally as with a complete mole. Often partial moles are recognized only after sponta-

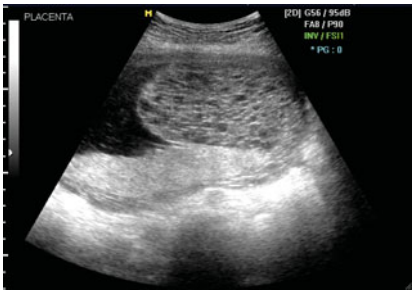

Figure 20-3 ■ Ultrasound image of the placenta in a twin gestation. Molar changes can be seen in one, thickened placenta while the placenta of the normal co-twin has the expected appearance.

Source: Courtesy of Angela Gray, MD. Obstetrix Medical Group of Colorado.

neous abortion, or they may go unnoticed. Unlike the complete mole, identifiable fetal parts may be present. Twin pregnancies in which a normal fetus coexists with a molar pregnancy have been reported. Because fetal development is not seen in complete moles, this can present a diagnostic pitfall leading to an erroneous diagnosis of a partial mole. (See Figure 20-3 ■).

Hydatidiform mole occurs in about 1 in 1500 pregnancies in the United States (ACOG, 2008c). The incidence of molar pregnancy increases with extremes in maternal age and has higher rates in certain populations, including Asia and Latin America.

Invasive mole (chorioadenoma destruens) is similar to a complete mole but involves the uterine myometrium. Treatment is the same as for a complete mole.

Choriocarcinoma is invasive, malignant trophoblastic disease that is usually metastatic and can be fatal. It is discussed in more detail shortly.

Clinical Therapy

Diagnosis of hydatidiform mole is often suspected in the presence of the following signs:

- Vaginal bleeding is almost universal with molar pregnancies and may occur as early as the fourth week or as late as the second trimester. It is often brownish, "like prune juice," because of liquefaction of the uterine clot, but it may be bright red.
- Anemia occurs frequently because of the loss of blood.
- Hydropic vesicles may be passed and, if so, are diagnostic (Figure 20-4 ■). With a partial mole, the vesicles are often smaller and may not be noticed by the woman.
- Uterine enlargement greater than expected for gestational age is a classic sign with complete moles, present in about 50% of cases. In the remainder of cases, the uterus is appropriate or small for the gestational stage. Enlargement is due to the proliferating trophoblastic tissue and to a large amount of clotted blood.
- Absence of fetal heart sounds in the presence of other signs of pregnancy is a classic sign of molar pregnancy. (Only rarely has a viable fetus been born in a partial molar pregnancy.)
- Markedly elevated serum hCG may be present because of continued secretion by the proliferating trophoblastic tissue. (Normally hCG levels increase from the time of implantation, peak at 60 to 70 days, and then decline slowly, reaching a low point at 100 to 130 days.)

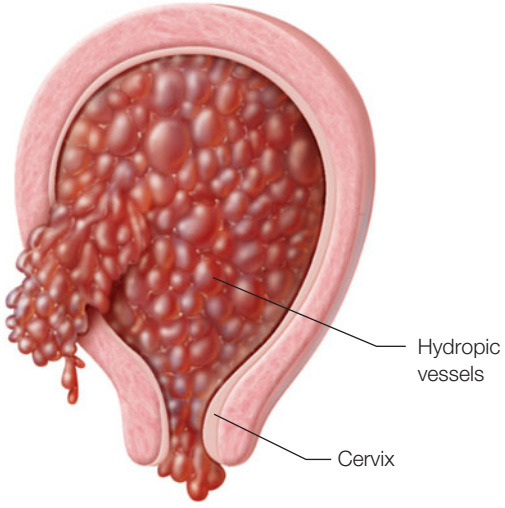

Figure 20-4 ■ Hydatidiform mole. A common sign is vaginal bleeding, often brownish (the characteristic "prune juice" appearance) but sometimes bright red. In this figure, some of the hydropic vessels are being passed. This occurrence is diagnostic for hydatidiform mole.

- Very low levels of maternal serum α-fetoprotein (MSAFP) are found.
- Hyperemesis gravidarum may occur, probably as a result of the high levels of hCG.
- Preeclampsia (discussed shortly) may be seen, especially if the molar pregnancy continues into the second trimester. Because preeclampsia is a disease of late pregnancy, if symptoms occur in the first half of pregnancy, molar pregnancy must be considered as the first diagnosis.
- Rarely, hyperthyroidism results from production of thyrotropin by molar tissue. It produces thyrotoxicosis, which may precipitate a clinical emergency.

Ultrasound is the primary means of diagnosing a molar pregnancy, usually after 6 to 8 weeks, when the vesicular enlargement of the villi can be identified.

Therapy begins with suction evacuation of the molar pregnancy and curettage of the uterus to remove all fragments of the placenta. Early evacuation decreases the possibility of other complications. If the woman is older and has completed her childbearing, or if there is excessive bleeding, hysterectomy may be the treatment of choice to reduce the incidence of malignant sequelae. Uterine contractions can cause trophoblastic tissue to be engulfed in the large venous sinusoids of the uterus. Therefore, stimulation of uterine contractions is avoided until the uterus is evacuated to prevent embolization of trophoblastic tissue to the lungs. The RhD antigen is contained in trophoblasts, therefore, at the time of evacuation of the uterus, Rh immune globulin must be administered to women with an Rh negative blood type (Berkowitz & Goldstein, 2009).

Complications associated with hydatidiform mole that require medical recognition and therapy include the following:

- Anemia
- Hyperthyroidism
- Infection, usually seen with late diagnosis and spontaneous abortion of the mole

- DIC
- Trophoblastic embolization of the lung, usually seen after molar evacuation of a significantly enlarged uterus (this creates a cardiorespiratory emergency)
- Ovarian cysts, which may be small or large enough to displace the uterus

Malignant gestational trophoblastic disease (GTD), usually choriocarcinoma, develops following evacuation of a molar pregnancy in about 20% of women (ACOG, 2008c). To detect this serious problem early and initiate treatment, follow-up care is essential. Follow-up for women who have had a molar pregnancy evacuated consists of baseline chest x-ray examination to detect metastasis and a repeat x-ray if chemotherapy is necessary. Continued high or rising hCG levels in women who have had molar pregnancy but are not currently pregnant suggest secretion of hCG by metastatic trophoblastic cells. Thus, radioimmunoassay hCG values should be determined weekly until negative three consecutive times, then should be monitored monthly for 6 months (Berkowitz & Goldstein, 2009). Effective contraception, preferably using hormonal contraceptives, is needed during this time to prevent pregnancy and the resulting confusion about the cause of changes in hCG level. In addition, pregnancy could mask an hCG rise associated with malignant GTD (Cunningham et al., 2010; Li, 2008).

If hCG plateaus or rises during this time or metastases are detected, chemotherapy is started immediately. Treatment at a center specializing in GTD is advised. Once pregnancy has been ruled out, a complete physical and pelvic examination, baseline hCG level, complete blood count and baseline blood chemistries, pelvic ultrasound, chest x-ray, and computed tomography (CT) of the brain, chest, abdomen and pelvis are done to stage the cancer and rule out metastatic spread. Chemotherapy is then begun using methotrexate alone or in combination with other chemotherapy agents (Li, 2008).

After treatment, careful follow-up monitoring of hCG levels is important. Malignant GTD is curable if diagnosed early and treated appropriately. The risk of a molar pregnancy in subsequent pregnancies is about 1% after the first one; after two molar pregnancies, the risk is 15% to 18% (Berkowitz & Goldstein, 2009).

Currently research is under way to identify risk factors for GTD and to examine the role of genetics in its development. In addition, efforts are under way to develop better, more sensitive ways to detect minimal levels of hCG and clinical trials are focusing on the effectiveness of established chemotherapy approaches in treating malignant GTD (Bess & Wood, 2006).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

It is important for nurses involved in antepartum care to be aware of symptoms of hydatidiform mole and observe for them at each antepartal visit. The classic symptoms used to diagnose molar pregnancy are found more frequently with the complete than with the partial mole. The partial mole may be difficult to distinguish from a missed abortion before evacuation.

When the woman is hospitalized for evacuation of the molar pregnancy, the nurse should monitor vital signs and vaginal bleeding for evidence of hemorrhage. In addition, the nurse determines whether abdominal pain is present and assesses the woman's emotional state and coping ability.

Nursing diagnoses that may apply to a woman with a hydatidiform mole include the following:

- ***Fear*** related to the possible development of choriocarcinoma
- ***Readiness for Enhanced Knowledge*** related to an expressed desire to understand the need for regular monitoring of hCG levels and the long-term implications of the disease
- ***Grieving*** related to the loss of the pregnancy

Nursing Plan and Implementation

Community-Based Nursing Care

When molar pregnancy is suspected, the woman needs emotional support. The nurse can relieve some of the woman's anxiety by answering questions about the disease process and explaining what ultrasound and other diagnostic procedures will entail. If a molar pregnancy is diagnosed, the nurse supports the childbearing family as they deal with their grief about the lost pregnancy. Healthcare counselors, the hospital chaplain, or their own clergy may be of assistance in helping them deal with this loss.

Hospital-Based Nursing Care

When the woman is hospitalized for evacuation of the molar pregnancy, explanation of the curettage procedure is necessary. Although the physician is responsible for providing this explanation, the woman and her partner may have many questions and concerns that the nurse can discuss with them. The nurse may also clarify areas of confusion or misunderstanding.

Typed and cross-matched blood must be available for surgery because of previous blood loss and the potential for hemorrhage. Oxytocin is administered to keep the uterus contracted and prevent hemorrhage. In addition, acute renal failure, a syndrome of rapid onset, may occur when significant hemorrhage results in absolute loss of fluid volume. Following surgery, the nurse carefully observes the woman's urinary output, watches for further signs of bleeding, and assesses for any signs of infection.

If the woman is Rh negative and not sensitized, she is given Rh immune globulin to prevent antibody formation. (See discussion on Rh sensitization later in this chapter.)

Health Promotion Education

The woman needs to know the importance of the follow-up visits. She is advised to use contraception to delay becoming pregnant again until after the follow-up program is completed.

Evaluation

Expected outcomes of nursing care include the following:

- The woman has a smooth recovery following successful evacuation of the molar pregnancy.
- The woman is able to explain GTD, its treatment, follow-up, and long-term implications for pregnancy.
- The woman and her partner are able to begin verbalizing their grief at the loss of their anticipated child.

- The woman is able to discuss the importance of follow-up assessment and indicates her willingness to cooperate with the regimen.

Care of the Woman with Hyperemesis Gravidarum

Nausea and vomiting of mild to moderate intensity are common during early pregnancy, occurring most commonly in the first trimester (see chapter 16 ∞). **Hyperemesis gravidarum** is a relatively rare condition, occurring in about 0.3% to 2% of all pregnancies, in which nausea and vomiting are so severe that they affect hydration and nutritional status (Goldberg, Szilagyi, & Graves, 2007; Holmgren, Aagaard-Tillery, Silver, et al., 2008). Dehydration, electrolyte imbalances, acidosis, weight loss, ketonuria, and, possibly, hepatic and renal damage are attributable to hyperemesis.

Hyperemesis can be a temporarily disabling condition in which affected women may need multiple hospitalizations and face disruption of work, family, or social routines. In rare instances, the psychologic impact is so extreme that a woman may request pregnancy termination. It occurs more frequently in nulliparous women, adolescents, women with a multiple gestation, women with increased body weight, certain ethnic groups, pregnancies complicated by gestational trophoblastic disease (GTD) or fetal abnormalities, women with a mother or sister who experienced hyperemesis, or women with a history of hyperemesis in a previous pregnancy (ACOG, 2009b).

The cause of hyperemesis during pregnancy is still unclear, but it has been suggested that hCG plays a role (Holmgren et al., 2008). An argument against this mechanism is that nausea and vomiting are not common in women with choriocarcinoma, which is characterized by high levels of hCG. Higher levels of estradiol as well as lower levels of prolactin have been implicated as well. Other mechanisms that may relate to hyperemesis are displacement of the gastrointestinal tract, hypofunction of the anterior pituitary gland and adrenal cortex, abnormalities of the corpus luteum, and psychologic factors. Hyperemesis is rare in populations of developing countries.

In severe cases, the pathology of hyperemesis begins with dehydration. This leads to fluid-electrolyte imbalance and alkalosis from the loss of hydrochloric acid. More prolonged vomiting can result in loss of predominantly alkaline intestinal juices and the occurrence of acidosis. Hypovolemia from dehydration leads to hypotension and increased pulse rate, with increased hematocrit and blood urea nitrogen levels and decreased urine output. Severe potassium loss (hypokalemia) interferes with the ability of the kidneys to concentrate urine and disrupts cardiac functioning. Starvation causes muscle wasting and severe protein and vitamin deficiencies. Jaundice, hyperpyrexia, and peripheral neuritis may develop. If inadequately or incorrectly treated, complications such as Wernicke encephalopathy, esophageal rupture, or even maternal death may occur.

The diagnostic criteria for hyperemesis include a history of intractable vomiting in the first half of pregnancy, dehydration, ketonuria, and a weight loss of 5% of prepregnancy weight.

Clinical Therapy

The goals of treatment include controlling vomiting, correcting dehydration, restoring electrolyte balance, and maintaining adequate nutrition. It may be beneficial to avoid environmental triggers such as odors (perfume, chemicals, food, smoke), stuffy rooms, heat, humidity, noise, and visual or physical motion, brushing teeth after a meal, and not getting enough rest. Frequent small meals of high-carbohydrate, low-fat content may be helpful. Carbonated or sour beverages taken in small quantities between meals also appear to help.

Complementary and alternative therapies have also been tried in treating hyperemesis because they may offer relief for nausea and vomiting of pregnancy. Ginger has been used for its beneficial effects on motion sickness and nausea. The use of acupuncture or acupressure may also cause a reduction in the severity of symptoms (ACOG, 2009a). Hypnosis has been helpful in some women.

Pyridoxine (vitamin B_6) is a reasonable first-line pharmacologic treatment for nausea and vomiting of pregnancy. It has a good safety profile and minimal side effects. It can be administered alone or with doxylamine succinate, an antihistamine that improves efficacy. This was the formulation of Bendectin, which was voluntarily withdrawn from the market in 1983 because of a lawsuit alleging teratogenicity. Scientific evidence supports its safety and efficacy in the reduction of symptoms. Typical dosing is pyroxidine 10 to 25 mg orally three times daily and one 25 mg over-the-counter tablet (sold as Unisom Sleep Tabs) at bedtime (Yankowitz, 2008). If this is not effective, other pharmacologic options include promethazine (Phenergan), metoclopramide (Reglan), and ondansetron (Zofran).

If the woman with intractable nausea and vomiting does not respond to frequent small meals of simple carbohydrates and the occasional use of antiemetics, she may require IV fluids on an outpatient basis. If the woman's symptoms do not improve, hospitalization may be necessary.

The initial workup should include an ultrasound to exclude the possibility of molar pregnancy. Initially the woman is given nothing by mouth; IV fluids are administered to correct dehydration. Potassium chloride is typically added to the IV infusion to prevent hypokalemia. Replacement of thiamine (vitamin B_1) and pyroxidine (vitamin B_6) is important to correct deficiencies of these vitamins and prevent peripheral neuropathy. Administration of dextrose solution before the correction of thiamine deficiency could lead to Wernicke encephalopathy (loss of memory, confusion). Desired urine output is a minimum of 1000 ml/24 hours.

If the woman does not respond to this management, total parenteral nutrition may be used to meet the caloric and nutritional needs of the woman and her fetus. When the woman's condition has improved, oral feedings are started. Six small dry feedings followed by clear liquids is one suggested treatment. Another method is 1 oz of water offered each hour, followed as tolerated by clear, then nourishing liquids, progressing on succeeding days to low-fat soft and regular diets.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

When a woman is hospitalized for control of vomiting, the nurse must regularly assess the amount and character of further emesis, intake and output, fetal heart rate, maternal vital signs, initial weight, evidence of jaundice or bleeding, and the woman's emotional state.

Nursing diagnoses that may apply to the woman with hyperemesis gravidarum include the following:

- ***Imbalanced Nutrition: Less Than Body Requirements*** related to persistent vomiting secondary to hyperemesis
- ***Fear*** related to the effects of hyperemesis or its treatment on fetal well-being

Nursing Plan and Implementation

Community-Based Nursing Care

The initial evaluation of the woman is designed to distinguish between morning sickness, which is amenable to self-care, and real nutritional risk. The nurse should take this opportunity to evaluate possible family and lifestyle stressors. It is wise to include both the woman and her family in the discussion of strategies to reduce nausea and vomiting she can try at home, including such tactics as small carbohydrate meals, high-protein snacks, total avoidance of fatty foods, resting with her feet up and head elevated, or slowly sipping carbonated beverages when nauseated. Herbal tea, such as spearmint, peppermint, raspberry, chamomile, or ginger root, may be helpful. Odors, very hot or cold liquids, ice, and straws should be avoided. If the nausea and vomiting progress to a point where oral intake is not tolerated and dehydration is evident, medical intervention is required.

Home Care

Parenteral therapy provided at home in collaboration with a physician and registered dietitian is sometimes used to allow the woman to remain in her home and help decrease healthcare costs. It also gives the nurse an opportunity to observe family interactions and evaluate the home environment. This assessment is often useful in determining the pregnant woman's level of support, any significant stressors in her life, her understanding of nutrition and self-care measures, and so forth.

Hospital-Based Care

Nursing care should be supportive and directed at maintaining a relaxed, quiet environment away from food odors or offensive smells. Once oral feedings are started, food should be attractively served. Oral hygiene is important because the mouth is dry and may be irritated from vomitus. Weight gain or loss should be monitored regularly. Because emotional factors have been found to play a major role in this condition, psychotherapy may be recommended. With proper treatment, the prognosis is favorable.

Health Promotion Education

As part of patient teaching, the nurse should review actions the woman can take to prevent or decrease nausea. These are discussed in chapter 16 ∞.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to explain hyperemesis gravidarum, its therapy, and its possible effects on her pregnancy.
- The woman's condition is corrected, and possible complications are avoided.

Care of the Woman with a Hypertensive Disorder

Hypertension is the most common medical disorder in pregnancy, accounting for up to 15% of prenatal hospitalizations. The incidence of hypertension among pregnant women ranges from 12% to 22%, and hypertension is directly responsible for 17.6% of maternal deaths in the United States (ACOG, 2008b).

The classification of hypertension in pregnancy is as follows (ACOG, 2008b):

- Preeclampsia-eclampsia
- Chronic hypertension
- Chronic hypertension with superimposed preeclampsia
- Gestational hypertension

The pathophysiology and collaborative care of women with these disorders are quite different; thus, each is discussed separately.

Preeclampsia and Eclampsia

Preeclampsia occurs in 5% to 8% of all pregnancies in the United States and 3% to 14% of all pregnancies worldwide; it is the most common hypertensive disorder in pregnancy (Duklina, Ayala, & Callaghan, 2009; Lim, Kim, Park, et al., 2008). It is estimated that 50,000 women die from preeclampsia each year worldwide. In the United States, it is the second leading cause of maternal death. Among women with chronic hypertension, 22% to 25% will develop this complication (Chappellee et al., 2008).

Preeclampsia, a syndrome that affects both mother and fetus, is clinically defined as an increase in blood pressure after 20 weeks' gestation accompanied by proteinuria in a previously normotensive woman. Edema is not included in the definition because it is a common feature in normal pregnancy (Martin, 2009). However, sudden onset of severe edema warrants close evaluation to rule out preeclampsia or other pathologic processes such as renal disease. It is important to remember that severe preeclampsia can occur without edema.

Eclampsia is the occurrence of a seizure in a woman with preeclampsia who has no other cause for seizure. Women who are going to develop preeclampsia usually become hypertensive before they develop proteinuria. In any event, the onset of hypertension in pregnancy warrants close observation.

Pathophysiology of Preeclampsia

Preeclampsia has been called a "disease of theories" because the true mechanisms behind the pathogenesis remain unclear. It has been suggested that mechanisms leading to the development of

preeclampsia include impaired trophoblast differentiation and invasion, placental and endothelial dysfunction, an immune reaction to paternal antigens, and an exaggerated systemic inflammatory response (Barton & Sibai, 2008). Alterations in the rennin-angiotensin system and insulin resistance may be involved in pathogenesis as well (Thadhani & Solomon, 2008).

Some pieces of the puzzle may be coming together as new research has suggested that the pathogenesis of preeclampsia may be related to an imbalance between circulating angiogenesis-related factors (Karumanchi & Lindheimer, 2008; Lim et al., 2008; Thadhani & Solomon, 2008). Angiogenesis, the process of neovascularization from preexisting blood vessels and vasculogenesis, the process of blood vessel generation from angioblast precursor cells, occurs in the placenta causing impaired placentation associated with preeclampsia (Kopcow & Karumanchi, 2007). Widespread systemic vascular dysfunction and microangiopathy is demonstrated in the mother, but not in the fetus (Kopcow & Karumanchi 2007). The placenta plays a central role in the development of the disease, for which the only known cure is birth of the fetus and removal of the placenta.

Key features of preeclampsia involve the failure of the uterine spiral arteries to transform from thick-walled muscular vessels to saclike flaccid vessels, exaggerated inflammatory response, and inappropriate endothelial-cell activation (Barton & Sibai, 2008). Characteristics of preeclampsia include maternal vasospasm resulting in decreased perfusion to virtually all organs, including the placenta (Figure 20-5 ■), a decrease in plasma volume, activation of the coagulation cascade, and

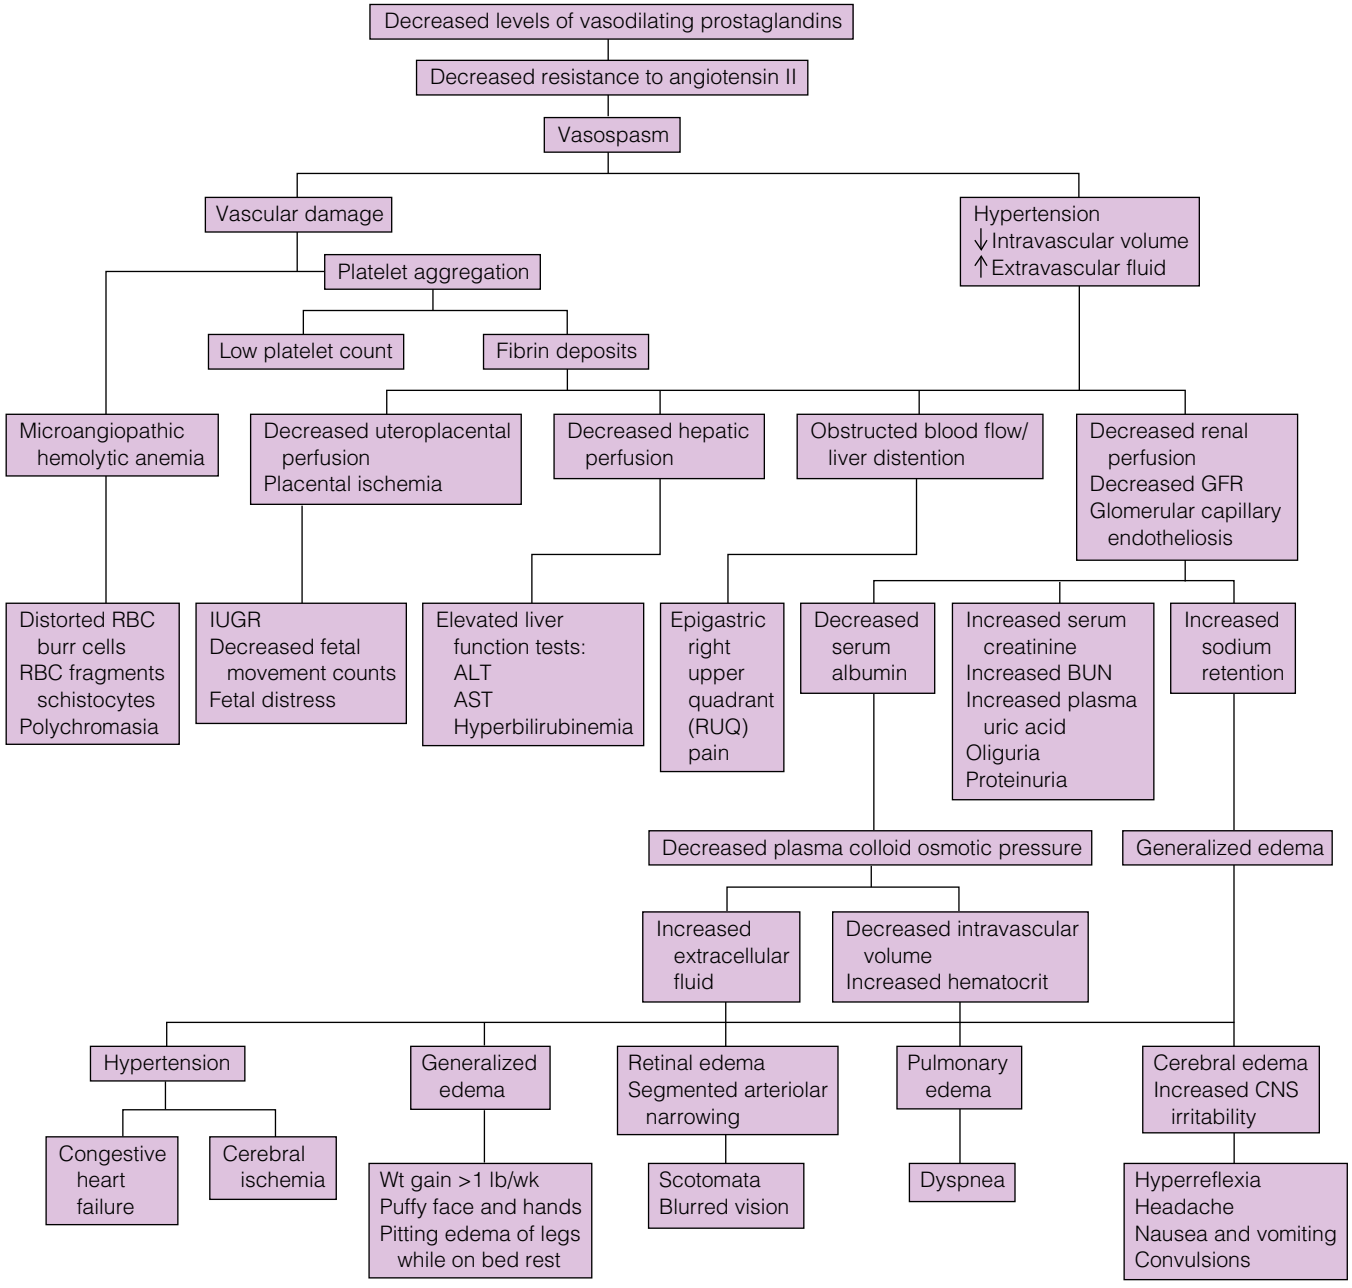

Figure 20-5 ■ Clinical manifestations and possible pathophysiology of preeclampsia-eclampsia.

alterations in glomerular capillary endothelium. The increased platelet activation and markers of endothelial activation can predate clinically evident preeclampsia by weeks or even months. In preeclampsia, a greater degree of placental infarction may be seen than occurs in normal pregnancy.

Women who develop preeclampsia become more sensitive to pressor agents (substances that increase blood pressure) rather than less sensitive to them, as in normal pregnancy. This response has been linked to the ratio between the prostaglandins prostacyclin and thromboxane. Prostacyclin, a vasodilator produced by endothelial cells, decreases blood pressure, prevents platelet aggregation, and promotes uterine blood flow. Thromboxane, produced by platelets, causes vessels to constrict and platelets to clump together. Prostacyclin is decreased in preeclampsia, allowing the potent vasoconstrictor and platelet-aggregating effects of thromboxane to dominate. These hormones are produced partially by the placenta, which would help explain the reversal of the condition when the placenta is removed and why the incidence is increased when there is a larger than normal placental mass, such as in hydrops, multiple pregnancy, or hydatidiform mole. There also seems to be an increased risk of preeclampsia in women with preexisting vascular disease. The role of prostacyclin-thromboxane imbalance in preeclampsia has prompted several randomized trials designed to evaluate the effect of low-dose aspirin (50–150 mg/day), which suppresses thromboxane, to prevent preeclampsia. It appears there is no effective intervention for the general maternity population, but low-dose aspirin may result in a modest risk reduction in women at moderate or high risk of the disease (Barton & Sibai, 2008).

With increasing use of assisted reproductive techniques to achieve pregnancy, potential obstetric risks have begun to be explored. Because these pregnancies also are distinct for a greater likelihood of advanced maternal age, obesity and polycystic ovary syndrome, multiple gestation, and nulliparity, which may potentially lead to pregnancy complications, it is difficult to separate the contribution of foreign genetic material (donor egg) from these other confounding variables (Barton & Sibai, 2008). A recent study of well-matched women concluded that in both singleton and multiple gestations, the use of donor eggs is associated with a significant increase in gestational hypertension and preeclampsia (Ness & Grainger, 2008). In addition, it has been shown that first pregnancies, teen pregnancies, out-of-wedlock pregnancies, and conception with a new partner increase the risk of preeclampsia. Paternal contribution to preeclampsia risk is also suggested by the observation that men who have previously fathered a child with a woman who developed preeclampsia are more likely to father a subsequent preeclamptic birth with a new partner (Barton & Sibai, 2008; Ness & Grainger, 2008).

Recently, attention has been directed to another theory, which postulates that uteroplacental ischemia acts as a trigger for preeclampsia, with other factors playing contributory roles. Although the prostacyclin-thromboxane imbalance may provide an explanation for the clinical features of preeclampsia, this theory is now being challenged as the primary cause. In the woman with preeclampsia, in addition to a reduced production of the vasoactive substance prostacyclin, there is also a decreased production of nitric oxide. Nitric oxide is a potent vasodilator and important regulator of maternal blood pressure. Nitric oxide synthesis in the placenta may play a meaningful role in maintaining a low-pressure, high-flow placental system and also may prevent intervillous thrombosis. The loss of normal vasodilatation of uterine arterioles results in decreased placental perfusion (Figure 20-6 ■), potentially leading to fetal growth restriction and chronic hypoxia or distress.

Hyperhomocysteinemia may play a role in the etiology or pathophysiology of preeclampsia through oxidative stress and endothelial dysfunction. Mild elevations of homocysteine have been found in normotensive women who go on to develop preeclampsia. Once preeclampsia is established, homocysteine levels are considerably increased. It is unclear whether the circulating levels of homocysteine have caused preeclampsia or if they reflect metabolic alterations resulting from the disease

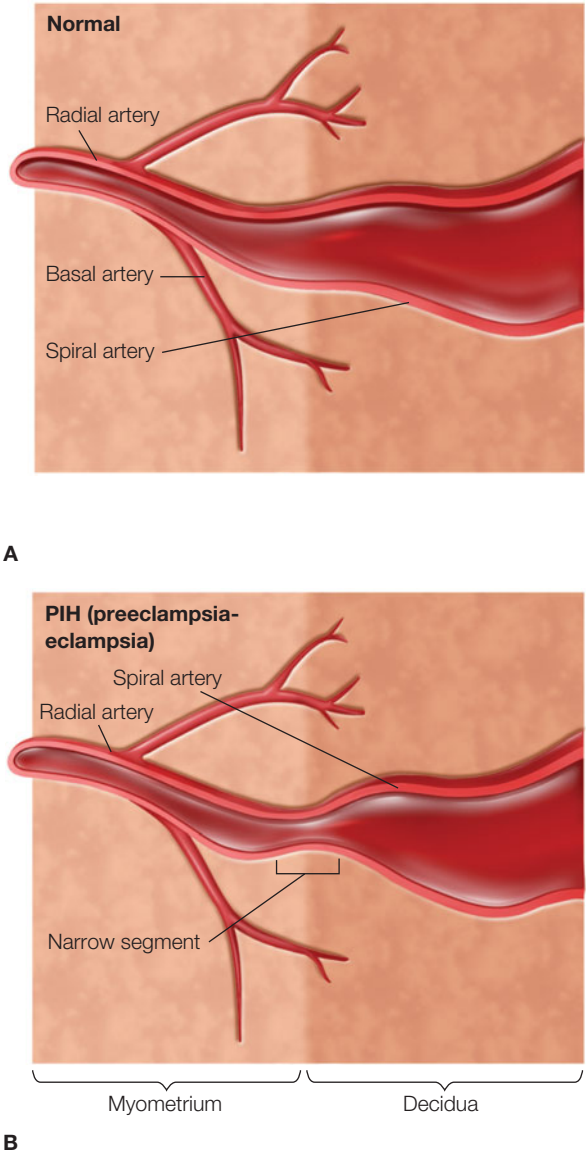

Figure 20-6 ■ A. In a normal pregnancy, the passive quality of the spiral arteries permits increased blood flow to the placenta. B. In preeclampsia, vasoconstriction of the myometrial segment of the spiral arteries occurs.

process. In the presence of regulatory gene mutations, deficiencies of vitamins B_6, B_{12}, or folic acid may cause a rise in homocysteine. If a causal link can be demonstrated, this might lead to strategies for preventing preeclampsia. In a study of approximately 4000 women who received folic acid supplementation, it was found that folic acid supplementation was associated with a decrease in plasma homocysteine and a reduced risk of preeclampsia (Wen et al., 2008).

Decreased renal perfusion is associated with preeclampsia. With a reduction in glomerular filtration rate (GFR), serum levels of creatinine, blood urea nitrogen (BUN), and uric acid begin to rise from normal pregnant levels, whereas urine output diminishes. For each 50% decrease in GFR, serum creatinine and BUN plasma levels double, whereas sodium is retained in increased amounts. Sodium retention results in increased extracellular volume and increased sensitivity to angiotensin II. The typical kidney lesion of preeclampsia involves swollen glomerular capillary endothelial cells containing fibrin deposits. Stretching of the capillary walls allows the large protein molecules, primarily albumin, to escape into the urine, decreasing serum albumin.

Edema is usually more profound in preeclampsia than in normal pregnancy although some of the most severe forms of the disease may occur without edema. The pathologic basis of edema is twofold:

1. The higher salt retention draws out intravascular fluid.
2. Plasma colloid osmotic pressure decreases because of serum albumin loss through edematous renal glomeruli and damaged vascular endothelium. This causes fluid movement to extracellular spaces.

The decreased intravascular volume causes increased viscosity of the blood and a corresponding rise in hematocrit.

HELLP Syndrome

HELLP syndrome (***h***emolysis, ***e***levated ***l***iver enzymes, and ***l***ow ***p***latelet count) is associated with severe preeclampsia, although it may occur in women with normal or minimally elevated blood pressure and no proteinuria. Hypertension or proteinuria may be absent in 10% to 15% of women with HELLP syndrome (Airoldi & Weinstein, 2007; Sibai, 2007). Ninety percent of women with HELLP syndrome present with symptoms before 36 weeks' gestation. In women with severe preeclampsia-eclampsia, the incidence of HELLP syndrome is 2% to 20% (ACOG, 2008b; Hay, 2008). Twenty-five percent first demonstrate the disease in the postpartum period (Hay, 2008).

The hemolysis that occurs is termed *microangiopathic hemolytic anemia.* It is thought that red blood cells are distorted or fragmented during passage through small, damaged blood vessels. Vascular damage is associated with vasospasm, and platelets aggregate at sites of damage, resulting in low platelet count (less than 100,000/mm^3). Elevated liver enzymes occur from blood flow that is obstructed because of fibrin deposits. Deposits of fibrin-like material found in the hepatic sinusoids cause obstruction and hepatocellular injury. This necrosis is the classic hepatic lesion associated with HELLP. Increase in intrahepatic pressure causes swelling of the liver. Liver distention causes epigastric pain and may ultimately result in rupture. Hyperbilirubinemia and jaundice may also be seen.

Symptoms can include nausea, vomiting, malaise, flulike symptoms, or epigastric pain. This can lead to misdiagnoses of gastroenteritis, hepatitis, gallbladder disease, pyelonephritis, renal disease, or thrombocytopenia purpura. Regardless of their blood pressure or the presence of protein in their urine, women presenting with the preceding symptoms should have a CBC with platelet count and liver enzymes drawn. Perinatal morbidity and mortality with HELLP syndrome are high; therefore, the possibility of HELLP should be considered carefully.

Women with HELLP syndrome are best cared for in a tertiary care center. Initially, the mother's condition should be assessed and stabilized, especially if her platelets are very low. The fetus is also assessed using a nonstress test and biophysical profile. All women with true HELLP syndrome should give birth regardless of gestational age.

Maternal Risks

Hypertensive disorders account for 16% of maternal mortality in developed countries (Cunningham et al., 2010). Preeclampsia can impact most organ systems, causing serious complications. Central nervous system (CNS) changes include hyperreflexia, headache, and eclamptic seizure. The underlying cause of the seizures is not known. Once thought to be from cerebral edema, there is some controversy as to whether cerebral edema is a feature of eclampsia or a postmortem phenomenon.

Intracerebral hemorrhage is a rare complication, but it is the most common cause of death in women with severe preeclampsia and eclampsia, being fatal in 50% to 65% of cases; those who survive may suffer permanent disability (Mihu, Costin, Mihu, et al., 2007). Risk factors for pregnancy-related stroke include hypertension, cardiac disease, infection, hyperemesis gravidarum, fluid and electrolyte imbalances, anemia/hemorrhage, sickle cell anemia, history of migraine headaches, smoking, drug abuse, thrombocytopenia, age greater than 35, and African American race (ACOG, 2008a).

Increased intraocular pressure can cause retinal detachment, but spontaneous reattachment usually occurs with reduction in blood pressure and diuresis.

Acute tubular necrosis may result from underperfusion of the kidneys. This is associated with hypovolemia and renal vasoconstriction. Although many women with preeclampsia will have oliguria, most do not develop acute tubular necrosis. One of the more common problems related to preeclampsia is pulmonary edema due to increased capillary permeability.

Thrombocytopenia complicates severe preeclampsia in about 7% to 11% of women (Ghulmiyyah & Sabai, 2006). The exact mechanism is not fully understood, but platelet consumption is believed to be related to endothelial damage and activation of thrombin. Abruptio placentae is a risk associated with preeclampsia. The release of procoagulants, such as thromboplastin, can result in acute disseminated intravascular coagulation (DIC).

Subcapsular hematoma of the liver is a rare but important occurrence in women with preeclampsia and HELLP syndrome. In addition to the signs of preeclampsia, physical examination may reveal hepatomegaly and peritoneal irritation.

Rupture of a subcapsular hematoma is a life-threatening event. The woman may complain of right shoulder pain or severe epigastric pain persisting for several hours before circulatory collapse is evident. This is a surgical emergency requiring a multidisciplinary approach to management. Maternal and fetal mortality is over 50%, and women who survive are at risk for adult pulmonary distress syndrome, pulmonary edema, and acute renal failure in the postoperative period.

Vaginal birth is preferable to cesarean birth in women with preeclampsia or HELLP syndrome. Aggressive induction of labor should take place regardless of the favorability of the cervix. Cesarean birth is considered if vaginal birth does not take place within a reasonable amount of time, usually 24 hours, or for the usual obstetric indications.

Fetal-Neonatal Risks

Preeclampsia is a primary cause of placental insufficiency and premature birth. In addition, it has numerous effects on the neonate.

Infants of women with preeclampsia during pregnancy tend to be small for gestational age (SGA) because of intrauterine growth restriction. The cause is related specifically to maternal vasospasm and hypovolemia, which result in fetal hypoxia and malnutrition. Placental abruption secondary to hypertension may result in fetal hypoxia or even death. In addition, the newborn may be premature because the treatment for the maternal condition may require early childbirth.

At birth, the newborn may be oversedated because of medications administered to the woman. The newborn may also have hypermagnesemia caused by treatment of the woman with large doses of magnesium sulfate.

Clinical Manifestations and Diagnosis

The most commonly occurring clinical manifestations and diagnoses are discussed here.

MILD PREECLAMPSIA The diagnosis of preeclampsia is made based on the presence of new onset hypertension and proteinuria. After 20 weeks' gestation, a blood pressure of 140 mm Hg systolic or 90 mm Hg diastolic on at least two occasions 6 hours apart in a woman who was previously normotensive before pregnancy is used for diagnosis. The blood pressure measurements should be no more than 7 days apart (Habli & Sibai, 2008).

With mild preeclampsia, proteinuria is generally between 300 mg/L (1+ dipstick) and 1 g/L (2+ dipstick). This is measured in a midstream clean-catch or catheter-derived urine specimen.

The gold standard for the measurement of proteinuria is the 24-hour urine. Excretion of more than 300 mg of protein in a 24-hour period is considered abnormal (Airoldi & Weinstein, 2007). This correlates approximately with a dipstick protein reading of 1+ (30 mg/dl) or greater if specific gravity is between 1.010 and 1.030. Protein measurement may vary throughout the 24-hour period, partly related to urine concentration. This can be adjusted for with the use of a protein/creatinine ratio rather than the simple protein concentration alone. Although edema is no longer considered a diagnostic criterion, generalized edema, seen as puffy face, hands, and dependent areas such as the ankles and lower legs, may be present. Edema is identified by a weight gain of more than 1.5 kg/month (3.3 lb) in the second trimester or more than 0.5 kg/week (1.1 lb) in the third trimester. Edema is assessed on a 1+ to 4+ scale.

SEVERE PREECLAMPSIA Severe preeclampsia may develop suddenly. The following clinical signs are often present (ACOG, 2008b):

- Blood pressure of 160/110 mm Hg or higher on two occasions at least 6 hours apart while the woman is on bed rest
- Proteinuria 5 g/L or higher in 24 hours or 3+ or greater on two random urine samples collected at least 4 hours apart
- Oliguria: urine output less than or equal to 500 ml in 24 hours
- Cerebral or visual disturbances
- Pulmonary edema or cyanosis
- Epigastric or right upper quadrant pain
- Impaired liver function (elevated hepatic enzymes–alanine aminotransferase (ALT) or aspartate aminotransferase (AST) to at least twice normal
- Thrombocytopenia (less than 100,000 platelets per cubic millimeter)
- Fetal growth restriction

Other signs or symptoms that may be present include severe headache or one that persists despite analgesic therapy, blurred vision or scotomata (spots before the eyes), narrowed segments on the retinal arterioles when examined with an ophthalmoscope, retinal edema (retinas appear wet and glistening) on funduscopy, dyspnea due to pulmonary edema, moist breath sounds on auscultation, pitting edema of lower extremities while on bed rest, epigastric pain, hyperreflexia, nausea and vomiting, irritability, and emotional tension.

ECLAMPSIA Eclampsia, characterized by convulsion or coma, may occur before the onset of labor, during labor, or early in the postpartum period. Late postpartum eclampsia (convulsions occurring more than 48 hours following birth) occurs rarely but has been documented. Some women experience only one convulsion, especially if it occurs late in labor or during the postpartum period. Others may have from 2 to 20 or more. Unless they occur extremely frequently, the woman often regains consciousness between convulsions.

Clinical Therapy

The goals of medical management are prevention of cerebral hemorrhage, convulsion, hematologic complications, and renal and hepatic diseases, and birth of an uncompromised newborn as close to term as possible. Reduction of elevated blood pressure is essential in accomplishing these goals.

ANTEPARTUM MANAGEMENT The only known cure for preeclampsia is birth of the infant. As mentioned earlier, recent research has focused on preventing preeclampsia in at-risk women through the use of low-dose (50 to 150 mg daily) aspirin begun between 12 and 18 weeks' gestation. Aspirin is known to block the action of an enzyme, cyclooxygenase, essential to the production of prostaglandins. This results in lowered levels of thromboxane, the vasoconstrictor. At the same time, levels of the vasodilator prostacyclin are not significantly affected.

Several dietary approaches have been suggested, including supplementation with zinc, magnesium, and fish oil. Results of trials have either been conflicting or have revealed minimal or no benefit from nutritional supplementation. Recent studies have examined Vitamin D supplementation and report a protective effect on preeclampsia development (Haugen et al., 2009). Supplementation with calcium may be effective for the mother, but the impact on the fetus is not clear (Meads, Cnossen, Meher, et al., 2008). Antioxidants (Vitamin C and E) have been advanced as potential protective mechanisms, but research does not support their effectiveness in reducing the risk of preeclampsia. One large, international study showed that antioxidants may actually increase adverse events, including fetal loss and premature rupture of the membranes (Xu, Perez-Cuevas, Xiong, et al., 2010). Based on available data, neither vitamin supplementation nor low-dose aspirin should be prescribed routinely for prevention of preeclampsia in nulliparous women (ACOG, 2008b; Barton & Sibai, 2008).

Home Care of Gestational Hypertension and Mild Preeclampsia In general, women with proteinuric preeclampsia should be admitted to the hospital. However, with changes in health care, more attention has been given to decreasing inpatient hospital days for women whose symptoms allow. Close maternal monitoring is essential to establish the severity and progression of the disease. The woman must be able to comply with frequent maternal/fetal evaluations and have ready access to medical care.

A woman should be considered for management at home if she meets the following criteria: blood pressure less than or equal to 150/100 mm Hg, proteinuria less than 1 g/24 hours or 3+ dipstick, platelet count greater than 120,000 mm^3, and normal fetal growth if not at term or showing signs of complicating factors such as vaginal bleeding. She must have a basic understanding of her condition, be able to recognize the signs and symptoms of worsening preeclampsia (Table 20-1), be able to accurately count fetal movements, be cooperative, and know when to call the doctor. Although decreased activity is generally recommended, she is not restricted to bed rest but is encouraged to rest frequently, especially in the left lateral position.

TABLE 20-1 Signs and Symptoms of Worsening Preeclampsia

- Increasing edema, especially of hands and face (If on bed rest, observe for sacral edema.)
- Worsening headache
- Epigastric pain
- Visual disturbances
- Decreasing urinary output
- Nausea/vomiting
- Bleeding gums
- Disorientation
- Generalized complaints of not feeling well

The woman monitors her blood pressure, weight, and urine protein daily. Weight gains of 1.4 kg (3 lb) in 24 hours or 1.8 kg (4 lb) in a 3-day period are generally causes for concern. Remote NSTs are performed on a daily to biweekly basis. Companies that provide this service have equipment that allows phone transmission of blood pressure readings as well as fetal monitor tracings. This eliminates concerns about inaccurate reporting on the part of the woman. Nursing contact varies from daily to weekly, depending on physician request. Laboratory testing regularly evaluates platelet counts, uric acid and BUN, liver enzymes, and 24-hour urine specimens for creatinine clearance and total protein. Estimates of fetal growth and amniotic fluid volume should be made at the time preeclampsia is diagnosed and repeated every 3 weeks if normal. Any woman with worsening symptoms or severe preeclampsia should be hospitalized.

RESEARCH EVIDENCE IN PRACTICE Preventing Preeclampsia

CLINICAL QUESTION
What role can rest play in helping decrease the risk of preeclampsia?

RESEARCH EVIDENCE
The most cost-effective and widely tested measure to prevent the development of preeclampsia is periodic rest periods for the mother during pregnancy. Rest is effective in preventing hypertension and proteinuria in women who began their pregnancy with normal blood pressure.

WHAT QUESTIONS REMAIN UNANSWERED?
How much rest is needed to gain the benefits of preeclampsia prevention without causing the adverse effects of lack of exercise?

WHAT IS BEST PRACTICE?
The most cost-effective preventative method without detectable adverse effects for mother and baby is rest periods of between 30 minutes and 4 hours, lying in the left lateral position.

CRITICAL THINKING
How can the nurse incorporate this evidence into prenatal teaching plans? What adverse events from excessive rest should be included in the routine prenatal assessment?

Meher, S. & Duley, L. (2006). Rest during pregnancy for preventing preeclampsia and its complications in women with normal blood pressure. *Cochrane Database of Systematic Reviews*. Issue 2. Article No.: CD005939. doi:10.1002/14651858.Cd005939

Hospital Care of Mild Preeclampsia The woman is placed on bed rest, primarily in the left lateral recumbent position, to decrease pressure on the vena cava, thereby increasing venous return, circulatory volume, and placental and renal perfusion. Improved renal blood flow helps decrease angiotensin II levels, promotes diuresis, and lowers blood pressure.

Her diet should be well balanced and nutritious. Sodium intake should be moderate, not to exceed 6 g/day. Excessively salty foods should be avoided, but strict sodium restriction and diuretics are no longer used in treating preeclampsia.

Tests to evaluate fetal status are done more frequently as a pregnant woman's preeclampsia progresses. These tests are described in detail in chapter 21 ∞. Monitoring fetal well-being is essential to achieving a safe outcome for the fetus. The following tests are used:

- Fetal movement record
- NST
- Ultrasonography at least every 3 to 4 weeks for serial determination of growth
- Biophysical profile
- Amniocentesis to determine fetal lung maturity
- Doppler velocimetry beginning at 30 to 32 weeks to screen for fetal compromise

Maternal well-being is monitored by the following:

- Blood pressure four times daily
- Daily weight and daily evaluation for worsening edema, persistent headache, visual changes, or epigastric pain
- Daily urine dipstick for protein
- Periodic assessment of laboratory values to include CBC with platelet count, liver function tests (AST, ALT), lactic dehydrogenase (LDH), uric acid, serum creatinine, bilirubin, and 24-hour urine for protein and creatinine clearance

Hospital Care of Severe Preeclampsia Any patient with severe preeclampsia is hospitalized immediately. It is widely accepted that childbirth should be considered in all pregnant women who develop preeclampsia after 34 weeks' gestation because the risks of prolonging the pregnancy are so severe for the mother. Expectant management may be used in selected women who are less than 34 weeks because the approach significantly improves neonatal outcomes (Cunningham et al., 2010; Habli & Sibai, 2008). Fetal well-being is assessed daily and birth is indicated regardless of gestational age if maternal or fetal condition worsens (Habli & Sibai, 2008). Other medical therapies for severe preeclampsia include the following:

- ***Bed rest.*** Bed rest must be complete. Stimuli that may bring on a convulsion should be reduced.
- ***Diet.*** A high-protein, moderate-sodium diet is given as long as the woman is alert and has no nausea or indication of impending convulsion.
- ***Anticonvulsants.*** Magnesium sulfate is the treatment of choice for seizure prophylaxis in preeclampsia and treatment of eclamptic convulsions and has been used for more than 60 years because of its CNS-depressant action (Costantine & Weiner, 2009; Pryde & Mittendorf, 2009). Blood levels of magnesium sulfate should be maintained at therapeutic levels (levels vary according to laboratory). Excessive blood levels may produce respiratory paralysis or cardiac arrest. (See Drug Guide: Magnesium Sulfate on page 468.) Anticonvulsant therapy may prevent seizures, but does not prevent the ultimate progression of the disease.
- ***Corticosteroids.*** Betamethasone or dexamethasone is often administered to the woman whose fetus has an immature lung profile to promote fetal lung maturation. Dexamethasone, which has the potency 1.25 times that of betamethasone, is often chosen for use with HELLP syndrome. Dexamethasone may be administered intravascularly, which may also influence its effectiveness. The benefits of corticosteroids in women with HELLP syndrome were first recognized when the drugs were given for fetal lung maturity enhancement to women with preterm gestations. Antepartum platelet counts stabilized or increased, whereas hepatic enzymes and LDH stabilized or decreased and mean arterial pressure and urinary output improved. The use of intravenous dexamethasone to improve maternal outcome in women with HELLP syndrome remains controversial (Katz, de Amorim, Figueiroa, et al., 2008; Sibai & Stella, 2009).
- ***Fluid and electrolyte replacement.*** The goal of fluid intake is to achieve a balance between correcting hypovolemia and preventing circulatory overload. Fluid intake may be oral or supplemented with IV therapy. IV fluids may be started "to keep lines open" in case they are needed for drug therapy, even when oral intake is adequate. Criteria vary for determining appropriate fluid intake. Electrolytes are replaced as indicated by daily serum electrolyte levels. Women with preeclampsia are at risk for hyponatremia (low blood sodium), which is indicative of low serum osmolality. A rapid decrease in serum osmolality can cause seizures as a result of cerebral dysfunction. It is imperative that serum sodium levels be evaluated to assess the need for fluid restriction and the switch from IV administration to an isotonic sodium chloride administration.
- ***Antihypertensives.*** The major indication for antihypertensive therapy is the prevention of stroke. In general, antihypertensive therapy is given for sustained systolic blood pressure of at least 160 mm Hg or diastolic blood pressures of 105 to 110 mm Hg or above (Habli & Sibai, 2008).

The therapeutic goal is to maintain the diastolic blood pressure between 90 and 100 mm Hg. Decreasing the diastolic below 90 mm Hg may decrease uterine blood flow, causing fetal compromise. Methyldopa is often used for long-term control of mild to moderate hypertension in pregnancy because it is effective and has a well-documented fetal and maternal safety record. However, its slow onset of action does not make it an option for treatment of elevated blood pressure in severe preeclampsia. Labetalol and hydralazine are commonly used drugs for the treatment of acute hypertension in pregnancy and are generally administered by IV boluses (McCoy & Baldwin, 2009). Labetalol should be avoided in women with asthma or congestive heart failure. Oral nifedipine acts rapidly and has favorable hemodynamic effects and fewer side effects than IV

hydralazine. Some guidelines recommend against using any calcium channel blocker with magnesium sulfate because of a potential drug interaction resulting in a neuromuscular blockade and hypotension. Based on the Magnesium Sulfate for Prevention of Preeclampsia Trial as well as a retrospective look at concurrent use of nifedipine and magnesium sulfate, there appears to be no clinically significant interaction between the two drugs (McCoy & Baldwin, 2009). If these medications are not successful in controlling blood pressure, sodium nitroprusside may be indicated for an acute emergency (McCoy & Baldwin, 2009; NIH, 2000).

Hospital Care of Eclampsia Eclampsia is defined as the occurrence of either seizure or coma associated with pregnancy and not caused by other neurologic disease. The overall incidence is about 1 in 2000 to 1 in 3448 (Cunningham et al., 2010). Seizures may be focal, multifocal, or generalized. The possible etiology of the seizure is likely related to cerebral vasospasm, edema, hemorrhage, ischemia, or loss of autoregulation of cerebral blood flow due to high systemic pressure (hypertensive encephalopathy) but no mechanism has been proven conclusively. Many women experience an increase in deep tendon reflexes (DTRs) before seizure, but seizures may also occur without hyperreflexia. The woman with preeclampsia should be monitored for signs and symptoms of impending eclampsia: scotomata, which can appear as dark spots or flashing lights in the field of vision; blurred vision; epigastric pain; vomiting; persistent or severe headache, generally frontal in location; neurologic hyperactivity; pulmonary edema; and cyanosis. Eclamptic seizures are almost always self limiting and generally last no more than 3 to 4 minutes.

If a seizure occurs, nursing assessment should include time of onset, progress of the seizure, body involvement, duration, presence of incontinence, status of the fetus, and signs of placental abruption. The airway should be maintained and oxygen administered during the seizure. The woman is positioned on her side to avoid aspiration. Suctioning may be necessary to keep the airway clear; a tongue blade should not be inserted into the back of the throat because it may stimulate the gag reflex. To prevent injury, side rails should be up and padded, but the woman should not be restrained.

Magnesium sulfate has long been used in the treatment of preeclampsia. A bolus of 6 g magnesium sulfate is administered intravenously over 20 to 30 minutes followed by 2–3 g/hour IV infusion (Habli & Sibai, 2008). In 10% of cases, an eclamptic woman will experience a second seizure. An additional bolus of 2 g of magnesium sulfate can be administered intravenously over 5 to 10 minutes. If convulsions continue, sodium amobarbitol is administered intravenously (Habli & Sibai, 2008).

Side effects with the loading dose may include flushing, a feeling of warmth, headache, nystagmus, nausea, dry mouth, and dizziness. Other side effects include lethargy and sluggishness and a risk of pulmonary edema if the woman has predisposing conditions such as multiple gestation or infection; has had excessive IV fluid administration; or has concurrent β-sympathomimetic therapy. See Drug Guide: Magnesium Sulfate for other side effects. Fetal side effects may include hypotonia and lethargy that persist for 1 or 2 days following birth, hypoglycemia, and hypocalcemia. (See chapter 26 ∞ for a discussion of magnesium sulfate and preterm labor.)

CLINICAL TIP

When caring for a woman with preeclampsia who is receiving IV magnesium sulfate, it is imperative to follow protocols for monitoring blood levels of magnesium. It is imperative to provide close surveillance of a woman receiving magnesium sulfate rather than relying only on blood levels to guide dosing. You are probably already aware of the common signs of increasing magnesium levels, such as diminished reflexes and decreased respiratory rate. However, there are some subtle clues you can also watch for that may suggest either the therapeutic or toxic range. When a woman's magnesium level is in the therapeutic range, she usually has some slurring of speech, awkwardness of movement, and decreased appetite. If the woman is slow to arouse, has slow/shallow respirations, or begins to have difficulty swallowing and begins to drool, she may be approaching the toxic range.

Antihypertensive agents are used to keep the diastolic blood pressure between 90 and 100 mm Hg, thus avoiding a potential reduction in uteroplacental blood flow or cerebral perfusion. The drugs used to achieve this goal are 5 to 10 mg bolus of hydralazine hydrochloride every 15 minutes to a maximum of 20 mg IV or 20 mg bolus of labetalol intravenously, followed by 20 to 80 mg every 10 minutes as needed to a maximum dose of 300 mg. An IV infusion of 1–2 mg/minute can be used in lieu of intermittent therapy. Nifedipine and nicardipine are oral options (McCoy & Baldwin, 2009).

During a seizure, fetal bradycardia, transient late decelerations, decreased variability, or compensatory tachycardia may occur. Stabilizing the mother can help the fetus recover in utero. If the fetal heart tracing remains nonreassuring for more than 10 to15 minutes despite maternal and fetal resuscitative efforts, emergency birth should be considered. An eclamptic seizure increases uterine irritability and may cause a precipitous birth. Therefore a minimum ratio of one nurse to one patient is imperative to assess fetal and maternal status. Although she may still be unconscious, the woman should be observed for onset of labor. The woman is also observed for signs of placental separation (see chapter 26 ∞). She should be checked every 15 minutes for vaginal bleeding, which may or may not be present with abruptio placentae. The abdomen is palpated for uterine rigidity.

Following a seizure, frequent auscultation of maternal lungs is required to assess for complications from aspiration and to rule out pulmonary edema, which is common in eclamptic patients. The woman is watched for circulatory and renal failure and for signs of cerebral hemorrhage. Furosemide (Lasix) may be given in low doses for pulmonary edema; digitalis may be given for circulatory failure. An indwelling Foley catheter is often inserted and intake and output are monitored hourly.

A woman may have a single convulsion or many convulsions, usually followed by a period of unresponsiveness. She may be combative and confused as she awakens, but having a

DRUG GUIDE Magnesium Sulfate

PREGNANCY RISK CATEGORY: B

OVERVIEW OF OBSTETRIC ACTION

Magnesium sulfate acts as a CNS depressant by decreasing the quantity of acetylcholine released by motor nerve impulses and thereby blocking neuromuscular transmission. This action reduces the possibility of convulsion, which is why magnesium sulfate is used in the treatment of preeclampsia. Because magnesium sulfate secondarily relaxes smooth muscle, it may decrease the blood pressure, although it is not considered an antihypertensive. Magnesium sulfate may also decrease the frequency and intensity of uterine contractions; as a result it is also used as a tocolytic in the treatment of preterm labor.

ROUTE, DOSAGE, FREQUENCY

Magnesium sulfate is generally given intravenously to control dosage more accurately and prevent overdosage. An occasional physician still prescribes intramuscular administration. However, it is painful and irritating to the tissues and does not permit the close control that IV administration does. The IV route allows for immediate onset of action. It must be given by infusion pump for accurate dosage.

FOR TREATMENT OF PREECLAMPSIA

Loading dose: 4–6 g magnesium sulfate is administered over a 20- to 30-minute period.

Maintenance dose: 2–3 g/hour via infusion pump (Habli & Sibai, 2008).

NOTE: Magnesium sulfate is excreted via the kidneys. Because women in preterm labor typically have normal renal function, they generally require higher levels of magnesium to achieve a therapeutic range than women who have preeclampsia and may have compromised renal function. Maintenance dose may need to be adjusted based on serum magnesium levels.

MATERNAL CONTRAINDICATIONS

Diagnosed maternal myasthenia gravis is the only absolute contraindication to the administration of magnesium sulfate (ACOG, 2008b). A history of myocardial damage or heart block is a relative contraindication to use of the drug because of the effects on nerve transmission and muscle contractility. Extreme care is necessary in administration to women with impaired renal function because the drug is eliminated by the kidneys, and toxic magnesium levels may develop quickly.

MATERNAL SIDE EFFECTS

Most maternal side effects are dose related. Lethargy and weakness related to neuromuscular blockade are common. Sweating, a feeling of warmth, flushing, and nasal congestion may be related to peripheral vasodilation. Other side effects include nausea and vomiting, constipation, visual blurring, headache, slurred speech, palpitations, and pulmonary edema. Signs of developing toxicity include depression or absence of reflexes, oliguria, confusion, respiratory depression, circulatory collapse, and respiratory paralysis. Rapid administration of large doses may cause cardiac arrest. A potential for uterine atony and postpartum hemorrhage may occur from magnesium's tocolytic effect. Magnesium can cause a rapid suppression of parathyroid hormone release which may cause a transient hypocalcemia. If symptoms of myoclonus, delirium, or EKG abnormalities are present, calcium gluconate should be administered.

EFFECTS ON FETUS/NEWBORN

The drug readily crosses the placenta. A transient decrease in fetal heart rate (FHR) baseline and variability may occur. In general, magnesium sulfate therapy does not pose a risk to the fetus. Ill effects in the newborn may actually be related to fetal growth retardation, prematurity, or perinatal asphyxia.

NURSING CONSIDERATIONS

1. Monitor the blood pressure closely during administration.
2. Monitor maternal serum magnesium levels as ordered (usually every 6–8 hours). Therapeutic levels are in the range of 4–8 mg/dl. Reflexes often disappear at serum magnesium levels of 9–12 mg/dl; respiratory depression may occur at levels of 14 mg/dl; cardiac arrest occurs at levels above 24–30 mg/dl.
3. Monitor respirations closely. If the rate is less than 12/minute, magnesium toxicity may be developing, and further assessments are indicated. Many protocols require stopping the medication if the respiratory rate falls below 12/minute.
4. Assess knee jerk (patellar tendon reflex) for evidence of diminished or absent reflexes. Loss of reflexes is often the first sign of developing toxicity. Also note marked lethargy or decreased level of consciousness and hypotension.
5. Determine urinary output. Output less than 30 ml/hour may result in the accumulation of toxic levels of magnesium.
6. If the respirations or urinary output fall below specified levels or if the reflexes are diminished or absent, no further magnesium should be administered until these factors return to normal.
7. The antagonist of magnesium sulfate is calcium. Consequently, an ampule of calcium gluconate should be available at the bedside. For respiratory paralysis or cardiac arrest, the usual dose is 1 g given IV over a period of about 3 minutes.
8. Monitor fetal heart tones continuously with IV administration.
9. Continue magnesium sulfate infusion for approximately 24 hours after birth as prophylaxis against postpartum seizures if given for preeclampsia.
10. If the mother has received magnesium sulfate close to birth, the newborn should be closely observed for signs of magnesium toxicity for 24–48 hours.

Note: Protocols for magnesium sulfate administration may vary somewhat according to agency policy. Consequently, individuals are referred to their own agency protocols for specific guidelines.

family member at her side helps to reduce her agitation. Also, it is important to avoid bright light, noises, and frequent disturbances. The most serious complication, cerebral hemorrhage, arises from uncontrolled hypertension. Loss of vision, which is usually temporary, is a sign of impending hemorrhage. IV options for the treatment of hypertension are hydralazine, labetalol, or nitroprusside. Nitroprusside has been restricted to hypertensive crises when childbirth is imminent and other medications have not worked. Fetal cyanide poisoning may occur if the drug is continued and birth is delayed. Use of nitroprusside requires an arterial line because of its quick action and profound effects on blood pressure.

INTRAPARTUM MANAGEMENT

Preeclampsia Labor may be induced by IV oxytocin when there is evidence of fetal maturity and cervical readiness. In very severe cases, cesarean birth may be necessary regardless of fetal maturity.

The woman may receive both IV oxytocin and magnesium sulfate simultaneously. Because magnesium sulfate has a depressant action on smooth muscle, uterine contractions may diminish, and labor may be augmented with oxytocin. Equipment and IV lines for both fluids must be checked frequently to ensure that they are being administered at the proper rate. Infusion pumps should be used to guarantee accuracy. Bags and tubing must be labeled carefully.

Narcotics may be given intravenously for pain relief in labor. An epidural, spinal, or combined spinal-epidural can be safely administered to the woman with preeclampsia in the absence of thrombocytopenia. Hypotension is a major concern and can be avoided by careful attention to technique and careful volume expansion. The woman with preeclampsia is in total body fluid overload but has a depleted intravascular volume, making her prone to hypotension when the vascular bed dilates in response to epidural/spinal administration.

Childbirth in the Sims' position should be considered. If the lithotomy position is used, a wedge should be placed under the right buttock to displace the uterus. The wedge should also be used if birth is by cesarean. Oxygen is administered to the woman during labor if the need is indicated by fetal response to the contractions.

Eclampsia If not in a tertiary care center, the woman with eclampsia is cared for in an intensive care unit until labor begins or is induced. Invasive hemodynamic monitoring of either central venous pressure (CVP) or pulmonary artery wedge pressure (PAWP) may be instituted using a Swan-Ganz catheter. Both these procedures carry risk to the woman, and the decision to use them should be made judiciously. Invasive hemodynamic monitoring may be indicated for the woman with the following (ACOG, 2008b):

- Oliguria
- Severe cardiac disease
- Severe renal disease
- Pulmonary edema resulting in impaired maternal oxygenation
- Refractory hypertension with administration of a vasoactive drug, such as nitroprusside or dopamine

When the woman's vital signs have stabilized, urinary output is good, and the maternal and fetal hypoxic and acidotic states are alleviated, birth of the fetus should be considered. Birth is the only known cure for preeclampsia-eclampsia. If the newborn will be preterm, it may be necessary to transfer the woman to a tertiary center for childbirth. The woman and her partner deserve careful explanation about the status of the fetus and woman and the treatment they are receiving. Plans for childbirth and further treatment must be discussed with them.

A pediatrician, neonatologist, or neonatal nurse practitioner must be available to care for the newborn at birth. This caregiver must be aware of all amounts and times of medication the woman has received during labor.

POSTPARTUM MANAGEMENT The woman with preeclampsia usually improves rapidly after childbirth, although seizures can still occur during the first 48 hours postpartum. A woman who has required magnesium sulfate antepartally will continue to receive the infusion for about 24 hours postpartum. Antihypertensive medication may also be required for a period of time.

Postpartum nurses should be acutely aware of the possibility of a worsening of the maternal condition in the immediate postpartum period. The potential for HELLP syndrome, liver rupture, or seizure continues. Some women may develop late postpartum eclampsia (seizures occurring more than 48 hours but less than 4 weeks postpartum). Thus it is important to provide education as to the warning signs of worsening disease prior to discharge.

When a woman's blood pressure remains above 150/100 mm Hg for 2 to 3 days postpartum, antihypertensive therapy should be used. Blood pressure should then be monitored at least weekly during the postpartum period. If blood pressure fails to return to normal by 12 weeks' postpartum, further evaluation is indicated to rule out underlying causes for hypertension.

In general, the recurrence rate of preeclampsia is approximately 18% in subsequent pregnancies, but the risk of recurrence depends upon several factors (Habli & Sibai, 2008). The rate is substantially higher in women with multiple gestations, early-onset preeclampsia-eclampsia, previous HELLP syndrome, preexisting hypertension, renal disease, or underlying vascular disease. Women who were normotensive in a previous pregnancy are at increased risk when they conceive with a new partner. Also, in vitro fertilization using donor eggs and/or donor sperm has a higher incidence of preeclampsia (Wiggins & Elliott, 2005).

Selective screening should be done for inherited coagulopathies (clotting disorders) in women who have had early-onset preeclampsia or a poor pregnancy history related to repeated miscarriages, intrauterine growth restriction, fetal demise, or prior history of a thrombotic event. An association between hyperhomocysteinemia and preeclampsia has been found. There is controversy surrounding the association of other hereditary thrombophilias and preeclampsia (Lockwood & Bauer, 2009). However, this information is important in patient counseling and management not only related to future pregnancies, but also to assess the woman's risk for thrombotic episodes outside of pregnancy.

NURSING CARE MANAGEMENT

See the Nursing Care Plan: The Woman with Preeclampsia for information on nursing care.

Nursing Assessment and Diagnosis

An essential part of nursing assessment is to obtain a baseline blood pressure early in pregnancy. Arterial blood pressure varies with position and is highest when the woman is sitting, intermediate when she is supine, and lowest when she is in the left lateral recumbent position. Therefore it is important that the woman be in the same position when the blood pressure is measured each visit.

Blood pressure is taken and recorded at each antepartal visit. If the blood pressure rises or if the normal slight decrease in blood pressure expected between 8 and 28 weeks of pregnancy does not occur, the woman should be followed closely.

Blood pressure elevations should be based on at least two determinations not more than 1 week apart. To minimize errors in blood pressure measurements and improve reproducibility, the following precautions should be taken when measuring blood pressure:

- Take blood pressure measurements while the woman is seated, with feet supported and her arm at the level of the heart.
- Use Korotkoff phase V (sound disappearance) to measure the diastolic pressure.
- Calibrate the mercury sphygmomanometer and use the nearest 2 mm measurement.
- If using an electronic device, use one that has been validated for pregnancy.

When blood pressure and other signs indicate that the preeclampsia is worsening, hospitalization is necessary to monitor the woman's condition closely. The nurse then assesses the following:

- ***Blood pressure.*** Blood pressure should be determined every 1 to 4 hours, more frequently if indicated by medication or other changes in the woman's status.
- ***Temperature.*** Temperature should be determined every 4 hours, every 2 hours if elevated or if premature rupture of the membranes (PROM) has occurred.
- ***Pulse and respirations.*** Pulse rate and respirations should be determined along with blood pressure.
- ***Fetal heart rate.*** The FHR should be determined with the blood pressure or monitored continuously with the electronic fetal monitor if the situation indicates.
- ***Urinary output.*** Every voiding should be measured. Frequently, the woman will have an indwelling catheter. In this case, hourly urine output can be assessed. Output should be 700 ml or greater in 24 hours or at least 30 ml per hour.
- ***Urine protein.*** Urinary protein is determined hourly if an indwelling catheter is in place or with each voiding. Readings of 3+ or 4+ indicate loss of 5 g or more protein in 24 hours.
- ***Urine specific gravity.*** Specific gravity of the urine should be determined hourly or with each voiding. Readings over 1.040 correlate with oliguria and proteinuria.
- ***Edema.*** The face (especially eyelids and cheekbone area), fingers, hands, arms (ulnar surface and wrist), legs (tibial surface), ankles, feet, and sacral area are inspected and palpated for edema. The degree of pitting is determined by pressing over bony areas.
- ***Weight.*** The woman is weighed daily at the same time, wearing the same robe or gown and slippers. Weighing may be omitted if the woman is to maintain strict bed rest, or a bed scale may be used.
- ***Pulmonary edema.*** The woman is observed for coughing, shortness of breath, or difficult breathing. The lungs are auscultated for moist respirations.
- ***Deep tendon reflexes.*** The woman is assessed for evidence of hyperreflexia in the brachial, wrist, patellar, or Achilles tendons (Table 20-2). The patellar reflex is the easiest to assess. (See Procedure 20-1: Assessing Deep Tendon Reflexes and Clonus.)
- ***Clonus.*** Clonus should also be assessed by vigorously dorsiflexing the woman's foot while her knee is held in a flexed position. Normally no clonus is present. If it is present, it is measured as one to four beats, or sustained, and is recorded as such.
- ***Placental separation.*** The woman should be assessed hourly for vaginal bleeding and/or uterine rigidity.
- ***Headache.*** The woman should be questioned about the existence and location of any headache.
- ***Visual disturbance.*** The woman should be questioned about any visual blurring or changes, including scotomata. The results of the daily funduscopic exam should be recorded on the chart.
- ***Epigastric pain.*** The woman should be asked about any epigastric pain. It is important to differentiate it from simple heartburn, which tends to be familiar and less intense. *Nausea and vomiting or right upper quadrant pain,* occasionally radiating to the back, are also of concern.
- ***Laboratory blood tests.*** Daily tests of hematocrit to measure hemoconcentration; BUN, creatinine, and uric acid levels to assess kidney function; clotting studies for any indication of thrombocytopenia or disseminated intravascular coagulation (DIC); liver enzymes; and electrolyte levels for deficiencies are all indicated.
- ***Level of consciousness.*** The woman is observed for alertness, mood changes, and any signs of impending convulsion or coma.
- ***Emotional response and level of understanding.*** The woman's emotional response should be carefully assessed so that support and teaching can be planned accordingly.

TABLE 20-2 Deep Tendon Reflex Rating Scale

RATING	ASSESSMENT
4+	Hyperactive; very brisk, jerky, or clonic response; abnormal
3+	Brisker than average; may not be abnormal
2+	Average response; normal
1+	Diminished response; low normal
0	No response; abnormal

NURSING CARE PLAN The Woman with Preeclampsia

INTERVENTION	RATIONALE
1. Nursing Diagnosis: Deficient Fluid Volume related to fluid shift from intravascular to extravascular space secondary to vasospasm **Goal:** Patient is restored to normal fluid volume levels.	
■ Encourage woman to lie in the left lateral recumbent position.	■ The left lateral recumbent position decreases pressure on the vena cava, thereby increasing venous return, circulatory volume, and placental and renal perfusion. Angiotensin II levels are decreased when there is improved renal blood flow, which helps to promote diuresis and lower blood pressure.
■ Assess blood pressure every 1 to 4 hours as necessary.	■ Frequent monitoring will assess for progression of the disorder and allow for early intervention to ensure maternal and fetal health and well-being.
■ Monitor urine for volume and proteinuria every shift or every hour per agency protocol.	■ Monitoring provides information to assess renal perfusion. Proteinuria is the last cardinal sign of preeclampsia to appear. As the disorder worsens, the capillary walls of the glomerular endothelial cells stretch, allowing protein molecules to pass into the urine. Normally urine does not contain protein. Reading of 3+ and 4+ indicate loss of 5 g or more protein in 24 hours. Urinary output decreases when there is a reduction of the glomerular filtration rate. Urinary output that falls below 30 ml per hour or less than 700 ml in a 24-hour period should be reported.
■ Assess deep tendon reflexes and clonus.	■ Hyperreflexia may occur as preeclampsia worsens. Eliciting deep tendon reflexes provides information about CNS status and is also used to assess for magnesium sulfate toxicity. Reflexes are graded on a scale of 0 to 4+ using the Deep Tendon Reflex Rating Scale. A rating of 4+ is abnormal and indicates hyperreflexia. A rating of 0 or no response is also abnormal and is seen with high maternal serum magnesium levels. Clonus, an abnormal finding, is present if the foot "jerks" or taps the examiner's hand, at which time the examiner counts the number of taps or beats. The presence of clonus indicates a more pronounced hyperreflexia and is indicative of CNS irritability.
■ Assess for edema.	■ Edema develops as fluid shifts from the intravascular to the extravascular spaces. Edema is assessed either by weight gain (more than 3.3 lb/month in the second trimester or more than 1.1 lb/week in the third trimester) or by assessing for pitting edema (assessed by using finger pressure to a swollen area, usually the lower extremities, and grading on a scale of 1+ to 4+).
■ Administer magnesium sulfate per infusion pump as ordered.	■ As preeclampsia worsens, the risk of an eclamptic seizure increases. Magnesium sulfate is the treatment of choice for seizures because of its CNS depressant action. As a secondary effect, magnesium sulfate relaxes smooth muscles and may therefore decrease the blood pressure. Magnesium sulfate is contraindicated in women with myasthenia gravis.
■ Assess for magnesium sulfate toxicity.	■ Side effects of magnesium sulfate are dose related. Therapeutic levels are in the range of 4.8–8.4 mg/dl. As maternal serum magnesium levels increase, toxicity may occur. Signs of toxicity include decreased or absent DTRs, urine output below 30 ml/hr, respirations below 12, and confusion.
■ Provide a balanced diet that includes 80–100 g/day or 1.5 g/kg/day of protein.	■ A diet rich in protein is necessary to replace protein that is excreted in the urine.
EXPECTED OUTCOME:	The signs and symptoms of preeclampsia will diminish as evidenced by decreased blood pressure, urine protein levels of zero, and a return of the deep tendon reflexes to normal.

(continued)

NURSING CARE PLAN The Woman with Preeclampsia continued

INTERVENTION	RATIONALE
2. Nursing Diagnosis: Risk for Injury (to the Fetus) related to uteroplacental insufficiency secondary to vasospasm **Goal:** The fetus avoids complications related to uteroplacental insufficiency.	
■ Instruct patient to count fetal movements 3 times a day for 20 to 30 minutes.	■ Fetal activity provides reassurance of fetal well-being. Decrease in fetal movement or cessation of movement may indicate fetal compromise.
■ Encourage patient to rest in the left lateral recumbent position.	■ Lying in the left lateral recumbent position decreases pressure on the vena cava, which increases venous return, circulatory volume, and placental and renal perfusion. Blood flow to the fetus is increased, thereby reducing the risk of fetal hypoxia and malnutrition.
Collaborative: Assist with serial ultrasounds.	■ Maternal vasospasm and hypovolemia result from preeclampsia, which may lead to intrauterine growth restriction and oligohydramnios. Ultrasound provides assessment of fetal growth and fluid levels.
■ Perform nonstress test as ordered.	■ A nonstress test is performed to assess the fetal heart rate in response to fetal movement. Accelerations of fetal heart rate with fetal movement may indicate the fetus has adequate oxygenation and an intact central nervous system. (Refer to chapter 21 ∞ for interpretation of NST results.)
■ Describe for the woman the purposes of a biophysical profile (BPP).	■ Preeclampsia or eclampsia places the woman at risk for uteroplacental insufficiency due to the loss of normal vasodilation of uterine arterioles and maternal vasospasm. This results in decreased uteroplacental perfusion, which may lead to fetal hypoxia. A BPP is one assessment tool used to evaluate fetal well-being. Providing explanation of the diagnostic test helps relieve anxiety and ensures the woman understands what the test evaluates and what the results mean.
■ Assist with amniocentesis to obtain lecithin/sphingomyelin (L/S) ratio.	■ Women with preeclampsia may give birth before term. Amniotic fluid may be analyzed to determine the maturity of the fetal lungs. An L/S ratio of 2:1 or greater indicates fetal lung maturity and is usually achieved by 35–36 weeks' gestation.
■ Explain the purpose of Doppler flow studies.	■ Doppler flow studies (umbilical velocimetry) help to assess placental function and sufficiency. Uteroplacental insufficiency is a risk for a woman with preeclampsia. If fetal growth restriction is present, Doppler velocimetry of the umbilical artery is useful for fetal surveillance.
EXPECTED OUTCOME:	The fetus will have an adequate supply of oxygen and nutrients as evidenced by absence of signs of nonreassuring fetal status and fetal diagnostic test results within normal limits.
3. Nursing Diagnosis: Ineffective Health Maintenance related to deficient knowledge about new diagnosis (preeclampsia) **Goal:** The woman will describe the condition and treatment regimen.	
■ Assess the woman and the family's understanding of preeclampsia and its implications for pregnancy.	■ This assessment provides information about the woman's cognitive level and her understanding of her diagnosis. Behavior changes occur when teaching strategies are appropriate for the woman and family's cognitive level.
■ Provide information about the disease process, impact on maternal well-being, risks of progression, implications for the fetus, and dangers of eclampsia.	■ Basic understanding of the condition and its implications is necessary for the woman to understand the treatment plan. A woman who shows signs of early preeclampsia often feels well and may have difficulty accepting the need to rest.
■ Emphasize the importance of self-monitoring for signs that her condition is worsening and the importance of regular prenatal care for the purpose of maternal and fetal surveillance.	■ The woman should be able to identify signs of disease progression, including evidence of increasing edema, decreased urine output, signs of cerebral disturbance (frontal headache, blurred vision, scotomata), epigastric or right upper quadrant pain, nausea or vomiting, and increased irritability.
EXPECTED OUTCOME:	Woman will demonstrate understanding of preeclampsia and its implications as evidenced by verbalization of basic condition, signs and symptoms of progression, importance of sufficient rest in side-lying position, and need to follow prescribed diet.

PROCEDURE 20-1 Assessing Deep Tendon Reflexes and Clonus

NURSING ACTION

Preparation

- Explain the procedure, indications for its use, and information that will be obtained.
- Check the patellar reflex and one other such as the biceps, triceps, or brachioradialis.

  Rationale: *DTRs are assessed to gain information about CNS irritability secondary to preeclampsia and to assess the effects of magnesium sulfate if the woman is receiving it.*

Equipment and Supplies

- Percussion hammer

> **CLINICAL TIP**
> If a percussion hammer is not available, you may use the side of your stethoscope or the side of your hand or the tips of the index and middle fingers to elicit DTRs.

Procedure

1. Elicit reflexes.
   - Patellar reflex. Position the woman with her legs hanging over the edge of the bed (feet should not be touching the floor). (See Figure 20-7 ■.) Briskly strike the patellar tendon, which is located just below the patella. Normal response is extension or a thrusting forward of the foot.

   Note: In an inpatient setting the patellar reflex is often assessed while the woman lies supine. Flex her knees slightly and support them.

   Rationale: *The correct position causes the muscle to be slightly stretched. Then when the tendon is stretched, with a tap the muscle should contract. Correct positioning and technique are essential to elicit the reflex.*

Figure 20-7 ■ Correct position for eliciting patellar reflex: sitting.
Source: Photographer, Elena Dorfman.

   - Biceps reflex. Flex the woman's arm 45 degrees at the elbow and place your thumb on the biceps tendon. Allow your fingers to hold the biceps muscle. Strike your thumb in a slightly downward motion and assess the response. Normal response is flexion of the arm.
   - Triceps reflex. Flex the woman's arm up to 90 degrees and allow her hand to hang against the side of her body. Using the percussion hammer, strike the triceps tendon just above the elbow. Normal response is contraction of the muscle, which causes extension of the arm.
   - Brachioradialis reflex. Flex the woman's arm slightly and lay it on your forearm with her hand slightly pronated. Using the percussion hammer, strike the brachioradialis tendon, which is found about 1 to 2 inches above the wrist. Normal response is pronation of the forearm and flexion of the elbow.
2. Grade reflexes. Reflexes are graded on a scale of 0 to 4+, as follows:

   4+ Hyperactive; very brisk, jerky, or clonic response; abnormal

   3+ Brisker than average; may not be abnormal

   2+ Average response; normal

   1+ Diminished response; low normal

   0 No response; abnormal

   Rationale: *Normally reflexes are 1+ or 2+. With CNS irritation, hyperreflexia may be present; with high magnesium levels, reflexes may be diminished or absent.*
3. Assess for clonus. With the woman's knee flexed and the leg supported, vigorously dorsiflex the foot, maintain the dorsiflexion momentarily, and then release (Figure 20-8 ■). With a normal response, the foot returns to its normal position of plantar flexion. Clonus is present if the foot "jerks" or taps against the examiner's hand. If so, record the number of taps or beats of clonus.

   Rationale: *Clonus occurs with more pronounced hyperreflexia and indicates CNS irritability.*
4. Report and record findings. For example: DTRs 2+, no clonus or DTRs 4+, 2 beats clonus.

Figure 20-8 ■ To elicit clonus, sharply dorsiflex the foot.
Source: Photographer, Elena Dorfman.

PROFESSIONALISM IN PRACTICE

Measuring Blood Pressure

Common errors in measuring blood pressure include the following:

- Incorrect cuff size—a cuff that is too small results in a falsely elevated BP, whereas one that is too large falsely lowers BP.
- Elevating the arm above the level of the heart, such as occurs when a woman lies on her left side using her right arm for a BP measurement, will falsely lower the BP 10 to 20 mm Hg.
- Korotkoff's phase—when BP is checked during pregnancy, the disappearance of the sound (phase V) is the preferred indicator rather than the muffling of the sound (phase IV).
- Anxiety, exercise, and smoking can elevate BP. Wait 10 minutes after the woman's arrival to check a resting BP.

In addition, the nurse continues to assess the effects of any medications administered. Because the administration of prescribed medications is an important aspect of care, the nurse is, of course, familiar with the more commonly used medications, their purpose, implications, and associated untoward or toxic effects.

Examples of nursing diagnoses that may apply for the pregnant woman with preeclampsia-eclampsia include the following:

- ***Deficient Fluid Volume*** related to fluid shift from the intravascular to extravascular space secondary to vasospasm and endothelial injury
- ***Risk of Injury*** related to convulsion secondary to cerebral edema
- ***Anxiety*** related to uncertain maternal and fetal status

Nursing Plan and Implementation

Community-Based Nursing Care

Case Study: Patient with Preeclampsia

A woman with preeclampsia has several major concerns. She may fear losing the fetus. She may worry about the impact of separation on her relationships with her husband and children should she be hospitalized. She may be concerned about finances—health insurance does not always cover all the tests, prolonged hospitalization, and other expenses that may be associated with complications during pregnancy. Finally, the woman may be depressed or resentful about being left alone or may feel bored. If she has small children, she may have difficulty providing for their care. The woman who does not have children may worry that she never will.

The nurse should identify and discuss each of these areas with the woman and her partner. It is necessary to explain to them the reasons for bed rest. A woman with mild preeclampsia may feel very well and be unable to see the need for resting even a few hours a day. The nurse can refer the couple to many community resources, such as homemaking services, a support group for the partner, or a hotline. Arrangements may be made for the partner to attend childbirth classes alone if the mother is not able to, or a nurse may be found to teach the classes privately. In addition, childbirth classes can be accessed over the Internet, thereby enabling the couple to participate together even if the woman is limited to bed rest at home.

The woman needs to know which symptoms are significant and should be reported at once. Usually, the woman with mild preeclampsia is seen once or twice a week, but she may need to come in earlier if symptoms indicate the condition is progressing. She must understand her diet plan, which must match her culture, finances, and lifestyle.

Hospital-Based Nursing Care

The development of worsening preeclampsia is a cause for increased concern to the woman and her family. The most immediate concerns of the woman and her partner usually are about the prognosis for herself and the fetus. The nurse can offer honest, hopeful information. The nurse can also explain the plan of therapy and the reasons for procedures to the extent that the woman or her partner is interested. The nurse should keep the couple informed of the fetal status and should also take the time to discuss other concerns the couple may express. The nurse provides as much information as possible and seeks other sources of information or aid for the family as needed. Nurses can offer to contact a member of the clergy or counselor for additional support if the couple so chooses. In addition, the nurse can provide educational videos that help address the couple's educational needs and access other support services including social services, a nutritionist, and even a lactation consultant if the woman is hospitalized for an extended period of time.

The nurse should maintain a quiet, low-stimulus environment for the woman. The woman should be placed in a private room in a quiet location where she can be watched closely. Visitors are limited to close family or main support persons. The woman should maintain the left lateral recumbent position most of the time, with side rails up for her protection. Unlimited phone calls are avoided because the phone ringing unexpectedly may be too jarring. To avoid a sense of isolation, however, some women find it preferable to limit calls to a certain time of the day rather than refusing all calls.

Nursing Management of Eclampsia

The occurrence of a convulsion is frightening to any family member who may be present, although the woman will not be able to recall it when she becomes conscious. Therefore, offering explanations to family members, and to the woman herself later, is essential.

When the tonic phase of the convulsion begins, the woman should be turned to her side (if she is not already in that position) to aid circulation to the placenta. Her head should be turned face down to allow saliva to drain from her mouth. Attempting to insert a padded tongue blade has been questioned, and in many facilities it is no longer advocated. In others, it is used if it can be done without force because it may prevent injury to the woman's mouth. The side rails should be padded or a pillow put between the woman and each side rail. After 15 to 20 seconds, the clonic phase starts. In approximately 30 to 90 seconds, when the thrashing subsides, intensive monitoring and therapy begin. An oral airway is inserted, the woman's nasopharynx is suctioned, and oxygen administration is begun by nasal catheter. The attending physician and the anesthesiologist should be notified immediately. Fetal heart tones are monitored

continuously. Maternal vital signs are monitored every 5 minutes until they are stable, then every 15 minutes.

Nursing Management During Labor and Birth

The plan of care for the woman with preeclampsia in labor depends on both maternal and fetal condition. The woman may have mild or severe preeclampsia, may become eclamptic during labor, or may have been eclamptic before the onset of labor. Therefore, careful monitoring of blood pressure and checking for edema and proteinuria are necessary for all women in labor. The prenatal record should be obtained so that current blood pressure readings may be compared with the baseline reading from early in her pregnancy.

The woman with preeclampsia in labor is kept positioned on her side as much as possible. Both woman and fetus are monitored carefully throughout labor. Signs of progressing labor are noted. In addition, the nurse must be alert for indications of worsening preeclampsia, placental separation, pulmonary edema, circulatory renal failure, and nonreassuring fetal status.

During the second stage of labor the woman is encouraged to push while lying on her side or with a wedge under her hip. If she is unable to do so comfortably or effectively, she can be helped to a semisitting position for pushing and resume the lateral position between each contraction. Birth is in the side-lying position if possible. If the lithotomy position is used, a wedge is placed under the woman's hip.

A family member is encouraged to stay with the woman as long as possible throughout labor and childbirth. This is especially needed if the woman has been transferred to a high-risk center from another facility. The woman in labor and the family member or support person should be oriented to the new surroundings and kept informed of progress and plan of care. When possible the woman should be cared for by the same nurses throughout her hospital stay.

Nursing Management During the Postpartum Period

The amount of postpartum vaginal bleeding should be noted carefully. Because the woman with preeclampsia is hypovolemic, even normal blood loss can be serious. Rising pulse rate and falling urine output are late indications of excessive blood loss. The uterus should be palpated frequently and massaged when needed to keep it contracted.

Blood pressure and pulse are checked every 4 hours for 48 hours. Hematocrit, platelets, uric acid, AST, and ALT may be measured daily. The woman is instructed to report any headache, visual disturbance, or epigastric pain. No ergot preparations, such as Methergine, are given because they have a hypertensive effect. Intake and output recordings are continued for 48 hours postpartum. Increased urinary output within 48 hours after birth is a highly favorable sign. With the diuresis, edema recedes and blood pressure returns to normal.

Postpartum depression can develop after the long ordeal of a difficult pregnancy. Family members are urged to visit, and as much mother-infant contact as possible should be allowed. There may be fears about a future pregnancy. The couple needs information about the chance of preeclampsia occurring again. They also should be given family-planning information. Combined oral contraceptives may be used if the woman's blood pressure has returned to normal by the time they are prescribed (usually 4 to 6 weeks postpartum). Progesterone-only pills may be prescribed regardless of hypertension and may be a good alternative for women with chronic hypertension or for those women who are breastfeeding.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to explain preeclampsia, its implications for her pregnancy, the treatment regimen, and possible complications.
- The woman suffers no eclamptic seizures.
- The woman and her caregivers detect signs of increasing severity of the preeclampsia or possible complications early so that appropriate treatment measures can be instituted.
- The woman gives birth to a healthy newborn.

Chronic Hypertension

Chronic hypertension exists when the blood pressure is 140/90 or higher before pregnancy or before the 20th week of gestation or persists 42 days following childbirth. If the diastolic blood pressure is greater than 80 mm Hg during the second trimester, chronic hypertension should be suspected. For the majority of chronic hypertensive women, the disease is mild. One of the challenges the healthcare team faces is differentiating chronic hypertension from preeclampsia. This is even more difficult if a woman arrives for her first prenatal visit during the second trimester when blood pressure is generally lower and preexisting hypertension is more difficult to recognize.

Early prenatal care is important to determine accurately the gestational age and the severity of hypertension. Adverse maternal and neonatal outcomes are increased in women with chronic hypertension, even if they do not develop superimposed preeclampsia. (Catov, Nohr, Olsen, et al., 2009; Chappell et al., 2008). These risks include fetal growth restriction, preterm birth, and cesarean birth, as well as the associated economic burden of longer maternal hospitalization and neonatal intensive care admission.

At the time of the first visit, the woman should be counseled on several aspects of her pregnancy:

- ***Nutrition.*** Sodium is limited to about 2.4 g per day; the woman is advised about recommended weight gain and healthy food choices.
- ***Bed rest.*** Frequent rest periods are advisable. At a minimum, the woman should rest twice a day for 1-hour periods of time.
- ***Medication.*** Studies have shown that women with mild chronic hypertension have outcomes similar to the general maternity population. Therefore, unless the blood pressure is over 150–160/100–110 mm Hg, antihypertensive medications are not used during pregnancy. Methyldopa or Labetalol are generally the first choice for use in pregnancy when medication is required. Angiotensin-converting enzyme (ACE) inhibitors are contraindicated during the 2nd and 3rd trimesters due to fetal risks of renal failure, IUGR, and death (ACOG, 2008a).

- ***Prenatal visits.*** Counseling regarding the importance of frequent prenatal visits to reduce the incidence of adverse outcomes for mother or fetus is stressed.
- ***Blood pressure monitoring.*** The woman and her partner can be taught how to monitor blood pressure at home and maintain a record to be brought to each prenatal visit. Home monitoring is often more accurate because the woman is in a familiar environment and relaxed.
- ***Fetal surveillance.*** Starting at about 24 weeks, the woman should begin to keep fetal movement records and notify her care provider of any significant decrease in fetal movement. Serial ultrasonography to assess fetal growth and amniotic fluid volume is indicated. Antepartum fetal testing may begin as early as 26 weeks.

During the first prenatal visit, the woman should have a thorough physical examination, which includes a funduscopic examination, blood pressure and pulses in all four extremities, and auscultation of chest and flanks. Laboratory work includes a urinalysis and culture; 24-hour urine for protein, creatinine clearance, sodium, and potassium; CBC; serum electrolytes; and a glucose tolerance test. The usual prenatal laboratory assessments and an ultrasound for confirming gestational age are also done if the woman is currently pregnant. Although essential hypertension is the most likely explanation for hypertension in early pregnancy, a thorough evaluation can rule out rare but serious causes of secondary hypertension such as pheochromocytoma or coarctation of the aorta.

A woman with chronic hypertension generally has more frequent prenatal visits. She should be seen every 2 to 3 weeks in the first two trimesters and then more frequently in the third trimester, depending on how she and the fetus are progressing. Twenty-four-hour urines, serum creatinine, uric acid, hematocrit, and ultrasound examinations are repeated at least once in the second and third trimesters.

Chronic Hypertension with Superimposed Preeclampsia

Preeclampsia develops in approximately 22% of women previously found to have chronic hypertension (Chappell et al., 2008). The development of superimposed preeclampsia can be difficult to diagnose. After 20 weeks' gestation the onset of proteinuria and worsening hypertension is suggestive of superimposed preeclampsia (ACOG, 2008a). If the woman has underlying renal disease, it may be very difficult to confirm the diagnosis of superimposed preeclampsia. A rise in serum uric acid is helpful in identifying preeclampsia, which frequently occurs late in the second trimester or early in the third.

Gestational Hypertension

Gestational hypertension exists when transient elevation of blood pressure occurs for the first time after midpregnancy without proteinuria or other signs of preeclampsia. The final determination that the woman has gestational hypertension is made in the postpartum period. If preeclampsia does not develop and blood pressure returns to normal by 12 weeks' postpartum, the diagnosis of gestational hypertension may be assigned. If the blood pressure elevation persists after 12 weeks' postpartum, the woman is diagnosed with chronic hypertension.

CLINICAL JUDGMENT

Case Study: Jillian Rundus

Jillian Rundus is a 31-year-old G1P0 who is 35 weeks' pregnant. She presents for a routine office visit with complaints of nausea and abdominal pain rating 7/10. She has had a headache and general malaise for 2 days. She denies visual changes. Upon examination, you find her to be alert and oriented and her physical exam is unremarkable with the exception of abdominal tenderness and a blood pressure of 170/110. She has had no previous history of hypertension. Fetal heart rate ranges from 140–150 beats per minute.

Critical Thinking

What should the nurse do at this time?

See www.nursing.pearsonhighered.com for possible responses.

Care of the Woman at Risk for Rh Alloimmunization

The Rh blood group is present on the surface of erythrocytes of most of the population. When it is present a person is said to be Rh positive. Those without the factor are Rh negative. If an Rh-negative person is exposed to Rh-positive blood, an antigen-antibody response occurs, antibodies are formed, and the person is said to be *sensitized.* Subsequent exposure to Rh-positive blood can then cause a serious reaction that results in agglutination and hemolysis of red blood cells (RBCs). Rh *alloimmunization* (sensitization), also called *isoimmunization,* most often occurs when an Rh-negative woman carries an Rh-positive fetus either to term or to termination by miscarriage or induced abortion. It can also occur if an Rh-negative nonpregnant woman receives an Rh-positive blood transfusion, experiences an Rh-positive tubal pregnancy, has an amniocentesis, or experiences any traumatic event that might allow Rh-positive fetal cells to enter the circulation of the Rh-negative woman.

A number of known RBC antigens are involved in the Rh system, all of which are controlled by three pairs of genes: Cc, Dd, and Ee. Antigens in the D group are usually involved with incompatibility between the mother and fetus, although there are more than 400 other "atypical" RBC antigens, and at least 43 have the potential to cause hemolytic disease of the fetus or newborn (Lobo, Nardozza, & Camano, 2006).

In the United States, only about 6 of every 1000 live births is complicated by maternal sensitization to the D red cell antigen (Moise, 2008a). Approximately 85% of white Americans, 92% to 95% of African Americans, and 98% to 99% of Asian and Native Americans are Rh positive (ACOG, 2006a). Screening of the Rh negative woman for D antibodies is widely accepted. The use of **Rh immune globulin** has resulted in a marked decrease in the prevalence of alloimmunization to the RhD antigen in pregnancy. However, some "atypical" antibodies can also cause fetal hemolysis. No prophylaxis is available to prevent the formation of other red cell antigens. Kell (anti-K1) antibody is an irregular (non-RhD) antibody in which the incidence is increasing (Moise, 2008a). It has been calculated that alloimmunization associated

with Kell occurs in approximately one of every 1000 pregnancies (Santiago, Ramos-Corpas, Oyonarte, et al., 2008). The Kell (K-1) antigen is found on the red cells of 9% of Caucasians and 2% of those of African descent. In the United States, current transfusion practices do not include the use of Kell negative blood. Two-thirds of the women sensitized to Kell have a history of previous blood transfusion that can be attributed to the etiology of their sensitization. In the case of Kell alloimmunization, unlike the pathogenesis of other antibodies, the mechanism that contributes to fetal and neonatal disease is the depression of fetal bone marrow. It appears that Kell alloimmunization can occur at lower maternal titers than the titers for D alloimmunization (critical titer 1:8 versus 1:16 for anti-D antibody) (Moise, 2008a).

Pathophysiology of RhD Alloimmunization

During a normal pregnancy, small amounts of fetal blood may cross the placenta. An Rh-negative mother whose fetus is Rh positive may develop anti-D antibodies in response to this exposure. During delivery of the placenta or as a result of trauma, even larger quantities of fetal blood can enter maternal circulation. After exposure to the Rh-positive antigen, the primary immune response is development of immunoglobulin M (IgM) antibodies. This primary response develops slowly over several weeks or months with a detectable titer developing 5 to 16 weeks after the sensitizing event. IgM antibodies are large and do not cross the placenta. Once a woman develops these antibodies, she is immunized for life.

Fetal RBCs express the RhD antigen at 38 days after conception. Although the risk is very low, in theory it is possible for RhD sensitization to occur during the first trimester. Fetal-maternal hemorrhage can occur with elective pregnancy termination, hemorrhage from an early threatened or spontaneous abortion, chorionic villus sampling, or ectopic pregnancy. Although the risk of sensitization is low and the evidence to support the use of Rh immune globulin in the first trimester is sparse, the reproductive implications of sensitization and the safety of Rh immune globulin makes it reasonable to treat Rh-negative women if the partner's blood type is not confirmed to be Rh negative. Following the primary response, a subsequent exposure to the RhD cells results in a more rapid production of immunoglobulin G (IgG) anti-D antibodies, developing as quickly as a few days after exposure. IgG is capable of crossing the placenta and coating the fetal RhD positive red cells, causing hemolysis. This secondary immune response may occur with exposure to a very small amount of RhD positive cells and produce a response stronger than the primary response (Figure 20-9 ■). Thus, although hemolysis is not generally a

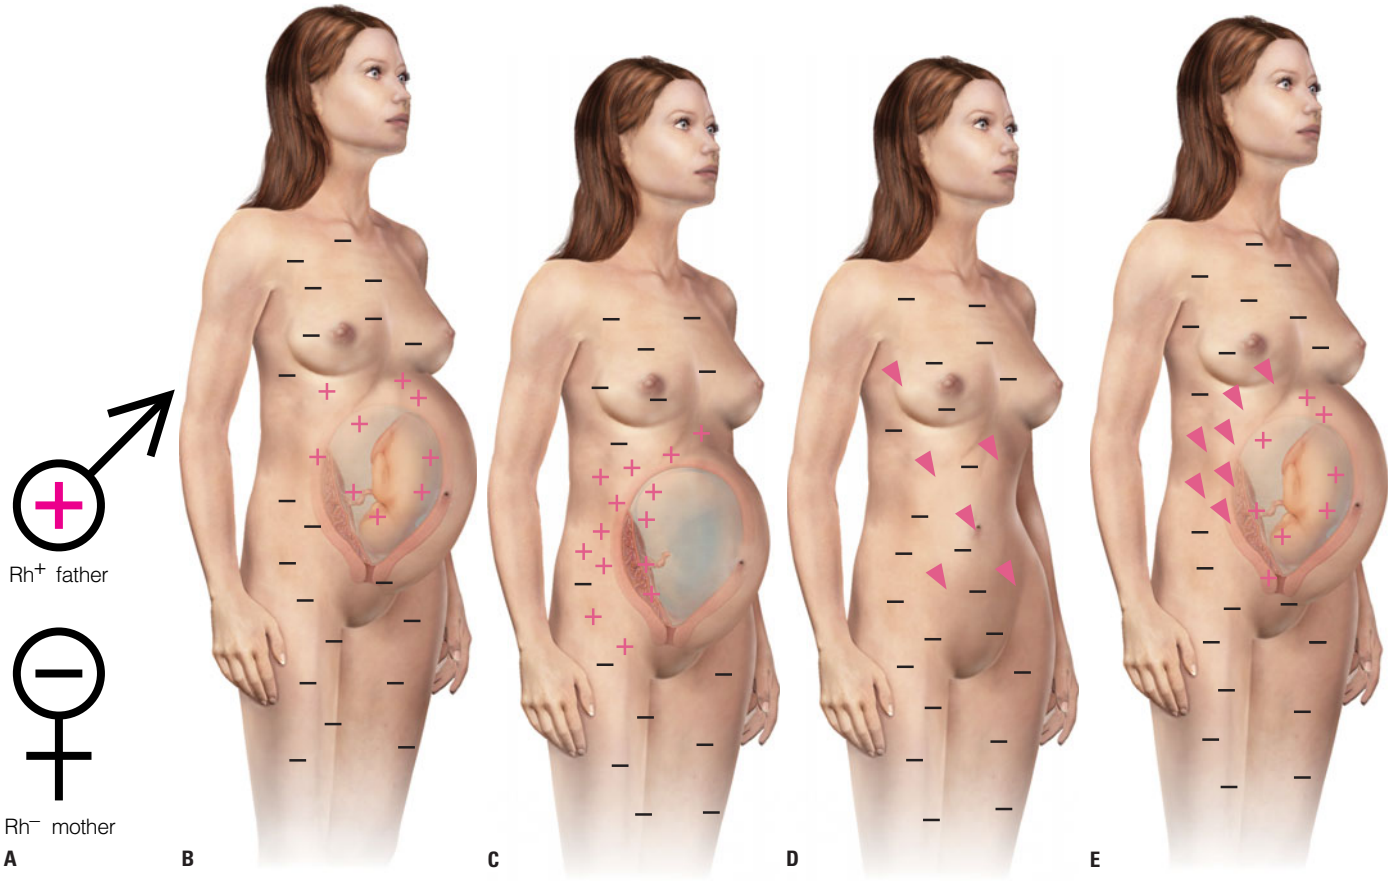

Figure 20-9 ■ Rh alloimmunization sequence. A. Rh-positive father and Rh-negative mother. B. Pregnancy with Rh-positive fetus. Some Rh-positive blood enters the mother's blood. C. As the placenta separates, the mother is further exposed to the Rh-positive blood. D. The mother is sensitized to the Rh-positive blood; anti-Rh-positive antibodies (triangles) are formed. E. In subsequent pregnancies with an Rh-positive fetus, Rh-positive red blood cells are attacked by the anti-Rh-positive maternal antibodies, causing hemolysis of red blood cells in the fetus.

problem for the fetus during a first pregnancy, it may create problems during subsequent pregnancies. There also may be an increased risk for fetal anemia when multiple maternal antibodies to other red cell antigen groups (collectively referred to as "irregular antibodies") are present as compared with anti-D antibodies alone. Specifically, the presence of anti-C, anti-E, and anti-e have an additive effect to that of the anti-D antibody on the fetus (Moise, 2008a).

The possibility also exists that an Rh-negative female fetus carried by an Rh-positive mother may become sensitized in utero. This female would not demonstrate signs of hemolytic disease, but because she would be sensitized before even becoming pregnant, she would have a positive antibody screen when receiving prenatal care with her first Rh-positive fetus. Mismatched blood transfusion of Rh-positive blood to an Rh-negative person can also result in sensitization. To prevent sensitization after exposure to Rh-positive blood, Rh immune globulin is administered.

Fetal-Neonatal Risks

The hemolysis caused by the maternal IgG antibodies in the fetus creates fetal anemia. The fetus responds by increasing RBC production. The presence of nucleated RBCs (erythroblasts) is why the term **erythroblastosis fetalis** was coined for this severe hemolytic disease of the fetus and newborn. If treatment is not initiated, this anemia can also cause marked fetal edema, called **hydrops fetalis**. Congestive heart failure may result. Although maternal sensitization can now be prevented by appropriate administration of Rh immune globulin, infants still die of hemolytic disease secondary to Rh incompatibility.

RBC destruction also leads to hyperbilirubinemia and jaundice (called *icterus gravis*), which can lead to neurologic damage (kernicterus).

Rh sensitization and the resultant hemolytic disease of the newborn are less common today because of the development of RhIgG. See chapter 34 ∞ for further discussion of kernicterus and of treatment of the newborn affected by Rh sensitization.

Screening for Rh Incompatibility and Sensitization

At the first prenatal visit, (1) a history is taken of past pregnancies, previous sensitization, abortions, blood transfusions, or children who developed jaundice or anemia during the neonatal period; (2) maternal blood type (ABO) and Rh factor are determined, and a routine Rh antibody screen is done; and (3) other medical complications, such as diabetes, infections, or hypertension, are identified. An antibody screen (*indirect Coombs' test*) is done to determine whether an Rh-negative woman is sensitized (has developed isoimmunity) to the Rh antigen. The indirect Coombs' test measures the number of antibodies in the maternal blood.

Occasionally, sensitization may occur antepartally because of small transplacental bleeds. To detect this, if the Rh-negative woman is not D-isoimmunized, a repeat D antibody determination should be made at 28 weeks' gestation. If it is negative, 300 mcg Rh immune globulin are administered prophylactically.

If the woman is Rh negative (dd), the father of the unborn child is asked to come into the clinic or physician's office to be assessed for his Rh factor and blood type. If he is homozygous for Rh positive (DD), all his offspring will be Rh positive. If he is heterozygous (Dd), 50% of his offspring will be Rh negative and 50% heterozygous for Rh positive. If the father is Rh negative, all their children will be Rh negative, and no Rh incompatibility with the mother will occur. If the father is Rh positive or the mother is known to have previously carried an Rh-positive fetus, further testing and careful management are needed.

In women who are alloimmunized, anti-D antibody titers should be determined every 2 to 4 weeks beginning at 16 to 18 weeks, biweekly during the third trimester, and the week before the due date. Traditionally, if the test shows a maternal antibody titer of 1:16 or greater, a delta optical density (ΔOD) analysis of the amniotic fluid is performed. (See later discussion.) If the titer is 1:16 or less late in pregnancy, birth at 38 weeks or spontaneous labor at term can be anticipated.

Negative antibody titers can consistently identify the fetus not at risk. However, the titers cannot reliably point out the fetus in danger because the level of the titer does not correlate with the severity of the disease. For instance, in a severely sensitized woman antibody titers may be moderately high and remain at the same level although the fetus is being more and more severely affected. Conversely, a woman sensitized by previous Rh-positive fetuses may show a high fixed antibody titer during a pregnancy in which the fetus is Rh negative. Fetal assessment includes Doppler measurement of the peak systolic velocity measurement of the middle cerebral artery, percutaneous umbilical cord blood sampling (PUBS), amniocentesis, amniotic fluid analysis, and ultrasound. Previously, PUBS was the only direct method of assessing the Rh status of a fetus. This procedure requires a highly skilled physician and places the fetus at greater risk than does an amniocentesis. It is now possible, however, to determine fetal Rh status from an amniotic fluid specimen using polymerase chain reaction (PCR). In Europe, fetal Rh genotyping from maternal blood is available and has been shown to be highly accurate. This is about to become common practice (Rouillac-Le Sciellour et al., 2007; Van der Schoot, Hahn, & Chitty, 2008). As the methodology improves, DNA typing of the fetus will clearly replace amniocentesis for this purpose.

Ideally, an early ultrasound should be done to determine gestational age. Thereafter serial ultrasounds and amniotic fluid analysis should be done to follow fetal progress. The presence of ascites and subcutaneous edema are signs of severe fetal involvement (fetal hydrops). Other indicators of the fetal condition include an increase in fetal heart size, hydramnios, and placental thickness and texture. Ultrasound evaluation cannot distinguish mild from severe fetal anemia unless hydropic changes are present. When RBCs are hemolyzed, bilirubin is a breakdown product. If fetal RBCs are being hemolyzed because of isoimmunization, the fetus may excrete bilirubin in the amniotic fluid with voiding. Historically, management of Rh disease was done with ΔOD analysis to determine the amount of bilirubin pigment found in the amniotic fluid. Normally the concentration of bilirubin pigments in the amniotic fluid declines during pregnancy. Elevated bilirubin levels are significant. Because the amount of bilirubin found in the amniotic fluid correlates roughly with the extent of the hemolysis, the

ΔOD analysis serves as an indirect predictor of the severity of the fetal anemia. To determine the ΔOD level, amniotic fluid, obtained by transabdominal amniocentesis, is separated from its cellular components by centrifuge. The amount of bilirubin pigment from the degradation of RBCs can then be measured by spectrophotometric analysis and plotted on a special chart called a Liley graph.

Readings within zone III (the highest zone) indicate a severely affected fetus who may require intrauterine transfusion every 1 to 2 weeks between weeks 26 and 32 until viability is reached, followed by birth, usually by cesarean. Neonatal exchange transfusion is anticipated. Prognosis is guarded. Fetal monitoring may identify the very ill fetus by documenting less movement or lack of movement. The appearance of sinusoidal pattern suggests fetal anemia and a deteriorating fetal condition (see chapter 23 ∞).

A new approach has replaced the use of the traditional technique of serial amniocentesis and ΔOD in the management of alloimmunized pregnancies. It is the use of velocimetry of the fetal middle cerebral artery (MCA) to monitor affected pregnancies for the detection of fetal anemia (ACOG, 2006a). It is believed that the decreasing fetal red cell mass and concurrent decrease in blood viscosity will result in an increase in fetal cardiac output. This, in turn, increases the velocity of the flow through the middle cerebral artery, which is demonstrated by an increase in the peak systolic velocities of the middle cerebral artery (PSV of MCA) (Pickelsimer et al., 2007). The noninvasive method of using Doppler ultrasonography to monitor fetal anemia via the measurement of the PSV of the MCA has been shown to be accurate and much safer than amniocentesis for detecting fetal anemia. PSVs correlate well with increasing levels of bilirubin in the amniotic fluid and should be monitored weekly (Moise, 2008b) (Figure 20-10 ■).

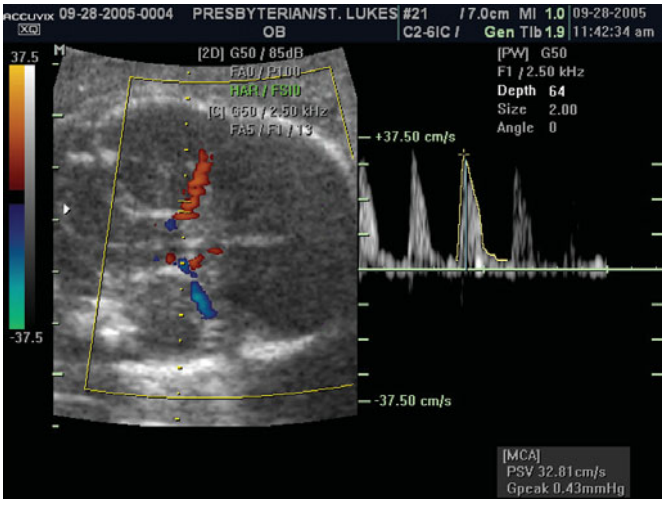

Figure 20-10 ■ Ultrasound measurement of peak systolic velocity (PSV) of the middle cerebral artery. The fetal middle cerebral arteries can be seen as major lateral branches of the circle of Willis and may be used during pregnancy to detect either fetal anemia or a fetal response to hypoxia as redistribution of cardiac output in favor of the brain, myocardium, and adrenal glands. This image demonstrates a flow velocity wave form and displays the normal continuous forward blood flow in the fetal cerebral arteries throughout the cardiac cycle. Normal peak systolic velocity values change throughout gestation, increasing with advancing gestational age. In the case of fetal anemia, the velocity of blood will be increased above the norms for gestational age. The PSV in the middle cerebral artery of this fetus is 32.81 cm/s, which is appropriate for this gestational age.

Clinical Therapy

The goal of medical management is the birth of a mature fetus who has not developed severe hemolysis in utero. This requires early identification and treatment of maternal conditions that predispose the infant to hemolytic disease, coordinated obstetric-pediatric treatment for the seriously affected newborn, and prevention of Rh sensitization if none is present.

Antepartum Management

Four Rh immune globulin products are now available: RhoGAM (the first approved for clinical use) and HyperRHO, which are administered intramuscularly, and Rhophlac and WinRho-SDF, which can be administered intramuscularly or intravenously. When the woman is Rh negative and not sensitized and the father is Rh positive or unknown, Rh immune globulin is given prophylactically at 28 weeks' gestation. It is also given after each spontaneous or induced abortion, ectopic pregnancy, chorionic villus sampling, multifetal pregnancy reduction, partial molar pregnancy, amniocentesis, PUBS, antepartum hemorrhage, fetal death in the second or third trimester, blunt trauma to the maternal abdomen, or external cephalic version.

Whether sensitization is the result of a blood transfusion or maternal-fetal hemorrhage for any reason, a Kleihauer-Betke or rosette test can be performed to determine the amount of Rh(D) positive blood present in the maternal circulation and to calculate the amount of Rh immune globulin needed. The standard dose of Rh immune globulin (300 mcg) can prevent sensitization after exposure of up to 30 ml of Rh(D) positive fetal whole blood or 15 ml of red cells. Up to five doses of Rh immune globulin can be administered in a 24-hour period. Should a large dose be required, it may be preferable to use one of the intravenous forms to avoid multiple injections (Moise, 2007).

Two primary interventions are used by the physician to aid the fetus whose blood cells are being destroyed by maternal antibodies: early birth of the fetus and intrauterine transfusion, both of which carry risks. Ideally, birth should be delayed until fetal pulmonary maturity is confirmed at about 36 to 37 weeks. Severely sensitized fetuses may require birth at 32 to 34 weeks. The use of Doppler ultrasonography of the PSV of the MCA, when properly performed, is an accurate predictor of fetal anemia. After 35 weeks' gestation, the false positive rate for the prediction of anemia increases, but in the presence of normal PSV of the MCA, weekly measurements can continue until the induction of labor is scheduled (Moise, 2008b).

Intrauterine transfusion is done to correct the anemia produced by the RBC hemolysis and thereby improve fetal oxygenation. This may be done either intravascularly through PUBS or intraperitoneally as early as 18 weeks. In a fetus who shows no signs of hydrops, a fetal blood sample should be used

to check for significant anemia (hematocrit greater than 30%) before starting transfusion therapy.

Intravascular transfusion has greatly improved the outcome for severely affected fetuses. Under ultrasound visualization, the umbilical vein is entered, and the fetus is temporarily paralyzed with 0.1 mg/kg estimated fetal weight of pancuronium bromide. A fetal hematocrit is obtained; then leukocyte-poor Rh-negative packed red blood cells (PRBCs) are transfused. The volume of PRBCs is determined by a formula based on estimated normal blood volume, the pretransfusion hematocrit, the hematocrit of the blood to be transfused, and the desired hematocrit. Repeat transfusions can be scheduled as necessary until the fetus is sufficiently mature to tolerate birth. If access to the umbilical vein is problematic, intrauterine transfusions can be performed by introducing the needle into the fetal abdomen and peritoneal cavity. Blood is transfused through a catheter into the peritoneal cavity, where diaphragmatic lymphatics absorb the RBCs into fetal circulation.

About 80% to 90% of transfused fetuses survive. The procedure poses risks for the fetus, however. Complications include nonreassuring fetal status, fetal hematoma, fetal-maternal hemorrhage, fetal death, and chorioamnionitis. Birth is delayed until at least 32 weeks' gestation if possible. Premature newborns are generally more susceptible to damage from hemolytic disease. They often require exchange transfusion and usually require intensive nursery care.

Postpartum Management

The goals of postpartum care are to prevent sensitization in the as-yet-unsensitized pregnant woman and to treat the isoimmune hemolytic disease in the newborn.

The Rh-negative mother who has no titer (indirect Coombs' negative, nonsensitized) and who has given birth to an Rh-positive fetus (direct Coombs' negative) is given an intramuscular injection of 300 mcg Rh immune globulin within 72 hours so that she does not have time to produce antibodies to fetal cells that entered her bloodstream when the placenta separated. This protocol reduces the incidence of antenatal sensitization dramatically. Rh immune globulin works to destroy the fetal cells in the maternal circulation before sensitization occurs, thereby blocking maternal antibody production. This provides temporary passive immunity for the mother, which prevents the development of permanent active immunity (antibody formation). The normal dose of Rh immune globulin should suppress the immune response to approximately 30 ml Rh-positive whole blood. As discussed previously, if a larger fetomaternal bleed might have occurred, a Kleihauer-Betke test can be performed to obtain an estimate of the extent of the bleed and the dose of Rh immune globulin can be increased as necessary.

Rh immune globulin is not given to the newborn or the father. It is not effective for and should not be given to a previously sensitized woman. However, sometimes after childbirth or an abortion, the results of the blood test do not clearly show whether the mother is already sensitized to the Rh antigen. In such cases, Rh immune globulin should be given because it will cause no harm.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

As part of the initial prenatal history the nurse asks the mother whether she knows her blood type and Rh factor. Many women are aware that they are Rh negative and that this status has implications for pregnancy. If the woman knows she is Rh negative, the nurse can assess the woman's knowledge of what that means. The nurse can also ask the woman whether she ever received Rh immune globulin, whether she has had any previous pregnancies and their outcome, and whether she knows her partner's Rh factor. Should the partner be Rh negative, there is no risk to the fetus, who will also be Rh negative. Uncertain paternity is an awkward situation; nevertheless, it is essential for the physician to have this information. Nurses often have a more intimate relationship with pregnant women, allowing them to obtain sensitive information that is vital in the management of pregnancy. When paternity is uncertain or the father is unavailable for testing, the fetus is assumed to be antigen positive until proven otherwise.

If the woman does not know what Rh immune type she is, intervention cannot begin until the initial laboratory data are obtained. If the woman is Rh negative, the father's blood type and zygosity, if he is Rh positive, are obtained. Once that is complete, the nurse plans intervention based on the findings.

If the woman becomes sensitized during her pregnancy, nursing assessment focuses on the knowledge level and coping skills of the woman and her family. The nurse also provides ongoing assessment during procedures to evaluate fetal well-being, such as ultrasound and amniocentesis.

Postpartally, the nurse reviews data about the Rh type of the fetus. If the fetus is Rh positive, the mother is Rh negative, and no sensitization has occurred, nursing assessment reveals the need to administer Rh immune globulin within 72 hours of birth. If inadvertently the dose of RhIgG is not given within the 72-hour window, some protection has been documented with administration within 13 days. The recommendation is to administer the dose up to 28 days after birth. Nursing diagnoses that might apply to the pregnant woman at risk for Rh sensitization include the following:

- ***Readiness for Enhanced Knowledge (Information About the Purpose of RhIgG)*** related to an expressed desire to understand the treatment of Rh incompatibility
- ***Ineffective Coping*** related to depression secondary to the development of indications of the need for fetal exchange transfusion

Nursing Plan and Implementation

During the antepartum period, the nurse explains the mechanisms involved in isoimmunization and answers any questions the woman and her partner may have. It is imperative that the woman understand the importance of receiving Rh immune globulin after every spontaneous or therapeutic abortion or ectopic pregnancy if she is not already sensitized. The nurse also

> "I've been a nurse for almost 40 years now. I remember when RhoGAM first started to be used—what a difference it made in the lives of so many women. Young women who are Rh negative today will hopefully never know the pain and tragedy the simple absence of a blood factor can mean. It is nothing short of miraculous!"

explains the purpose of the Rh immune globulin administered at 28 weeks if the woman is not sensitized.

If the woman is sensitized to the Rh factor, it poses a threat to any Rh-positive fetus she carries. The nurse provides emotional support to the family to help them deal with their grief and any feelings of guilt about the infant's condition. Should an intrauterine transfusion become necessary, the nurse continues to provide emotional support while also assuming responsibilities as part of the healthcare team.

During labor, the nurse caring for an Rh-negative woman who has not been sensitized ensures that the woman's blood is assessed for any antibodies and also has been crossmatched for Rh immune globulin. On the postpartum unit, the nurse generally is responsible for administering the Rh immune globulin (see Procedure 20-2: Administration of Rh Immune Globulin [RhoGAM, HyperRHO, Rhophlac, and WinRho-SDF]).

Table 20-3 summarizes the major considerations in caring for an Rh-negative woman. The treatment of the newborn with isoimmune hemolytic disease is discussed in chapter 34 ∞.

TABLE 20-3 Rh Sensitization

When trying to work through Rh problems, the nurse should remember the following:

- A potential problem exists when an Rh-negative mother and an Rh-positive father conceive a child who is Rh positive.
- In this situation, the mother may become sensitized or produce antibodies to her fetus's Rh-positive blood.

The following tests are used to detect sensitization:

- Indirect Coombs' tests—done on the mother's blood to measure the number of Rh-positive antibodies.
- Direct Coombs' test—done on the infant's blood to detect antibody-coated Rh-positive RBCs.

Based on the results of these tests, the following may be done:

- If the mother's indirect Coombs' test is negative and the infant's direct Coombs' test is negative (confirming that sensitization has not occurred), the mother is given Rh immune globulin within 72 hours of birth.
- If the mother's indirect Coombs' test is positive and her Rh-positive infant has a positive direct Coombs' test, Rh immune globulin is *not* given; in this case, the infant is carefully monitored for hemolytic disease.
- It is recommended that Rh immune globulin be given at 28 weeks antenatally to decrease possible transplacental bleeding concerns.
- Rh immune globulin is also administered after each abortion (spontaneous or therapeutic), antepartum hemorrhage mismatched blood transfusion, ectopic pregnancy, amniocentesis, chorionic villus sampling (CVS), percutaneous umbilical blood sampling (PUBS), fetal cephalic version, or maternal trauma.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to explain the process of Rh sensitization and its implications for her unborn child and for subsequent pregnancies.
- If the woman has not been sensitized, she is able to explain the importance of receiving Rh immune globulin when necessary and cooperates with the recommended dosage schedule.
- The woman gives birth to a healthy newborn.
- If complications develop for the fetus (or newborn), they are detected quickly, and therapy is instituted.

Care of the Woman at Risk Due to ABO Incompatibility

ABO incompatibility is somewhat common (occurring in 15% to 25% of pregnancies) but rarely causes significant hemolysis (Black & Maheshwari, 2009). In most cases, ABO incompatibility is limited to type O mothers with a type A or B fetus. The group B fetus of a group A mother and the group A fetus of a group B mother are only occasionally affected. Group O infants, because they have no antigenic sites on the RBCs, are never affected regardless of the mother's blood type. The incompatibility occurs as a result of the maternal antibodies present in her serum and interaction between the antigen sites on the fetal RBCs.

Anti-A and anti-B antibodies are naturally occurring; that is, women are naturally exposed to the A and B antigens through the foods they eat and through exposure to infection by gram-negative bacteria. As a result, some women have high serum anti-A and anti-B titers before they become pregnant. Once the woman becomes pregnant, the maternal serum anti-A and anti-B antibodies cross the placenta and produce hemolysis of the fetal RBCs. With ABO incompatibility, the first infant is frequently involved, and no relationship exists between the appearance of the disease and repeated sensitization from one pregnancy to the next.

Unlike the case of Rh incompatibility, treatment is never warranted antepartally. As part of the initial assessment, however, the nurse should note whether the potential for an ABO incompatibility exists. This alerts caregivers so that following birth the newborn can be assessed carefully for the development of hyperbilirubinemia (see chapter 34 ∞). Affected neonates usually have only mild anemia and the severity of the disease demonstrated with the first-born infant is generally similar in all subsequent pregnancies (Black & Maheshwari, 2009).

Care of the Woman Requiring Surgery During Pregnancy

Although elective surgery should be delayed until the postpartum period, essential surgery can generally be undertaken during pregnancy. Approximately 1 in 500 pregnant women requires general surgery (Dietrich, Hill, & Hueman, 2008. Surgery does pose some risks. The incidence of spontaneous

PROCEDURE 20-2 Intramuscular Administration of Rh Immune Globulin (RhoGAM, HyperRHO, Rhophlac, WinRho-SDF)

NURSING ACTION

Preparation

- Confirm that Rh immune globulin is indicated by checking the woman's prenatal or intrapartal record to verify that she is Rh negative. Then confirm that sensitization has not occurred—maternal indirect Coombs' negative. Postpartally, confirm that the baby is Rh positive but not sensitized (direct Coombs' negative) and that the mother's indirect Coombs' is negative. Rh immune globulin is *not* indicated if the infant is Rh negative, too.

  Rationale: *Rh immune globulin is only indicated for Rh-negative, unsensitized women.*

- Confirm that the woman does not have a history of allergies to immune globulin preparations by checking entries on medication allergies in her chart and by asking her whether she has ever had any allergic reactions to medications, globulins, or blood products.

  Rationale: *Rh immune globulin is made from the plasma portion of blood. Allergic reactions are possible.*

- Explain purpose and procedure. Have consent form signed if required by agency policy.

  Rationale: *Many agencies require separate consent for the administration of Rh immune globulin because it is a blood product. The woman should clearly understand the purpose of the Rh immune globulin, its rationale, the administration procedure, and any related risks. Generally the primary side effects are redness and tenderness at the injection site and allergic responses.*

Equipment and Supplies

- Rh immune globulin, which is obtained from the blood bank or pharmacy according to agency protocol. Lot numbers for the drug and the cross-match should be the same.
- Syringe and IM needle

Procedure

1. Confirm the woman's identity and administer one vial of 300 mcg Rh immune globulin IM in the deltoid muscle.

   Rationale: *The normal 300-mcg dose provides passive immunity following exposure to 15 ml of transfused RBCs or 30 ml of fetal blood.*

2. An immune globulin microdose is used after miscarriage, elective abortion, ectopic pregnancy, or molar pregnancy occurring within the first 12 weeks' gestation. Antepartally, the Rh immune globulin is generally given within 3 hours but not longer than 72 hours of the event.
3. If a larger bleed is suspected at birth (as in cases of severe abruptio placentae), additional doses may be administered at one time using multiple sites at regular intervals as long as all doses are given within 72 hours of childbirth.
4. Provide opportunities for the woman to ask questions and express concerns.

   Rationale: *Many women, especially primigravidas, are not aware of the risks for an Rh-positive fetus of a sensitized Rh-negative mother. They need to understand the importance of receiving Rh immune globulin for each pregnancy to ensure continued protection.*

5. Chart according to agency policy. Most agencies chart lot number, route, dose, and patient education.

CLINICAL TIP

In most cases, Rh immune globulin is administered in the deltoid muscle. However, in an extremely thin woman, or in the cases of a larger-than-normal dose, consider administering the medication in the ventrogluteal or posterior gluteal site. You may also divide the dose into multiple injections. Both Rhophlac and WinRho-SFD may be administered intravenously.

abortion is increased for women who have surgery in the first trimester. The risks to the pregnancy can be significantly reduced when surgery can be delayed until the second trimester or to the postpartum period. Surgery during the third trimester is difficult because of the enlarging uterus and an increased risk of preterm labor.

The most common nonpregnancy-related indications for surgical treatment are appendicitis, cholecystitis, bowel obstruction, melanoma, ovarian disorders, breast or cervical disease, or trauma (Dietrich, Hill, & Hueman, 2008). Although general preoperative and postoperative care are similar for pregnant and nonpregnant women, special considerations must be kept in mind whenever the surgical patient is pregnant. The early second trimester is the best time to operate because there is less risk of causing spontaneous abortion or early labor, and the uterus is not so large as to impinge on the abdominal field.

The preoperative chest radiograph and electrocardiogram, which are routine for persons over age 40, should be done on the same basis for the pregnant woman. If a chest radiograph is done, the fetus should be shielded from the radiation. Because of decreased intestinal motility and decreased free gastric acid secretion during pregnancy, stomach emptying time is delayed, which increases risk of vomiting during induction of anesthesia and during the postoperative period. Therefore, a nasogastric tube may be recommended before major surgery. An indwelling urinary catheter prevents bladder distention, decreases risk of injury to the bladder, and promotes ease of monitoring output. Sequential compression devices (SCDs) or support stockings during and after surgery help prevent venous stasis and the development of thrombophlebitis. Fetal heart tones must be monitored before, during, and after surgery.

Pregnancy causes increased secretions of the respiratory tract and engorgement of the nasal mucous membrane, often making breathing through the nose difficult. Because of this, pregnant women often need an endotracheal tube for respiratory support during surgery. Caregivers must guard against maternal hypoxia during surgery because uterine circulation will be decreased and fetal oxygenation can decline very quickly.

During surgery and the recovery period, the woman is positioned to allow optimal uteroplacental-fetal circulation. A wedge is placed under her hip to tip the uterus and thereby avoid pressure by the fetus on the maternal vena cava.

Spinal or epidural anesthesia is preferred because local anesthetics are not associated with birth defects. Caution must be exercised because this type of anesthesia may produce hypotension and respiratory apnea in the pregnant woman. The frequency and degree of the hypotension increase with higher anesthetic levels. This can be prevented in many cases with a preanesthetic infusion of 900 to 1000 ml of fluid.

Blood loss during surgery is monitored carefully. Measurement of fetal heart tones gives the best indication of blood loss. Because of the normal increased blood volume of pregnancy, uterine blood flow may be reduced significantly before the maternal blood pressure begins to fall. Fluid replacement should be done with balanced electrolyte solution and, if needed, with whole blood.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

During the preoperative period, the nurse assesses the pregnant woman's health status in the same way that any preoperative patient is assessed. Is there any sign of respiratory infection, fever, urinary tract infection, or anemia? Are laboratory values all within normal limits for surgery (except in the case of emergency surgery, which may, of necessity, be done even with abnormal laboratory values)? Do the woman and her family understand the surgical procedure? Do they know what to expect postoperatively? Do they have any questions or concerns?

The nurse also considers the impact of surgery on the woman's pregnancy. Is the fetal heart rate normal? Does the woman understand the implications of surgery with regard to her pregnancy? How is she coping?

Intraoperatively, fetal heart rate is assessed if at all possible. Postoperatively, the nurse completes all necessary postoperative assessments and also continues to assess fetal status, primarily by monitoring the fetal heart rate.

Nursing diagnoses that might apply to the pregnant woman who requires surgery include the following:

- ***Anxiety*** related to lack of knowledge of preoperative and postoperative procedures
- ***Fear*** related to the possible effect of surgery on fetal outcome

Nursing Plan and Implementation

Much of the nurse's care during the preoperative period is directed toward the educational needs of the woman and her family. The nurse plans time to review the procedure and answer any questions the family may have. The nurse recognizes that the need for surgery during the woman's pregnancy is probably very distressing for the family. The nurse works to help decrease their anxiety by providing information and emotional support.

Postoperatively, the nurse is caring for two patients: the mother and her unborn child. In addition to monitoring the status of both, the nurse considers both in providing care. If surgery is done in the first trimester, the nurse should be aware of the potential teratogenic effect of any medications prescribed and should discuss the implications with the surgeon and obstetrician. During the third trimester, the nurse, recognizing the potential for vena caval syndrome if the woman lies flat on her back, helps the woman maintain a side-lying position. To avoid inadequate oxygenation, the nurse encourages the woman to turn, breathe deeply, and cough regularly and also to use any ventilation therapy, such as incentive spirometry, to avoid developing pneumonia. The pregnant woman is also at increased risk for thrombophlebitis, so the nurse applies SCDs or antiembolism stockings, encourages leg exercises while the woman is confined to bed, and begins ambulation as soon as possible. In addition, the nurse encourages the woman to maintain or resume an adequate diet as soon as possible. If cultural factors influence the woman's dietary practices, the nurse and dietitian should work together to meet the woman's needs.

Discharge teaching is especially important. The woman and her family should have a clear understanding of what to expect regarding activity level, discomfort, diet, medications, and any special considerations. In addition, they ought to know any warning signs that they should report to their physician immediately.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to explain the surgical procedure, its risks and benefits, and its implications for her pregnancy.
- Caregivers maintain adequate maternal oxygenation throughout surgery and postoperatively.
- Potential complications are avoided or detected early and treated successfully.
- The woman is able to describe any necessary postdischarge activities, limitations, and follow-up and agrees to cooperate with the recommended regimen.
- The woman maintains her pregnancy successfully.

Care of the Woman Suffering Trauma from an Accident

Accidents and injury are the leading causes of death in women of reproductive age. Major trauma complicates 3% to 8% of all pregnancies (Brown, 2009). When the woman is critically injured, fetal death occurs at least 40% of the time (ACOG, 2006b). Approximately 66% to 75% of all traumas during pregnancy are the result of motor vehicle accidents, and these accidents are the leading cause of fetal and maternal death (ACOG, 2006b; Brown, 2009). Falls and assaults—including domestic violence—are the next most common causes of injury.

In early pregnancy, body changes increase the potential for injury through fatigue, fainting spells, and hyperventilation. Late in pregnancy, the woman has less balance and coordination

and may fall. Her protruding abdomen is vulnerable to a variety of minor injuries. The fetus is usually well protected by the amniotic fluid, which distributes the force of a blow equally in all directions, and by the muscle layers of the uterus and abdominal wall. In early pregnancy, while the uterus is still in the pelvis, it is shielded from blows by the surrounding pelvic organs, muscles, and bony structures. Trauma that causes concern includes blunt trauma, from an automobile accident, for example; penetrating abdominal injuries, such as knife or gunshot wounds; and the complications that commonly accompany maternal trauma, such as shock, premature labor, and spontaneous abortion.

The normal physiologic changes of pregnancy have clinical implications for victims of trauma. Blood volume increases by 40% to 50% and cardiac output increases 30% to 50% above prepregnant levels (Gordon, 2007). Generally, the pregnant woman has a greater volume of blood loss compared with a nonpregnant woman before evidence of shock is seen. The pregnant woman with significant volume loss is able to maintain hemodynamic stability temporarily by decreasing uteroplacental perfusion, thereby compromising fetal status. In the second and third trimesters, supine positioning can decrease blood return to the heart and cause overt hypotension and even loss of consciousness. During pregnancy, minute ventilation and oxygen consumption increase. This makes the gravid woman more susceptible to hypoxemia with apnea. Clotting factors normally increase in pregnancy, making it a hypercoagulable state. Thus, the risk of thrombosis after injury is increased. Disseminated intravascular coagulation (DIC) occurs commonly with severe trauma. Because the normal fibrinogen level in pregnancy is increased to between 350 and 400 mg/dl, normal nonpregnant values may indicate early DIC.

Maternal mortality most often occurs from head trauma or hemorrhage. Uterine rupture results from strong deceleration forces in an automobile accident in only 0.1% to 1% of pregnant women (ACOG, 2006b). All automobile passengers should wear seat belts. The small risk of uterine or placental injury from seat belt use is far outweighed by the fact that maternal death is the most common cause of fetal death. The use of seat belts by pregnant women has been shown to decrease morbidity and mortality of the mother. The National Highway Transportation Safety Administration recommends that pregnant women place the shoulder harness portion of the seatbelt over the collarbone between the breasts and the lap portion under the pregnant abdomen as low as possible on the hips and across the upper thighs (Brown, 2009). Traumatic separation of the placenta can occur even if the site of injury is remote from the abdomen. It results in a high rate of fetal mortality. Premature labor is another serious hazard to the fetus, often following rupture of membranes during an accident. Premature labor can ensue even if the woman is not injured.

Fractures of the pelvis can result in significant retroperitoneal hemorrhage. If there is an unstable or dislocated fracture of the pelvis, cesarean birth will probably be necessary, but with a slightly displaced pelvic fracture, vaginal birth may be attempted. Hematuria or difficulty placing a urinary catheter may be associated with injuries to the bladder or urethra.

Penetrating trauma includes gunshot wounds and stab wounds. The mother generally fares better than the fetus if the penetrating trauma involves the abdomen as the enlarged uterus is likely to protect the mother's bowel from injury. Unfortunately, the fetal injury rate is as high as 71% with gunshot wounds and 42% with stabbings (Brown, 2009).

Clinical Therapy

The goals of clinical therapy are to stabilize the injury and promote well-being for both mother and fetus. Thus clinical therapy initially focuses on ensuring airway adequacy, maintaining ventilation and adequate circulatory volume, controlling acute bleeding, and splinting fractures to prevent vascular or tissue injury. The Glascow Coma Scale is useful in evaluating for neurologic deficit. Once the mother is stabilized, fetal status is assessed.

Care must be taken at the scene of the injury to avoid the development of supine hypotensive syndrome. At approximately 20 weeks of gestation, compression of the inferior vena cava can result in a reduction of cardiac output when the woman is in a supine position. A wedge placed under the woman's right hip displacing the uterus to the left is critical in restoring cardiac output. A neck brace is used if a neck injury is suspected, or the woman is placed on a backboard and the entire board is tilted to displace the uterus. Prompt treatment of maternal hypotension or hypovolemia also averts poor fetal oxygenation. Obstetric consultation is necessary to ensure that the needs of both mother and fetus are met.

In cases of noncatastrophic trauma, that is, where the mother's life is not directly threatened, fetal monitoring for 4 hours should be sufficient if there is no vaginal bleeding, uterine tenderness, contractions, or leaking amniotic fluid. Abruptio placentae may occur following a blow to the abdomen as the flexible myometrium of the uterus sustains a contour-changing impact that the relatively inelastic placenta cannot match. The increased intrauterine pressure during the blow further shears the placenta from the underlying decidua basalis. Abruptio placentae may occur in up to 5% of women who sustain minor injuries and in up to 35% of women who sustain major abdominal trauma. Increased uterine irritability in the first few hours following trauma helps identify women who may be at high risk for this potentially catastrophic complication. Of those women who contract every 10 minutes or more, 20% will have placental abruption. Ultrasonography does not seem to be as sensitive as fetal monitoring for diagnosing abruptio placentae. In women who have experienced significant maternal trauma, most cases of placental abruption evolve within 24 hours. Placental abruption occurs in 40% or more of women who have sustained severe blunt abdominal trauma and in 3% of those who have sustained minor trauma (Brown, 2009). If the woman is bleeding, contracting, or has uterine tenderness or a nonreassuring fetal heart rate tracing, a 24- to 48-hour observation is recommended. If uterine contractions are fewer than every 10 minutes and bleeding is not present, with a reassuring fetal heart rate tracing, monitoring for 4 to 6 hours is probably sufficient (Brown, 2009).

Fetomaternal hemorrhage may occur and is more likely in women whose placenta is located on the anterior wall of her uterus (Brown, 2009). Fetal jeopardy from significant fetal

hemorrhage is generally accompanied by fetal tachycardia, loss of variability, or a sinusoidal fetal heart rate pattern. A Kleihauer-Betke test may be useful in helping identify unsensitized Rh-negative women who have experienced fetal-maternal bleeds due to trauma. Rh immune globulin should be given to any unsensitized Rh-negative woman to be certain she is covered for small fetal hemorrhages that may be below the sensitivity of the Kleihauer-Betke test.

There has been controversy about the use of beta-adrenergic tocolytics in pregnant women following trauma because of the concerns regarding hemodynamic instability and the potential for masking uterine irritability or contractions that forewarn of abruptio placentae. Radiographic studies should be performed as needed to evaluate injuries regardless of fetal exposure.

When cardiopulmonary resuscitation (CPR) is performed on the pregnant woman late in gestation, perimortem cesarean birth is advocated if CPR is unsuccessful in the first 4 minutes. Chest compressions are less effective in the third trimester because of compression of the inferior vena cava by the gravid uterus. Cesarean birth alleviates this compression and improves resuscitation efforts in both the fetus and the mother (Brown, 2009).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Each individual must be assessed according to the type and extent of her injuries. As with all trauma victims, initial assessments focus on adequacy of the airway, evidence of breathing, existence of cardiovascular stability, extent of injury, and a brief neurologic assessment. When an injured woman is pregnant, it is necessary to assess fetal status as well to avoid fetal hypoxia. Frequent maternal blood gas determinations are indicated if respiratory function is compromised.

Ongoing assessments include evaluation of uterine tone, contractions and tenderness, fundal height, fetal heart rate, intake and output and other indicators of shock, normal postoperative evaluation in those women requiring surgery, determination of neurologic status, and assessment of mental outlook and anxiety level.

Nursing diagnoses that might apply to the pregnant woman suffering trauma include the following:

- ***Acute Pain*** related to the effects of the trauma experienced
- ***Constipation*** related to immobility secondary to the effects of the accident
- ***Fear*** related to the effects of the trauma on fetal well-being

Nursing Plan and Implementation

As a member of the healthcare team the nurse is actively involved in the ongoing assessment of the status of the woman and fetus. The nurse also has a primary responsibility to assess the childbearing woman's emotional state. The trauma victim must be oriented to her situation and receive explanation and reinforcement as necessary to help her understand any interventions. Family members should be involved as appropriate. The nurse also gives the pregnant woman an opportunity to discuss her feelings and concerns.

Evaluation

Expected outcomes of nursing care include the following:

- The woman and her family are able to understand the effects of the trauma on her and on her unborn child.
- Adequate maternal oxygenation is maintained to ensure fetal well-being.
- The woman's pain is adequately relieved, and her trauma is treated.
- Potential complications are quickly identified, and appropriate interventions are instituted.
- The woman gives birth to a healthy newborn.
- If the trauma results in fetal demise, the woman is able to verbalize her feelings and begin working through the grief process.

Care of the Battered Pregnant Woman

The true extent of domestic violence during pregnancy is difficult to determine. Estimates suggest that violence during pregnancy affects up to 23% of women (AAP & ACOG, 2007b; Lutgendorf et al., 2009); however, these statistics are most likely understated because many victims are unwilling to disclose their experiences. In addition, child abuse occurs in 33% to 77% of families in which there is abuse of adults (AAP & ACOG, 2007b).

Domestic violence frequently has its onset during pregnancy, or increases if already present. Battering may result in psychologic distress, loss of pregnancy, preterm labor, low-birth-weight infants, injury to the fetus, and fetal death. Complications such as poor maternal weight gain, infection, anemia, and second and third trimester bleeding are also seen more frequently among pregnant women who are abused. Women who are battered may also experience sexual abuse and are at increased risk of contracting sexually transmitted infections from their partner. This pattern of violence may escalate during pregnancy and may occur even more frequently in the postpartum period. In some instances, abuse may decrease during pregnancy, and the woman feels safe while she is pregnant only to have the abuse resume shortly after childbirth. These women may repeatedly become pregnant to escape abuse (ACOG, 2009a). The first step toward helping the battered woman is to identify her. Regularly scheduled prenatal visits are a window of opportunity for domestic violence screening and intervention. The woman needs support, confidence in her decision making, and the recognition that she can help herself.

Chronic psychosomatic symptoms can be an indicator of abuse. The woman may have nonspecific or vague complaints. It is important to assess old scars around the head, chest, arms, abdomen, and genitalia. Any bruising or evidence of pain is also evaluated. The nurse should be especially alert for signs of bruising or injury to the woman's breasts, abdomen, or genitals because these areas are common targets of violence during pregnancy. Other indicators include a decrease in eye contact, silence when

the partner is in the room, and a history of nervousness, insomnia, drug overdose, or alcohol problems. Frequent visits to the emergency department and a history of accidents without understandable causes are possible indicators of abuse.

The goals of treatment are to identify the woman at risk, increase her decision-making abilities to decrease the potential for further abuse, and provide a safe environment for her and her unborn child. In a prospective observational study, investigators found that women who declined to be interviewed about domestic violence were found to be at greater risk for adverse pregnancy outcomes when compared with women who reported experiencing verbal or physical abuse. Twenty-seven percent of women who are abused and living in a violent environment will demonstrate abusive behaviors toward the children in that home (AAP & ACOG, 2007b).

Screening must be done in a private setting and by using direct questions. ACOG recommends that *all* women be screened for intimate partner violence. During pregnancy, women should be screened multiple times because they may not disclose abuse if they are asked only one time, or the abuse may begin later in pregnancy. The suggested schedule for screening is at the first prenatal visit, at least once per trimester, and at the postpartum visit. See chapter 9 ∞ for discussion of specific screening questions.

Once domestic violence is identified, the next step is to determine the immediate safety of the woman. She needs to be aware of community resources available to her, such as emergency shelters; police, legal, and social services; and counseling. It is important to establish an exit plan in situations of ongoing violence. Pocket cards and resource materials can be handed to women or left in restrooms for them to pick up. Nurses need to recognize that, ultimately, it is the woman's decision either to seek assistance or to return to old patterns. For further information, see chapter 9 ∞.

Care of the Woman with a Perinatal Infection Affecting the Fetus

Fetal infection may develop at any time during pregnancy. In general, perinatal infections are most likely to cause harm when the embryo is exposed during first trimester organ development. Infections later in pregnancy create various concerns such as growth restriction, nonimmune hydrops, and neurologic disturbances. The most commonly occurring viral and parasitic infections that may have an impact on the fetus if acquired during pregnancy include toxoplasmosis, rubella, cytomegalovirus, herpes simplex virus, group B streptococcus, and parvovirus B19.

Toxoplasmosis

Toxoplasmosis is caused by the protozoan *Toxoplasma gondii (T. gondii).* The domestic cat is the only definitive host for toxoplasmosis and the infective oocysts are passed in its feces. In the United States, there are between 400 and 4000 cases of congenital toxoplasmosis annually or 0.8 per 10,000 live births; in Europe it is estimated to be 10 cases per 10,000 live births (Cunningham et al., 2010).

T. gondii is acquired through ingestion of undercooked meat, contact with feline feces either in the soil or through the cat litter box, and rarely through transplantation of an infected organ (Pappas, Roussos, & Falagas, 2009). It is innocuous in most adults, resembling a minor viral illness, but can be devastating to the immunosuppressed person. For example, in a woman with systemic lupus erythematosus or AIDS who has had a previous infection with *T. gondii,* the latent infection may reactivate, increasing the risk of perinatal transmission (Pappas et al., 2009). A primary infection contracted shortly before or during pregnancy can profoundly affect the fetus and create long-term sequelae for those children and adults.

Fetal-Neonatal Risks

Maternal infection during the first trimester is associated with the lowest incidence of fetal infection, but when it occurs, first trimester infection typically results in more severe fetal damage and often ends in a spontaneous abortion. The highest rate of fetal infection (72%) occurs when the mother contracts the infection in the last month of pregnancy, but most infants are born without clinical signs of infection (Cunningham et al., 2010). Up to 50% of these infants will develop signs and symptoms if left untreated (Johnson, 2009).

In very mild cases, retinochoroiditis (inflammation of the retina and choroid layer of the eye) may be the only recognizable damage, and it and other manifestations may not appear until adolescence or young adulthood. Severe neonatal disorders associated with congenital infection include convulsions, coma, microcephaly, and hydrocephalus. The infant with a severe infection may die soon after birth. Survivors are often blind, deaf, and severely retarded. Treatment of the mother can reduce the incidence of fetal infection by 60% (ACOG, 2008f).

Clinical Therapy

The goal of medical treatment is to identify the woman at risk for toxoplasmosis and to treat the disease promptly if diagnosed. Diagnosis can be made by serologic testing, including the IgM and IgG fluorescent antibody tests. Elevated IgM titers are detectable 5 days after infection and may remain elevated for 1 year or more (ACOG, 2008f). Therefore, it is not a reliable test for diagnosing recent infection; a positive IgG and negative IgM in the third trimester or any positive IgM result should be followed by confirmatory testing. Polymerase chain reaction (PCR) for *T. gondii* DNA in amniotic fluid is the best way to diagnose fetal infection. Ultrasound can reveal findings suggestive of severe fetal infection such as ascites, ventriculomegaly, microcephaly, and growth restriction (ACOG, 2008f).

Women in whom maternal infection is established should receive spiramycin to decrease the frequency of fetal transmission, particularly in the first trimester. Spiramycin does not reliably cross the placenta; thus, while it can reduce the risk of congenital infection, it does not treat an established infection. If fetal infection is suspected, spiramycin should be replaced with pyrimethamine/sulfadiazine/folinic acid after the 18th week of pregnancy. Spiramycin is not commercially available in the United States, but can be obtained if an Investigational New Drug number is procured from the Food and Drug Administration (FDA) (Cunningham et al., 2010).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The incubation period for the disease is 10 days. The woman with acute toxoplasmosis may be asymptomatic, or she may develop myalgia, malaise, rash, splenomegaly, fever, headache, and enlarged posterior cervical lymph nodes. Symptoms usually disappear in a few days or weeks.

Nursing diagnoses that might apply to the pregnant woman with toxoplasmosis include the following:

- ***Readiness for Enhanced Knowledge (Toxoplasmosis)*** related to a desire to understand the ways in which a pregnant woman can contract the disease
- ***Grieving*** related to potential effects on infant of maternal toxoplasmosis

Nursing Plan and Implementation

The nurse caring for women during the antepartal period has the primary opportunity to discuss methods of prevention of toxoplasmosis with the childbearing woman. The woman must understand the importance of avoiding poorly cooked or raw meat, especially pork, beef, lamb, and, in the arctic region, caribou. Ten percent to 70% of lamb, 25% of pork, and 10% of beef samples have been reported to have *T. gondii* cysts. Fruits and vegetables should be washed. She should avoid contact with the cat litter box by having someone else clean it. In addition, because it takes approximately 48 hours for a cat's feces to become infectious, the litter should be cleaned frequently. The nurse should also discuss the importance of the woman wearing gloves when gardening and of avoiding garden areas frequented by cats.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to discuss toxoplasmosis, its method of transmission, the implications for her fetus, and measures she can take to avoid contracting it.
- The woman implements health measures to avoid contracting toxoplasmosis.
- The woman gives birth to a healthy newborn.

Rubella

Rubella is a mild illness in children and adults. In fact, up to 60% of the cases are subclinical. On the other hand, rubella infection in the fetus can have overwhelming consequences. In the United States, large epidemics of rubella are rare because of immunization. Still, today there are pockets of unvaccinated people and cases continue to occur among infants born to women who emigrate from countries without rubella vaccination programs, or where programs have recently been put into place (Johnson, 2009). Estimates suggest that in the United States up to 10% of women are susceptible to rubella (Cunningham et al., 2010). Prepubertal girls and nonpregnant women of childbearing age who do not have antirubella antibodies should be immunized with the live, attenuated rubella vaccine. Although no fetal infection has resulted from immunization of a pregnant woman, pregnancy should be avoided for 1 month after immunization. Nurses need to be aware of the importance of postpartum immunization of the nonimmune woman to decrease unnecessary perinatal transmission.

Fetal-Neonatal Risks

The period of greatest risk for the teratogenic effects of rubella on the fetus is during the first trimester when maternal-fetal transmission occurs in up to 80% of cases of maternal rubella infection (Cunningham et al., 2010). Defects are rare when infection develops after 20 weeks' gestation (AAP & ACOG, 2007a). The most common clinical signs of rubella syndrome are congenital cataracts, sensorineural deafness, and congenital heart defects (particularly patent ductus arteriosus). Other abnormalities, such as mental retardation or cerebral palsy, may become evident in infancy. Diagnosis in the newborn can be conclusively made in the presence of these conditions and with an elevated rubella IgM antibody titer at birth.

Infants born with congenital rubella syndrome are infectious and should be isolated. These infants may continue to shed the virus for up to 12 months and, unless nasopharyngeal and urine cultures done after 3 months of age are negative for the rubella virus, should be considered contagious (AAP & ACOG, 2007a).

Clinical Therapy

The best therapy for rubella is prevention. Live, attenuated vaccine is available and should be given to all children. Women of childbearing age should be tested for immunity and vaccinated if susceptible and if it is established that they are not pregnant. Health counseling in high school and in premarital clinic visits can stress the importance of screening before planning a pregnancy. As part of the prenatal laboratory screen the woman is evaluated for rubella using hemagglutination inhibition (HAI), a serology test. The presence of a 1:18 titer or greater is evidence of immunity. A titer less than 1:8 indicates susceptibility to rubella.

Because the vaccine is made with attenuated virus, pregnant women are not vaccinated. However, it is considered safe for newly vaccinated children to have contact with pregnant women. Children should be given a single dose of the rubella vaccine at 1 year of age or at 15 months as part of the measles, mumps, and rubella (MMR) vaccine. All rubella-susceptible women should receive the MMR vaccine in the postpartum period.

If a woman who is pregnant becomes infected during the first trimester, therapeutic abortion may be an alternative.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

A woman who develops rubella during pregnancy may be asymptomatic or may show signs of a mild infection, including a maculopapular rash, lymphadenopathy, muscular achiness, and joint pain. The presence of IgM antirubella antibody is diagnostic of a recent infection. These titers remain elevated for approximately 1 month following infection.

Nursing diagnoses that may apply to the woman who develops rubella early in her pregnancy include:

- ***Ineffective Coping*** due to an inability to accept the possibility of fetal anomalies secondary to maternal rubella exposure
- ***Risk for Ineffective Health Maintenance*** related to lack of knowledge about the importance of rubella immunization before becoming pregnant

Nursing Plan and Implementation

Nursing support and understanding are vital for the couple contemplating abortion because of a diagnosis of rubella. Such a decision may initiate a crisis for the couple who have planned their pregnancy. They need objective data to understand the possible effects on their fetus and the prognosis for the offspring.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to describe the implications of rubella exposure during the first trimester of pregnancy.
- If exposure occurs in a woman who is not immune, she is able to identify her options and make a decision about continuing her pregnancy that is acceptable to her and her partner.
- The nonimmune woman receives the rubella vaccine during the early postpartum period.
- The woman gives birth to a healthy infant.

Cytomegalovirus

Cytomegalovirus (CMV) belongs to the herpes simplex virus group and causes both congenital and acquired disorders. The significance of this virus in pregnancy is related to its ability to be transmitted by asymptomatic women across the placenta to the fetus or by the cervical route during birth.

The virus can be found in urine, saliva, cervical mucus, semen, and breast milk (Tremblay, 2009). It can be passed between humans by any close contact such as kissing, breastfeeding, and sexual intercourse. Asymptomatic CMV infection is particularly common in children and gravid women. Transmission is common in day care centers, where excretion rate is as high as 70%, especially among children between 1 and 3 years of age (Tremblay, 2009). It is a chronic, persistent infection in that the individual may shed the virus continually over many years. The cervix can harbor the virus, and an ascending infection can develop after birth. Although the virus is usually innocuous in adults and children, it may be fatal to the fetus.

Accurate diagnosis in the pregnant woman is best documented by seroconversion. Shedding of the virus in urine and saliva can be intermittent and does not distinguish primary infection from recurrent infection. Identification of the virus in amniotic fluid by PCR or culture is the most sensitive and specific way of diagnosing congenital infection. This is even superior to fetal blood sampling and can be done earlier in pregnancy and with less risk to the fetus. Ultrasound findings may include fetal hydrops, growth restriction, hydramnios, cardiomegaly, and fetal ascites. At present no treatment exists for maternal CMV or for the congenital disease in the newborn.

Fetal-Neonatal Risks

CMV is the most common viral cause of infection in the human fetus. It infects 0.5% to 2% of newborns. Although 85% to 90% of infected fetuses will be asymptomatic at birth, the remaining 10% to 15% will have abnormalities of varying severity (Johnson, 2009). There is a 20% to 30% mortality rate among the symptomatic infants, and 90% of the survivors have significant neurologic complications. Subclinical infections in the newborn are capable of producing intellectual disability (mental retardation) and auditory deficits, sometimes not recognized for several months, or learning disabilities not seen until childhood. CMV may be the most common cause of intellectual disability.

For the fetus, this infection can result in extensive intrauterine tissue damage that leads to fetal death; it can result in fetal survival but with microcephaly, hydrocephaly, cerebral palsy, or intellectual disability; or it can result in fetal survival with no damage at all.

The infected newborn is often SGA. The principal tissues and organs affected are the blood, brain, and liver. However, virtually all organs are potentially at risk. Hemolysis leads to anemia and hyperbilirubinemia. Thrombocytopenia and hepatosplenomegaly may also develop.

Currently no effective therapy exists to manage this infection. A recent placebo-controlled, randomized, double-blind trial evaluated a CMV vaccine and has shown that it has the potential to decrease cases of maternal and congenital CMV infection (Pass et al., 2009).

Herpes Simplex Virus

It has been estimated that 1 in 6 people between the ages of 14 and 49 (16.2%) is infected with genital herpes in the United States (Centers for Disease Control and Prevention [CDC], 2010a). Herpes simplex virus (HSV-I or HSV-II) infection can cause painful lesions in the genital area. Lesions may also develop on the cervix. This condition and its implications for nonpregnant women are discussed in chapter 6 ∞. However, because the presence of herpes lesions in the genital tract may profoundly affect the fetus, herpes infection as it relates to a pregnant woman is discussed here.

Fetal-Neonatal Risks

According to data from the United States, the incidence of neonatal herpes infection is 1:3500 live births (Society of Obstetricians & Gynaecologists of Canada [SOGC], 2008). A primary herpes simplex infection can increase the risk of spontaneous abortion when infection occurs in the first trimester. Preterm labor (PTL), intrauterine growth restriction, and neonatal infection are greater risks if the primary infection occurs late in the second trimester or early in the third trimester. Recurrent infections during pregnancy do not appear to increase the risk for abortion or low-birth-weight infants.

Up to 80% of new cases of genital HSV may be caused by HSV-1, especially in adolescents and young adults (Hollier, 2009a). The risk to the fetus varies with the route of birth and whether the lesion that is present at the time of birth is primary or recurrent. If HSV-1 or HSV-2 is acquired close to the time of labor, the risk of transmission is 30% to 60% for a vaginal birth (AAP & ACOG, 2007a). Exposure of the newborn to a

recurrent lesion drops the risk of transmission to between 2% and 5% (SOGC, 2008). For a woman with either a primary or a secondary outbreak of genital herpes during labor, or symptoms that may indicate an impending outbreak, the preferred method of childbirth is cesarean birth. Although fetal transmission with recurrent outbreaks is low, a cesarean birth is warranted because of the serious nature of the disease in the newborn. An estimated number of 1500 to 2000 newborns contract herpes each year, with 85% of neonatal herpes resulting from viral transmission near the time of birth. Most newborns infected with HSV are born to women who have unrecognized or asymptomatic infections (AAP & ACOG, 2007a). Despite the small risk of asymptomatic shedding, vaginal birth is appropriate for women with a history of HSV but no evidence of active genital disease at the time of childbirth (SOGC, 2008).

The infected infant is often asymptomatic at birth but symptoms can occur anytime after birth and up to 4 weeks of age (Johnson, 2009). Symptoms include fever (or hypothermia), jaundice, seizures, and poor feeding. Approximately one half of infected infants develop the characteristic vesicular skin lesions. Infants with disseminated disease present the earliest, usually within the first week after delivery. CNS symptoms generally occur during the second or third week. All infants who have neonatal herpes should be evaluated promptly and treated with acyclovir (CDC, 2009).

Clinical Therapy

A woman planning pregnancy who has no history of HSV but who has had a partner with genital HSV should have type-specific serology testing to determine her risk of acquiring HSV. If she is already pregnant, this should be done as early in pregnancy as possible.

Antiviral therapy is recommended after 36 weeks' gestation for women who experience recurrent outbreaks during pregnancy (SOGC, 2008). Oral antiviral therapies are available, including acyclovir (Zovirax), famciclovir, and valacyclovir. Famciclovir and valacyclovir have an advantage of better absorption and a longer half-life than acyclovir. Currently, there is no evidence that there are any adverse fetal effects related to exposure to any of these drugs during any trimester (Kriebs, 2008). Acyclovir, valacyclovir, and famciclovir have a Category B_m pregnancy classification (Briggs, Freeman, & Yaffee, 2008a). The CDC (2009) does not recommend the routine use of antivirals for recurrent infection during pregnancy but recognizes that the use of acyclovir near term may reduce the need for cesarean birth. The dosage is unchanged during pregnancy.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

During the initial prenatal visit, it is important to learn whether the woman or her partner have had previous herpes infections. If so, ongoing assessment is indicated as pregnancy progresses.

Nursing diagnoses that may apply to the pregnant woman with HSV include the following:

- ***Acute Pain*** related to the presence of lesions secondary to herpes infection
- ***Ineffective Coping*** related to depression secondary to the risk to the fetus if herpes lesions are present at birth

Nursing Plan and Implementation

Nurses need to be particularly concerned with patient education about this fast-spreading disease. Women should be informed about what herpes is, how it is spread, and preventive measures. Condoms do not afford complete protection (approximately 50% effective); therefore, couples should be advised to abstain from sexual contact while prodromal symptoms or lesions are present (APP & ACOG, 2007a; Kriebs, 2008). Women should also receive information about the association of genital herpes with spontaneous abortion, neonatal mortality and morbidity, and the possibility of cesarean birth. A woman needs to inform her future healthcare providers of her infection. She also should know of the possible association of genital herpes with cervical cancer and the importance of a yearly Pap smear.

The woman who acquired HSV as an adolescent may be concerned by the possible risks as a mature young adult who wants to have a family. Patients may be helped by counseling that allows expression of the anger, shame, and depression so often experienced by women with herpes. Literature may be helpful and is available from many public health agencies.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to describe her infection with regard to its method of spread, expected medical therapy, comfort measures, implications for her pregnancy, and long-term implications.
- The woman has appropriate cultures done as recommended throughout her pregnancy.
- The woman gives birth to a healthy infant.

Group B Streptococcus Infection

Group B streptococcus (GBS) infection is a bacterial infection found in the lower GI or urogenital tract. Women may transmit GBS to their fetus in utero or during childbirth. During the 1970s, GBS was recognized as the leading infectious cause of neonatal sepsis and mortality and remains so today (Hollier, 2009b). Fortunately, improved recognition and rapid treatment of infected infants has reduced morbidity and mortality rates considerably. Currently fewer than 10% of neonatal cases of GBS are fatal.

An estimated 10% to 30% of pregnant women are carriers of GBS. Rates of colonization vary by ethnicity, with African American women being colonized at twice the rate of Caucasian women (AAP & ACOG, 2007a; Hollier, 2009b). Colonization may be intermittent, transient, or chronic, and it is likely that nearly every woman is GBS colonized at some time. The reservoir for GBS is thought to be the gastrointestinal tract. In symptomatic women, GBS is responsible for considerable maternal morbidity from infections such as pyelonephritis, chorioamnionitis, postpartum endometritis, sepsis, wound infections, and in rare instances, meningitis (Hollier, 2009b).

Fetal-Neonatal Risks

GBS may result in unexpected intrapartum stillbirths (Cunningham et al., 2010). Newborns become infected either by vertical

transmission from the mother as the fetus passes through the birth canal, resulting in early onset GBS in the first week of life, or from horizontal transmission from colonized nursery personnel or colonized infants, which may result in late onset GBS (Hollier, 2009b). Although most newborns who are born to colonized mothers will be born healthy, the transmission rate is influenced by how heavily the mother is colonized, whether or not she is persistently culture positive, the site of colonization (rectal versus vaginal), as well as other risk factors.

Risk factors for GBS neonatal sepsis include the following:

- Prematurity
- Maternal intrapartum fever
- Membranes ruptured for longer than 18 hours
- A previously infected infant with GBS disease
- GBS bacteriuria in the current pregnancy
- Young maternal age
- African American or Hispanic race

GBS causes severe, invasive disease in affected infants. In newborns, the majority of cases occur within the first week of life and are thus designated as early-onset disease. Late-onset disease occurs 1 week or more after birth. Early-onset GBS is often characterized by signs of serious illness including respiratory distress or pneumonia, apnea, and shock. Infants with late-onset GBS often develop meningitis. Long-term neurologic complications are common in survivors of both types of GBS.

Clinical Therapy

Guidelines for the detection of carriers and preventive treatment of newborns at risk include the following (AAP & ACOG, 2007a; Hollier 2009b):

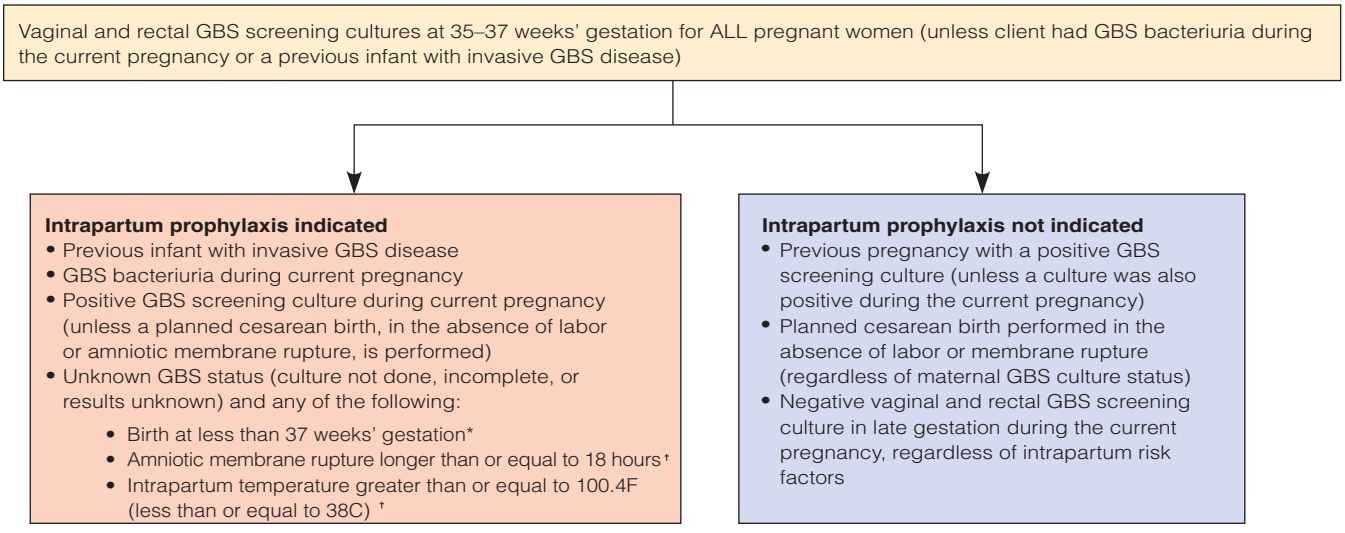
- All pregnant women should be screened for both vaginal and rectal GBS colonization at 35 to 37 weeks' gestation. Treatment should be based on these results, even if cultures were done earlier in pregnancy.
- Women identified as GBS carriers should receive antibiotic prophylaxis at the onset of labor or the rupture of membranes.
- Women with GBS in their urine in any concentration should receive antibiotic prophylaxis intrapartally because such women typically have heavy colonization with GBS and thus have an increased risk of giving birth to a newborn with early-onset disease. These women do not need vaginal and rectal cultures at 35 to 37 weeks because therapy is already indicated.
- Women who have already given birth to a newborn with invasive GBS disease should receive intrapartum antibiotic prophylaxis. Culture-based screening is not necessary for them.
- If the results of GBS screening are not known when labor begins, prophylaxis is indicated for women with any of the following risk factors: gestation less than 37 weeks, membranes ruptured equal to or longer than 18 hours, temperature greater than 100.4°F (38°C).

Intrapartum prophylaxis is not indicated in the following circumstances:

- Women who undergo a cesarean birth and have not been in labor and have intact membranes do not require GBS prophylaxis regardless of their GBS status.
- Positive GBS culture in a previous pregnancy with a negative culture result in the current pregnancy.
- Negative vaginal and rectal GBS screening results done at the appropriate gestational age regardless of intrapartum risk factors.

Figure 20-11 ■ provides an algorithm for assessing the need for intrapartum antibiotic prophylaxis.

Intrapartum antibiotic therapy is recommended as follows: initial dose of penicillin G 5 million units IV followed by



* If onset of labor or rupture of amniotic membrane occurs at less than 37 weeks' gestation and there is a significant risk for preterm birth (as assessed by the clinician).
† If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS prophylaxis.

Figure 20-11 ■ Indications for intrapartum antibiotic prophylaxis to prevent perinatal GBS disease under a universal prenatal screening strategy based on combined vaginal and rectal cultures collected at 35 to 37 weeks' gestation from all pregnant women.

Source: Centers for Disease Control and Prevention (CDC).

2.5 million units IV every 4 hours until childbirth. Alternately, ampicillin 2 g initial dose IV followed by 1 g IV every 4 hours until childbirth may be used. Women at high risk for an anaphylactic reaction to penicillin because of marked allergy may be treated with clindamycin or erythromycin if the GBS is sensitive to those agents. When GBS resistance is an issue or susceptibility is unknown, vancomycin is an alternative (Hollier, 2009b; Matteson, Lievense, & Catanzaro, 2008).

Human B19 Parvovirus

Human B19 parvovirus causes erythema infectiosum or fifth disease in children. It is a mild disease in adults that produces a characteristic "slapped cheek" rash. More than one half of pregnant women are immune to parvovirus B19 (AAP & ACOG, 2007a). Incubation period to maternal symptoms, when they occur, is 4 to 14 days. Symptoms in adults include myalgia; coryza (inflammation of the nasal membranes with profuse nasal discharge); and headache, fever, and nausea, which coincides with contagiousness. In some cases, a week later this phase may be followed by an erythematous maculopapular rash on the trunk and limbs. Arthropathy (any disease or condition affecting a joint) is a common manifestation in women and adolescents and may be the only clinical symptom of the infection (Tolfvenstam & Broliden, 2009). Nonimmune women with school-aged children are more likely to acquire parvovirus, and serologic evaluation should be performed if the pregnant woman has been exposed to a child diagnosed with fifth disease. Epidemics are noted about every 3 to 4 years (Tolfvenstam & Broliden, 2009).

Although there is a low risk of fetal morbidity, transplacental (vertical) transmission is reported to be as high as 33% with a fetal loss rate of less than 10%. Fetal infection is associated with spontaneous abortion, fetal hydrops, and stillbirth. Severe effects occur most frequently with maternal infection before 20 weeks' gestation (AAP & ACOG, 2007a). The major fetal concern is nonimmune hydrops and fetal anemia, which, if left untreated, may result in death. Asymptomatic infections can resolve spontaneously with a mean time span between maternal infection and fetal symptoms of 6 weeks (Tolfvenstam & Broliden, 2009).

Weekly measurements of peak systolic velocity of the MCA (middle cerebral artery) are indicated. Values of greater than 1.5 multiples of the median (MoM) for gestational age have been associated with fetal anemia. Hydrops may be seen up to 8 weeks after maternal infection; however, they may not always occur even in the face of marked anemia. In up to one third of fetuses, there may be spontaneous resolution of hydrops. If hydrops and fetal anemia are diagnosed, intrauterine fetal transfusion may reduce the mortality from about 50% to 18% (Tolfvenstam & Broliden, 2009).

Fetal death may occur at 4 to 12 weeks' postinfection; therefore, fetal surveillance should be maintained for 8 to 12 weeks. The risk of fetal death remains several months post maternal infection even when fetal hydrops is not evident. In fetuses who survive the infection, long-term development appears to be normal.

Other Infections in Pregnancy

Table 20-4 summarizes other urinary tract, vaginal, and sexually transmitted infections that put pregnancy at risk. (These are described in detail in chapter 6 ∞). Spontaneous abortion is frequently the result of a severe maternal infection, and research links infection with prematurity. In addition, if the pregnancy is carried to term in the presence of infection, the risk of maternal and fetal morbidity and mortality increases. Thus it is essential to maternal and fetal health that infection be diagnosed and treated promptly.

TABLE 20-4 Infections That Put Pregnancy at Risk

CONDITION AND CAUSATIVE ORGANISM	SIGNS AND SYMPTOMS	TREATMENT	IMPLICATIONS FOR PREGNANCY
Urinary Tract Infections (UTI)			
Asymptomatic bacteriuria (ASB): *Escherichia coli, Klebsiella, Proteus* most common	Bacteria present in urine on culture with no accompanying symptoms.	Oral sulfonamides early in pregnancy, ampicillin and nitrofurantoin (Furadantin) in late pregnancy. Antibody sensitivity results will guide the selection of an appropriate antibiotic.	Women with ASB in early pregnancy may go on to develop cystitis or acute pyelonephritis by third trimester if not treated. Oral sulfonamides taken in the last few weeks of pregnancy may lead to neonatal hyperbilirubinemia and kernicterus.
Cystitis (lower UTI): Causative organisms same as for ASB	Dysuria, urgency, frequency, low-grade fever, and hematuria may occur. Urine culture (clean catch) shows ≠ leukocytes. Presence of 10^5 (100,000) or more colonies bacteria per ml urine.	Same	If not treated, infection may ascend and lead to acute pyelonephritis. Suppressive therapy is recommended for bacteriuria that persists after 2 or more courses of therapy during pregnancy. Nitrofurantoin 50–100 mg at bedtime for the duration of pregnancy is a common choice (Eckert, 2009).
Acute pyelonephritis: Causative organisms same as for ASB	Sudden onset. Chills, high fever, flank pain. Nausea, vomiting, malaise. May have decreased urine output, severe colicky pain, dehydration. Increased diastolic BP, positive fluorescent antibody (FA) test, low creatinine clearance. Marked bacteremia in urine culture, pyuria, WBC casts.	Hospitalization; IV antibiotic therapy. Other antibiotics safe during pregnancy include carbenicillin, methenamine, cephalosporins. Catheterization if there is no urine output. Supportive therapy for comfort. Follow-up urine cultures are necessary.	Increased risk of premature birth and intrauterine growth restriction (IUGR). These antibiotics interfere with urinary estriol levels and can cause false interpretations of estriol levels during pregnancy.

(continued)

TABLE 20-4 Infections That Put Pregnancy at Risk continued

CONDITION AND CAUSATIVE ORGANISM	SIGNS AND SYMPTOMS	TREATMENT	IMPLICATIONS FOR PREGNANCY
Vaginal Infections			
Vulvovaginal candidiasis (yeast infections): *Candida albicans*	Often thick, white, curdy discharge, severe itching, dysuria, dyspareunia. Diagnosis based on presence of hyphae and spores in a wet-mount preparation of vaginal secretions.	Intravaginal insertion of miconazole butoconazole, or other topical azole preparation, or clotrimazol vaginal tablets at bedtime for 1 week. Cream may be prescribed for topical application to the vulva if necessary (CDC, 2006).	If the infection is present at birth and the fetus is born vaginally, the fetus may contract thrush.
Bacterial vaginosis: *Gardnerella vaginalis*	Thin, watery, yellow gray discharge with foul odor often described as "fishy." Wet-mount preparation reveals "clue cells." Application of potassium hydroxide (KOH) to a specimen of vaginal secretions produces a pronounced fishy odor.	Metronidazole 250 mg PO TID × 7 days or metronidazole 500 mg PO BID × 7 days or clindamycin 300 mg PO BID × 7 days (CDC, 2010b).	CDC (2006) reports that multiple studies have failed to demonstrate a teratogenic effect from metronidazole. BV during pregnancy is associated with PROM, PTL, intra-amniotic infection, and endometritis postpartally (CDC, 2006).
Trichomoniasis: *Trichomonas vaginalis*	Occasionally asymptomatic. May have frothy greenish gray vaginal discharge, pruritus, urinary symptoms. Strawberry patches may be visible on vaginal walls or cervix. Wet-mount preparation of vaginal secretions shows motile flagellated trichomonads.	Single 2-g dose of metronidazole orally (CDC, 2006).	Increased risk for PROM, preterm birth, and low birth weight.
Chlamydial infection: *Chlamydia trachomatis*	Women are often asymptomatic. Symptoms may include thin or purulent discharge, urinary burning and frequency, or lower abdominal pain. Lab test available to detect monoclonal antibodies specific for *Chlamydia*.	Doxycycline, ofloxacin, and levofloxacin are contraindicated during pregnancy. Thus, pregnant women are treated with azithromycin or amoxicillin followed by repeat culture in 3 weeks (CDC, 2006).	Infant of woman with untreated chlamydial infection may develop newborn conjunctivitis, which can be treated with erythromycin eye ointment (but not silver nitrate). Infant may also develop chlamydial pneumonia. May be responsible for premature labor and fetal death.
Syphilis: *Treponema pallidum,* a spirochete	Primary stage: chancre, slight fever, malaise. Chancre lasts about 4 weeks, then disappears. Secondary stage occurs 6 weeks to 6 months after infection. Skin eruptions (condyloma latal), also symptoms of acute arthritis, liver enlargement, iritis, chronic sore throat with hoarseness. Diagnosed by blood tests such as VDRL, RPR, FTA, ABS. Dark-field examination for spirochetes may also be done.	Treatment for pregnant women follows the regimen recommended for the general population and is based on the stage of syphilis. For early latent syphilis (less than 1 year duration), 2.4 million units benzathine penicillin G IM. For late latent syphilis (more than 1 year duration) or latent syphilis of unknown duration, 2.4 million units benzathine penicillin G IM once a week for 3 weeks. Pregnant women who are allergic to penicillin should be desensitized and then treated with penicillin. Sexual partners should also be screened and treated (CDC, 2006).	Syphilis can be passed transplacentally to the fetus. If untreated, one of the following can occur: second trimester abortion, stillborn infant at term, congenitally infected infant, uninfected live infant.
Gonorrhea: *Neisseria gonorrhoeae*	Majority of women asymptomatic; disease often diagnosed during routine prenatal cervical culture. If symptoms are present they may include purulent vaginal discharge, dysuria, urinary frequency, inflammation, and swelling of the vulva. Cervix may appear eroded.	Nonpregnant women are treated with a single dose of ceftriaxone IM or a single dose of cefixime orally plus treatment for chlamydia if not ruled out. Fluoroquinolones (ciprofloxacin, ofloxacin, or levofloxacin) are no longer recommended for the treatment of gonorrhea because of the prevalence of fluoroquinolone-resistant gonorrhea (CDC, 2007). Pregnant women should be treated with a cephalosporin (ceftriaxone, cefixime); if they cannot tolerate a cephalosporin, they should receive spectinomycin (CDC, 2006).	Infection at time of birth may cause ophthalmia neonatorum in the newborn.
Condylomata acuminata: caused by a papilloma virus	Soft, grayish pink lesions on the vulva, vagina, cervix, or anus.	Podophyllin, podofilox, and imiquimod are contraindicated during pregnancy. Some caregivers recommend removing warts by surgical methods or laser because the warts can proliferate and become friable (bleed easily) during pregnancy.	Possible teratogenic effect of podophyllin. Large doses have been associated with fetal death. The HPV vaccine is not recommended during pregnancy; however, it is safe to administer during breastfeeding (AAP & ACOG, 2007a).

FOCUS YOUR STUDY

- Several health problems associated with bleeding arise from the pregnancy itself, such as spontaneous abortion, ectopic pregnancy, and gestational trophoblastic disease. The nurse needs to be alert to early signs of these situations, to guard the woman against heavy bleeding and shock, to facilitate the medical treatment, and to provide educational and emotional support.
- Hyperemesis gravidarum, excessive vomiting during pregnancy, may cause fluid and electrolyte imbalance, dehydration, and signs of starvation in the mother and, if severe enough, death of the fetus. Treatment is aimed at controlling the vomiting, correcting fluid and electrolyte imbalance, correcting dehydration, and improving nutritional status.
- Hypertension may exist before pregnancy or, more often, may develop during pregnancy. Preeclampsia can lead to growth retardation for the fetus and, if untreated, may lead to convulsions (eclampsia) and even death for the mother and fetus. A woman's understanding of the disease process helps motivate her to maintain the required rest periods in the left lateral position. Antihypertensive or anticonvulsive drugs may be part of the therapy.
- Rh incompatibility can exist when an Rh-negative woman and an Rh-positive partner conceive a child who is Rh positive. The use of Rh immune globulin has greatly decreased the incidence of severe sequelae due to Rh incompatibility because the drug "tricks" the body into thinking antibodies have been produced in response to the Rh antigen.
- The impact of surgery or trauma on the pregnant woman and her fetus is related to timing in the pregnancy, seriousness of the situation, and other factors influencing the situation.
- Physical violence often begins or continues during pregnancy. The nurse needs to be alert for signs of abuse, including bruising or injury to the breasts, abdomen, and genitals. The nurse should provide the woman information about violence and about community resources available to assist her.
- Toxoplasmosis, rubella, cytomegalovirus, parvovirus B19, herpes, group B streptococcus (GBS) infection, and other perinatal infections all pose a grave threat to the fetus. Prevention is the best therapy. There is no known treatment for rubella or parvovirus B19, but antimicrobial drugs are available for toxoplasmosis, herpes, and GBS. A vaccine for CMV may be available in the near future.
- Universal screening for GBS is now recommended for all pregnant women at 35 to 37 weeks' gestation.

CRITICAL THINKING IN ACTION

Source: George Dodson/Pearson Education.

Carol Smith, a 40-year-old, single, G2, P0010, presents to you at 32 weeks' gestation while you are working in the birthing unit. Her chief complaint is severe headache, nausea, and trouble seeing. She describes "blackened areas" in her visual fields bilaterally. Her prenatal record reveals long-term substance abuse, depression, and hypertension currently treated with nifedipine 60 mg by mouth once in the morning. You note that she has had two prenatal visits with this pregnancy. You determine her blood pressure to be 170/110; deep tendon reflexes are 3+, clonus negative. She has general edema and 3+ protein uria. You place Carol on the external fetal monitor to observe for fetal well-being and any contractions. You position her on her left side with her head elevated and use pillows for comfort. You observe that the fetal heart rate is 143–148 with decreased long-term variability. No fetal heart rate decelerations or accelerations are noted. The uterus is soft, and no contractions are palpated or noted on the fetal monitor.

Carol asks you why she should stay on her left side.

1. How would you explain the importance of the left side-lying position when on bed rest?
2. You administer nifedipine 10 mg sublingual and a loading dose of magnesium sulfate 4 gm IV piggyback to the main IV line of Ringer's lactate. What findings would indicate that Carol has therapeutic levels of magnesium?
3. What signs of magnesium toxicity should you monitor Carol for?
4. Carol asks if magnesium sulfate will affect her infant. How would you answer her?
5. Which signs of premature labor would you ask Carol to notify you of if she experiences?

CHAPTER 21

Assessment of Fetal Well-Being

My first pregnancy was very complicated and I hoped for a healthy baby throughout, but my baby did not survive. This experience made us very reserved and anxious through our next pregnancy as we could only do so much to ensure the well-being of our baby. We enjoyed seeing our baby's heartbeat on ultrasound and feeling it move inside me. We were happy to have certain tests and technology to assist us in tracking the health of our baby.

LEARNING OUTCOMES

1. Describe the various psychologic responses to antenatal testing.
2. Identify indications and interpret findings for ultrasound examinations performed in the first trimester.
3. Describe the procedures used in the first trimester to confirm fetal viability.
4. Delineate the use of ultrasound in the second trimester to assess fetal life, number, presentation, anatomy, age, and growth.
5. Identify the indications and procedures for fetal movement awareness, the nonstress test, and vibroacoustic stimulation.
6. Compare the indications and procedures for contraction stress test, biophysical profile, and amniotic fluid index.
7. Explain the purpose of sequential and contingent testing and quadruple testing and the implications of abnormal values.
8. Contrast the use of amniocentesis and chorionic villus sampling in detecting a fetus with a chromosomal disorder.
9. Discuss fetal fibronectin and transvaginal measurement of cervical length as predictors of preterm labor.
10. Discuss how the lecithin/sphingomyelin ratio of the amniotic fluid and phosphatidylglycerol (PG) can be used to assess fetal lung maturity.

KEY TERMS

Alpha-fetoprotein (AFP) *518*
Amniocentesis *519*
Amniotic fluid index (AFI) *505*
Beta human chorionic gonadotropin (beta hCG) *501*
Biophysical profile (BPP) *514*
Birth defects *518*
Cervical funneling *500*
Chorionic villus sampling (CVS) *522*
Contraction stress test (CST) *511*
Cordocentesis *524*
Fetal fibronectin (fFN) *524*
Intrauterine growth restriction (IUGR) *517*
Late decelerations *513*
Lecithin/sphingomyelin (L/S) ratio *525*
Macrosomia *517*
Maternal serum alpha-fetoprotein (MSAFP) *518*
Nonstress test (NST) *508*
Nuchal folds *503*
Nuchal translucency testing *503*
Oligohydramnios *514*
Phosphatidylglycerol (PG) *525*
Surfactant *525*
Ultrasound *498*
Viability *501*
Vibroacoustic stimulation (VAS) *510*

Every parent dreams of a perfectly healthy baby and indeed the vast majority of babies are born healthy. However, maternal conditions, genetics, and environmental influences continue to adversely affect a small percentage of babies. Although the antenatal fetal assessment techniques discussed in this chapter are designed to maximize the chances of identifying a fetus at risk, a perfect pregnancy outcome can never be predicted or guaranteed.

Although the United States spends a greater percentage of its gross national product on health care than any other country, it continues to have a higher infant mortality rate than many other industrialized countries (American Public Health Association, 2009). Reproductive technologies significantly raise the cost of health care. These technologic advances are not without risks; therefore, prevention of perinatal morbidity must always be a primary goal. The decision to use the tests discussed in this chapter is made by the childbearing family only after a careful analysis of their risks and costs compared with their possible benefit to the mother or her fetus. The nurse communicates the value of various antenatal testing options in relationship to the patient's gestational age. In addition, limitations of the testing options should be discussed.

Psychologic Reactions to Antenatal Testing

Little has been written about the psychologic impact of antenatal diagnostic testing on childbearing families; however, several studies indicate that the need for testing usually provokes fear (Harpel, 2008). Nurses often play a key role not only in teaching families about various testing options, but also in providing clarity and emotional support to the woman and her family undergoing antenatal testing. To decrease anxiety and alleviate fear for the woman and her family, the nurse provides clear, concise explanations of possible results from testing and management options after the testing has been completed. See Table 21-1 for sample nursing approaches to pretest teaching. Although the family may approach antenatal testing with a great deal of anxiety, normal results may reassure parents; however, distress may persist with false-positive screening results, equivocal results, and positive results that indicate additional testing needs.

Some tests, such as ultrasound, have become almost routine, and many couples view this antepartum test as an expected part of the prenatal care. However, the American College of Obstetricians and Gynecologists (ACOG), the American Institute for Ultrasound in Medicine (AIUM), and the American College of Radiology (ACR) advise against use of ultrasonography during pregnancy without an identified medical indication (ACOG, 2009; ACR, 2007; AIUM, 2008a,b). Its use in improving pregnancy outcomes is controversial. It has been found to be effective in identifying multiple gestation, fetal anomalies, placental disorders, and fetal malposition (Cunningham et al., 2010). All women should be counseled appropriately prior to undergoing any antenatal testing, including ultrasonography, in order to minimize shock and confusion with adverse findings. When more invasive testing is recommended, it may evoke fear and anxiety in the woman and her partner as they consider the reason for the test, the risk to the fetus and woman during the test, and the implications of the test results. All testing should be presented as optional and only performed when the woman so desires.

TABLE 21-1 Sample Nursing Approaches to Pretest Teaching

Assess whether the woman knows the reason the screening or diagnostic test is being offered or recommended.
Examples:
"What has your doctor/nurse-midwife told you about this test?"
"Sometimes tests are done for many different reasons. Can you tell me why you are having this test?"
"What is your understanding about what the test will show?"
Provide an opportunity for questions.
Examples:
"What questions do you have about the test?"
"What things about the test are unclear to you?"
Explain the test procedure, paying particular attention to any preparation the woman needs to do prior to the test.
Example:
"The test that has been ordered for you is designed to . . . " (Add specific information about the particular test. Give the explanation in simple language.)
Validate the woman's understanding of the preparation.
Example:
"Tell me what you will have to do to get ready for this test."
Give permission for the woman to continue to ask questions if needed.
Example:
"I'll be with you during the test. If you have any questions at any time, please don't hesitate to ask."

NURSING CARE MANAGEMENT

Nurses in a variety of settings have an opportunity to provide care to families undergoing antenatal testing. Antenatal assessment tests are performed by perinatal nurse practitioners and/or nurses who have received additional specialized perinatal education and practice. The nurse, whatever the role, is a vital link between the woman and the physician or certified nurse-midwife. Nurses also need to provide easy to understand information to the mother and family. The nurse should encourage the family to ask questions, voice concerns and fears, and become actively involved in the antenatal testing process. Nurses are often responsible for the follow-up care that is needed as a result of test findings, such as arranging for additional testing and interpreting results. Nurses also need to answer questions the family or woman may have and provide emotional support.

Nursing Assessment and Diagnosis

Nursing assessment begins with a history of the present prenatal course and identifying possible indications for a particular diagnostic test. Examples may include identifying possible testing related to advanced maternal age, previous history of a child with a birth defect, or the presence of a particular maternal medical condition. The nurse assesses the woman and her partner's

knowledge about the reason the test is being offered or advised, the information that the woman and her support person have about the test, their questions and concerns, and the presence of any psychosociocultural factors that may influence the teaching or learning process. During the test and afterward, the nurse completes needed assessments to monitor the status of the woman and her fetus.

The primary nursing diagnoses are directed toward providing information about the screening or diagnostic test and minimizing any risks to the woman and her unborn child. Examples of nursing diagnoses that may be applicable include:

- ***Health-Seeking Behavior: Health Education*** related to fetal assessment testing due to an expressed desire to understand its purpose, benefits, risks, and alternatives
- ***Fear*** related to the risks of a specific test or possible unfavorable test results
- ***Risk for Impaired Attachment*** because of high-risk label attached to the pregnancy
- ***Anxiety*** related to the potential outcomes or unfavorable test results

Nursing Plan and Implementation

The nursing plan of care is directed toward each specific nursing diagnosis. The nurse generally plays a vital role in providing needed and desired information about the screening or diagnostic test. The nurse also functions as an advocate for the expectant woman by helping her clarify question areas and obtain needed information. The nurse frequently knows the areas of greatest concern for women and can anticipate many of their fears. When the woman is not able to verbalize questions, the nurse can assist by providing information that answers questions that other women have had. For example, many women undergoing an amniocentesis fear pain during the procedure. The nurse can inform the woman that she will feel pressure during the insertion of the needle and may feel subsequent cramping, which can last for several hours. The nurse can provide information about the procedure itself and follow-up monitoring to evaluate fetal well-being.

It is important for the nurse to realize that women react differently to pregnancy and testing. The nurse's role is to remain nonjudgmental and to offer support when needed. Establishing a trusting relationship increases the possibility that a woman will talk to the nurse and share her concerns and emotional needs. The nurse is often the one to coordinate services the woman may need, such as community resources for financial, psychologic, or social support.

Nurses working in community clinics have an integral role in performing fetal surveillance tests throughout the antepartum period. Nurses may find themselves not only performing some of these tests, such as nonstress tests, but also performing comprehensive assessments of the woman's health, her family dynamics, and her living situation. Community health nurses often have a more accurate understanding of the woman's physical resources, such as the adequacy of living conditions, proximity to healthcare resources, and availability of public transportation. It is often the nurse who has the most contact with the pregnant woman. Because of this, the nurse is in an excellent position to provide anticipatory guidance, reiterate teaching provided by the woman's healthcare provider, and monitor her current plan of care. The nurse should approach each encounter with calmness, compassion, and honesty.

Evaluation

The nurse evaluates the woman and her family's understanding of antepartum testing procedures. Determining if the family understands the indication for follow-up testing is imperative. The nurse should also assess whether the teaching methods used are effective for that family. Evaluation should include both physical and psychologic factors. In addition, the nurse determines if adequate resources, such as social support and physical resources, are available for the pregnant woman. Women from different cultures may need additional support because they may encounter language and other cultural barriers.

Ultrasound in Obstetrics

Ultrasound

Ultrasound has become one of the most commonly used diagnostic and screening tools in pregnancy (Cunningham et al., 2010). For the last 20 years, it has played a critical role in the practice of obstetrics. Because ultrasound is used widely to assess fetal well-being in all 3 trimesters, it also is discussed within this framework later in the chapter.

Ultrasound is a diagnostic procedure that uses high-frequency sound waves exceeding 20,000 cycles per second, greater than what the human ear can hear, to produce an image that varies based on the density of the structure under the transducer. The reflected energy creates a small electrical voltage that is displayed on the screen. Very dense components, such as bone, appear white on the screen, whereas soft tissues appear gray and fluid appears black (Cunningham et al., 2010). Instruments used in ultrasonography operate at 2 to 10 megahertz (MHz). The higher the frequency of the sound, the shallower the depth of penetration but the better the resolution of the image produced. Ultrasound uses a device called a *transducer* to turn the sound waves into electrical signals. Transducers can be used either transabdominally (Figure 21-1 ■), operating at 3 to 5 MHz,

Figure 21-1 ■ Ultrasound scanning permits visualization of the fetus in utero.

Source: Photographer, Elena Dorfman.

Figure 21-2 ■ Transvaginal ultrasound transducer.
Source: Photographer, Elena Dorfman.

or transvaginally (Figure 21-2 ■), operating at 5 to 10 MHz (ACOG, 2009). These transducers and their use are described fully later in the chapter.

Ultrasound can be used to produce images called *sonograms* in several different ways. In motion mode (M mode), the reflected echo generates a moving display. This is how fetal cardiac activity is seen. Brightness modulation (B mode) converts the signals into varying degrees of brightness and produces a two-dimensional image. Three-dimensional ultrasound uses algorithms to vary opacity, transparency, and depth to project an image. This allows curved structures such as the fetal face to be viewed (Figure 21-3 ■).

Extent of Ultrasound Exams

According to the American College of Obstetricians and Gynecologists (ACOG), ultrasound examinations are classified as standard or basic, limited (identifying only certain components), or specialized (sometimes referred to as detailed) (2009). A *limited ultrasound* may be used to address a specific question, or determine specific information. A limited ultrasound should not take the place of a standard ultrasound evaluation (ACOG, 2009). Following are examples of information that can be obtained by a limited ultrasound:

- Determine fetal presentation before or during labor.
- Locate the placenta.
- Confirm fetal heart activity.
- Estimate amniotic fluid volume.
- Diagnose multiple gestation.
- Evaluate interval growth.
- Evaluate the cervix.
- Guide amniocentesis.

A *standard ultrasound examination* is performed during the second or third trimester. It includes an evaluation of fetal presentation, fetal number, amniotic fluid volume, placental position, cardiac activity, fetal biometry, and anatomic survey. A standard ultrasound should also attempt to evaluate the maternal cervix and the uterus and ovaries when feasible. A specialized, or detailed, examination is performed when an anomaly is suspected, and the components of the exam are determined by the expert conducting the examination. These components may include fetal Doppler, biophysical profile, fetal echocardiogram, amniotic fluid assessment, or additional biometric studies (ACOG, 2009).

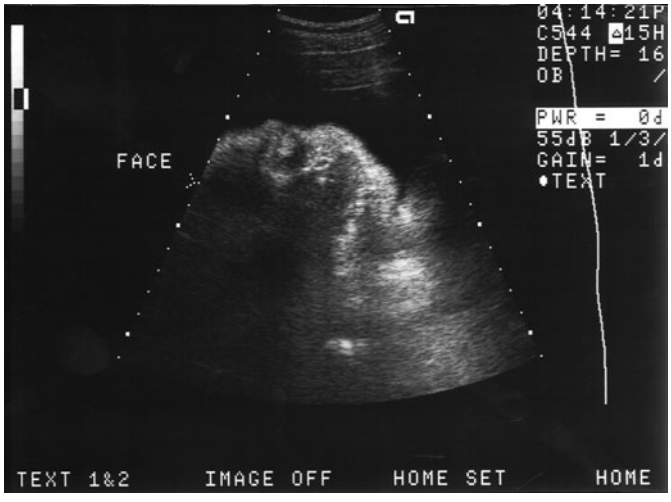

Figure 21-3 ■ Ultrasound of the fetal face.

Methods of Ultrasound Scanning

The two most common methods of ultrasound scanning are *transabdominal* and *transvaginal* scanning.

Transabdominal Ultrasound

In the transabdominal approach, a transducer is moved across the abdomen (see Figure 21-1). The woman is usually scanned with a full bladder, except when ultrasound is used to localize the placenta before amniocentesis. When the bladder is full, the examiner can assess other structures, especially the vagina and cervix, in relation to the bladder. This is particularly important when vaginal bleeding is noted and placenta previa is the suspected cause. It can also determine if vaginal bleeding is being caused by premature dilatation of the cervix. The woman is advised to drink 1 to 1.5 quarts of water approximately 2 hours before the examination, and she is asked to refrain from emptying her bladder. If the bladder is not sufficiently filled, she is asked to drink 3 to 4 (8 oz) glasses of water and is rescanned 30 to 45 minutes later (Hobbins, 2007).

Transmission gel is generously spread over the woman's abdomen, and the sonographer slowly moves a transducer over the abdomen to obtain a picture of the contents of the uterus. Testing takes 20 to 30 minutes. The woman may feel discomfort from pressure applied over a full bladder. In some instances, the sonographer may advise the woman to urinate a small amount to relieve the discomfort. In addition, if the woman lies on her back during the test, shortness of breath can develop. This may be relieved by elevating her upper body during the test. The woman may also develop dizziness or postural hypotension related to compression of the inferior vena cava by the uterus.

Transvaginal Ultrasound

The transvaginal (or endovaginal) method uses a probe inserted into the vagina (see Figure 21-2). Once inserted, the transvaginal probe is close to the structures being imaged and so produces a better, clearer image. The improved images obtained by transvaginal ultrasound have enabled sonographers to identify structures and fetal characteristics earlier in pregnancy (McAuliffe et al., 2005). Transvaginal ultrasound is used to assess the gestational sac, the presence or absence of a yolk sac or embryo, the crown rump length to most accurately determine gestational age, the presence of cardiac motion, and fetal number. The uterus, cervix, and adnexal structures are also examined and recorded. Transvaginal ultrasound can most accurately identify shortened cervical length and **cervical funneling** (a cone-shaped indentation in the cervical os), indicating cervical incompetence or risk of preterm labor (ACOG, 2009).

After the procedure is fully explained to the woman, she is prepared in the same manner as for a pelvic examination: in lithotomy position, with appropriate drapes to provide privacy, and a female attendant in the room. It is important that the woman's buttocks are at the end of the table so that, once inserted, the probe can be moved in various directions. The small, lightweight vaginal transducer is covered with a specially fitted sterile sheath, a condom, or one finger of a latex or vinyl glove. Ultrasound coupling gel is then applied to the covering, making insertion into the vagina easier and providing a medium for enhancing the ultrasound image. In addition to providing a clearer image than the transabdominal method, the transvaginal procedure can be accomplished with an empty bladder. Most women do not feel discomfort during the exam. The probe is smaller than a speculum, so insertion is usually completed with ease. The woman may feel some movement of the probe during the exam as various structures are imaged. Some women may want to insert the probe themselves to enhance their comfort; others may feel embarrassed even to be asked. The certified nurse-midwife, physician, or ultrasonographer offers the choice based on the clinician's comfort level and the rapport the clinician has established with the woman.

Safety of Ultrasound

In the last 20 years, the use of ultrasound as a diagnostic tool in pregnancy has increased exponentially, and there is no evidence of physical harm to the fetus (Abramowicz, 2007; ACOG, 2009). The World Health Organization (WHO) concludes ultrasonography in pregnancy is not associated with increased risk of childhood malignancy, impaired physical or neurological development, cognitive ability, or mental disease. In fact, no adverse maternal, fetal, or neonatal outcomes have been identified (Torloni et al., 2009). The Food and Drug Administration (FDA) has stated that obstetric sonograms fall within an acceptable level of safety because they use low-intensity ultrasound, however they do not approve of nonmedical uses such as videos and pictures for "keepsakes" (AIUM, 2008a).

Is there such a category as "routine ultrasound" in pregnancy? Not necessarily, according to ACOG (2009). In large studies, researchers compared several outcomes between a group of women who had ultrasound examinations performed and a group of women who did not. Outcomes included perinatal mortality, Apgar score, birth weight, maternal outcome, detections of multiple gestation and abnormalities, as well as cost-effectiveness. The group that had ultrasound examinations showed higher rates of detection of multiple gestations and abnormalities. There were no significant differences in outcomes related to the other factors (Cunningham et al., 2010). ACOG endorses American College of Radiology (ACR) (2007) practice guidelines for obstetric ultrasound indications:

- Estimation of gestational age
- Evaluation of cervical insufficiency
- Evaluation of fetal growth or fetal well-being
- Evaluation of vaginal bleeding
- Determination of fetal presentation
- Evaluation of abdominal or pelvic pain
- Suspected multiple gestation
- Significant discrepancy between uterine size and clinical date
- Evaluation of pelvic mass or uterine abnormality
- Examination of suspected hydatidiform mole
- Adjunct to special procedures including amniocentesis, cervical cerclage placement, or external cephalic version
- Evaluation for premature rupture of membranes or premature labor
- Evaluation of suspected fetal death
- Evaluation of suspected ectopic pregnancy
- Evaluation of suspected amniotic fluid abnormalities
- Evaluation of suspected placental abruption
- Evaluation of abnormal biochemical markers
- Follow-up evaluation of fetal anomaly
- Follow-up evaluation of placental location for suspected placenta previa
- Evaluation of those with history of previous congenital anomaly
- Evaluation of fetal condition in late presentation for prenatal care
- To assess findings that may increase the risk of chromosomal abnormalities
- To screen for fetal anomalies

Who Should Perform Ultrasound Examinations?

The accuracy of ultrasound as a diagnostic tool is highly dependent on the knowledge, skills, and judgment of the person performing the exam. Licensed medical practitioners, following published standards and guidelines, perform ultrasound examinations. The practitioner's training includes indications as well as limitation of obstetrical ultrasound (ACOG, 2009). The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) has set guidelines and nursing practice competencies for experienced maternal-newborn nurses to perform limited ultrasound exams. The guidelines indicate that the nurse must complete an educational program that includes didactic presentations and a clinical practicum (Simpson & Creehan, 2008). All ultrasound examinations and interpretations should be recorded and documented.

NURSING CARE MANAGEMENT

The nurse plays a key role in providing the mother and family with information related to the ultrasound procedure itself and expected outcomes. The nurse answers questions and helps clarify ultrasound findings. Some women, especially those who lack insurance coverage, may worry about the cost of the test itself. The nurse can discuss the rationale for obtaining an ultrasound and what will be done with the information once it is obtained. The nurse provides support for the woman and her family, recognizing that some women may feel anxious or fearful.

Assessment of Fetal Well-Being in the First Trimester

The first trimester represents a crucial time for establishing fetal viability and determining an accurate gestational age. Ultrasound can be used during the first trimester to help determine certain characteristics, including some chromosomal disorders. There are a variety of methods that the practitioner can use to determine fetal well-being in early pregnancy.

Viability

Viability, or the potential for the pregnancy to result in a live infant, is the first issue to consider in pregnancy. A positive urine pregnancy test does not confirm viability, but represents the presence of beta human chorionic gonadotropin (hCG) hormone. This hormone becomes present in the bloodstream when the developing embryo implants into the uterus at approximately 10 to 14 days after conception has occurred (Cunningham et al., 2010). Bleeding is the most common symptom causing a woman to question the viability of her pregnancy. One in four women will experience bleeding in her pregnancy; nevertheless, half of such women will continue to have viable pregnancies (Cunningham et al., 2010). Bleeding can also be associated with a nonviable pregnancy in cases of spontaneous abortion (miscarriage) or ectopic (tubal) pregnancy. Serial quantitative beta hCG testing, progesterone-level testing, and ultrasound can be used to distinguish a normally developing fetus from an ectopic pregnancy, which, if undiagnosed, carries a high rate of maternal morbidity.

Quantitative Beta hCG Testing

Beta human chorionic gonadotropin (beta hCG) is a product of the trophoblast or placenta and is a very accurate marker of the presence of pregnancy and placental health. Beta hCG is detectable in the blood serum of approximately 5% of pregnant women by 8 days after conception, and in virtually all pregnancies by 11 days. The level in the serum approximately doubles every 2 days in the first 10 days of pregnancy, peaking at 60 to 90 days after conception (Cunningham et al., 2010) (Table 21-2). In early pregnancy, two quantitative beta hCG levels drawn 48 hours apart serve as an excellent test of the viability of the pregnancy. Conversely, if the beta hCG level remains stable or falls over 48 hours, a miscarriage or ectopic pregnancy should be suspected. See chapter 20 ∞ for a discussion of beta hCG testing in ectopic pregnancy.

TABLE 21-2 Approximate Beta hCG Values in Pregnancy

GESTATIONAL AGE (WEEKS)	BETA HCG VALUES (MILLI–INTERNATIONAL UNITS/ML)
1–2	16–156
2–3	101–4870
3–4	1110–31,500
4–5	2560–82,300
5–6	23,100–151,000
6–7	27,300–233,000
7–11	20,900–291,000
11–16	6140–103,000
16–21	4720–80,100
21–39	2700–78,100

Although not routine in all pregnancies, serologic evaluation is indicated in women with a history of spontaneous abortion, ectopic pregnancy, or risk of ectopic pregnancy (intrauterine device in place, previous pelvic inflammatory disease, or reversal of a tubal sterilization). Women who are spotting should also have a beta hCG level drawn to ensure adequate levels. Many women who have conceived through assisted reproductive methods also have their beta hCG levels monitored to ensure the pregnancy is developing normally.

The 48 hours between the beta hCG tests can be an extremely anxious time for the couple. To offer effective counseling, the nurse must understand the information these tests provide, as well as their limitations. For example, the woman may not know why she must wait 48 hours for a repeat blood test. The nurse needs to allow time for the woman and her partner, if present, to express their anxiety and fears. False reassurances should not be offered. Instead, attention is directed toward helping them cope with the inherent uncertainty that occurs while the exams are being completed and until a definitive diagnosis can be made.

Progesterone Level Testing

Progesterone is secreted in early pregnancy by the corpus luteum until approximately 8 weeks' gestation at which point the placenta begins to manufacture its own progesterone. Low levels of progesterone are associated with spontaneous abortions and ectopic pregnancies (Cunningham et al., 2010). Although progesterone levels are not routinely tested in early pregnancy, they can be assessed by performing a simple blood test when there is a history of spontaneous abortions or spotting in early pregnancy. Progesterone levels above 25 ng/ml are typically associated with normally developing intrauterine pregnancies. Progesterone levels that are below 5 ng/ml typically indicate a nonviable fetus. Levels between 5 ng/ml and 25 ng/ml are inconclusive. Approximately 10% of women have progesterone levels below 25 ng/ml (Cunningham et al., 2010). The nurse notifies the physician or certified nurse-midwife if levels are low. The physician or certified nurse-midwife, in conjunction with the woman's desires, bases the decision of whether or not to supplement progesterone during early pregnancy on current

progesterone levels, past history of spontaneous abortions, and/or presence of spotting or vaginal bleeding. However, supplementing with progesterone also has the potential of prolonging an inevitable nonviable pregnancy. Low progesterone levels can be treated by giving the woman progesterone either orally or via vaginal suppositories. This supplementation is warranted throughout the first trimester. After 12 gestational weeks, supplements are not needed because the placenta will make adequate progesterone levels (Cunningham et al., 2010).

Ultrasound

The sonographic landmarks (presence of gestational sac, cardiac motion, embryo development) of normal early pregnancy, detected by transvaginal ultrasound, are very predictable. Up to about 4 1/2 to 5 weeks of gestation, before the appearance of a gestational sac, only the endometrial stripe can be seen in the uterus. The gestational sac at first appears empty and may be confused with the pseudogestational sac of ectopic pregnancy. A true gestational sac is associated with beta hCG levels of 1800 milli–International Units/ml if the sonogram is being done transvaginally and 6500 milli–International Units/ml if the sonogram is being done transabdominally. At approximately 5 1/2 weeks the yolk sac, a small round structure sometimes resembling a "double ring," is visible within the gestational sac. It is an embryonic structure, so its appearance provides strong evidence supporting the presence of an intrauterine pregnancy (Seungdamrong et al., 2008). At 6 to 6 1/2 weeks, the embryo itself becomes visible, and shortly thereafter cardiac activity is detectable (Creasy, Resnik, Iams, et al., 2008). During the ultrasound examination, the gestational sac and embryo (crown rump length) are measured to determine gestational age (Figure 21-4 ■).

Gestational Age

Determination of an accurate expected date of birth (EDB) early in pregnancy is essential for evaluating well-being throughout the pregnancy. Labor contractions that may be perfectly normal at 37 weeks could be a problem if they occur prior to 34 weeks. Conversely, a 40-week pregnancy inadvertently thought to be 42 weeks may result in an unnecessary and risk-laden induction of labor. Much of the physician's or midwife's efforts are aimed at determining the most accurate EDB possible. Traditional means of establishing an EDB are documenting a reliable last menstrual period (LMP) from the woman, measuring uterine size, noting the date of the first audible fetal heart tones, and noting the date of quickening (the first recognized fetal movement). A definite and normal LMP established early in pregnancy is considered the most reliable indicator of an EDB (Hoffman et al., 2008). Problems occur if the woman cannot recall her LMP, if her menstrual cycles were extremely irregular, if she was lactating, if she was using hormonal contraception, or if she had bleeding in early pregnancy.

An early transvaginal or abdominal sonogram is indicated when there is a need to establish an accurate gestational age. The crown-rump length is considered the most accurate sonographic measurement for gestational age if performed between 6 and 12 weeks' gestation. It is accurate to within plus or minus 3 to 5 days of the EDB based on the crown-rump length (Cunningham et al., 2010) (Figure 21-5 ■). This means that an ultrasound performed at 6 weeks would be accurate in predicting the EDB within either 3 to 5 days before or 3 to 5 days after the predicted EDB by LMP. Beyond 12 weeks, the fetus begins to curve and the crown-rump length loses its accuracy (Cunningham et al., 2010). For example, if an EDB based on a 10-week sonogram is September 9, it is reasonable to expect that date determined by LMP is accurate from September 4 through September 14. After the first trimester, gestational age is obtained by a combination of measurements of femur length, abdominal circumference, and biparietal diameter (Figure 21-6 ■). Gestational age by sonogram is reliable in the second trimester to plus or minus 7 to 14 days. For example, if a due date of October 1 is given by a second trimester sonogram, the reasonable date of birth can be from September 16 through October 14. Although practice may vary, most physicians and midwives do not change a due date based on the second trimester sonogram unless there is a discrepancy of greater than 11 to 14 days from the LMP. After 26 weeks, fetal growth rates are less uniform, making ultrasound an inappropriate means of determining gestational age. Specifically, during the third trimester, ultrasound can estimate an EDB with plus or minus 14 to 21 days of accuracy. See Table 21-3.

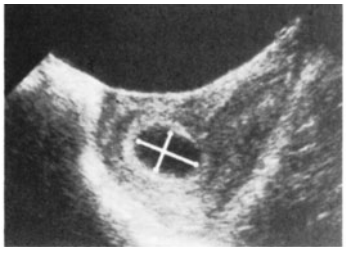

Figure 21-4 ■ Measurement of the gestational sac. The ultrasound shows the uterus; the blackened oval area is the gestational sac. The fluid in the gestational sac does not generate echoes from the ultrasound and thus appears dark in contrast to the uterine tissue surrounding it. The lines through the gestational sac represent measurements that are taken.

TABLE 21-3 Parameters for Estimating Gestational Age

SOURCE OF EVIDENCE	WHEN OBTAINED	ESTIMATED ACCURACY
In vitro fertilization	At conception	Less than 1 day
Ultrasound measurement of crown-rump length	6–10 weeks	3 days
Clinical measurement of normal uterus	Less than 12 weeks	7 days
Ultrasound measurement of biparietal diameter	Less than 20 weeks	7 days
Ultrasound measurement of biparietal diameter	20–26 weeks	10 days
Ultrasound measurement of biparietal diameter	26–30 weeks	14–21 days
Ultrasound measurement of biparietal diameter	Greater than 30 weeks	21–28 days

Determining an accurate EDB early in pregnancy can be extremely important later in pregnancy if there is inadequate uterine or fetal growth. An accurate EDB based on a first trimester ultrasound can assist the physician or certified nurse-midwife in diagnosing intrauterine growth restriction (to be discussed later in this chapter).

Nuchal Translucency Testing

Nuchal translucency testing is a combination of an ultrasound and a maternal serum test that is used to screen fetuses between 11 weeks and 1 day and 13 weeks and 6 days to determine if a fetus is at risk for a chromosomal disorder, such as Down syndrome (trisomy 21), trisomy 13, and trisomy18. The ultrasound assesses the accumulation of fluid between the posterior cervical spine and the overlying skin in the fetal neck, known as **nuchal folds**. If the nuchal folds are greater than 3 mm, the incidence of Down syndrome is increased (ACOG, 2007b). The test is performed in conjunction with a maternal serum blood test in which biochemical markers PAPP-A and free beta hCG are obtained to calculate the risk of having an affected fetus. The combination of blood testing and the ultrasound screening test is 82% to 87% accurate for detecting Down syndrome (ACOG, 2007b). Because the screening is noninvasive, there are no maternal or fetal risks. If an abnormal test result is obtained, the mother is referred for diagnostic testing, such as a chorionic villus sampling (CVS) or amniocentesis. During nuchal translucency testing, the presence or absence of a nasal bone may be examined because three European studies have found the absence of the fetal nasal bone in 66.7% to 80% of Down syndrome fetuses. However, a study in the United States found this to be less accurate because of ethnic variations within the population (ACOG, 2007a).

Assessment of Fetal Well-Being in the Second Trimester

The second trimester is considered by many to be the most advantageous time for basic obstetric ultrasound for several reasons. First, the relative uniformity of fetal growth during the first 20 weeks allows biometric measurements that continue to provide an accurate estimation of gestational age. Second, the large volume of amniotic fluid relative to the fetal size allows for excellent images of fetal anatomy. Finally, fetal anatomy can be visualized in extreme detail, allowing confirmation of normal anatomy. The ideal time for the second trimester basic sonogram is 18 to 24 weeks. There is some evidence that sonograms done at 20 to

22 weeks may be easier to perform and less likely to require an additional scan than one done at 18 weeks (ACOG, 2009).

A standard (comprehensive) second trimester sonogram provides the following information about the fetus, placenta, and uterine conditions (ACOG, 2009):

- Fetal life
- Fetal number
- Fetal presentation
- Presence of abnormal heart rate or rhythm
- Evaluation of fetal anatomy
- Gestational age and growth
- Amniotic fluid volume
- Placental localization, including relationship to cervical os
- Umbilical cord, including the number of vessels present
- Uterine anatomy

In addition, multiple gestations should be assessed for chorionicity, amnionicity, comparison of fetal sizes, the amount of amniotic fluid on each side of the membrane, and fetal genitalia if visible (ACOG, 2009).

Fetal Life

Presence of cardiac motion confirms fetal life. If gestational age has already been established and fetal heart tones have been visualized with an ultrasound or heard with a Doppler in the first trimester, then absence of cardiac motion in the second trimester is consistent with fetal demise.

Fetal Number

The second trimester is an ideal time to identify multiple gestation or the number of fetuses in the uterus. The number of placentas and their location can also be noted at this point.

Fetal Presentation

Although an ultrasound in the second trimester can determine whether a fetus is in the breech, transverse, or vertex position, the large amount of amniotic fluid relative to the fetal size along with the lack of fetal engagement makes it highly likely that the noted presentation will change repeatedly before birth (Cunningham et al., 2010). Fetal presentation is commonly documented on a second trimester ultrasound, but it is not usually of any clinical significance.

Fetal Anatomy Survey

A systematic examination of the fetal parts is conducted to identify possible abnormalities. Components of this examination include the fetal parts discussed in the following sections.

Head

The skull should be symmetrical with the cranium ossified and intact. The ventricular system (passageways within the brain) is evaluated. The choroids should appear symmetrical. The choroid plexuses are found within the ventricles of the brain and in the subarachnoid space around the brain and spinal cord. They produce cerebral spinal fluid. Choroid cysts, if noted, are usually benign but have been associated with chromosomal abnormalities in 1% of fetuses (Creasy et al., 2008). The nuchal fold thickness should be measured because thickening of the nuchal fold, the skin at the base of the fetal skull, has also been associated with certain chromosomal abnormalities.

The most dramatic abnormality diagnosed by ultrasound is anencephaly (a neural tube defect in which a portion of the fetal brain is missing). It is abnormal not to see the bony structures of the skull above the orbits of the eye after 14 weeks' gestation. The skull is brightly echogenic (appearing white because of its increased density) and is easily visualized. Failure to see the skull should alert the experienced examiner to the possibility of anencephaly (Cunningham et al., 2010).

Spine

The spine is examined both sagittally and coronally for the presence of a sac or an outward splaying of the vertebrae laminae. Either of these conditions may suggest a possible spinal cord defect such as spina bifida.

Thorax and Heart

A transverse plane of the fetal thorax provides valuable information about the size, shape, and symmetry of the chest. The size, location, and axis of the heart are also evaluated. A four-chambered view of the heart should demonstrate ventricles and atria of approximately equal size and an intact intraventricular septum. The heart occupies one quarter to one third of the chest cavity on transverse image. The lungs should have a homogenous appearance. The diaphragm should be imaged. Chest size is correlated with lung size.

Abdomen

The bladder, stomach, and kidneys should all be visualized. The fetal stomach and bladder can be seen on ultrasound by 14 weeks. Persistent failure to visualize the fetal stomach can be due to various fetal abnormalities, the most common being esophageal atresia. Mild dilation of the renal pelvis of less than 10 mm is rarely progressive and usually physiologic (Creasy et al., 2008). The abdominal wall should be visualized to be intact. A transverse image of the umbilical cord should reveal a three-vessel cord. Insertion site of the umbilical cord is also carefully inspected.

Extremities

The femur is the only bone routinely measured on the basic ultrasound. If the length seems abnormal, a more comprehensive exam is performed to compare it with the lengths of the other long bones. The upper extremities and the presence of hands and feet are also documented.

Gestational Age and Growth

The Hadlock method uses an average of measures of the biparietal diameter, head circumference, abdominal circumference, and femur length to estimate gestational age (Figures 21-7 to 21-10 ■). Comparison of measures made at intervals to standardized measures can be used to estimate fetal growth (Creasy et al., 2008).

Amniotic Fluid Volume

Amniotic fluid volume changes with gestational age. In general, a subjective assessment of amniotic fluid volume as

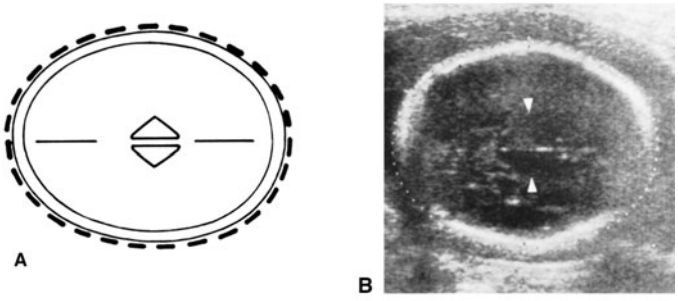

Figure 21-7 ■ Measurement of the head circumference. A. Diagram showing a dotted line outlining the head, which indicates the correct place to make a circumference measurement. B. Ultrasound transaxial scan showing the thalami (arrowheads), positioned in midline. A dotted line created by the digitizer outlines the correct parameter, just outside of the hyperechoic calvarium to obtain a circumference measurement.

decreased, normal, or increased is adequate during the second trimester examination. However, the **amniotic fluid index (AFI)** is another method of reporting fluid volume (Cunningham et al., 2010). The AFI is calculated by dividing the maternal abdomen into four quadrants with the umbilicus as the reference point. The deepest vertical pocket of fluid in each quadrant is then measured, and these four measurements are summed to calculate the AFI.

Placenta Location

The placenta's appearance, location, and relationship to the cervical os should be evaluated to assess for the possible complication of a placenta previa. Placental positions that are noted by sonogram in early pregnancy may not correlate well with the location at the time of birth. Factors such as the woman's position during the assessment or overdistention of the bladder may give a false-positive diagnosis of placenta

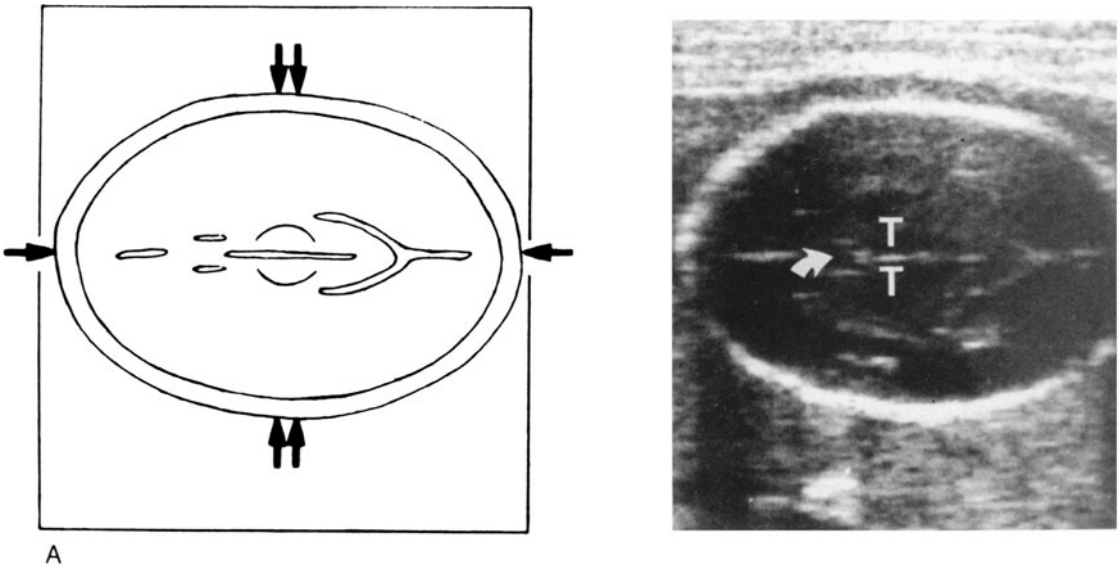

Figure 21-8 ■ Measurement of the cephalic index. A. The biparietal diameter (double arrows) and fronto-occipital diameter (single arrows) are both taken outer edge to outer edge. A ratio of the two gives the cephalic index. B. Ultrasound transaxial scan of the fetal head of the thalami (T) and cavum septi pellucidi (curved arrow).

previa. Therefore, a possible low-lying placenta or placenta previa that is identified on a second trimester ultrasound must be confirmed by a follow-up sonogram in the third trimester (Creasy et al., 2008).

Survey of Uterine Anatomy

The uterus is assessed to examine maternal anatomy and identify any uterine defects or abnormalities. Adnexal (ovarian) masses or cysts may be noted. Uterine myomas (fibroids) are common and must be noted and monitored because they may grow more quickly in pregnancy, affecting the growth and well-being of the fetus or causing overdistention of the uterus, leading to preterm labor or birth (Cunningham et al., 2010). Ultrasound may also be used to measure both cervical length and dilatation of the internal cervical os. A shortened cervix and a dilated internal os noted by ultrasound have been used to predict preterm birth. However, false-positive results using this technique may be common since the degree of effacement or dilatation may be inaccurate. Some obstetricians will schedule weekly transvaginal ultrasound to measure cervical length beginning at 20 weeks for their patients who have a history of preterm labor or cervical incompetence, and for women with a cervical cerclage (a suture placed in the cervix) (Creasy et al., 2008) (see chapter 26 ∞ and Figure 26-1 ∞ on page 663).

RESEARCH EVIDENCE IN PRACTICE

Assessing Amniotic Fluid Volume as a Measure of Fetal Well-Being

CLINICAL QUESTION

What intrapartum estimate of amniotic fluid volume identifies a pregnancy that is at risk for an adverse outcome?

RESEARCH EVIDENCE

Amniotic fluid supports and protects the fetus during development. A decreased amount of amniotic fluid (oligohydramnios) can occur for a variety of reasons, including fetal abnormalities, intrauterine growth problems, preeclampsia, or postterm pregnancy. When oligohydramnios is diagnosed during pregnancy, cesarean birth or labor induction may be recommended to prevent adverse pregnancy outcomes. The estimation of amniotic fluid volume, then, becomes an important diagnostic test during late pregnancy.

The American College of Obstetricians and Gynecologists (ACOG) recommends an ultrasound with evaluation of amniotic fluid volume when there is any suspicion of fetal growth restriction or oligohydramnios. Amniotic fluid volume may be assessed using either an amniotic fluid index (AFI) or a measure of an amniotic fluid pocket. In calculating the amniotic fluid index, the ultrasound operator divides the uterine cavity into four quadrants. The largest vertical diameter of a fluid pocket is measured in each quadrant, and the four measures are summed to provide a single AFI value. The single deepest vertical pocket (SDVP) is measured by finding the length, width, and depth of the largest amniotic fluid pocket in the uterus, regardless of its quadrant.

Multiple randomized trials and a meta-analysis have been conducted to determine which method of estimating amniotic fluid volume is associated with the best outcomes. More than 4000 women were included in these studies and reviews.

Both measures are effective in identifying oligohydramnios, although the AFI was more sensitive than the SDVP. While AFI may appear to be a superior method for this reason, it resulted in more cesarean births and labor inductions without significant improvement in fetal outcomes (admission to a neonatal intensive care unit; umbilical artery pH of less than 7.1; presence of meconium; Apgar score of less than 7 at 5 minutes). Neither technique identified mothers who subsequently experienced fetal distress in labor.

WHAT QUESTIONS REMAIN UNANSWERED?

There is no specific recommendation as to the value of the SDVP that suggests adverse outcomes for the pregnancy. A threshold has yet to be developed that is associated with a reduction in adverse perinatal outcomes.

WHAT IS BEST PRACTICE?

An estimate of amniotic fluid volume using the single deepest vertical pocket technique is an effective diagnostic tool for mothers at risk of intrauterine growth restriction or oligohydramnios.

CRITICAL THINKING

What are the risk factors that would suggest that amniotic fluid volume should be assessed in the prenatal period?

Assessment of Fetal Well-Being in the Third Trimester

Various maternal and prenatal conditions warrant antenatal testing during the third trimester. The type of testing performed is determined by the specific condition and the choice of the physician or certified nurse-midwife.

Conditions Warranting Fetal Surveillance

There are several indications for surveillance of fetal well-being in the third trimester. The following maternal and prenatal conditions require regular assessment (Cunningham et al., 2010):

Maternal Conditions

- Hypertensive disorders
- Type 1 diabetes mellitus
- Chronic renal disease
- Cyanotic heart disease
- Systemic lupus erythematosus
- Hyperthyroidism (poorly controlled)
- Antiphospholipid syndrome
- Hemoglobinopathies

Prenatal Conditions

- Preeclampsia
- Decreased fetal movement
- Oligohydramnios
- Hydramnios
- Intrauterine growth restriction
- Postterm pregnancy
- Isoimmunization (moderate to severe)
- Previous fetal demise
- Multiple gestation
- Known fetal anomaly
- Abnormal biochemical test results

Fetal Movement Assessment

Fetal movement assessment is considered an acceptable, noninvasive, cost-effective method of fetal surveillance in both high- and low-risk pregnancies. Monitoring fetal movement serves as an indirect measure of fetal central nervous system integrity and function. The coordination of whole-body movement in the fetus requires complex neurologic control. For this reason, clinicians generally agree that vigorous fetal movement provides reassurance of fetal well-being and oxygenation. A reduction in activity is often associated with complications of chronic rather than acute nonreassuring fetal status as the compromised fetus decreases its oxygen requirements by reducing activity. Documented cessation of activity warns of the possibility of preterm birth, asphyxia, intrauterine growth restriction, and fetal death (Flenady et al., 2009). It is these observations that provide the rationale for utilizing fetal movement counting as a means of antepartum fetal surveillance.

There is considerable variation in fetal movement that depends on the individual and the gestational age of the fetus. Fetal movement first begins to occur as early as 7 weeks, although the movements are too fine to be perceived until approximately 16 weeks for a multiparous woman and up to 20 weeks for those who are primiparous. Muscle tone is limited before 28 weeks (Blackburn, 2007). Certain substances such as tobacco smoke, drugs, alcohol, and caffeine have been shown to affect fetal movements. Altered fetal movements will usually reverse after drug clearance. There have been conflicting reports on whether carbohydrate intake increases fetal movement. Some studies suggest a decrease in fetal movements with maternal fasting (Cunningham et al., 2010).

Several methods are used to assess fetal movement perceived by the pregnant woman. The woman should be clearly instructed regarding the specific technique used and the importance of recognizing decreased fetal activity. Instruction is usually started at 28 weeks' gestation. Fetal movements peak at 26 to 32 weeks and then start to decrease because of the constraints of the uterine environment (Blackburn, 2007). Continued encouragement, education, and support by nurses within the office of the physician, midwife, or community clinic is important. The expectant woman should also be instructed to call the office if at any time she is concerned about a decrease in fetal movement from the fetus's usual daily pattern. The procedure for fetal movement assessment is discussed in chapter 16 ∞.

Pregnant women need to understand that fetal movements are significant and that they change during pregnancy, both in number and strength. The expectant woman should be reassured that there are fetal rest-sleep cycles during which minimal or no movement may occur for up to 40 minutes. After 28 weeks, if less than the expected movements are perceived by the pregnant woman, further fetal surveillance tests, such as the nonstress test, may be used to assess fetal well-being. See Patient Teaching: What to Tell the Pregnant Woman About Assessing Fetal Activity in chapter 16 ∞.

> "In 1981, I visited the First International Peace Hospital in Shanghai. At the prenatal clinic, the mothers and fathers were given a jar that contained many small black stones. The couple was instructed to complete a fetal movement count each day by starting at a similar time and then placing a stone in the jar each time they felt the baby move. Toward the end of the pregnancy, the father was encouraged to place his hand on the expectant mother's abdomen and feel the movements. Then he was responsible for placing the stones in the jar. The mothers and fathers seemed so proud when they brought their recording of the movements back to the clinic for review.
>
> Since that visit, I have often wondered what it would have been like to hold my newborn in my arms and look at the jar of stones. A simple jar but so special."

Nonstress Test

The **nonstress test (NST)** has become a widely accepted method of evaluating fetal status. (See Procedure 21-1.) This test involves using an external electronic fetal monitor to obtain a tracing of the fetal heart rate (FHR) and observation of acceleration of the FHR with fetal movement. The test is based on the knowledge that the fetus is normally active throughout pregnancy and that fetal activity will result in acceleration of the FHR when the normal fetus moves. Accelerations of the FHR imply an intact central and autonomic nervous system that is not being affected by intrauterine hypoxia. FHR acceleration in response to fetal movement is, therefore, an accepted sign of fetal health. It must be noted, however, that a nonreactive NST is not diagnostic of fetal compromise. In other words, failure to provide evidence of fetal health does not indicate that the fetus is in trouble.

The advantages of the NST are that it is relatively quick, inexpensive, and easy to interpret; it can be done in an outpatient setting and there are no known side effects. The disadvantages are that it is sometimes difficult to obtain a suitable tracing because the woman has to recline and be relatively still for 20 to 30 minutes, and the fetus may be in a sleep cycle at the time the test is performed, resulting in a nonreactive test result or need for extended monitoring (Cunningham et al., 2010).

Fetal age must be considered in the use and evaluation of NSTs. The central nervous system (parasympathetic and sym-

PROCEDURE 21-1 Performing a Nonstress Test (NST)

NURSING ACTION

Preparation

- Explain the procedure, the information it provides, and the process for completing the test.
- Ask the woman if she has recently eaten or smoked cigarettes.

  Rationale: *The test should be performed after the woman has eaten. Cigarette smoking can adversely affect the test results, so the woman should be counseled to avoid smoking prior to testing.*
- Ask the woman to void.

  Rationale: *The procedure will take at least 20 minutes to complete and the woman will need to remain in semi-Fowler's or a side-lying position and will be unable to void without interrupting the testing procedure.*

Equipment and Supplies

External fetal monitor with a monitoring strip

Blood pressure cuff

Procedure

1. Place the woman in a semi-Fowler's position with a small pillow or towel placed under her right hip after she has voided.
2. Place the ultrasound transducer from the external fetal monitor on the woman's abdomen over the FHR (typically over the fetal back or chest) so a tracing can be obtained on the monitoring strip.
3. If the FHR is not consistently recorded on the monitoring strip, adjust the ultrasound transducer until an adequate reading is obtained.

   Rationale: *Fetal or maternal movement can cause an inconsistency in the FHR on the monitoring strip. Multiple adjustments may be needed to obtain consistency in recording the FHR.*
4. Place the tocodynamometer (pressure transducer) on the woman's abdomen over the uterine fundus.

   Rationale: *Contractions are best detected when the device is directly placed on the uterine fundus.*
5. Obtain baseline measurements, including blood pressure, fetal activity, variations in the FHR during fetal movement, and contractions, for 20 minutes.

   Rationale: *Baseline measurements provide a reference for normal maternal and fetal assessment parameters.*
6. Perform the test for 20 minutes but it may be extended up to 40 minutes.

   Rationale: *Testing may be extended for the additional 20 minutes if the fetus is in a sleep cycle.*
7. Give the woman a handheld marker to indicate when she feels fetal movement.

   Rationale: *Fetal movement is accompanied by an increase in the FHR in the healthy fetus. Lack of FHR accelerations may be an indication of uteroplacental perfusion problems.*
8. Interpret the results as reactive or nonreactive.

   Rationale: *A reactive NST has two or more fetal heart accelerations within a 20-minute period. The FHR acceleration must be at least 15 beats per minute above baseline for at least 15 seconds from baseline to baseline. A nonreactive NST is one that lacks sufficient FHR accelerations over a 40-minute period (Cunningham et al., 2010).*
9. Explain the results to the woman and relate information from the healthcare provider regarding further management needs or additional follow-up that is needed.

   Rationale: *The nurse is the key communicator in providing information regarding the test results and their meaning to the woman.*

Documentation

Document baseline maternal and fetal assessment information that was obtained before and during the test. The results of the test should be documented along with information regarding how the information was reported to the healthcare provider. The specific name of the healthcare provider and date and time should be recorded. Any additional orders and instructions to the client should be documented. Verbalization of understanding of the test results by the woman should be documented along with her understanding of follow-up instructions and future appointments.

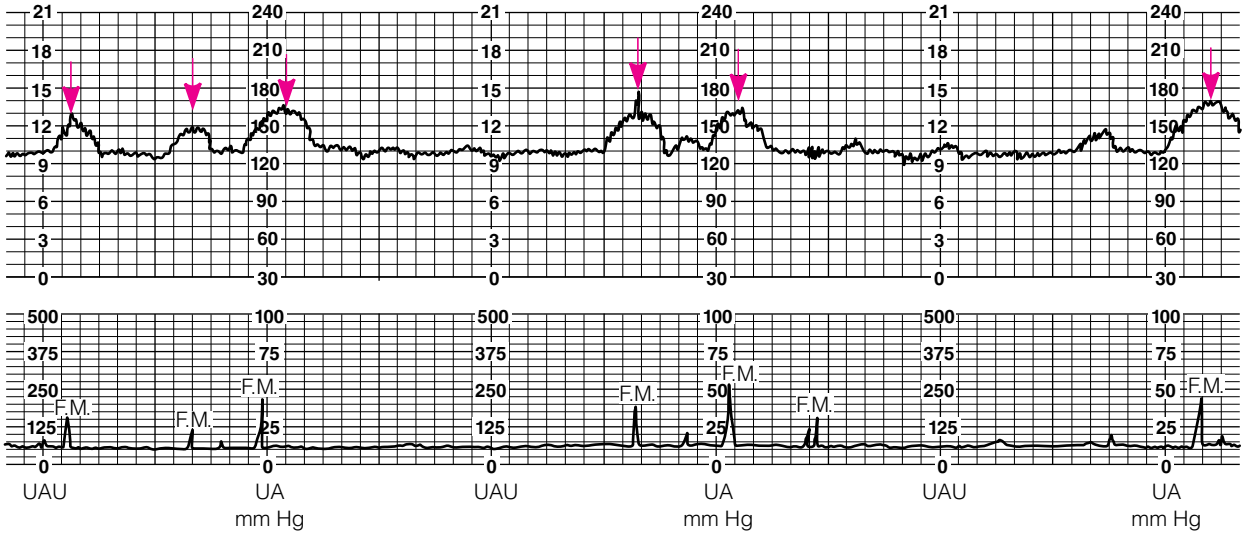

Figure 21-11 ■ Example of a reactive nonstress test (NST). Accelerations of 15 beats/min lasting 15 seconds with each fetal movement (FM). Top of strip shows fetal heart rate (FHR); bottom of strip shows uterine activity tracing. Note that FHR increases (above the baseline) at least 15 beats and remains at that rate for at least 15 seconds before returning to the former baseline.

pathetic nervous systems) of the fetus is not sufficiently mature to allow frequent accelerations of the heart rate when fetal movement occurs until 30 to 32 weeks of gestation. Acceleration patterns are directly affected by gestational age. The acme of acceleration is 15 beats per minute or more above the baseline rate. The acceleration lasts 15 seconds or longer for less than 2 minutes in fetuses at or beyond 32 weeks (Figure 21-11 ■). There must be at least two accelerations within a 20-minute period. Before 32 weeks, accelerations are defined as having an acme of 10 beats per minute or more for 10 seconds or longer (Cunningham et al., 2010). One study examined FHR pattern changes that occurred with advancing gestational age. Mean baseline FHR, signal loss, and fetal movement all decreased in advancing gestational age (Cunningham et al., 2010).

The NST can be used as an assessment tool in any pregnancy but is especially useful in the presence of diabetes, preeclampsia, intrauterine growth restriction, spontaneous rupture of membranes, multiple gestation, postdates, and other high-risk pregnancy conditions. These conditions can lead to a decline in uteroplacental functioning, which can result in decreased oxygenation to the fetus and eventual asphyxia. Testing intervals may vary, depending on the condition of the mother and fetus and recommendations of various experts. Most clinicians test twice weekly for high-risk patients and once a week for other conditions (Cunningham et al., 2010).

Procedure for Performing an NST

The NST is usually scheduled during daytime hours. It may be performed either in the office or hospital setting. Women are requested to be nonfasting and to have refrained from recent cigarette smoking because this can adversely affect test results. The NST is typically performed with the woman in the semi-Fowler's position with a small pillow or blanket under the right hip to displace the uterus to the left. The FHR is monitored by the placement of an electronic fetal monitor (see discussion in chapter 23 ∞). Either one or two belts are placed around the woman's abdomen. One belt holds the ultrasound transducer to record the FHR and the other holds a tocodynamometer that detects uterine or fetal movement. The FHR is usually monitored for 20 minutes, but monitoring may be extended to 40 minutes if it appears the fetus is in a sleep cycle. The woman is often requested to record each fetal movement by the use of self-operated markers. Under ideal conditions, a correlation of more than 90% between maternal perceived and actual fetal movements can be achieved; however, typically more than 40% of actual movements remain undetected by pregnant women (Flenady et al., 2009). Recent studies have examined NST administration in alternative positions, such as walking or in a sitting position. These studies found maternal perceptions of fetal movements was highest in the reclining position, but the walking and sitting positions resulted in a shortened time period to obtain two accelerations (Flenady et al., 2009).

Interpretation of the NST

NSTs are categorized as either reactive or nonreactive. The most common definition of a reactive (normal) test is that there are two or more fetal heart accelerations within a 20-minute period, with or without fetal movement discernible by the woman. The FHR acceleration must be at least 15 beats per minute above the baseline and last 15 seconds from baseline to baseline. A nonreactive (abnormal) NST is one that lacks sufficient FHR accelerations over a 40-minute period (Figure 21-12 ■) (Cunningham et al., 2010). Again, it is important to take into account the gestational age of the fetus. Both fetal movement and the amplitude of the FHR accelerations increase with gestational age.

Spontaneous decelerations of the FHR, known as variable decelerations, that occur during the testing period must also be noted. Variable decelerations may be observed in up to 50% of NSTs. Variable decelerations, if nonrepetitive and brief (less than 30 seconds), do not indicate fetal compromise nor the need for obstetric intervention (Cunningham et al., 2010). In contrast, repetitive variable decelerations (at least 3 in 20 minutes),

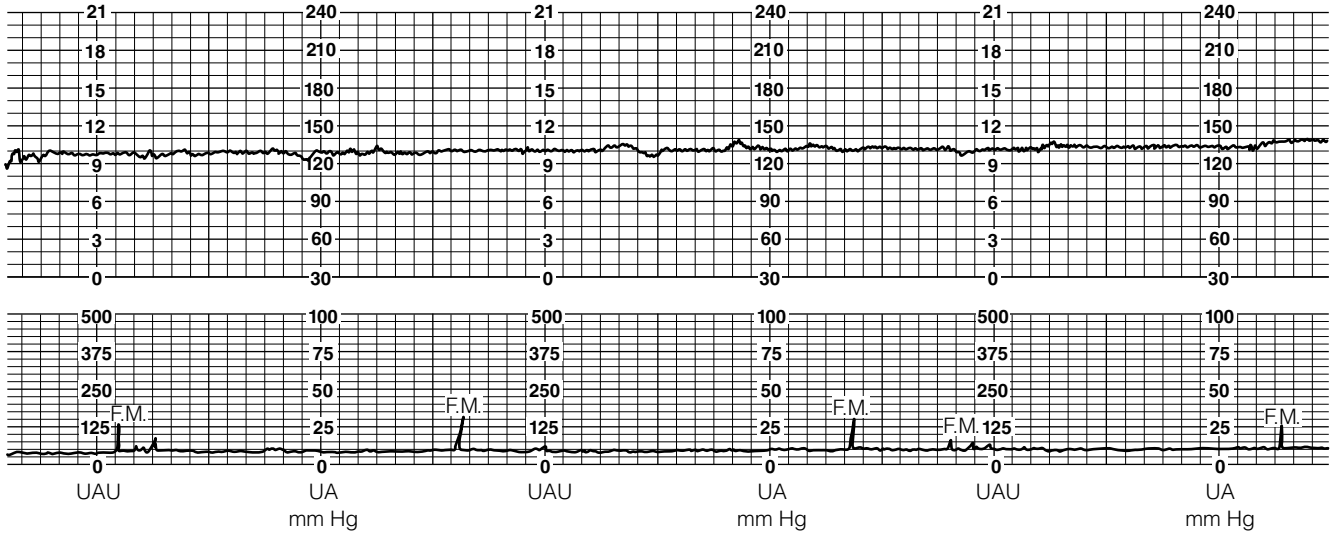

Figure 21-12 ■ Example of a nonreactive NST. There are no accelerations of FHR with fetal movement (FM). Baseline FHR is 130 beats/min. The tracing of uterine activity is on the bottom of the strip.

even if mild, have been associated with an increased risk of cesarean birth for nonreassuring intrapartum FHR pattern. The prognosis for decelerations lasting 1 minute or longer is even more ominous (Cunningham et al., 2010). It is the responsibility of the nurse performing this test to consult the physician or nurse-midwife for further evaluation of fetal status if there is any question concerning the reactivity of the test or the presence of repetitive decelerations.

Clinical Management

The clinical management of a woman following an NST may vary. If the NST is reactive after 20 minutes, the test is concluded and the woman is rescheduled for further testing as indicated by the condition of, or risk factors present for, the mother and/or fetus. The interval between testing is typically 1 week if the maternal medical condition is stable. Testing may be performed twice weekly if warranted by maternal or fetal risk factors. Any significant deterioration in the maternal medical status requires fetal reevaluation regardless of the amount of time that has elapsed since the last test (Cunningham et al., 2010).

NURSING CARE MANAGEMENT

The nurse first must ascertain the woman's understanding of the NST. The nurse then reviews the indications for the NST, the equipment being used, and the procedure before beginning the test. The nurse positions the woman and applies the electronic fetal monitor. Maternal blood pressure is monitored during the NST to determine whether hypotension is present. The nurse administers the NST, may or may not interpret the results, and reports the findings to the family physician/obstetrician or certified nurse-midwife and the patient. The nurse uses this opportunity to assess learning needs concerning the importance of fetal movement and provides information and teaching.

Vibroacoustic Stimulation

Vibroacoustic stimulation (VAS), also called *FAST* for *fetal acoustic stimulation test* or *VST* for *vibroacoustic stimulation test*, is an application of sound and vibration to the mother's abdomen to stimulate movement in the fetus (Figure 21-13 ■). A device is used that delivers 90 dB of sound for 1 to 3 seconds to the fetus with the purpose of changing the fetal sleep cycle, thereby accelerating the FHR (Cunningham et al., 2010).

NSTs that are interpreted as nonreactive often depict the normal state of quiet sleep by the fetus, which can last for up to 40 minutes. In these cases, VAS can be used to facilitate the timely interpretation of the NST. The typical VAS response of a healthy term fetus shows a rise of at least 10 beats per minute in baseline, occurring within 10 seconds and lasting from 5 to 10 minutes. Gestational age influences the reliability and reproducibility of the fetal response. The purpose of the VAS is to improve the specificity and efficiency of interpretation of FHR monitoring patterns. Although many obstetricians and certified nurse-

Figure 21-13 ■ Vibroacoustic stimulation testing.

Source: Photographer, Elena Dorfman.

midwives are enthusiastic about the VAS test because of its potential to minimize the need for more invasive follow-up testing, concerns for fetal hearing loss prevent universal use of this exam. Hearing loss has been demonstrated in newborns whose mothers were exposed to chronic levels of sound at 90 dB or more (Creasy et al., 2008). Although there are no documented cases of newborn hearing loss related to VAS, some advocate judicious use of this exam. Others have advocated simply rescheduling the NST in 1 to 2 hours when the fetus is likely to have moved from the quiet sleep state that may have resulted in the first nonreactive test as an alternative to VAS.

Contraction Stress Test

The **contraction stress test (CST)** is a means of evaluating the respiratory function (oxygen and carbon dioxide exchange) of the placenta (i.e., uteroplacental function). (See Procedure 21-2.) It enables the healthcare team to identify the fetus at risk for intrauterine asphyxia by observing the response of the FHR to the stress of uterine contractions (spontaneous or induced). During contractions, intrauterine pressure increases. Blood flow to the intervillous space of the placenta is reduced momentarily, thereby decreasing oxygen transport to the fetus. A healthy fetus usually tolerates this reduction well. If the placental reserve is insufficient, fetal hypoxia, depression of the myocardium, and a decrease in FHR occur (Blackburn, 2007).

Indications and Contraindications

The CST is indicated for pregnancies at risk for placental insufficiency or fetal compromise because of any of the following (Cunningham et al., 2010):

- Intrauterine growth restriction
- Diabetes mellitus
- Postdates (42 or more weeks' gestation)
- Nonreactive NST
- Abnormal or suspicious biophysical profile

Contraindications for the CST are the following:

- Third trimester bleeding (placenta previa, marginal abruptio placentae, or unexplained vaginal bleeding)
- Previous cesarean birth with classical uterine incision
- Instances in which the risk of possible preterm labor outweighs the advantage of the CST, including:
  a. Premature rupture of the membranes
  b. Incompetent cervix or Shirodkar-Barter operation (cerclage—surgical procedure in which an incompetent cervix is encircled with a suture to prevent it from dilating before term) (See chapter 26 ∞.)
  c. Multiple gestation

CST Procedure

A necessary component of the CST is the presence of three uterine contractions of at least 40 seconds' duration in 10 minutes. The response of the FHR when contractions occur provides data on the fetal status. The contractions may occur spontaneously, or they may be induced by oxytocin (Pitocin) or nipple stimulation. The most common method of stimulating uterine contractions for a CST has been intravenous administration of oxytocin, but many facilities now use breast self-stimulation to obtain a CST (see later discussion) (Cunningham et al., 2010). This method is based on the fact that endogenous oxytocin is produced in response to stimulation of the breasts or nipples.

The CST is performed on an outpatient basis by qualified maternity nurses well acquainted with fetal monitoring and the interpretation of various FHR patterns. Most facilities require that the test be administered in or near the labor and birth unit so that treatment is available in the event that adverse reactions to oxytocin stimulation occur. The procedure, reasons for administering the test, equipment, and normal variations in monitoring that occur during the test should be clearly explained before the test to alleviate the woman's apprehension. A consent form may be signed.

During the test, the woman assumes a semi-Fowler's or sidelying position to avoid supine hypotension. The ultrasonic transducer (from the electronic fetal monitor) is placed on the woman's abdomen over the area of the fetal back or chest so that the FHR can be accurately recorded on the monitoring strip. (See chapter 23 ∞ for further discussion of fetal monitoring.) To record uterine contractions, the tocodynamometer (pressure transducer) is placed over the area of the uterine fundus. For the first 15 to 20 minutes, the nurse records baseline measurements, including blood pressure, fetal activity, variations of the FHR during fetal movement, and spontaneous contractions. In addition, pertinent medical and obstetric information may be obtained from the woman to aid in her further management.

After the baseline recording is done, an intravenous oxytocin contraction stress test or breast self-stimulation test (BSST) is done.

CLINICAL TIP

When performing a contraction stress test (CST), provide comfort measures to the woman who may experience discomfort during the procedure.

INTRAVENOUS OXYTOCIN CST In a CST using intravenous oxytocin, an electrolyte solution such as lactated Ringer's solution is started as a primary infusion. A piggyback infusion of oxytocin in a similar solution is attached. An infusion pump is used so that the amount of oxytocin being infused can be measured accurately. The administration procedure is the same as that for inducing labor through oxytocin administration (see chapter 28 ∞). Oxytocin is administered until three uterine contractions lasting 40 to 60 seconds occur in a 10-minute period (called the 10-minute window). If late decelerations occur with all three contractions, the oxytocin infusion is discontinued. The woman's blood pressure and pulse are assessed every 15 minutes and recorded on the tracing.

CST WITH BREAST SELF-STIMULATION TEST (BSST) A woman receiving a BSST is instructed to stimulate her nipples with her fingers, palms, or a warm, moist face cloth, either directly or through her clothing, for 2 minutes or until a contraction begins. Stimulation may also be done mechanically by the use of a breast pump. Once the contraction begins, the woman

PROCEDURE 21-2 Performing a Contraction Stress Test (CST)

NURSING ACTION

Preparation

- Explain the procedure, the information it provides, and the process for completing the test.
- Ask the woman to void.

  Rationale: *The procedure will take at least 10 minutes to complete and the woman will need to remain in semi-Fowler's or a side-lying position and will be unable to void without interrupting the testing procedure.*
- Advise the woman that if uterine contractions are not occurring spontaneously, intravenous oxytocin or breast stimulation may be needed to perform the test.

  Rationale: *The test requires three contractions lasting at least 40 seconds in duration in a 10-minute period in order to be performed.*

Equipment and Supplies

External fetal monitor with a monitoring strip

Blood pressure cuff

Procedure

1. Place the woman in a semi-Fowler's or side-lying position after she has voided.
2. Place the ultrasound transducer from the external fetal monitor on the woman's abdomen over the FHR (typically over the fetal back or chest) so a tracing can be obtained on the monitoring strip.
3. If the FHR is not consistently recorded on the monitoring strip, adjust the ultrasound transducer until an adequate reading is obtained.

   Rationale: *Fetal or maternal movement can cause an inconsistency in the FHR on the monitoring strip. Multiple adjustments may be needed to obtain consistency in recording the FHR.*
4. Place the tocodynamometer (pressure transducer) on the woman's abdomen over the uterine fundus.

   Rationale: *Contractions are best detected when the device is directly placed on the uterine fundus.*
5. Obtain baseline measurements, including blood pressure, fetal activity, variations in the FHR during fetal movement, and contractions, for 15 to 20 minutes.

   Rationale: *Baseline measurements provide a reference for normal maternal and fetal assessment parameters.*
6. If less than three contractions lasting at least 40 seconds are occurring within a 10-minute period, administer intravenous oxytocin or instruct the woman in the breast stimulation technique until three contractions in a 10-minute period are occurring. The method chosen is based on the healthcare provider's orders and the woman's preference.

   Rationale: *If the woman has a preference over one method or another, the healthcare provider should be made aware of that preference.*
7. If using intravenous oxytocin, start an electrolyte solution as a primary infusion and attach a piggyback infusion of oxytocin in a similar solution using an infusion pump.

   Rationale: *Intravenous oxytocin is always infused using a piggyback line because a small quantity is infusing. An infusion pump should be used to ensure accuracy.*
8. Administer oxytocin and increase at regular intervals per agency protocol until three contractions lasting 40 to 60 seconds occur in a 10-minute period.

   Rationale: *Because there are several formulas used to mix oxytocin and several different protocols to increase the dosage, specific agency protocol should be consulted regarding the preparation of the oxytocin solution and the dosage and interval increases used within the facility.*
9. If using breast self-stimulation (BSST), instruct the woman to stimulate her breasts with her fingers, palms, or a warm, moist washcloth, either directly or through her clothing for 2 minutes or until a contraction begins.

   Rationale: *Breast stimulation will facilitate the natural release of oxytocin by the woman's body. Some women may prefer a more natural method of testing and may prefer BSST over intravenous oxytocin.*
10. Instruct the woman to stop the stimulation once the contraction occurs and to restart the stimulation if a contraction has not occurred within 5 minutes (Creasy et al., 2008).

    Rationale: *Continuous breast stimulation can result in uterine hyperstimulation, which can lead to a uterine rupture.*
11. Advise the woman to increase the frequency of stimulation as needed to obtain three contractions within a 10-minute period.
12. Interpret the test as negative, positive, equivocal-suspicious, equivocal-hyperstimulatory, or unsatisfactory and report the findings to the healthcare provider immediately.

    Rationale: *The CST interpretations are based on specific criteria and should be reported to the healthcare provider as soon as the results are obtained. The results provide data regarding uteroplacental perfusion and indicate whether the fetus can withstand the stress of uterine contractions.*
13. Explain the results to the woman and relate information from the healthcare provider regarding further management needs or additional follow-up that is needed.

Documentation

Document baseline maternal and fetal assessment information that was obtained before and during the test. The results of the test should be documented along with information regarding how the information was reported to the healthcare provider. The specific name of the healthcare provider and date and time should be recorded. Any additional orders and instructions to the client should be documented. Verbalization of understanding of the test results by the woman should be documented along with her understanding of follow-up instructions and future appointments.

is instructed to stop the stimulation, waiting to restart if another contraction has not followed by 5 minutes. It is important to monitor the frequency of contractions to avoid uterine hyperstimulation.

Interpretation and Clinical Management

A CST is usually not done before 28 weeks' gestation, primarily for two reasons. First, in light of a positive test, birth and extrauterine survival would be questionable at such an early gestational age. Second, sufficient research has not been done to determine whether the same test results apply to a fetus of this gestation. CST is usually done no earlier than 32 to 34 weeks' gestation and typically in preparation for induction of labor.

INTERPRETATION OF CST RESULTS A CST can be interpreted once three moderately strong contractions of 40 to 60 seconds' duration have been noted in a 10-minute window of time. A CST can be interpreted as negative, positive, equivocal, or unsatisfactory (Table 21-4). Cunningham et al. (2010) offered the following CST interpretations:

Negative—The absence of late or significant variable decelerations (the most common deceleration pattern noted during labor; attributed to umbilical cord compression or occlusion) is considered a reassuring sign that the fetus is receiving sufficient transfer of oxygen through the placenta (Figure 21-14 ■).

Positive—The presence of **late decelerations** (a symmetrical decrease in FHR beginning at or after the peak of the contraction and returning to baseline only after the contraction has ended following 50% or more of contractions, even if the contraction frequency is fewer than three in 10 minutes) is a sign of uteroplacental insufficiency and may indicate that the fetus is not receiving adequate oxygenation (Figure 21-15 ■).

Equivocal-suspicious—The presence of intermittent late decelerations or significant variable decelerations should be viewed as a suspicious finding that merits follow-up testing.

TABLE 21-4 Interpretation of the Contraction Stress Test

RESULT	INTERPRETATION
Negative	No late or significant variable decelerations.
Positive	Late decelerations following 50% or more of contractions (even if the contraction frequency is fewer than three in 10 minutes).
Equivocal	
Suspicious	Intermittent late decelerations or significant variable decelerations.
Hyperstimulatory	Fetal heart rate decelerations that occur in the presence of contractions more frequent than every 2 minutes or lasting longer than 90 seconds.
Unsatisfactory	Fewer than three contractions in 10 minutes or an uninterpretable tracing.

Source: ACOG Practice Bulletin No. 9, October 1999. Clinical Management Guidelines for Obstetrician-Gynecologists, *pp. 2–3.*

Equivocal-hyperstimulatory—FHR decelerations may occur in the presence of contractions that occur more frequently than every 2 minutes or that last longer than 90 seconds. This test should be repeated after hyperstimulation has been rectified and the patient has been hydrated and allowed to rest.

Unsatisfactory—The CST cannot be interpreted if fewer than three contractions lasting 40 to 60 seconds occur in a 10-minute window of time.

CST results are also evaluated for the presence of accelerations that would meet the criteria of the NST. Combining the CST assessment with NST results showing characteristics such as variability of the FHR baseline and the presence of other types of decelerations helps the clinician determine the best management plan for the fetus.

CLINICAL MANAGEMENT BASED ON CST RESULTS In most cases, a negative CST with a reactive NST is the desired result. The uteroplacental perfusion is sufficient at present to allow the fetus to withstand the stress of uterine contractions. Retesting

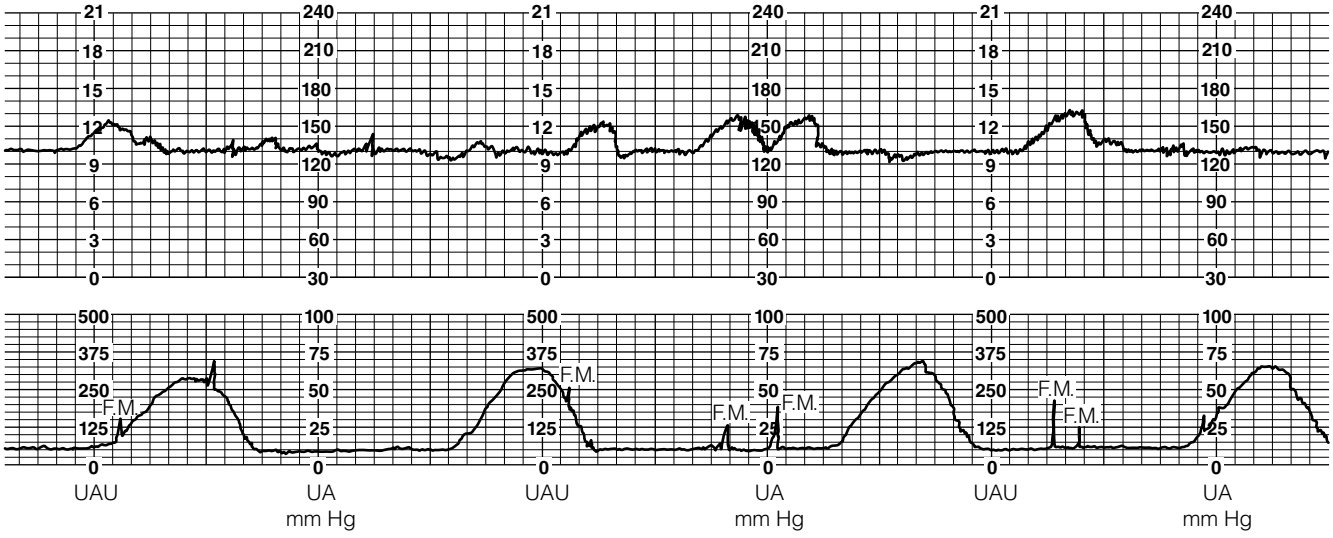

Figure 21-14 ■ Example of a negative CST (and reactive NST). The baseline FHR is 130 beats/min with acceleration of FHR of at least 15 beats/min lasting 15 seconds with each fetal movement (FM). Uterine contractions recorded on the bottom half of the strip indicate three contractions in 8 minutes.

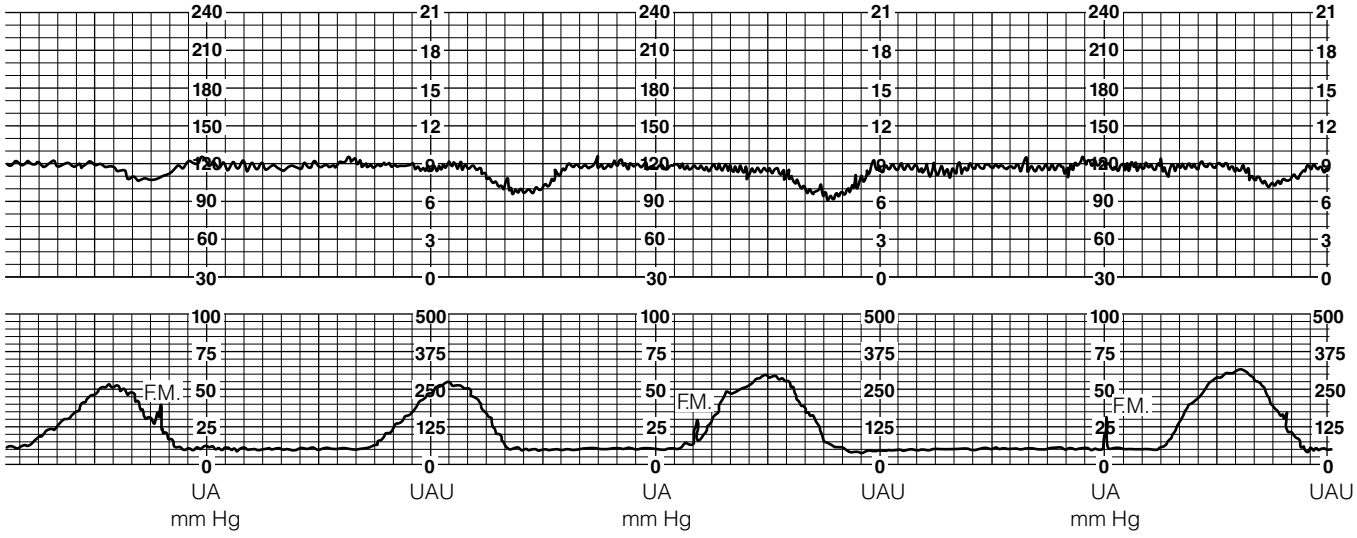

Figure 21-15 ■ Example of a positive contraction stress test (CST). Repetitive late decelerations occur with each contraction. Note that there are no accelerations of FHR with three fetal movements (FM). The baseline FHR is 120 beats/min. Uterine contractions (bottom half of strip) occurred four times in 12 minutes.

would most likely be scheduled in 7 days. If the pregnant woman is diabetic, the CST schedule would remain the same, except an NST would be done in 3 to 4 days (Creasy et al., 2008). A negative CST with a nonreactive NST is more difficult. It should be assessed very carefully for subtle late decelerations. If there are none, a CST would be repeated in 7 days.

All equivocal tests should be repeated in 24 hours, especially in the presence of a postterm pregnancy (Creasy et al., 2008). If the gestation is less than 37 weeks, then other surveillance methods should be added.

A positive CST with a nonreactive NST presents evidence that the fetus would probably not withstand the stress of labor. If the gestation is 32 weeks or over, a cesarean birth should be scheduled (Creasy et al., 2008).

NURSING CARE MANAGEMENT

The nurse ascertains the woman's or couple's understanding of the CST before the procedure and the possible results. The nurse reviews the reasons for the CST and the procedure before beginning the test. The nurse then applies the external fetal monitor to the maternal abdomen. If oxytocin is to be used, the nurse inserts an intravenous line and begins the medication. If a BSST is being conducted, the nurse instructs the woman on self-stimulation of the breast or on the appropriate use of the breast pump. Continuous monitoring of the contraction pattern is warranted to ensure that hyperstimulation of the uterus or fetal compromise does not occur. The nurse then reports the findings to the physician or certified nurse-midwife and explains the results to the woman.

Amniotic Fluid Index

Assessment of amniotic fluid volume is based on the rationale that decreased uteroplacental perfusion may lead to diminished fetal renal blood flow, decreased urination, and, ultimately, **oligohydramnios** (decreased amniotic fluid volume). Fetal urine output and fetal swallowing are the major determinants of amniotic fluid volume. Oligohydramnios may be the result of diminished urinary output caused by fetal hypoxemia. The resulting placental insufficiency may cause hypoxia and hence oligohydramnios. Therefore, assessment of long-term uteroplacental function may be performed by evaluating amniotic fluid volume (Gabbe et al., 2007). Some poor pregnancy outcomes, such as intrauterine growth restriction, postterm pregnancy, and nonreassuring fetal status in labor, have been associated with abnormalities of amniotic fluid volume. The procedure for performing an amniotic fluid index (AFI) was discussed previously on page 505.

An AFI value of 5 or less serves as a red flag that requires some type of further assessment or management decision (Cunningham et al., 2010). The gestational age of the fetus and the composite maternal condition may influence management decisions, leading to additional testing, induction of labor, or cesarean birth.

Biophysical Profile

The **biophysical profile (BPP)** represents an assessment of five fetal biophysical variables:

- FHR acceleration
- Fetal breathing
- Fetal movements
- Fetal tone
- Amniotic fluid volume

The first criterion is assessed with the NST. The other variables are assessed by ultrasound scanning. By combining these five assessments, the BPP helps to identify the compromised fetus and confirm the healthy fetus. Average testing time is usually less than 8 minutes, with 90% of normal testing completed within the first 4 minutes (Devoe, 2008). A time period of 30 minutes is selected for BPP testing (ultrasound components) to account for the average duration of sleep-wake cycles in the normal fetus, which are approximately 20 minutes.

TABLE 21-5 Criteria for Normal and Abnormal Assessments of the BPP

COMPONENT	NORMAL (SCORE = 2)	ABNORMAL (SCORE = 0)
Fetal breathing movements	Greater than or equal to 1 episode of rhythmic breathing lasting greater than or equal to 30 sec within 30 min	Less than 30 sec of breathing in 30 min
Gross body movements	Greater than or equal to 3 discrete body or limb movements in 30 min (episodes of active continuous movement considered as single movement)	Less than or equal to 2 movements in 30 min
Fetal tone	Greater than or equal to 1 episode of extension of a fetal extremity with return to flexion, or opening or closing of hand	No movements or extension/flexion
Reactive fetal heart rate Nonstress test	Greater than or equal to 2 accelerations of greater than or equal to 15 beats/min for greater than or equal to 15 sec in 20–40 min	0 or 1 acceleration in 20–40 min
Amniotic fluid volume	At least 1 pocket of anmiotic fluid of at least 2 cm AFI >5	Less than 1 pocket of amniotic fluid measuring less than 2 cm

Indications for the biophysical profile include those situations in which the NST and CST would be done. Assessment of these fetal biophysical activities is most useful in the evaluation of women who experience decreased fetal movement (who might subsequently have a nonreactive NST) and in the management of intrauterine growth restriction, preterm labor, gestational diabetes, postterm pregnancies, and premature rupture of the membranes (PROM) (Devoe, 2008).

The two most important components of the BPP are the NST and the amniotic fluid volume index. The NST reflects the intactness of the nervous system and the AFI reflects kidney perfusion. A normal AFI indicates that shunting has not occurred and that the fetal kidneys are adequately functioning. Reactive NST and normal fluid therefore reflect fetal well-being.

Specific criteria for normal and abnormal assessments are delineated in Table 21-5. Normal variables are assigned a score of 2 each and abnormal variables a score of 0 (zero). Thus, the highest score possible for a normal fetus is 10.

Clinicians suggest that management not be based solely on BPP scores. Biophysical activities of the fetus that develop first are the last to disappear when all activities are arrested because of asphyxia (Devoe, 2008). Those that are the last to develop are the most sensitive to hypoxia, and their disappearance can be noted first. For example, fetal tone (exhibited by flexion of the extremities) is the first to develop and the last activity to cease during asphyxia. Other activities in the normal developmental sequence are fetal movement, followed by fetal breathing, and then reactivity of the FHR. Therefore, FHR reactivity is the most sensitive to hypoxia (Cunningham et al., 2010). One of the first indications of fetal compromise is a nonreactive NST. Table 21-6 outlines BPP test interpretation and the recommended management (Cunningham et al., 2010).

Modified Biophysical Profile

The biophysical profile is labor intensive and expensive. It requires a trained person in ultrasonic visualization of the fetus. In addition, studies have shown that when the four dynamic ultrasound variables are normal, the probability of encountering an abnormal (nonreactive) NST is exceedingly small (Devoe, 2008). For these reasons, a modified biophysical profile (BPP) has been developed. This test consists of an NST and a measurement of the AFI, both of which reflect long-term uteroplacental function. The

TABLE 21-6 BPP Test Interpretation and Recommended Management

TEST SCORE	INTERPRETATION	PERINATAL MORTALITY WITHIN 1 WEEK WITHOUT INTERVENTION	MANAGEMENT
10/10	Normal nonasphyxiated fetus	Less than 1/1000	No fetal indication for intervention; repeat test weekly except in patient with diabetes and pregnancies that are postterm (twice weekly)
8/10 (normal fluid) 8/8 if no NST done	Risk of fetal asphyxia extremely rare	Less than 1/1000	Same as above
8/10 (abnormal fluid)	Chronic fetal asphyxia suspected	89/1000	Induce birth
6/10	Possible fetal asphyxia	89/1000	If amniotic fluid volume abnormal, induce birth
			If normal fluid at greater than 36 weeks with favorable cervix, induce birth
			If repeat test less than or equal to 6, induce birth
			If repeat test greater than 6, observe and repeat per protocol
4/10	Probable fetal asphyxia	91/1000	Repeat testing same day; if BPP score less than or equal to 6, induce birth
2/10	Almost certain fetal asphyxia	125/1000	Induce birth
0/10	Certain fetal asphyxia	600/1000	Induce birth

functioning of the placenta is important because a poorly functioning placenta (placental dysfunction) may result in diminished fetal renal perfusion, leading to oligohydramnios. The amniotic fluid volume assessment can therefore be used to evaluate long-term uteroplacental function. A modified BPP is considered normal if the amniotic fluid volume is greater than 5 cm and if the NST is reactive. The test is abnormal if either the NST is nonreactive or the AFI is 5 or less. The frequency of this test is the same as with the standard BPP.

Doppler Flow Studies

Recent advances in ultrasound technology have made it possible to study noninvasively the blood flow changes that occur in maternal and fetal circulations in order to assess placental function. An ultrasound beam, like that provided by the pocket Doppler (a handheld ultrasound device), is directed at the umbilical artery. The signal is reflected off the red blood cells moving within the vessels, and the subsequent "picture" (waveform) that is received looks like a series of waves. The highest velocity peak of the waves is the systolic measurement, and the lowest point is the diastolic velocity. The umbilical artery waveform can then be analyzed to provide information about velocity of blood flow in the vessel (Kiserud, Ebbing, Kessler, et al., 2007). Examples of these waveforms are displayed in Figures 21-16 ■ and 21-17 ■.

The most common evaluation of blood flow velocity is the systolic to diastolic (S/D) ratio. The S/D ratio normally decreases as the fetus nears term. This phenomenon reflects the decreasing resistance of placental and umbilical vasculature to allow for greater umbilical blood flow to meet the needs of a growing fetus. The S/D ratio is considered abnormal if it is elevated above the 95th percentile for gestational age or reversed after 18 to 20 weeks of gestation (Peterson, Wong, Urs, et al., 2009). Absent or reversed end-diastolic flow signifies increased impedance and is uniquely associated with intrauterine growth restriction. It is also associated with a high perinatal mortality rate (Peterson et al., 2009).

A decrease in fetal cardiac output or an increase in resistance of placental vessels will reduce umbilical artery blood flow. Doppler velocimetry is best used when intrauterine growth restriction is diagnosed, whether it occurs as an idiopathic process (cause unknown) or in the presence of hypertension or preeclampsia (Peterson et al., 2009). No benefit has been demonstrated for umbilical artery velocimetry for other conditions such as postterm pregnancy, diabetes, systemic lupus erythematosus, or antiphospholipid antibody syndrome. Also, it has not been shown to be of value as a screening test for detecting fetal compromise in the general obstetric population (Cunningham et al., 2010).

Evaluation of Placental Maturity

Placental maturity is evaluated by a grading process that uses ultrasound to measure the changes in the basal layer, chorionic plate, and intervening placental substance. A grade of 0 through III is assigned (grade III is the most mature, showing extensive calcifications) (Figure 21-18 ■). Placentas with multiple calcifications are less likely to function as adequately as those with lower grades. Certain factors can cause a placenta to mature, including maternal smoking, postterm pregnancy, and certain

Journal of Obstetric, Gynecologic, & Neonatal Nursing, *19(4), 475–481 (Figure 4, p. 478). Washington, DC: Author. ©1990 by the Association of Women's Health, Obstetric and Neonatal Nurses. All rights reserved.*

maternal conditions, such as preeclampsia and gestational diabetes. Placental grade may be used to correlate with other findings; however, placental grade alone does not dictate management of a pregnancy (Cunningham et al., 2010).

Estimation of Fetal Weight

Estimating the fetal weight in the third trimester of pregnancy is an important aspect of fetal assessment. Particularly, findings of the fetal weight at either end of the spectrum—inadequate fetal growth or excessive fetal growth—are critical risk factors for alterations in fetal well-being.

Intrauterine growth restriction (IUGR), also known as *inadequate fetal growth,* is a term used to describe any fetus that falls below the 10th percentile in ultrasonic estimation of weight at a given gestational age. Other terms to describe the small fetus include *low birth weight, small for gestational age,* and *intrauterine growth retardation (IUGR).* IUGR may or may not be associated with prematurity.

The etiology of IUGR can be separated into either fetoplacental or maternal origin. Fetoplacental etiologies would include infections, genetic abnormalities, and placental abnormalities. Maternal etiologies stem from reduced uteroplacental blood flow associated with hypertension, poor maternal weight gain, poor nutrition, substance use such as tobacco or medications, anemia, or chronic illness (Cunningham et al., 2010).

If a fetus is suspected to have IUGR, the management includes careful surveillance of the fetus with NSTs and BPPs and continuous assessment of growth through sonographic assessment. In addition to regular fetal surveillance, women with IUGR are instructed to do daily fetal movement assessments (previously discussed in this chapter) and to maintain bed rest. If growth ceases altogether or if other nonreassuring fetal factors occur (nonreassuring FHR patterns), delivery may be warranted.

Macrosomia (excessive fetal growth) is defined by ACOG (2009) as weight greater than 4000 to 4500 g (8 lb 13 oz to 9 lb 4 oz). If a fetus is suspected to be macrosomic, the management of the labor and birth is carefully evaluated to prevent birth-related

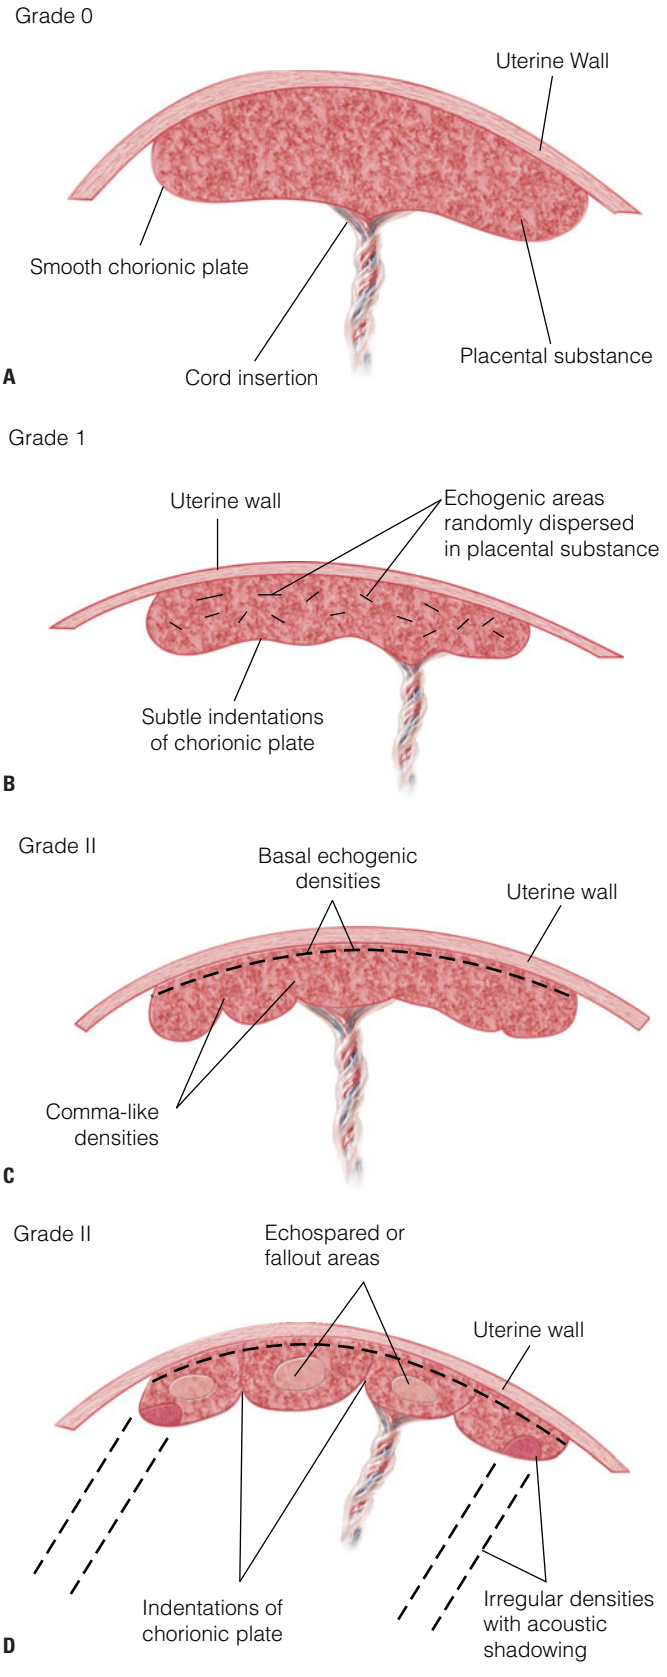

Figure 21-18 ■ Placental grading. A. Diagram showing the ultrasonic appearance of a grade 0 placenta. B. Diagram showing the ultrasonic appearance of a grade I placenta. C. Diagram showing the ultrasonic appearance of a grade II placenta. D. Diagram showing the ultrasonic appearance of a grade III placenta.

complications such as *shoulder dystocia* (an intrapartum event that occurs when the infant's head has been delivered, but the shoulders remain wedged behind the mother's pubic bone, causing a difficult birth of the infant with potential for maternal or fetal injury).

The diagnosis of fetal macrosomia is imprecise. The accuracy of estimated fetal weight using ultrasound biometry and that obtained with clinical palpation by the obstetrician or certified nurse-midwife has yielded similar results (Nahum, 2007). Clinical palpation of the fetus is done using the Leopold's maneuver. The clinician places both hands on the uterus and traces the fetal outline moving his or her hands down along the sides of the maternal abdomen. This maneuver gives the clinician information about the estimated size of the fetus and its position in utero (see chapter 23 ∞ and Figure 23-7 ∞ on page 571). Measuring the fundal height (measured in centimeters with a tape measure from the symphysis pubis to the fundus of the uterus) is another tool in estimating fetal growth. According to ACOG (2009), these two primary methods for the clinical estimation of fetal weight should be combined to produce a more accurate measurement. Experienced providers may also ask the woman to provide her own estimate of the fetal weight if she has had a previous birth based on how big she perceives the baby to be in comparison to her last pregnancy.

The greatest risk factor for macrosomic infants is birth trauma due to a shoulder dystocia. When macrosomia is present, a potential shoulder dystocia should be anticipated if the woman is giving birth vaginally. The woman should be positioned in McRobert's position (legs flexed and pulled back toward her shoulders) (see Figure 27-12 ∞ on page 712) with the head of the bed lowered. A stool should be readily available in the event that suprapubic pressure is needed. If the physician or certified nurse-midwife requests suprapubic pressure, the nurse applies pressure directly over the symphysis pubis to aid in dislodging the fetal shoulder (see chapter 27 ∞). Having a woman get on all fours is also an acceptable first step to releasing the shoulder (Coppus, Langenveld, & Oei, 2007).

Women who are undergoing a trial of labor (TOL) after a previous cesarean birth should be counseled on the risks of a shoulder dystocia when macrosomia is suspected. In addition, a macrosomic fetus may decrease the likelihood of a successful vaginal birth after cesarean (VBAC), especially if the previous cesarean birth was performed for cephalopelvic disproportion (see chapter 27 ∞). Although macrosomia is not a contraindication to a trial of labor, a TOL without a previous vaginal birth when the fetus is macrosomic increases the risk of uterine rupture (Cunningham et al., 2010).

Other Diagnostic Tests

Birth defects, defined as structural abnormalities present at birth, are the leading cause of infant mortality and a major contributor to infant morbidity in the United States. Birth defects account for 1 in 5 infant deaths in the United States annually (March of Dimes, 2009). Birth defects affect 8 million children worldwide and affect 6% of all infants born each year (March of Dimes, 2009). In the United States, 1 in 33 infants are born with a birth defect (March of Dimes, 2009). Infant mortality due to birth defects has not declined as rapidly as overall infant mortality. It has been estimated that approximately 20% of all birth defects are due to gene mutations, and 5% to 10% are due to exposure to a teratogen such as drugs, chemicals, or radiation. About half of all birth defects remain unexplained (March of Dimes, 2009).

Rapidly developing technologies of biochemical markers and ultrasonography aid in the prenatal diagnosis of fetal anomalies and genetic disorders. Some of the better known genetic tests include the screening test for alpha-fetoprotein and the amniocentesis or chorionic villi diagnostic tests. As discussed in chapter 12 ∞, conditions that can be diagnosed prenatally include trisomies 21, 18, and 13, spina bifida and anencephaly, cystic fibrosis, and some familial conditions (Cunningham et al., 2010).

Maternal Serum Alpha-Fetoprotein (MSAFP)

Alpha-fetoprotein (AFP) is a fetal protein that is excreted from the fetal yolk sac during the first 6 weeks of pregnancy. The production of AFP is then taken over by the fetal liver as the pregnancy progresses. AFP levels can be high or low, each with different implications to the fetus. If the fetus has a neural tube defect (NTD), the AFP levels will be elevated. The incidence of NTDs is 1 per 2000 births and is the most commonly occurring birth defect in the United States (March of Dimes, 2009). NTDs can range from *anencephaly* (absence of a portion of the fetal brain that is incompatible with extrauterine life) to *spina bifida* (an incomplete closure of the vertebral arch that may allow protrusion of the meningeal tissue, spinal cord, or nerve roots through the opening on the spinal cord, and which is associated with lower extremity paralysis, incontinence, and developmental delay).

Quadruple Check

Maternal serum alpha-fetoprotein (MSAFP) is a component of the screening test, the "quadruple check" that utilizes the multiple markers, including AFP, hCG, diameric inhibin-A, and estriol to screen pregnancies for NTD, trisomy 21 (Down syndrome), and trisomy 18. Screening can be performed between 15 and 22 weeks' gestation (15 to 16 yields the most accurate results) (Cunningham et al., 2010). ACOG (2009) recommends that all pregnant women be offered aneuploidy screening. See chapter 12 ∞ for a discussion of chromosomal testing and analysis. Recent studies have shown that using a second trimester ultrasound along with MSAFP testing had a higher detection rate than this quadruple marker screening test alone. Even higher detection rates can be achieved by looking for nuchal translucency. For that reason, many practitioners perform both ultrasound testing and serologic screening (ACOG, 2007a,b).

Universal screening should be offered to all women, because 90% of NTD cases occur in women with no risk factors. MSAFP screening detects approximately 85% of open neural tube defects. Most causes of NTDs are unknown; however, risk factors include a previous fetus with an NTD, maternal age less than 20 or greater than 35 years, primiparity or grandmultiparity, low socioeconomic status with nutritional deficiencies, English or Irish ancestry, and inadequate folic acid intake (Cunningham et al., 2010).

The MSAFP is the first marker used in the quadruple check. Most laboratories use a cutoff of 2 to 2.5 multiples of the mean (MoM) of AFP to define a test as abnormally high. The lower the cutoff, the greater the detection rate but also the higher the false-positive rate. Levels of 2.5 to 3.5 MoM are considered indiscriminate because both normal and abnormal fetuses typically test within this zone. Levels greater than 3.5 MoM are outside the normal distribution and are at high risk for a neural tube defect. Using a cutoff of 2 to 2.5 MoM would yield a 90% detection rate, resulting in 3% to 5% of positive screens with a 2% to 6% false-positive rate (Creasy et al., 2008). The majority of women with an elevated MSAFP do not have affected fetuses. In 90% to 95% of the group with an elevated MSAFP, the elevation is caused from other variables, such as incorrect gestational age, more than one fetus, other fetal anomalies such as gastroschisis (a hole in the abdominal wall that allows the abdominal contents to protrude outside the body), and fetal death (Cunningham et al., 2010).

The quadruple screen has also been used to screen for trisomy 21 (Down syndrome), which is the most common chromosomal abnormality found in live births, and for trisomy 18, which is less common, but usually results in death of the infant within the first year of life (see chapter 12 ∞). Unlike NTDs, the risk of Down syndrome and trisomy 18 increases with increasing maternal age; thus genetic counseling and diagnostic testing are usually offered to women who will be 35 years of age or older at their estimated date of birth (EDB).

Abnormal test results are generally defined as a calculated Down syndrome risk of 1 in 270 or 1 in 200 (depending on the laboratory). Women who have abnormal results are counseled about these risks and offered a diagnostic test such as amniocentesis, which is considered to be greater than 99% accurate in the diagnosis of chromosomal anomalies.

Screening tests require patient education and counseling to avoid confusion and undue stress. A key point for the nurse to understand and reinforce to the patient is that the MSAFP and the quadruple check are screening tests, and are ***not*** diagnostic. The nurse has an important role in educating the woman about various aspects of these tests. The importance of an accurate gestational age determination before taking the test cannot be overstated. A miscalculated gestational age may result in the incorrect interpretation of the MSAFP level, causing extreme stress to the woman and her family. In addition, further testing is required. An elevation of the MSAFP requires recalculation with an accurate gestational age and repeat test, and a low MSAFP may require an amniocentesis. The nurse also educates the patient on the importance of proper timing of the MSAFP. As stated earlier, the ideal time for screening is between 15 and 18 weeks. False-positives can occur with tests done either before or after this window in the gestation.

All healthcare providers should be sensitive to the ethical issues these screening tests present to the childbearing family. What benefit would knowing the results of an abnormal MSAFP provide? If the fetus has an NTD, the family and healthcare provider can use this information before the birth to choose the appropriate birth site or birth type. (An infant with an NTD would need to be born in a tertiary care center where immediate care could be given to the infant if needed.) Knowing an infant has Down syndrome would not necessarily change an obstetric decision about birth method or site, but it would give the family time for psychologic preparation, a chance to talk with social services and support groups, or the opportunity to opt for termination of the pregnancy.

Amniocentesis

Amniocentesis is a procedure used for genetic diagnosis. A sterile needle (under ultrasound guidance) is inserted into the uterine cavity through the maternal abdomen so a small amount of amniotic fluid can be removed, and genetic testing is performed. Amniocentesis is performed between 15 and 20 weeks' gestation. Two large studies in the United States and Canada have confirmed the safety and the 99% diagnostic accuracy of this procedure (Cunningham et al., 2010).

Amniocentesis can make chromosomal and biochemical determinations (enzyme analysis, AFP measurement for neural tube defects, blood typing, or cytogenetic, metabolic, or other DNA testing) and can validate abnormalities detected by ultrasound. Later in pregnancy, from about 30 to 39 weeks' gestation, amniocentesis may be done for lung maturity studies, such as lecithin/sphingomyelin ratio and the presence of phosphatidylglycerol and phosphatidylcholine (see discussion on p. 525) (Cunningham et al., 2010).

Indications for Amniocentesis

The following conditions are commonly considered indications for amniocentesis:

- Pregnant women who will be 35 or older on their due date. The risk of having an infant with a chromosomal problem such as Down syndrome increases with the age of the woman (see chapter 12 ∞).
- Couples who already have had a child with a birth defect or have a family history of certain birth defects.
- Pregnant women with other abnormal screening or genetic test results.

Procedure for Performing Amniocentesis

Amniocentesis is done on an outpatient basis but needs to be performed near a birthing area in case acute nonreassuring fetal status is encountered. The pregnant woman should be placed in a left lateral tilt position by placing a wedge under her right hip to prevent hypotension during the procedure.

The abdomen is scanned by ultrasound to locate the placenta, the fetus, and an adequate pocket of fluid. The needle insertion site is of the utmost importance because the fetus, placenta, umbilical cord, bladder, and uterine arteries must all be avoided (Figure 21-19 ■). The importance of locating the placenta cannot be stressed enough, especially in cases of Rh isoimmunization, in which trauma to the placenta increases fetal–maternal transfusion and worsens the isoimmunization (see chapter 20 ∞). If the amniocentesis is being performed in the last few weeks of pregnancy, the fetus may occupy what appears to be all the available space in the uterus, and there is a normal decrease in the amount of amniotic fluid; however, with the aid of ultrasound, fluid can be located. The amniocentesis is then done before the fetus has the opportunity to move.

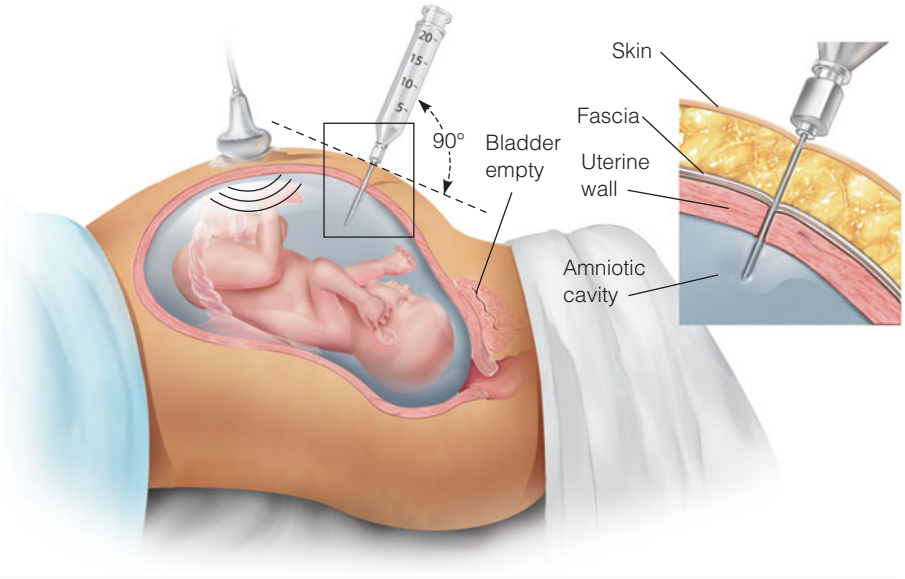

Figure 21-19 ■ Amniocentesis. The woman is usually scanned by ultrasound to determine the placental site and to locate a pocket of fluid. As the needle is inserted, three levels of resistance are felt when the needle penetrates the skin, fascia, and uterine wall. When the needle is placed within the amniotic cavity, amniotic fluid is withdrawn.

After the abdomen is scanned, the abdominal skin is cleansed with povidone-iodine (Betadine). The woman is given the option of a local anesthetic for the insertion site. A 22-gauge spinal needle is inserted into the uterine cavity. Generally, fluid immediately flows into the needle. The first few drops are discarded; a syringe is then attached to the needle, and the fluid is aspirated (Figure 21-20 ■). From 15 to 20 ml of amniotic fluid are withdrawn, placed in brown-tinted test tubes (to shield the fluid from light to prevent breakdown of bilirubin and other pigments), and sent to the laboratory for analysis. The needle is withdrawn using ultrasound, and the insertion site is evaluated for streaming (movement of fluid), which would indicate bleeding into the amniotic fluid. The FHR is monitored to assess fetal well-being. If the woman's vital signs and the FHR are normal, she is allowed to leave (see Procedure 21-3) (Cunningham et al., 2010).

If the collected amniotic fluid is contaminated with blood, the fluid should be centrifuged immediately. The woman is observed for alterations in the FHR. The blood should be tested to determine whether it is maternal or fetal.

Rh-negative women are given Rh immune globulin after amniocentesis, provided that they are not already sensitized.

Risks/Side Effects

Minor complications are infrequent and may include transient vaginal spotting, cramping, or amniotic fluid leakage in 1% to 2% of cases performed. Chorioamnionitis may occur in fewer than 1 in 1000 cases. Needle injuries to the fetus are rare when ultrasound guidance is used. Fetal loss rate is less than 0.5% (1 in 200) (Creasy et al., 2008). When early amniocentesis is performed (11 to 14 weeks) there is a higher pregnancy loss and complication rate than with traditional amniocentesis (Cunningham et al., 2010). This is due to the lack of membrane fusion to the uterine wall, which makes the puncture of the sac difficult, and to the fact that there is less fluid to withdraw (ACOG, 2007b).

Figure 21-20 ■ During amniocentesis, amniotic fluid is aspirated into a syringe.

CLINICAL TIP

Have the woman lie on her left side to ensure adequate placental perfusion.

PROCEDURE 21-3 Assisting During Amniocentesis

NURSING ACTION

Preparation

- Explain the procedure and the indications for it and reassure the woman.
- Determine whether an informed consent form has been signed. If not, verify that the woman's doctor has explained the procedure and ask her to sign a consent form.

  Rationale: *It is the physician's responsibility to obtain informed consent. The woman's signature indicates her awareness of the risks and gives her consent to the procedure.*

Equipment and Supplies

22-gauge spinal needle with stylet

10- and 20-ml syringes

1% lidocaine (Xylocaine)

Povidone-iodine (Betadine)

Three 10-ml test tubes with tops (amber colored or covered with tape)

Rationale: *Amniotic fluid must be protected from light to prevent breakdown of bilirubin.*

Procedure: Sterile Gloves

1. Obtain baseline vital signs including maternal blood pressure (BP), pulse, respirations, temperature, and fetal heart rate (FHR) before procedure begins.
2. Monitor BP, pulse, respirations, and FHR every 15 minutes during procedure.

   Rationale: *Baseline information is essential to detect any changes in maternal or fetal status that might be related to the procedure.*
3. The physician uses real-time ultrasound to determine the location of the placenta and to locate a pocket of amniotic fluid. Provide gel for the ultrasound and assist with the procedure as needed.
4. Cleanse the woman's abdomen.

   Rationale: *Cleansing the abdomen before needle insertion helps decrease the risk of infection.*
5. The physician dons gloves, inserts the needle into the identified pocket of fluid (see Figure 21-19), and withdraws a sample.
6. Obtain the test tubes from the physician. Label the tubes with the woman's correct identification and send to the lab with the appropriate lab slips.
7. Monitor the woman and reassess her vital signs.
   - Determine the woman's BP, pulse, respirations, and the FHR.
   - Palpate the woman's fundus to assess for uterine contractions.
   - Monitor her using an external fetal monitor for 20 to 30 minutes after the amniocentesis.
   - Determine a treatment course to counteract any supine hypotension and to increase venous return and cardiac output.

   Rationale: *Monitoring maternal and fetal status postprocedure provides information about response to the procedure and helps detect any complications such as inadvertent fetal puncture.*
8. Assess the woman's blood type and determine any need for Rh immune globulin.
9. Administer Rh immune globulin if indicated (see Procedure 20.2 ∞ on page 482).

   Rationale: *To prevent Rh sensitization in an Rh-negative woman, Rh immune globulin is administered prophylactically involving amniocentesis.*
10. Instruct the woman to report any of the following changes or symptoms to her primary caregiver:
    - Unusual fetal hyperactivity or, conversely, any lack of fetal movement
    - Vaginal discharge—either clear drainage or bleeding
    - Uterine contractions or abdominal pain
    - Fever or chills

    Rationale: *These are signs of potential complications and require further evaluation.*
11. Encourage the woman to engage only in light activities for 24 hours and to increase her fluid intake.

    Rationale: *Decreased maternal activity helps decrease uterine irritability and increase uteroplacental circulation. Increased fluid intake helps replace amniotic fluid through the uteroplacental circulation.*
12. Complete the client record. Record the type of procedure, the date and time, and the name of the physician who performed the procedure. Also record the maternal-fetal response, disposition of the specimen, and discharge teaching.

Documentation

The nurse documents maternal and fetal responses to the procedure. Maternal vital signs, including level of discomfort, should be recorded. The FHR, presence of contractions, bleeding, and fluid leakage should be documented. Discharge instructions and abnormal symptoms that need to be reported to the physician should also be documented.

NURSING CARE MANAGEMENT

The nurse assists the physician during the amniocentesis (see Procedure 21-3: Assisting During Amniocentesis). In addition, the nurse supports the woman undergoing amniocentesis. Women are usually apprehensive about the procedure as well as about the information that will be obtained. The physician explains the procedure before the woman signs the consent form. As it is being performed, the woman may need additional emotional support. She may become anxious during the procedure. She may also become lightheaded, nauseated, and diaphoretic

from lying on her back with a heavy uterus compressing the abdominal vessels, so it is important to have her in a lateral tilt with a wedge placed under her right hip. The nurse can provide support to the woman by further clarifying the physician's instructions or explanations, by relieving the woman's physical discomfort when possible, and by responding verbally and physically to the woman's need for reassurance.

Chorionic Villus Sampling

Much like amniocentesis, **chorionic villus sampling (CVS)** is a procedure that is used to detect genetic, metabolic, and DNA abnormalities. CVS involves obtaining a small sample (5 to 40 mg) of chorionic villi from the edge of the developing placenta. CVS is performed in some medical centers for first trimester diagnosis after 9 completed weeks (ACOG, 2007b). Villi in the chorion frondosum, present from 8 to 12 weeks' gestation, are believed to reflect fetal chromosome, enzyme, and DNA content, thereby permitting earlier diagnosis than can be obtained by amniocentesis. CVS cannot detect neural tube defects, however, and the MSAFP test should still be performed at 16 weeks.

Risks and Benefits of CVS

The woman should be aware of the risks and benefits of CVS. There is a spontaneous abortion risk of 0.3% in cases. This rate is only slightly higher than the 0.1% in cases of a second-trimester amniocentesis (Cunningham et al., 2010). Other references cite 0.5% to 1.0% of CVS procedures and 0.25% to 0.50% of amniocentesis procedures. There is also an incidence of 1 in 3000 births of fetal limb reduction defects (a portion of a finger or a toe is missing), especially when the CVS is performed before 9 1/2 weeks' gestation. Therefore, it is not recommended that CVS be performed before 10 weeks' gestation (ACOG, 2007b).

Additional risks of CVS include failure to obtain tissue, rupture of membranes, leakage of amniotic fluid, vaginal spotting or bleeding, chorioamnionitis (0.5% of cases), intrauterine infection, maternal tissue contamination of the specimen, oromandibular defects, and Rh isoimmunization. Rh-negative women are given Rh immune globulin to cover the risk of immunization from the procedure (Cunningham et al., 2010).

Like amniocentesis, CVS can detect fetal karyotype, hemoglobinopathies (e.g., sickle cell anemia and alpha and some beta thalassemias), phenylketonuria, alpha antitrypsin deficiency, Down syndrome, Duchenne muscular dystrophy, and factor IX deficiency. Early sex determination can be made so that pregnancies with a male fetus who would be affected in X-linked disorders can be identified (Creasy et al., 2008). Because NTDs are not diagnosed by this test, all mothers undergoing CVS should be offered MSAFP screening at 15 to 20 weeks' gestation. A major disadvantage of the earlier testing (CVS) is that if a woman later has an abnormal MSAFP test indicating an increased risk of NTDs, she may then have to undergo an amniocentesis, thus again putting the fetus at risk with an additional invasive procedure.

One of the greatest advantages to a woman undergoing this procedure is earlier diagnosis and decreased waiting time for results. Whereas amniocentesis is not done until at least 16 weeks' gestation, CVS is performed between 10 and 12 weeks. The CVS results are obtained in 24 hours if the direct preparation method is used and in 7 to 10 days when tissue culture is used. Earlier diagnosis may relieve many of the personal, social, and psychologic concerns of families, particularly if therapeutic abortion is being considered. There may be less emotional stress involved with having an abortion at an earlier stage of gestation. First trimester abortions are also easier to perform, require less time, and are less costly.

Procedure for CVS

Before CVS, an ultrasound is done to determine placental location, uterine position (retroverted or anteverted), and presence of intervening structures (i.e., bowel, blood vessels). Various equipment can be used to aspirate chorionic villi from the placenta.

After counseling regarding diagnosis and procedure techniques, preliminary blood work may be obtained. The morning of the procedure, the woman is asked to drink fluids to fill her bladder because displacement of an anteverted uterus by a full bladder may aid in positioning the uterus for catheter insertion. Ultrasound is used to determine uterine position, cervical position, gestational sac size, and crown-rump length measurement and to identify the area of placental formation and cord insertion.

For the transcervical CVS the woman is placed in lithotomy position, the vulva is cleansed with povidone-iodine solution (Betadine), and a sterile speculum is inserted into the vagina. The vaginal vault and cervix are cleansed with the same solution to decrease contamination from the vagina into the uterus. The anterior lip of the cervix is sometimes grasped with a tenaculum to aid in straightening anteflexion of the uterus. The catheter (or cannula) is slowly inserted under ultrasound guidance through the endocervix to the sampling site at the extra-amniotic placental edge (outside the gestational sac). The obturator is withdrawn from the catheter. A 30-ml syringe, containing 3 to 4 ml of tissue culture medium with heparin, is attached, and a sample of villi is aspirated by using a pressure of 20 to 30 ml. The contents of the syringe are flushed into a petri dish containing nutrient medium, and the villi are inspected microscopically and prepared for cell culture.

For the transabdominal sampling, the woman is placed in the supine position. After the skin is cleansed with Betadine and local anesthesia is given, an 18- or 20-gauge needle is inserted percutaneously through the maternal abdominal wall and uterine myometrium. The tip of the needle is advanced into the long axis of the chorion frondosum under ultrasound guidance. Chorionic villi are obtained by repeated, rapid aspirations of the syringe containing tissue culture medium and heparin.

A normal CVS result indicating normal chromosomal configuration in the first trimester does not ensure a healthy infant. Routine prenatal care and appropriate follow-up are needed. Follow-up ultrasound and lab evaluation of each pregnancy must be done after performance of this procedure to evaluate fetal status. Further neonatal follow-up studies are necessary to evaluate the long-term effects of this technique.

Through the Eyes of a Nurse Genetic Testing Options in Pregnancy

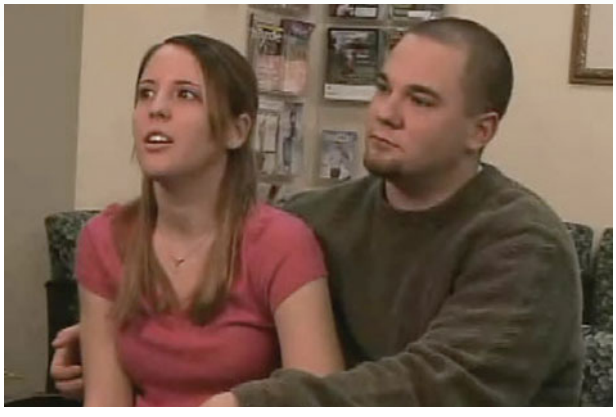
Family's Experience

"There seems like there are so many tests available, we are really confused about what to do. We don't feel like we have any risk factors, but we want to make sure our baby is healthy. What tests should we get? Which ones do we really need?"

Nurse's Response

"There are various testing options. I can explain your options and help you weigh the pros and cons of each test. Because of your age and the fact that you do not have any risk factors identified in your medical or family history, you would not be a candidate for the amniocentesis or chorionic villus sampling tests. You may want to consider the other optional tests though, such as the quadruple screen, nuchal translucency test, and cystic fibrosis testing.

"The quadruple screen is a test that screens for neural tube defects and trisomy 18 and 21. This test is only a screening tool, which means it does not tell you if your baby *definitely* has one of these problems. It could help us know if your baby is at risk though. The test is not perfect and you can get false-positives or false-negatives. If the test did come back abnormal, you have other testing options such as a more detailed sonogram or an amniocentesis.

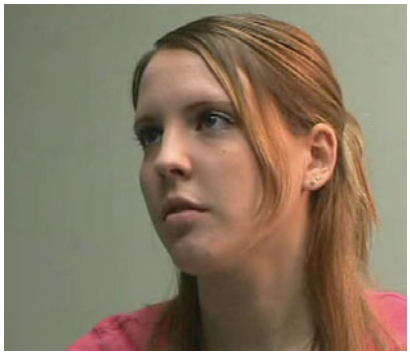


"The nuchal translucency test is a blood test and sonogram combined that screens for trisomy 18 and 21. The test is more accurate than the quadruple screen and is done earlier. Some insurance may not cover the test though, so you will need to call your insurance company to see if it is covered.

"The cystic fibrosis test screens for known gene mutations that cause cystic fibrosis. If your screen is positive, we will then have the father of the baby tested to determine if he is also a carrier. If you are both carriers, there is a 25% chance that the baby could have the disease. If only one of you is a carrier, there would be a chance the baby would also be a carrier, but the baby could not inherit the disease."

Nurse's Actions and Rationale

The nurse's role is to explain all testing options and to answer questions related to the various tests. The nurse presents the information in an objective manner without expressing a personal opinion. The couple must weigh each choice carefully and determine what tests are right for them. The nurse can also provide written resource material to the couple. The couple should be allowed to discuss the information and make an informed decision.



NURSING CARE MANAGEMENT

Before the test, the nurse ascertains the woman's understanding of CVS, its uses, the procedure, and the possible results. The nurse provides opportunities for questions and acts as an advocate when additional questions or concerns are raised. The nurse completes assessments following the procedure, including monitoring for vaginal bleeding or fluid leakage, excessive cramping, and basic maternal vital signs.

The nurse supports the woman or couple and encourages them to express any feelings and fears regarding the procedure and also regarding the decision-making process if abortion is being considered. That supportive role continues if abortion is chosen, even though the nurse may not be present for the procedure. It is important that support be provided following the procedure by the nurse who established a relationship with the couple previously.

Cordocentesis

Cordocentesis (also called *percutaneous umbilical blood sampling [PUBS]*) is a technique used to obtain pure fetal blood from the umbilical cord while the fetus is in utero. This procedure has been used for diagnosis of hemophilias, hemoglobinopathies, fetal infections, chromosome abnormalities, nonimmune hydrops, and isoimmune hemolytic disorders, as well as assessment of fetal hemoglobin and hematocrit for calculation of transfusion requirements in the second and third trimesters (Acar et al., 2007). During the 1990s, PUBS was used more frequently; however, its use is now more limited to the diagnosis of anemia and for treatment of fetal anemia when hemoglobin levels fall below 10 g/dl or hematocrit is less than 30%. Although now less commonly used, cordocentesis can also be used for the following (Creasy et al., 2008):

- Rapid fetal karyotyping and genotyping
- Diagnosis of fetal infection (cytomegalovirus, toxoplasmosis, parvovirus, rubella)
- Platelet disorders
- Fetal blood grouping
- Diagnosis and treatment of isoimmunization
- Assessment of fetal well-being (pH, Po_2)
- Fetal metabolic disorders

The woman is scanned with an ultrasound transducer with sterile probe cover. A 25-gauge spinal needle is inserted into her abdomen through the skin alongside the transducer and into the fetal umbilical vein approximately 1 to 2 cm from the insertion of the cord into the placenta. The stylet is removed from the needle, and fetal blood is aspirated into a syringe containing an anticoagulant. Red blood cell size is determined to distinguish fetal from maternal cells. A paralytic agent, such as pancuronium bromide (Pavulon), may be given to prevent fetal movement during the procedure. If the mother is given a medication to help her relax, care must be taken to avoid oversedating her and causing deep breathing. Deep chest/diaphragmatic respirations can interfere with accurate puncture of the umbilical vein (Creasy et al., 2008).

Within the last 10 years, improvements in ultrasonographic technique have made PUBS a relatively safe procedure with overall fetal loss rate less than 2%. The complication rate after PUBS is less than 0.5%. Complications include failure to obtain a sample, bleeding from the sampling site, premature rupture of membranes, chorioamnionitis, and fetal bradycardia (Acar et al., 2007). PUBS is used with less and less frequency because newer tests have replaced the need for a direct fetal sample.

NURSING CARE MANAGEMENT

The nurse collaborates with other members of the healthcare team to provide care for the woman for whom PUBS is recommended. Although a genetic counselor and/or obstetrician will have explained the risk for genetic defects and other disorders, the woman and her partner may need help to understand the procedure and its risks. They may need anticipatory guidance to help lessen their anxiety, as well as emotional support during the procedure and follow-up evaluation and testing. Support can come in many forms, including encouraging relaxation, providing reassurance, and giving the woman information throughout the procedure. The nurse may need to assist with coordination of financial and social service resources. The nurse can help promote relaxation during the procedure by instructing the woman in shallow breathing techniques. The nurse completes assessments during and immediately following the procedure and in some cases performs an NST test following the procedure.

Fetal Fibronectin

Fetal fibronectin (fFN) is a glycoprotein produced by the trophoblast and other fetal tissues. The absence of cervicovaginal fFN between 20 and 34 weeks' gestation has been shown to be a strong predictor of a woman not experiencing preterm birth due to spontaneous preterm labor or premature rupture of membranes. Positive findings indicate a 99% probability of birth within the next 2 weeks (Cunningham et al., 2010). Positive findings should lead to follow-up including a sterile speculum exam, nitrazine testing, and an evaluation of a slide of cervico-vaginal secretions to assess for the presence of ferning, which would indicate the prescence of amniotic fluid. Levels of fFN can be measured with an enzyme immunoassay. Its presence is indicative of further evaluation, such as an ultrasound for cervical length, funneling, dilatation, and cultures to rule out an infectious process. Because vaginal examinations, sexual intercourse within the previous 24 hours, some vaginal creams, and medications can cause false findings, these should be avoided prior to fFN testing.

Evaluation of Fetal Lung Maturity

In managing the woman and fetus at risk, the physician is constantly faced with the possibility of having to induce the birth of an infant before term and before the onset of labor. There are many indications for early termination of pregnancy, including

repeat cesarean birth, premature rupture of membranes, diabetes, hypertensive conditions in the pregnant woman, and placental insufficiency. Unfortunately, the most common cause of perinatal mortality is prematurity, especially in infants weighing 1500 g or less and with particular complications arising from pulmonary immaturity (Cunningham et al., 2010). Birth of an infant with immature pulmonary function frequently results in respiratory distress syndrome (RDS), also known as *hyaline membrane disease* (see chapter 34 ∞).

Because gestational age, birth weight, and the rate of development of organ systems do not necessarily correspond, it may be necessary to determine the lung maturation of the fetus by amniotic fluid analysis before elective childbirth. In these cases, amniocentesis is performed, and concentrations of certain phospholipids in the amniotic fluid are measured. In many cases, birth of the infant can be delayed until the lungs show maturity.

Lecithin/Sphingomyelin Ratio

The alveoli of the lungs are lined by a substance called **surfactant**, which is composed of phospholipids. Surfactant lowers the surface tension of the alveoli during extrauterine respiratory exhalation. By lowering the alveolar surface tension, surfactant stabilizes the alveoli, and a certain amount of air always remains in the alveoli during expiration (Cunningham et al., 2010). When a newborn with mature pulmonary function takes his or her first breath, a tremendously high pressure is needed to open the lungs. Upon breathing out, the lungs do not collapse, and about half the air in the alveoli is retained. An infant born too early, when synthesis of surfactant is incomplete, is unable to maintain lung stability, resulting in underinflation of the lungs and development of RDS.

Fetal lung maturity can be assessed by determining the ratio of two components of surfactant—lecithin and sphingomyelin. Early in pregnancy the lecithin concentration in amniotic fluid is less than that of sphingomyelin (0.5:1 at 20 weeks), resulting in a low **lecithin/sphingomyelin (L/S) ratio**. At about 30 to 32 weeks' gestation, the amounts of the two substances become equal (1:1). The concentration of lecithin begins to exceed that of sphingomyelin, and at 35 weeks the L/S ratio is 2:1. When at least two times as much lecithin as sphingomyelin is found in the amniotic fluid, RDS is very unlikely (Creasy et al., 2008). Clinical outcomes, including respiratory distress and other respiratory disorders, should be correlated in individual institutions before specific ratios indicating pulmonary maturity are accepted. Infants of diabetic mothers (IDMs) are an exception to this finding and have a high incidence of false-positive results (i.e., the L/S ratio is thought to indicate lung maturity, but after birth the baby develops RDS). Although the same ratios are used, it is important to remember that even when IDMs are term (greater than 37 weeks' gestational age), delayed lung maturation can occur because the high blood sugars interfere with biochemical development. A delay in lung maturation has also been found in babies whose mothers have nonhypertensive renal disease and isoimmunization (Creasy et al., 2008).

Some types of chronic intrauterine fetal stress cause an acceleration of lung maturation in the fetus. Prolonged rupture of membranes (over 24 hours) results in acceleration of lung maturation by approximately 1 week and therefore has a protective effect. Although the L/S ratio is the most universally used test for evaluating pulmonary maturity, the results are not accurate when blood or meconium contaminates the amniotic fluid (ACOG, 2008).

The L/S ratio remains a cumbersome and labor-intensive test despite numerous changes to the original technique. Moreover, improper handling can affect results. For these reasons, many institutions are looking to other fetal lung maturity tests that are being developed.

Phosphatidylglycerol

Phosphatidylglycerol (PG) is the second most abundant phospholipid in surfactant. PG appears at about 36 weeks' gestation and increases in amount until term. In instances of diabetes complicated by premature rupture of membranes, vascular disease, or severe preeclampsia, PG may be present before 35 weeks' gestation. PG is not measured in specific concentrations; rather, the mere presence of this substance is associated with very low risk of RDS, and the absence of PG is associated with the development of RDS (Creasy et al., 2008).

PG determination is also useful in blood-contaminated specimens. Because PG is not present in blood or vaginal fluids, its presence in a vaginal specimen is reliable for indicating lung maturity.

In recent years lung maturity has been most frequently assessed by a combination of L/S ratio and PG. Lung maturity apparently can be confirmed in most pregnancies if PG is present in conjunction with an L/S ratio of 2:1.

Fluorescence Polarization

The fluorescence polarization (TDx-FLM II) test was developed in the 1990s and utilizes fluorescence polarization to measure the ratio of surfactant to albumin (S/A) in uncentrifuged amniotic fluid. The results are reported quantitatively in mg/g. The test has been used as a predictive indicator for predicting RDS in preterm infants. Values greater than 55 mg/g in a non-diabetic woman (or greater than 70 mg/g in a diabetic woman) indicate fetal lung maturity. The test can be conducted in 1 hour or less. Although blood and amniotic fluid can interfere with the findings, it should not result in immature results being reported as mature findings. Amniotic fluid collected vaginally that indicates fetal lung maturity should be considered accurate (Cunningham et al., 2010).

NURSING CARE MANAGEMENT

In women whose amniotic membranes are prematurely ruptured, a vaginal specimen is obtained for analysis. The nurse assists the certified nurse-midwife or physician by gathering appropriate supplies. Typically, a sterile speculum, a light source, a sterile syringe or a nasogastric tube, and appropriate collection tubes are needed. The nurse positions the woman for the speculum exam while providing information about the collection process. The nurse places the woman in a lithotomy

position and places her legs in stirrups. If stirrups are not available, the nurse can place a bedpan upside down and position the woman with her buttocks on the bedpan to facilitate collection of the vaginal fluid. The certified nurse-midwife or physician gathers vaginal secretions with a syringe and places the specimen in a collection tube (Cunningham et al., 2010).

In women undergoing early birth for medical indications (uncontrolled preeclampsia or eclampsia or uncontrolled diabetes) when the amniotic membranes are intact, evaluation of fetal lung maturity may be obtained through amniocentesis. See previous discussion on page 521 regarding nursing care management for the woman undergoing amniocentesis.

FOCUS YOUR STUDY

- Nurses often play a key role not only in teaching families about various testing procedures, but also in providing clarity and emotional support to the woman and her family undergoing antenatal testing.
- Ultrasound offers a valuable means of assessing intrauterine fetal growth because the growth can be followed over a period of time. It is noninvasive and painless, allows the physician to study the gestation serially, is nonradiating to both the woman and her fetus, and to date has shown no known harmful effects.
- Using ultrasound, the gestational sac may be detected as early as 5 or 6 weeks after the last menstrual period. Measurement of the crown-rump length in early pregnancy is most useful for accurate dating of a pregnancy. The most important and frequently used ultrasound measurements in the second trimester are biparietal diameter, head circumference, abdominal circumference, and femur length.
- Maternal assessment of fetal activity is very useful as a screening procedure in evaluation of fetal status.
- A nonstress test (NST) measures fetal heart rate (FHR) during fetal activity; FHR normally increases in response to fetal activity. The desired result is a reactive test.
- A contraction stress test (CST) provides a method for observing the response of the FHR to the stress of uterine contractions. The desired result is a negative test.
- A fetal biophysical profile (BPP) includes five fetal variables (breathing movement, body movement, tone, amniotic fluid volume, and FHR reactivity). It assesses the fetus at risk for intrauterine compromise.
- Aneuploidy screening includes nuchal translucency and PAPP-A and Beta hCG or quadruple screening of AFP, hCG, diameric inhibin-A, and estriol.
- Amniocentesis can be used to obtain amniotic fluid for testing. A variety of tests is available to evaluate the presence of disease, genetic conditions, and fetal maturity.
- Chorionic villus sampling is a procedure that obtains fetal karyotype in the first trimester. It is used to diagnose hemoglobinopathies (e.g., sickle cell anemia and alpha and some beta thalassemias), phenylketonuria, alpha antitrypsin deficiency, Down syndrome, Duchenne muscular dystrophy, and factor IX deficiency.
- Percutaneous umbilical blood sampling (PUBS) is a technique used in the second and third trimesters for fetal diagnosis, assessment, and therapy.
- The lecithin/sphingomyelin (L/S) ratio of the amniotic fluid can be used to assess fetal lung maturity. The presence of phosphatidylglycerol may also provide information about fetal lung maturity. The fluorescence polarization (TDx-FLM II) test can be used as a predictive indicator for predicting RDS in preterm infants.

CRITICAL THINKING IN ACTION

Patricia Adams is a 20-year-old, married, G2, P0010 at 36 weeks' gestation with gestational diabetes. She presents to you during her prenatal visit with a complaint of decreased fetal movement for the "last day or so." Her OB history includes a 13 lb weight gain, hematocrit of 29%, diastolic BP ranging 80–96 mm Hg, and 1+ proteinuria. A 19-week ultrasound demonstrated no fetal anatomic defects. A hemoglobin A_1c at 23 weeks was 5.8%. Patricia has had weekly NST since 28 weeks' gestation. You place Patricia on the fetal monitor for an NST. You obtain vital signs of T 97°F, P 88, R 14, BP 130/88. After 30 minutes you observe that the fetal heart rate baseline is 160–165, long-term variability is decreased, and repetitive variable decelerations are occurring. No contractions are noted. The fetus is very active. You notify the physician of the fetal heart rate baseline and unsatisfactory NST. The physician orders a biophysical profile (BPP) for fetal well-being. You describe and explain the biophysical profile test to Patricia.

1. How would you describe and explain the biophysical profile test?
2. To heighten Patricia's awareness of fetal movement, how would you instruct her to do a daily fetal movement record (FMR)?
3. Explain when Patricia should contact her care provider.
4. Discuss the significance of fetal movement.
5. Explore factors that decrease fetal movements.

Processes and Stages of Labor and Birth

Just as a woman's heart knows how and when to pump, her lungs to inhale, and her hand to pull back from fire, so she knows when and how to give birth.

—Virginia DiOrio

LEARNING OUTCOMES

1. Examine the five critical factors that affect the labor process.
2. Describe the physiology of labor.
3. Discuss premonitory signs of labor.
4. Differentiate between false and true labor.
5. Describe the characteristics of the four stages of labor and their accompanying phases.
6. Describe the physiologic and psychosocial changes that are indicative of the maternal progress during each of the stages of labor.
7. Summarize maternal systemic responses to labor.
8. Describe fetal adaptations to labor.

In the final weeks of pregnancy, both mother and baby begin to prepare for birth. The fetus develops and grows in readiness for life outside the womb. The expectant woman undergoes various physiologic and psychosocial changes that gradually prepare her for childbirth and for the role of mother. The onset of labor begins a remarkable change in the relationship between the woman and her baby. During labor, particularly at the end, a woman instinctively knows she is engaging in one of the most important tasks she will ever do. A precious life is about to emerge. In those hours and moments the birth process may seem to carry all the power in the universe. The mother-to-be and her partner may be stretched beyond all of their normal limits of concentration, purpose, endurance, and pain. The dynamic nature of this experience is what makes the birth of a baby both a physiologic and a psychosocial transition into parenthood.

Critical Factors in Labor

Five factors are important in the process of labor and birth: the birth passageway (birth canal), the passenger (fetus), the physiologic forces of labor, the position of the mother, and the woman's psychosocial considerations (Table 22-1). The progress of labor is critically dependent on the complementary relationship of these five factors. Abnormalities that affect any component of these critical forces can alter the outcome of labor and jeopardize both the expectant woman and her baby. Complications during labor and birth are discussed in chapter 27 ∞.

TABLE 22-1 Critical Factors in Labor

1. **Birth passage**
   - Size of the maternal pelvis (diameters of the pelvic inlet, midpelvis, and outlet)
   - Type of maternal pelvis (gynecoid, android, anthropoid, platypelloid, or a combination)
   - Ability of the cervix to dilate and efface and ability of the vaginal canal and the external opening of the vagina (the introitus) to distend
2. **Fetus**
   - Fetal head (size and presence of molding)
   - Fetal attitude (flexion or extension of the fetal body and extremities)
   - Fetal lie
   - Fetal presentation (the body part of the fetus entering the pelvis in a single or multiple pregnancy)
3. **The relationship between the passage and the fetus**
   - Engagement of the fetal presenting part
   - Station (location of fetal presenting part in the maternal pelvis)
   - Fetal position (relationship of the presenting part to one of the four quadrants of the maternal pelvis)
4. **Physiologic forces of labor**
   - Frequency, duration, and intensity of uterine contractions as the fetus moves through the passage
   - Effectiveness of the maternal pushing effort
5. **Psychosocial considerations**
   - Mental and physical preparation for childbirth
   - Sociocultural values and beliefs
   - Previous childbirth experience
   - Support from significant others
   - Emotional status

Birth Passageway

The true pelvis and soft tissues of the cervix, vagina, and the pelvic floor form the birth passageway. The true pelvis is the critical factor of the passageway because the fetus must progress through this bony canal during the vaginal birth process. The true pelvis is divided into three sections: the inlet, the pelvic cavity (midpelvis), and the outlet. The four classic types of pelvises are *gynecoid, android, anthropoid,* and *platypelloid* (see Figure 10-15 ∞ on page 203). Implications of each type for childbirth are described in Table 22-2. The ability of the cervix to dilate and efface and the ability of the vaginal canal and the external opening of the vagina (the introitus) to distend are additional factors of the birth passageway. See chapter 10 ∞ for a discussion of each part of the pelvis, and chapter 15 ∞ for techniques to assess the size and shape of the pelvis.

Birth Passenger (Fetus)

Several aspects of the fetus's body and the way the fetus moves through the mother's birth canal are considered critical factors of the passenger that affect the outcome of labor. These inter-

TABLE 22-2 Implications of Pelvic Type for Labor and Birth

PELVIC TYPE	PERTINENT CHARACTERISTICS	IMPLICATIONS FOR BIRTH
Gynecoid	Inlet rounded with all inlet diameters adequate Midpelvis diameters adequate with parallel side walls Outlet adequate	Favorable for vaginal birth
Android	Inlet heart-shaped with short posterior sagittal diameter Midpelvis diameters reduced Outlet capacity reduced	Not favorable for vaginal birth Descent into pelvis is slow Fetal head enters pelvis in transverse or posterior position with arrest of labor frequent
Anthropoid	Inlet oval in shape, with long anteroposterior diameter Midpelvis diameters adequate Outlet adequate	Favorable for vaginal birth
Platypelloid	Inlet oval in shape, with long transverse diameters Midpelvis diameters reduced Outlet capacity inadequate	Not favorable for vaginal birth Fetal head engages in transverse position Difficult descent through midpelvis Frequent delay of progress at outlet of pelvis

Note: Description of pelvic shape is exaggerated for easier comprehension.

acting factors are: the fetal head, fetal attitude, fetal lie, fetal presentation, and fetal position. The placenta must also pass through the birth canal but rarely impedes the labor process, except in cases of placenta previa (see chapter 26 ∞ for placental complications).

Fetal Head

The fetal head is composed of bony parts, which can either hinder childbirth or make it easier. Once the head (the least compressible and largest part of the fetus) has been born, the birth of the rest of the body is rarely delayed.

The fetal skull has three major parts: the face, the base of the skull (cranium), and the vault of the cranium (roof). The bones of the face and cranial base are well fused and essentially fixed. The base of the cranium is composed of the two temporal bones, each with a sphenoid bone and an ethmoid bone. The bones composing the vault are the two frontal bones, the two parietal bones, and the occipital bone (Figure 22-1 ■). These bones are not fused, allowing this portion of the head to adjust as it passes through the narrow portions of the maternal pelvis. The cranial bones overlap under pressure of the powers of labor and the demands of the unyielding pelvis. This overlapping is called **molding**.

The **sutures** of the fetal skull are membranous joints that unite the cranial bones. Sutures allow for molding of the fetal head and help the clinician identify the position of the fetal head during vaginal examination. The important sutures of the cranial vault are as follows (see Figure 22-1).

- ***Frontal (mitotic) suture.*** Located between the two frontal bones; becomes the anterior continuation of the sagittal suture
- ***Sagittal suture.*** Located between the parietal bones; divides the skull into left and right halves; runs anteroposteriorly, connecting the two fontanelles
- ***Coronal sutures.*** Located between the frontal and parietal bones; extend transversely left and right from the anterior fontanelle (bregma)

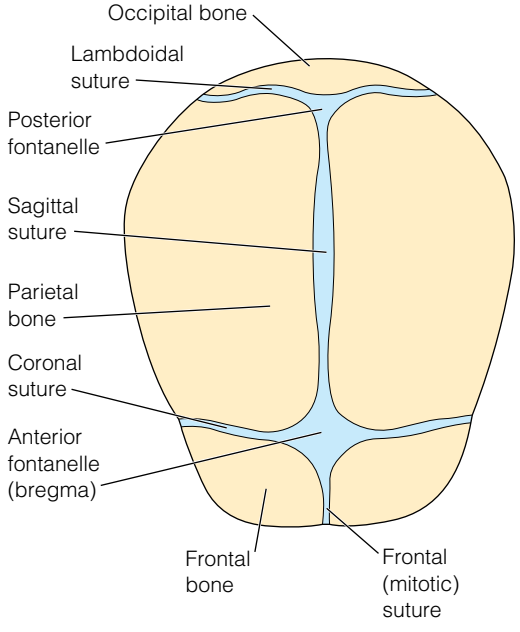

Figure 22-1 ■ Superior view of the fetal skull.

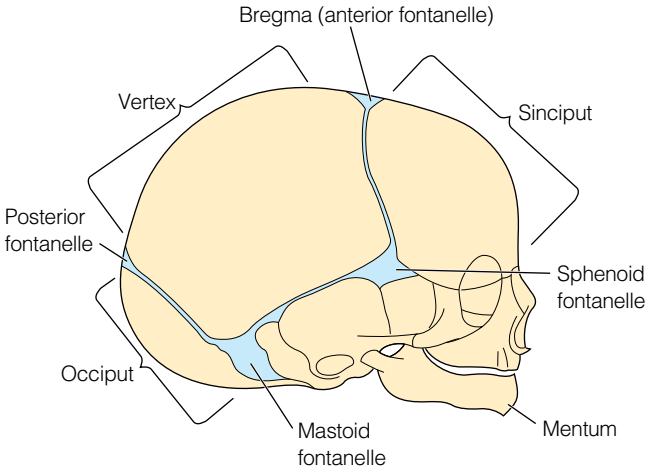

Figure 22-2 ■ Lateral view of the fetal skull identifying the landmarks that have significance during birth.

- ***Lambdoidal suture.*** Located between the two parietal bones and the occipital bone; extends transversely left and right from the posterior fontanelle

The intersection of several cranial sutures forms an irregular space that is enclosed by a membrane and called a **fontanelle**. The anterior and posterior fontanelles are clinically useful in identifying the position of the fetal head in the pelvis and in assessing the status of the newborn after birth. The greater, or anterior, fontanelle (bregma) is diamond shaped, measures 2 to 3 cm, and is situated at the junction of the sagittal, coronal, and frontal sutures. It permits growth of the brain by remaining unossified for as long as 18 months. The lesser, or posterior, fontanelle is shaped like a small triangle, measures about 1 to 2 cm, and is situated at the intersection of the sagittal and lambdoidal sutures. It closes within 8 to 12 weeks after birth.

Following are several other important landmarks of the fetal skull (Figure 22-2 ■):

- ***Mentum.*** The fetal chin
- ***Sinciput.*** The anterior area known as the brow
- ***Vertex.*** The area between the anterior and posterior fontanelles
- ***Occiput.*** The area of the fetal skull occupied by the occipital bone, beneath the posterior fontanelle

The diameters of the fetal skull vary considerably within normal limits. Some diameters shorten and others lengthen as the head is molded during labor. Fetal head diameters are measured between the various landmarks on the skull (Figure 22-3A ■). For example, the suboccipitobregmatic diameter is the distance from the undersurface of the occiput to the center of the bregma (anterior fontanelle). The biparietal diameter is the largest part of the fetal head (Figure 22-3B ■).

Fetal Attitude

Fetal attitude refers to the relation of the fetal body parts to one another. Fetal attitude describes the posture the fetus assumes as it conforms to the shape of the uterine cavity. The normal attitude of the fetus is termed *general flexion,* where the head is flexed so that the chin is on the chest with the arms

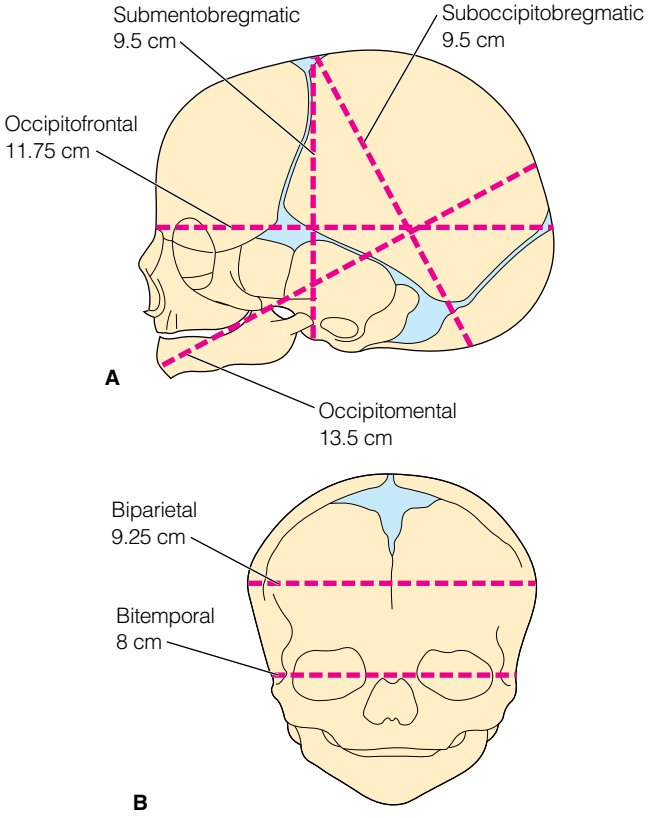

Figure 22-3 ■ A. Anteroposterior diameters of the fetal skull. When the vertex of the fetus presents and the fetal head is flexed with the chin on the chest, the smallest anteroposterior diameter (suboccipitobregmatic) enters the birth canal. B. Transverse diameters of the fetal skull.

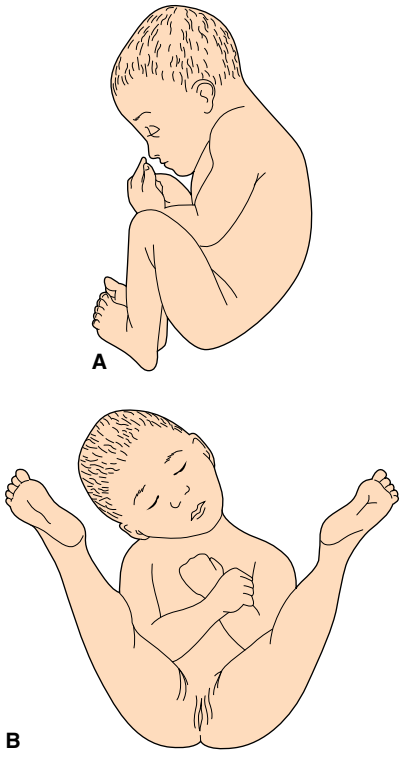

Figure 22-4 ■ Fetal attitude. A. The attitude (or relationship of body parts) of this fetus is normal. The head is flexed forward with the chin almost resting on the chest. The arms and legs are flexed. B. In this view, the head is tilted to the right. Although the arms are flexed, the legs are extended.

crossed over the chest, and the legs flexed at the knees with the thighs on the abdomen (Figure 22-4A ■).

Changes in fetal attitude, particularly in the position of the head, cause the fetus to present larger diameters of the fetal head to the maternal pelvis. These deviations from a normal fetal attitude often contribute to a longer, more difficult labor (Figure 22-4B ■).

Fetal Lie

Fetal Lie

Fetal lie refers to the relationship of the long, or cephalocaudal, axis (spinal column) of the fetus to the long, or cephalocaudal, axis of the mother. The fetus may assume either a longitudinal (vertical) or a transverse (horizontal) lie. A *longitudinal lie* occurs when the cephalocaudal axis of the fetus is parallel to the woman's spine. A *transverse lie* occurs when the cephalocaudal axis of the fetal spine is at a right angle to the woman's spine (see Figure 27-11 ∞) on page 710. A transverse lie is associated with a shoulder presentation and can lead to complications in the later stages of labor. This is discussed in detail in chapter 27 ∞. Table 22-3 identifies the characteristics associated with a longitudinal versus a transverse fetal lie.

TABLE 22-3 Characteristics Associated with Longitudinal Versus Transverse Fetal Lie

FETAL LIE	ATTITUDE	PRESENTING PART	LANDMARK
Longitudinal Lie (99.5%)			
Cephalic presentation (96% to 97%)	Flexion of fetal head onto chest	Vertex (posterior part—occiput)	Occiput (O)
	Military (no flexion, no extension)	Vertex (median part)	Occiput (O)
	Partial extension	Brow	Forehead (frontum) (Fr)
	Complete extension of the head	Face	Chin (mentum) (M)
Breech presentation (Approximately 3%)			
Complete breech	Flexed hips and knees	Buttocks	Sacrum (S)
Frank breech	Flexed hips, extended knees with legs against abdomen and chest	Buttocks	Sacrum (S)
Footling breech: single, double	Extended hips and at least one knee extended with foot in cervical canal	Feet (one or two)	Sacrum (S)
Kneeling breech: single, double	Extended hips, flexed knees	Knees	Sacrum (S)
Transverse or Oblique Lie (Approximately 0.5%)			
Shoulder presentation	Variable	Shoulder, arm	Scapula (Sc or A)

Fetal Presentation

Fetal presentation is determined by fetal lie and refers to the body part of the fetus that enters the maternal pelvis first and leads through the birth canal during labor. The **presenting part** or the portion of the fetus that is felt through the cervix on vaginal examination determines the presentation. Fetal presentation may be cephalic (head first), breech (buttocks or feet first), or shoulder.

The most common presentation is cephalic. When this presentation occurs, labor and birth are more likely to proceed normally. Breech and shoulder presentations are associated with difficulties during labor and do not proceed as normal; therefore, they are called **malpresentations**. (See chapter 27 ∞ for discussion of malpresentations.)

CEPHALIC PRESENTATION The fetal head presents to the birth passage in approximately 97% of term births. The cephalic presentation can be further classified into vertex, sinciput, brow, or face presentation according to the degree of flexion or extension of the fetal head (attitude).

Vertex Presentation When the presenting part is the occiput, the presentation is noted as vertex.

- Vertex is the most common type of presentation.
- The fetal head is completely flexed onto the chest.
- The smallest diameter of the fetal head (suboccipitobregmatic) presents to the maternal pelvis (Figure 22-5A ■).

Sinciput Presentation

- The fetal head is partially flexed.
- The occipitofrontal diameter presents to the maternal pelvis (Figure 22-5B ■).
- The top of the head is the presenting part.

Brow Presentation

- The fetal head is partially extended.
- The occipitomental diameter, the largest anteroposterior diameter, is presented to the maternal pelvis (Figure 22-5C ■).

Face Presentation

- The fetal head is hyperextended (complete extension).
- The submentobregmatic diameter presents to the maternal pelvis (Figure 22-5D ■).

BREECH PRESENTATION A breech presentation indicates that the presenting part is the lower extremities or buttocks. Breech presentations occur in approximately 3% of all term births (Cunningham et al., 2010). These presentations are classified according to the attitude of the fetus's hips and knees. In all variations of the breech presentation (complete, frank, or footling breech), the sacrum (the bone on the buttocks that is felt when palpating) is the landmark.

Complete Breech

- The fetal knees and hips are both flexed, the thighs are on the abdomen, and the calves are on the posterior aspect of the thighs.
- The buttocks and feet of the fetus present to the maternal pelvis.

Frank Breech

- The fetal hips are flexed, and the knees are extended.
- The buttocks of the fetus present to the maternal pelvis.

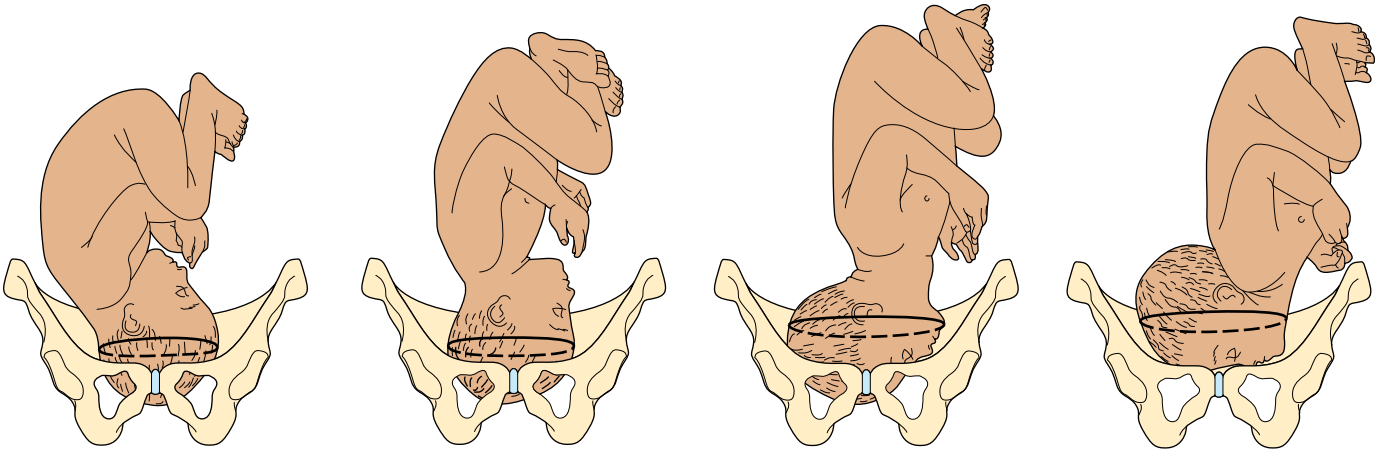
Footling Breech

- The fetal hips and legs are extended.
- The feet of the fetus present to the maternal pelvis.
- In a single footling one foot presents; in a double footling both feet present.

SHOULDER PRESENTATION When the fetal shoulder is the presenting part, the fetus is in a transverse lie and the acromion process of the scapula is the landmark. This type of presentation occurs less than 1% of the time (Cunningham et al., 2010).

Relationship of Maternal Pelvis and Presenting Part

The third critical factor, in addition to the birth passage and fetus, is the relationship between these two factors. When assessing the relationship of the maternal pelvis and the presenting



A Suboccipitobregmatic diameter **B** Occipitofrontal diameter **C** Occipitomental diameter **D** Submentobregmatic diameter

Figure 22-5 ■ Cephalic presentation. A. Vertex presentation. Complete flexion of the head allows the suboccipitobregmatic diameter to pre-sent to the pelvis. B. Sinciput (median vertex) presentation (also called *military presentation*) with no flexion or extension. The occipitofrontal diameter presents to the pelvis. C. Brow presentation. The fetal head is in partial (halfway) extension. The occipitomental diameter, which is the largest diameter of the fetal head, pre-sents to the pelvis. D. Face presentation. The fetal head is in complete extension, and the submentobregmatic diameter presents to the pelvis.

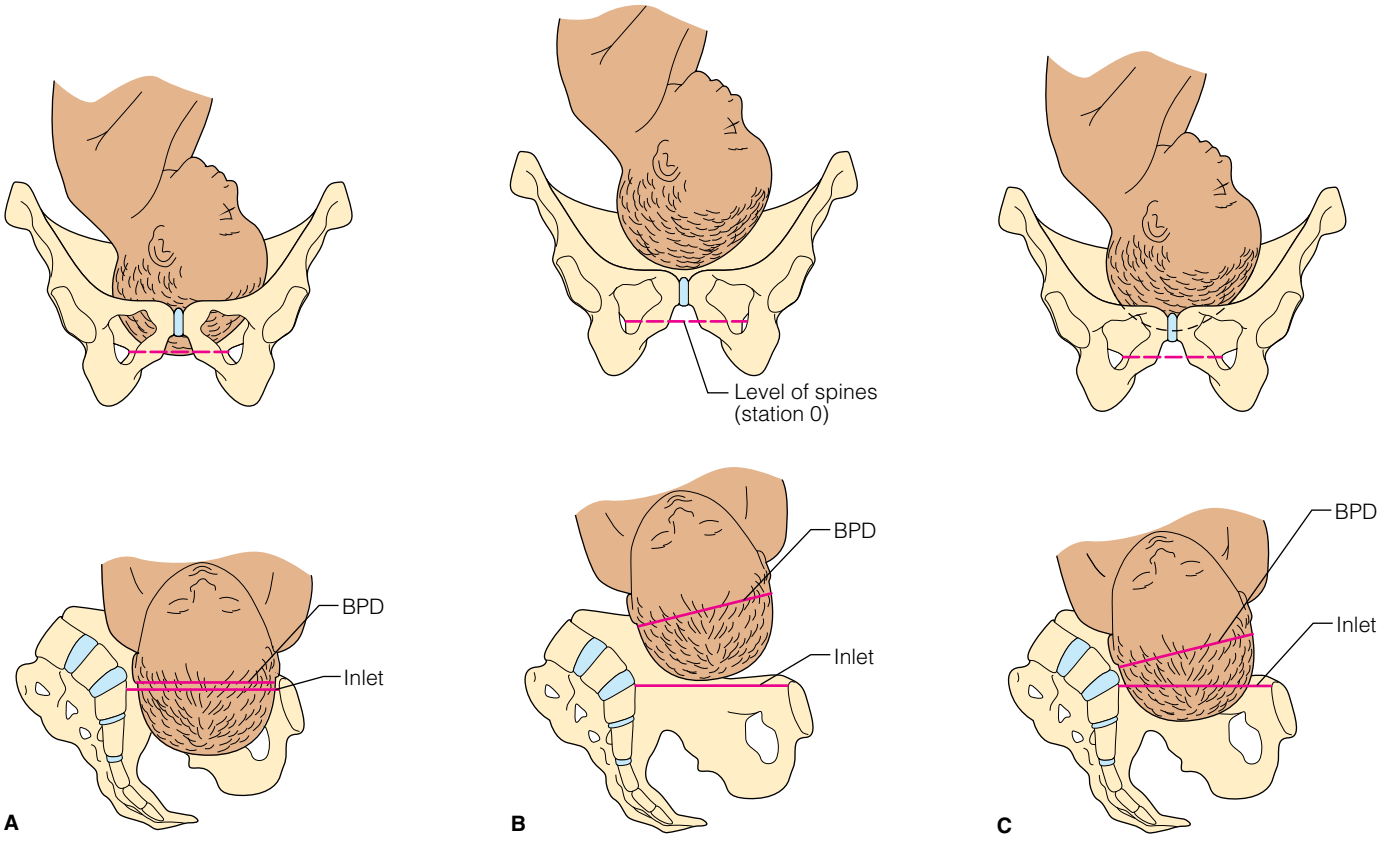


Figure 22-6 ■ Process of engagement in cephalic presentation. A. Engaged. The biparietal diameter (BPD) of the fetal head is in the inlet of the pelvis. In most instances, the presenting part (occiput) will be at the level of the ischial spines (0 station). B. Floating. The fetal head is directed down toward the pelvis but can still easily move away from the inlet. C. Dipping. The fetal head dips into the inlet but can be moved away by exerting pressure on the fetus.

part of the fetal body, the nurse considers engagement, station, and fetal position.

Engagement

Engagement of the presenting part occurs when the largest diameter of the presenting part reaches or passes through the pelvic inlet (Figure 22-6A ■). When the fetal head is flexed, the biparietal diameter is the largest dimension of the fetal skull to pass through the pelvic inlet in a cephalic presentation. The intertrochanteric diameter (transverse diameter between the right and left trochanter) is the largest to pass through the inlet in a breech presentation.

Engagement can be determined by vaginal examination. In primigravidas, engagement usually occurs 2 weeks before term. Multiparas, however, may experience engagement several weeks before the onset of labor or during the process of labor.

The presenting part is said to be *floating* (or *ballottable*) when it is freely movable above the inlet (see Figure 22-6B ■). When the presenting part begins to descend into the inlet, before engagement has truly occurred, it is said to be dipping into the pelvis (see Figure 22-6C ■).

Station

Station refers to the relationship of the presenting part to an imaginary line drawn between the ischial spines of the maternal pelvis. In a normal pelvis the ischial spines mark the narrowest diameter through which the fetus must pass. These spines are not sharp protrusions but rather blunted prominences at the midpelvis. The ischial spines as a landmark have been designated as zero station (Figure 22-7 ■). If the presenting part is higher than the ischial spines, a negative number is assigned, noting centimeters above zero station. Station −5 is at the inlet, and station +4 is at the outlet. If the presenting part can be seen at the woman's perineum, birth will occur momentarily. During labor the presenting part should move progressively from the negative stations to the midpelvis at zero station and into the positive stations. Failure of the presenting part to descend in the presence of strong contractions may be due to disproportion between the maternal pelvis and fetal presenting part.

Fetal Position

Fetal position refers to the relationship of the landmark on the presenting fetal part to the anterior, posterior, or sides (right or left) of the maternal pelvis. The landmark on the fetal presenting part is related to four imaginary quadrants of the maternal pelvis: left anterior, right anterior, left posterior, and right posterior. These quadrants designate where the presenting part is directed. If the landmark is directed toward the center of the side of the pelvis, fetal position is designated as transverse, rather than anterior or posterior.

The landmark chosen for vertex presentations is the occiput, and the landmark for face presentations is the mentum. In

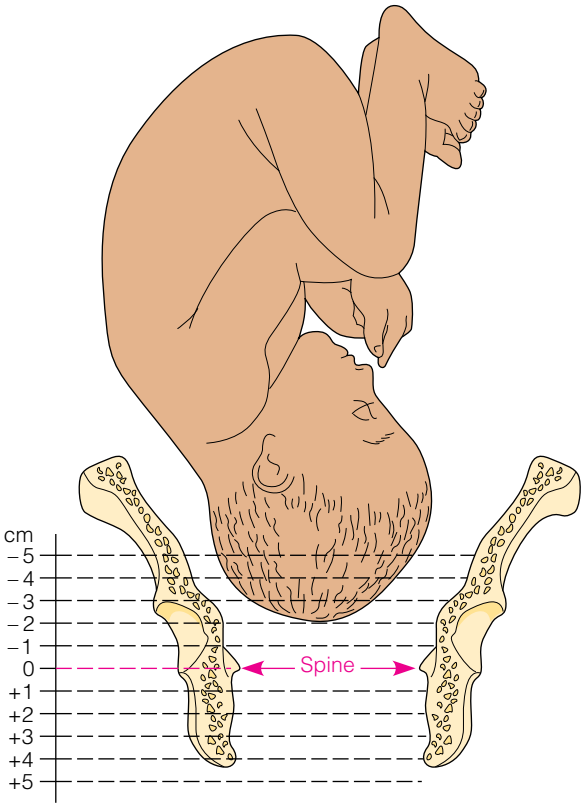

Figure 22-7 ■ Measuring the station of the fetal head while it is descending. In this view the station is −2.

breech presentations the sacrum is the designated landmark, and the acromion process on the scapula is the landmark in shoulder presentations.

In summary, three notations are used to describe the fetal position:

1. Right (R) or left (L) side of the maternal pelvis
2. The landmark of the fetal presenting part: occiput (O), mentum (M), sacrum (S), or acromion (scapula [Sc]) process (A)
3. Anterior (A), posterior (P), or transverse (T), depending on whether the landmark is in the front, back, or side of the pelvis

The abbreviations of these notations help the healthcare team communicate the fetal position. Thus, when the fetal occiput is directed toward the back and to the left of the passage, the abbreviation used is LOP (left-occiput-posterior). The following is a list of positions for various fetal presentations, some of which are illustrated in Figure 22-8 ■.

Positions in Vertex Presentation

ROA Right-occiput-anterior
ROT Right-occiput-transverse
ROP Right-occiput-posterior
LOA Left-occiput-anterior
LOT Left-occiput-transverse
LOP Left-occiput-posterior

Positions in Face Presentation

RMA Right-mentum-anterior
RMT Right-mentum-transverse
RMP Right-mentum-posterior
LMA Left-mentum-anterior
LMT Left-mentum-transverse
LMP Left-mentum-posterior

Positions in Breech Presentation

RSA Right-sacrum-anterior
RST Right-sacrum-transverse
RSP Right-sacrum-posterior
LSA Left-sacrum-anterior
LST Left-sacrum-transverse
LSP Left-sacrum-posterior

The term *dorsal (D)* is added when denoting the fetal position in a shoulder presentation; it refers to the fetal back. Thus the abbreviation RADA indicates that the acromion process of the scapula is directed toward the woman's right, and the fetus's back is anterior.

Positions in Shoulder Presentation

RADA Right-acromion-dorsal-anterior
RADP Right-acromion-dorsal-posterior
LADA Left-acromion-dorsal-anterior
LADP Left-acromion-dorsal-posterior

The fetal position influences labor and birth. For example, the fetal head presents a larger diameter in a posterior position than in an anterior position. A posterior position increases the pressure on the maternal sacral nerves, causing the laboring woman to experience backache and pelvic pressure. As a result, the woman may bear down or feel the urge to push earlier than needed. In addition, the second stage of labor may be prolonged when the fetal head remains in a posterior position.

The most common fetal position is occiput anterior. When this position occurs, the labor and birth are more likely to proceed normally. Positions other than occiput anterior are more frequently associated with problems during labor; therefore, they are called malpositions. (See chapter 27 ∞ for discussion of malpositions and their management.)

Assessment techniques to determine fetal position include inspection and palpation of the maternal abdomen and vaginal examination. (See chapter 23 ∞ for further discussion of assessment of fetal position.)

Physiologic Forces of Labor

Primary and secondary forces work together to deliver the fetus, the fetal membranes, and the placenta from the uterus into the external environment. The *primary force* is uterine muscular contractions, which cause the changes of the first stage of labor—complete effacement and dilatation of the cervix. The *secondary force* is the use of abdominal muscles to push during the second stage of labor. The pushing adds to the primary power after full dilatation.

Contractions

Uterine contractions are rhythmic tightenings and shortenings of the uterine muscles during labor. Each contraction has three phases: (1) *increment,* the "building up" of the contraction (the longest phase); (2) *acme,* or the peak of the contraction; and

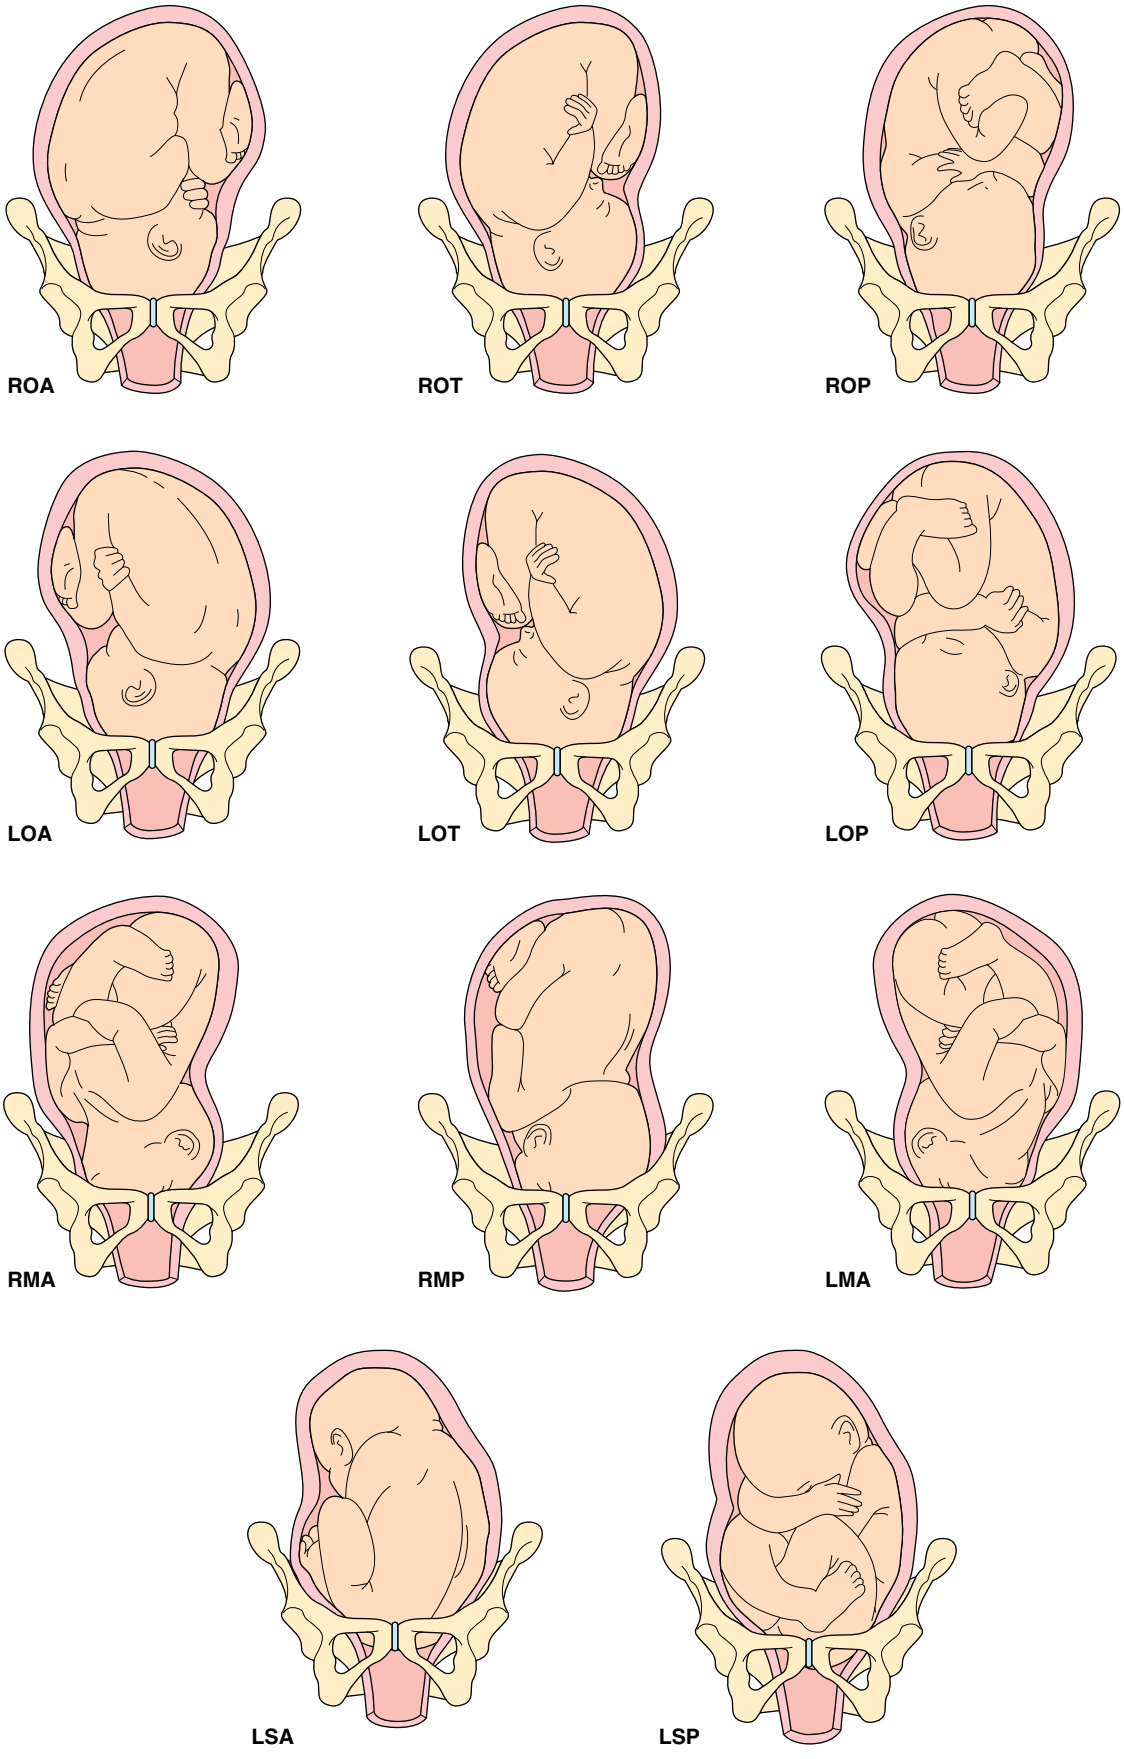

Figure 22-8 ■ Categories of presentation.

Source: Courtesy of Ross Laboratories, Columbus, OH.

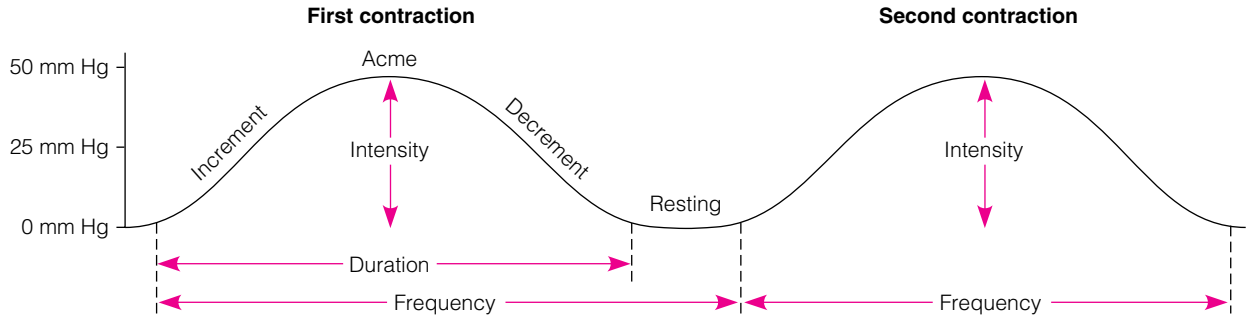

Figure 22-9 ■ Characteristics of uterine contractions.

(3) *decrement,* or the "letting up" of the contraction. Between contractions is a period of relaxation. This period of relaxation allows uterine muscles to rest and provides respite for the laboring woman. It also restores uteroplacental circulation, which is important to fetal oxygenation and adequate circulation in the uterine blood vessels.

When describing uterine contractions during labor, caregivers use the terms *frequency, duration,* and *intensity.*

Frequency refers to the time between the beginning of one contraction and the beginning of the next contraction. The **duration** of each contraction is measured from the beginning of the contraction to the completion of the contraction (Figure 22-9 ■). In beginning labor, the duration is 30 to 40 seconds. As labor continues, duration increases to 30 to 90 seconds (Cunningham et al., 2010).

Intensity refers to the strength of the uterine contraction during acme. In most instances the intensity is estimated by palpating the contraction, but it may be measured directly with an intrauterine catheter attached to an electronic fetal monitor. Intensity of uterine contractions cannot be accurately measured by external monitoring with an electronic fetal monitor, because several variables affect the external monitor, including maternal weight, specifically the amount of adipose tissue, and positioning of the monitor on the maternal abdomen. When estimating intensity by palpation, the nurse determines whether it is mild, moderate, or strong by judging the amount of indentability of the uterine wall during the acme of a contraction. If the uterine wall can be indented easily, the contraction is considered mild. Strong intensity exists when the uterine wall cannot be indented. Moderate intensity falls between these two ranges. When intensity is measured with an intrauterine catheter, the normal resting tonus (between contractions) is about 10 to 12 mm Hg of pressure. During acme the intensity ranges from 25 to 40 mm Hg in early labor, 50 to 70 mm Hg in active labor, 80 to 100 mm Hg during transition, and greater than 100 mm Hg while the woman is pushing in the second stage (Cunningham et al., 2010). (See chapter 23 ∞ for further discussion of assessment techniques.)

At the beginning of labor the contractions are usually mild, of short duration, and relatively infrequent. As labor progresses, duration and intensity increase, and the frequency is every 2 to 3 minutes. Because the contractions are involuntary, the laboring woman cannot control their duration, frequency, or intensity.

Bearing Down

After the cervix is completely dilated, the maternal abdominal musculature contracts as the woman pushes. This pushing is called *bearing down.* The pushing aids in the expulsion of the fetus and the placenta. If the cervix is not completely dilated, bearing down can cause cervical edema (which retards dilatation), possible tearing and bruising of the cervix, and maternal exhaustion. The combined involuntary pressure of the uterine contractions and the voluntary muscle contractions of the abdomen force the fetus toward the outlet so birth can occur.

Psychosocial Considerations

Thus far, the discussion has focused on physical influences on labor outcomes. But the final critical factor is the parents' psychosocial readiness, including their fears, anxieties, birth fantasies, and level of social support. Similar psychosocial factors affect both parents. Both are making a transition into a new role, and both have expectations of themselves and their partner during the labor and birth experience. Although many prospective parents attend childbirth preparation classes, they still tend to be concerned about what labor will be like. Concerns include whether they will each be able to perform the way they expect, whether the discomfort and pain will be more than the mother expects or is able to cope with, whether the father or partner can provide helpful support, and whether they can maintain a sense of control and be advocates for themselves (McKellar, Pincombe, & Henderson, 2008). In addition, both partners face an irrevocable event—the birth of a new family member—and, consequently, disruption of lifestyle, relationships, and self-image.

Many women have preconceived ideas about what birth should be like and some fear "losing control" of their body functions, emotions, or ability to handle the pain associated with labor. Women whose birth experiences do not meet their preconceived ideas may feel loss and disappointment. They may also feel that they have failed to live up to the expectations of friends, family, and peers.

Various factors influence a woman's reaction to labor and contribute to a positive birth experience (Table 22-4). Her accomplishment of the tasks of pregnancy, usual coping mechanisms in response to stressful life events, previous experiences, support system, preparation for childbirth, and cultural influences are all significant factors (Goldbort, 2009).

Many women have dreams about their birthing experience, their infant, and their early parenting experiences. Dreaming

TABLE 22-4 Factors Associated with a Positive Birth Experience

- Motivation for the pregnancy
- Attendance at childbirth education classes
- A sense of competence or mastery
- Self-confidence and self-esteem
- Positive relationship with partner
- Maintaining control during labor
- Support from partner or other person during labor
- Not being left alone in labor
- Trust in the medical/nursing staff
- Having personal control of breathing patterns, comfort measures
- Choosing a physician/certified nurse-midwife who has a similar philosophy of care
- Receiving clear information regarding procedures

and fantasizing about the unborn baby is a developmental process of pregnancy (Alhusen, 2008). The nurse can encourage the woman to share her dreams and fantasies and use them as a tool to examine the woman's expectations, fears, and coping mechanisms. This can assist the woman in forming a maternal role and facilitate bonding with her fetus.

When a woman is facing labor, especially for the first time, she may worry about her ability to withstand the pain of contractions. Some women may place great emphasis on withstanding the pain of childbirth stoically—without medication, crying, moaning, or making other sounds. The nurse's role is to help childbearing families explore options and identify interventions to help each woman cope with the discomfort of labor in a way that is acceptable to her.

The laboring woman's support system may also influence the course of labor and birth. Although some women may prefer not to have a support person or family member with them, for many women the presence of her partner and other significant persons (especially the nurse) tends to have a positive effect. A labor partner's presence at the bedside provides a means to enhance communication and to demonstrate feelings of love. Communication needs may include talking and the use of affectionate and understanding words from the partner. Showing love may take the form of holding hands, hugging, or touching (McKellar, Pincombe, & Henderson, 2008).

How the woman views the birth experience in hindsight may have implications for mothering behaviors. A significant relationship exists between the birth experience and mothering behaviors. It appears that any activities by the expectant woman or by healthcare providers that enhance the birth experience will be beneficial to the mother-baby connection. The father's experience of childbirth and his opportunities for bonding may have important implications for fathering as well (Goldbort, 2009).

Physiology of Labor

In addition to considering the five critical factors affecting the progress of labor and birth, it is essential to explore the physiology of the normal labor experience.

Possible Causes of Labor Onset

Labor usually begins between the 38th and the 42nd week of gestation, when the fetus is mature and ready for birth. Despite medical advances, there is still no full understanding of the biochemical substances and interactions that stimulate labor and birth. Some important aspects have been identified. For example, estrogen is known to stimulate uterine muscle contractions to permit softening, stretching, and eventual thinning of the cervix. Collagen fibers in the cervix are broken down by the action of enzymes such as collagenase and elastase. As the collagen fibers change, their ability to bind is decreased because of increasing amounts of hyaluronic acid (which loosely binds collagen fibrils) and decreasing amounts of dermatan sulfate (which tightly binds collagen fibrils). There is also an increase in the water content of the cervix. All these changes result in a weakening and softening of the cervix, which facilitates cervical stretching and effacement.

Hypotheses have also been formed about the roles of progesterone withdrawal, of prostaglandin, and of corticotropin-releasing hormone.

Progesterone Withdrawal Hypothesis

Progesterone produced by the placenta relaxes uterine smooth muscle by interfering with conduction of impulses from one cell to the next. For this reason, the uterus is usually without coordinated contractions during pregnancy. Biochemical changes toward the end of gestation result in decreased availability of progesterone to myometrial cells. The decrease in availability may be associated with a yet-unknown antiprogestin that inhibits the relaxant effect on the uterus but allows other progesterone actions such as lactogenesis (Challis, 2008).

Prostaglandin Hypothesis

Although the exact relationship between prostaglandin and the onset of labor is not yet established, the effect is clinically demonstrated by the successful induction of labor after vaginal application of prostaglandin E. In addition, preterm labor may be stopped by using an inhibitor of prostaglandin synthesis such as indomethacin (Challis, 2008).

The amnion and decidua are the focus of research on the source of prostaglandins. Once prostaglandin is produced, stimuli for its synthesis may include rising levels of estrogen, decreased availability of progesterone, increased levels of oxytocin or response to oxytocin, platelet-activating factor, and endothelin-1 (Challis, 2008).

Corticotropin-Releasing Hormone Hypothesis

Corticotropin-releasing hormone (CRH) is also a focus for researchers. Its possible role in onset of labor is suggested by the fact that CRH concentration increases throughout pregnancy, with a sharp increase at term. Also, CRH may play a role in increased risk for preterm birth, and CRH levels are elevated in multiple gestations. Finally, CRH is known to stimulate the synthesis of prostaglandin F and prostaglandin E by amnion cells (Goldenberg, Culhane, Iams, et al., 2009).

Myometrial Activity

In true labor the uterus divides into two portions. This division is known as the *physiologic retraction ring.* The upper portion,

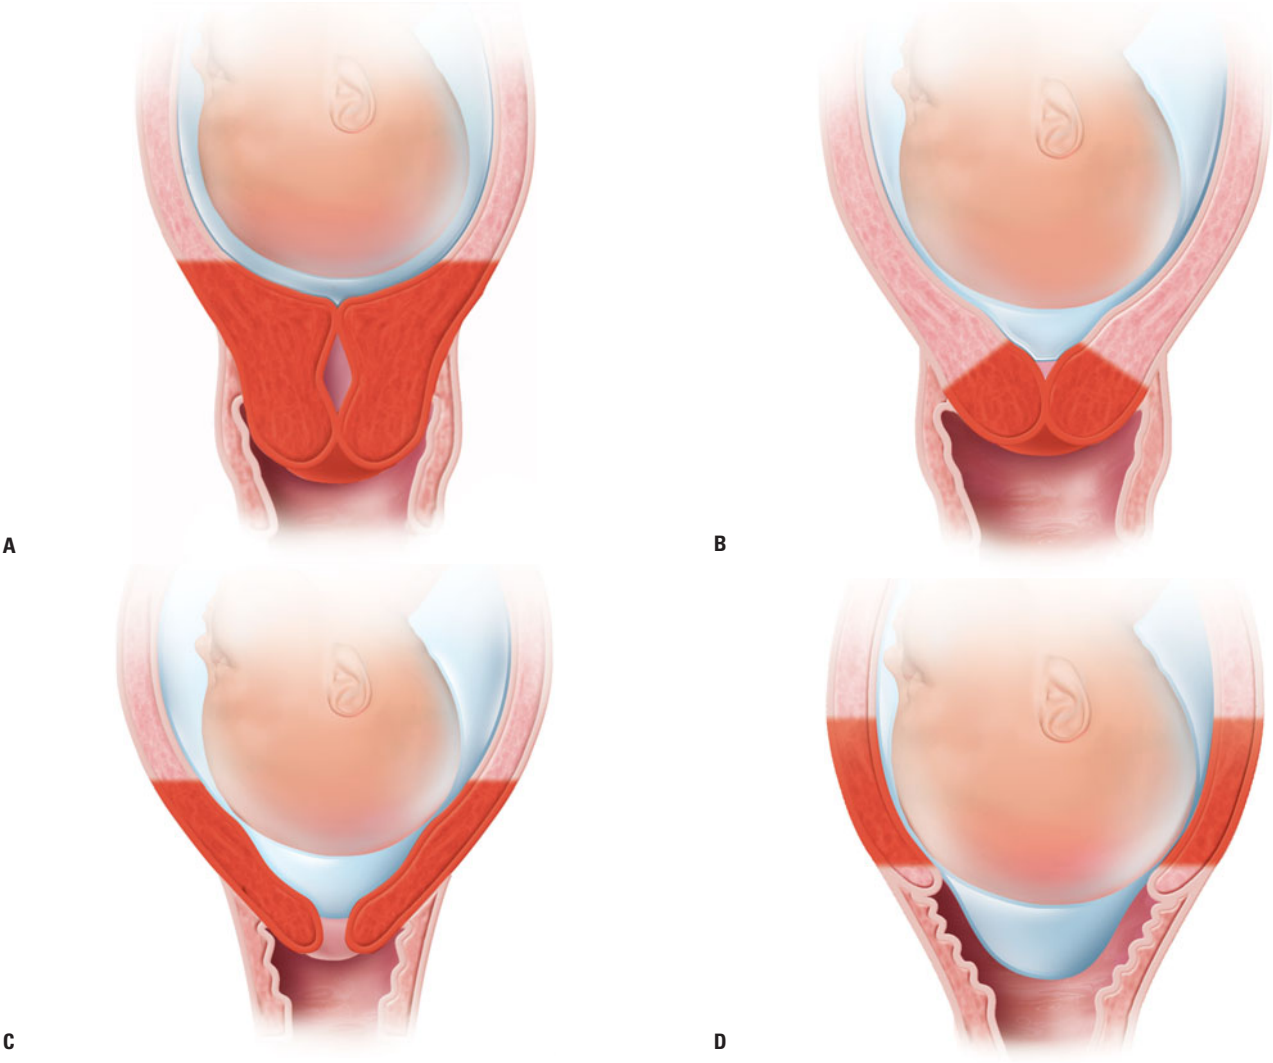

Figure 22-10 ■ Effacement of the cervix in the primigravida. A. At the beginning of labor, there is no cervical effacement or dilatation. The fetal head is cushioned by amniotic fluid. B. Beginning cervical effacement. As the cervix begins to efface, more amniotic fluid collects below the fetal head. C. Cervix is about one half (50%) effaced and slightly dilated. The increasing amount of amniotic fluid below the fetal head exerts hydrostatic pressure on the cervix. D. Complete effacement and dilatation.

which is the contractile segment, becomes progressively thicker as labor advances. The lower portion, which includes the lower uterine segment and cervix, is passive. As labor continues, the lower uterine segment expands and thins out.

With each contraction, the muscles of the upper uterine segment shorten and exert a longitudinal traction on the cervix, causing effacement. **Effacement** is the taking up (or drawing up) of the internal os and the cervical canal into the uterine side walls. The cervix changes progressively from a long, thick structure to a structure that is tissue-paper thin (Figure 22-10 ■). In primigravidas effacement usually precedes dilatation. The uterine muscle remains shorter and thicker and does not return to its original length. This phenomenon is known as *brachystasis.* The space in the uterine cavity decreases as a result of brachystasis, and this places downward pressure on the fetus (Cunningham et al., 2010).

The uterus elongates with each contraction, decreasing the horizontal diameter. This elongation causes a straightening of the fetal body, pressing the part of the fetus in the upper portion of the uterus against the fundus and thrusting the presenting part down toward the lower uterine segment and the cervix. The pressure exerted by the fetus is called *fetal axis pressure.* As the uterus elongates, the longitudinal muscle fibers are pulled upward over the presenting part. This action and the hydrostatic pressure of the fetal membranes cause **cervical dilatation**. The cervical os and cervical canal widen from less than 1 cm to approximately 10 cm, allowing birth of the fetus. When the cervix is completely dilated and retracted up into the lower uterine segment, it can no longer be palpated.

The round ligament pulls the fundus forward, aligning the fetus with the bony pelvis. This facilitates engagement of the presenting part. Pressure exerted on the cervix by the presenting part aids in both effacement and cervical dilatation (Gabbe et al., 2007).

Musculature Changes in the Pelvic Floor

The levator ani muscle and fascia of the pelvic floor draw the rectum and vagina upward and forward with each contraction,

Rupturing Membranes

along the curve of the pelvic floor. As the fetal head descends to the pelvic floor, the pressure of the presenting part causes the perineal structure, which was once 5 cm in thickness, to change to a structure less than 1 cm thick. A normal physiologic anesthesia is produced as a result of the decreased blood supply to the area. The anus everts, exposing the interior rectal wall as the fetal head descends forward (Cunningham et al., 2010).

Premonitory Signs of Labor

Most primigravidas and many multiparas experience one or more of the following signs and symptoms of impending labor.

Lightening

Lightening describes the effects that occur when the fetus begins to settle into the pelvic inlet (engagement). With fetal descent, the uterus moves downward, and the fundus no longer presses on the diaphragm, which eases breathing.

However, with increased downward pressure of the presenting part, the woman may notice the following (Cunningham et al., 2010):

- Leg cramps or pains due to pressure on the nerves that course through the obturator foramen in the pelvis
- Increased pelvic pressure
- Increased venous stasis, leading to edema in the lower extremities
- Increased urinary frequency
- Increased vaginal secretions resulting from congestion of the vaginal mucous membranes

Braxton Hicks Contractions

Before the onset of labor, *Braxton Hicks contractions*—the irregular, intermittent contractions that have been occurring throughout the pregnancy—may become uncomfortable. The pain seems to be in the abdomen and groin but may feel like the "drawing" sensations experienced by some women with dysmenorrhea. When these contractions are strong enough for the woman to believe she is in labor, she is said to be in false labor.

Cervical Changes

Considerable change occurs in the cervix during the prenatal and intrapartal period. At the beginning of pregnancy the cervix is rigid and firm, and it must soften so that it can stretch and dilate to allow fetal passage. This softening of the cervix, called *ripening,* is under the influence of hormonal factors discussed shortly.

Bloody Show

During pregnancy, cervical secretions accumulate in the cervical canal to form a barrier called a *mucous plug.* With softening and effacement of the cervix, the mucous plug is often expelled, resulting in a small amount of blood loss from the exposed cervical capillaries. The resulting pink-tinged secretions are called **bloody show**.

Bloody show is considered a sign of impending labor, usually within 24 to 48 hours. Vaginal examination that includes manipulation of the cervix may also result in a blood-tinged discharge, which is sometimes confused with bloody show. However, this discharge is typically brownish in color and is not accompanied by the mucous plug.

Rupture of Membranes

In approximately 12% of women, the amniotic membranes rupture before the onset of labor. This is called **rupture of membranes (ROM)**. After membranes rupture, 80% of women will experience spontaneous labor within 24 hours. If membranes rupture and labor does not begin spontaneously within 12 to 24 hours, labor may be induced to avoid infection (once the membranes have ruptured there is an open pathway into the uterine cavity). An induction of labor is done only if the pregnancy is near term.

At the beginning of labor, the amniotic membranes bulge through the cervix in the shape of a cone. When the membranes rupture, the amniotic fluid may be expelled in large amounts. **Spontaneous rupture of membranes (SROM)** generally occurs at the height of an intense contraction with a gush of the fluid out of the vagina. If engagement has not occurred, the danger exists that the umbilical cord may be expelled with the fluid (prolapsed cord). In addition, because of these potential problems, the woman is advised to notify her certified nurse-midwife or physician and proceed to the hospital or birthing center. In some instances the fluid is expelled in small amounts and may be confused with episodes of urinary incontinence associated with urinary urgency, coughing, or sneezing. The discharge should be checked to ascertain its source and to determine further action. (See chapter 23 ∞ for assessment techniques.) In some instances, the membranes are ruptured by the certified nurse-midwife or physician, using an instrument called an amniohook. This procedure is called *amniotomy* or *artificial rupture of membranes (AROM)* and is discussed in chapter 28 ∞.

Spontaneous rupture of membranes and leakage of amniotic fluid before the onset of labor at any gestational age is known as *premature rupture of membranes (PROM)*. When the membranes rupture and leakage of amniotic fluid from the vagina occurs before 37 weeks of gestation, the term *preterm premature rupture of membranes (PPROM)* is used. PPROM occurs in up to 25% of all cases of preterm labors, complicates more than 3% of pregnancies each year, and is associated with more than one third of preterm births (Goldenberg, Culhane, Iams et al., 2009). Infection often precedes PPROM. When PPROM is suspected, strict sterile technique should be used in any vaginal examination. (For a complete discussion of PROM and PPROM, see chapter 26 ∞.)

Sudden Burst of Energy

Some women report a sudden burst of energy approximately 24 to 48 hours before labor. The cause of the energy spurt is unknown. In prenatal teaching the nurse should warn prospective mothers not to overexert themselves during this energy burst so that they will not be excessively tired when labor begins.

Other Signs

Other premonitory signs include the following:

- Weight loss of 2.2 to 6.6 kg (1 to 3 lb) resulting from fluid loss and electrolyte shifts produced by changes in estrogen and progesterone levels
- Increased backache and sacroiliac pressure from the influence of relaxin hormone on the pelvic joints

- Diarrhea, indigestion, or nausea and vomiting just before the onset of labor (the causes of these signs are unknown)

Differences Between True Labor and False Labor

The contractions of true labor produce progressive dilatation and effacement of the cervix. They occur regularly and increase in frequency, duration, and intensity. The discomfort of true labor contractions usually starts in the back and radiates around to the abdomen. The pain is not relieved by ambulation (in fact, walking may intensify the pain) or by resting.

The contractions of false labor do not produce progressive cervical effacement and dilatation. Classically, they are irregular and do not increase in frequency, duration, and intensity. The contractions may be perceived as a hardening or "balling up" without discomfort, or discomfort may occur mainly in the lower abdomen and groin. The discomfort may be relieved by ambulation, changes of position, resting, or a hot bath or shower (Cunningham et al., 2010). A comparison of true labor and false labor is provided in Table 22-5.

TABLE 22-5 Comparison of True Labor and False Labor

TRUE LABOR	FALSE LABOR
Contractions are at regular intervals.	Contractions are irregular.
Intervals between contractions gradually shorten.	Usually no change.
Contractions increase in duration and intensity.	Usually no change.
Discomfort begins in back and radiates around to abdomen.	Discomfort is usually in abdomen.
Intensity usually increases with walking.	Walking has no effect on or lessens contractions.
Cervical dilatation and effacement are progressive.	No change.
Contractions do not decrease with rest or warm tub bath.	Rest and warm tub baths lessen contractions.

Nurse's Response to False Labor

During the third trimester, the woman will find it helpful to learn the characteristics of true labor contractions as well as the premonitory signs of ensuing labor. The nurse informs the woman that false labor is common and many times cannot be distinguished from true labor except by vaginal examination. She must feel free to come in for accurate assessment of labor and should be counseled not to feel foolish if the labor is false.

In addition, false labor can last for several hours and can be exhausting. The nurse can suggest interventions to decrease the anxiety and physical discomforts associated with false labor such as walking, changing position, or a warm tub bath.

Stages of Labor and Birth

To assist caregivers, common terms have been developed as benchmarks to subdivide the process of labor into *stages* and *phases* of labor. It is important to note, however, that these represent theoretic separations in the process. A laboring woman will not usually experience distinct differences from one to the other. The first stage begins with the beginning of true labor and ends when the cervix is completely dilated at 10 cm. The second stage begins with complete dilatation and ends with the birth of the infant. The third stage begins with the birth of the infant and ends with the expulsion of the placenta.

Some clinicians identify a fourth stage of labor. During this stage, which lasts 1 to 4 hours after expulsion of the placenta, the uterus effectively contracts to control bleeding at the placental site (Cunningham et al., 2010). Nursing care of the laboring woman is discussed in chapter 24 ∞.

The following discussion characterizes the four stages and their accompanying phases.

Case Study: Patient in First Stage of Labor

First Stage

The first stage of labor is divided into the latent or early, active, and transition phases (Table 22-6). Each phase of labor is characterized by physical and psychologic changes.

Latent or Early Phase

The latent or early phase begins with the onset of regular contractions. As the cervix begins to dilate it also effaces, although little or no fetal descent is evident. For a woman in her first labor (nullipara), the latent or early phase averages 8.6 hours but should not exceed 20 hours. This early phase in

TABLE 22-6 Characteristics of Labor

	FIRST STAGE			SECOND STAGE
	LATENT (EARLY) PHASE	ACTIVE PHASE	TRANSITION PHASE	
Nullipara	8.6 hr	4.6 hr	3.6 hr	Up to 3 hr
Multipara	5.3 hr	2.4 hr	Variable	0–30 min
Cervical dilatation	0–3 cm	4–7 cm	8–10 cm	
Contractions				
Frequency	Every 3–30 min	Every 2–5 min	Every 1 1/2–2 min	Every 1 1/2–2 min
Duration	20–40 sec	40–60 sec	60–90 sec	60–90 sec
Intensity	Begin as mild and progress to moderate; 25–40 mm Hg by intrauterine pressure catheter (IUPC)	Begin as moderate and progress to strong, 50–70 mm Hg by IUPC	Strong by palpation; 70–100 mm Hg by IUPC	Strong by palpation; 70–90 mm Hg by IUPC

Care Plan Activity: Labor Progress in the First Stage of Labor

multiparas averages 5.3 hours but should not exceed 14 hours (Cunningham et al., 2010).

Uterine contractions become established during the latent phase and increase in frequency, duration, and intensity. They may start as mild contractions lasting 20 to 40 seconds with a frequency of 3 to 30 minutes. They average 25 to 50 mm Hg by intrauterine pressure catheter (IUPC) at acme (Cunningham et al., 2010).

In the early or latent phase of the first stage of labor, contractions are usually mild. The woman feels able to cope with the discomfort. She may be relieved that labor has finally started. Although she may be anxious, she is able to recognize and express those feelings of anxiety. The woman is often talkative and smiling and is eager to talk about herself and answer questions. Excitement is high, and her partner or other support person is often as elated as she is.

Active Phase

When the woman enters the early *active phase,* her anxiety tends to increase as she senses the intensification of contractions and pain. She begins to fear a loss of control and may use a variety of coping mechanisms. Some women exhibit a decreased ability to cope and a sense of helplessness. Women who have support persons and family available may experience greater satisfaction and less anxiety than those without support. During this phase the cervix dilates from about 4 to 7 cm. Fetal descent is progressive. The cervical dilatation should be at least 1.2 cm per hour in nulliparas and 1.5 cm per hour in multiparas (Cunningham et al., 2010).

First Stage of Labor and Transition

Transition Phase

The transition phase is the last part of the first stage. When the woman enters the transition phase, she may demonstrate significant anxiety. She becomes acutely aware of the increasing force and intensity of the contractions. She may become restless, frequently changing position. By the time the woman enters the transition phase, she is often inner directed and tired. She may fear being left alone at the same time the support person may be feeling the need for a break. The nurse should reassure the woman that she will not be left alone. It is crucial that the nurse be available as a relief support at this time and keep the woman informed about where her labor support people are, if they leave the room.

Cervical dilatation slows as it progresses from 8 to 10 cm and the rate of fetal descent increases. The average rate of descent is at least 1 cm per hour in nulliparas and 2 cm per hour in multiparas. The transition phase should not be longer than 3 hours for nulliparas and 1 hour for multiparas (Cunningham et al., 2010). The total duration of the first stage may be increased by approximately 1 hour if epidural anesthesia is used.

During the active and transition phases, contractions become more frequent, are longer in duration, and increase in intensity. At the beginning of the active phase, the contractions have a frequency of 2 to 5 minutes, a duration of 40 to 60 seconds, and are strong in intensity. During transition, contractions have a frequency of 1 1/2 to 2 minutes, a duration of 60 to 90 seconds, and are strong in intensity (Cunningham et al., 2010).

Second Stage of Labor

As dilatation approaches 10 cm, there may be increased rectal pressure and an uncontrollable urge to bear down, an increase in bloody show, and ROM (if this has not already occurred). The woman may also fear that she will be "torn open" or "split apart" by the force of the contractions. The woman may experience a sensation of pressure so great with the peak of a contraction that it seems to her that her abdomen will burst open. The woman should be informed that this is a normal sensation and reassured that such bursting will not happen.

During transition the woman will most likely withdraw into herself. Increasingly she may doubt her ability to cope with labor. The woman may become apprehensive and irritable. Although she may be terrified of being left alone, she may not want anyone to talk to her or touch her. However, with the next contraction she may ask for verbal and physical support. She may need help regaining focus. Other characteristics that may accompany this phase include the following:

- Hyperventilation, as the woman increases her breathing rate
- Restlessness
- Difficulty understanding directions
- A sense of bewilderment and anger at the contractions
- Generalized discomfort, including low back pain, shaking, and cramping in the legs
- Increased sensitivity to touch
- Increased need for partner's and/or nurse's presence or support
- Increased apprehension and irritability
- Statements that she "can't take it anymore"
- Requests for medication
- Hiccupping, belching, nausea, or vomiting
- Beads of perspiration on the upper lip
- Increasing rectal pressure
- Curling of her toes
- Loss of control
- Crying or yelling

The woman in this phase is anxious to "get it over with." She may be amnesic and sleep between her now-frequent contractions. Her support persons may start to feel helpless and may turn to the nurse for increased participation as their efforts to alleviate her discomfort seem less effective.

Second Stage

The second stage of labor begins when the cervix is completely dilated (10 cm) and ends with birth of the infant. The second stage is typically completed within 2 hours after the cervix becomes fully dilated for primigravidas (multiparas average 15 minutes). The use of epidural anesthesia may extend the duration of the second stage an additional hour. Contractions continue with a frequency of 1 1/2 to 2 minutes, a duration of 60 to 90 seconds, and strong intensity. Descent of the fetal presenting part continues until it reaches the perineal floor.

As the fetal head descends, the woman has the urge to push because of pressure of the fetal head on the sacral and obturator nerves. As she pushes, intra-abdominal pressure is exerted from contraction of the maternal abdominal muscles. As the fetal head continues its descent, the perineum begins to bulge, flatten, and move anteriorly. The amount of bloody show may increase. The labia begin to part with each contraction. Between contractions, the fetal head appears to recede. With succeeding contractions and maternal pushing effort, the fetal head descends farther.

RESEARCH EVIDENCE IN PRACTICE

Passive Descent Versus Immediate Pushing in Women with Epidural Analgesia

CLINICAL QUESTION

Which method of pushing—passive descent or active pushing upon full cervical dilatation—most benefits women with epidural analgesia?

RESEARCH EVIDENCE

Epidural analgesia has become a common method of pain management for laboring women, yet one of its side effects is a decrease in a woman's lower body sensations. This may inhibit the natural urge to push upon full cervical dilatation. Traditionally, active management of labor meant that women were directed to push immediately upon full cervical dilatation, whether they felt the urge or not. The chief concern leading to this practice was that an extended second stage of labor was deleterious for both mother and baby, leading to acidosis, maternal exhaustion, and neonatal morbidity.

The natural second stage of labor includes a period of rest and descent, often described as passive descent. This practice involves allowing the woman to delay pushing until she feels the urge to push, or the head is visible vaginally.

A group of obstetric and gynecologic nurse experts conducted a meta-analysis of studies comparing the effects and outcomes of immediate pushing versus passive descent in women with epidural analgesia. The results demonstrated that immediate pushing did not reduce the incidence of acidosis or shorten the second stage of labor. Indeed, prolonged active pushing was shown to increase the incidence of fetal and maternal acidosis, increased the risk of having an instrument-assisted birth, and decreased the chance a woman would have a spontaneous vaginal birth. Pushing time was lengthened with immediate pushing as compared to passive descent.

Furthermore, passive descent had additional benefits in that it allowed for further fetal descent and rotation, better situating the fetus in the woman's pelvis. It also caused further release of oxytocin that augmented the progress of labor. These findings suggest that the duration of active pushing should be limited, not the duration of the second stage of labor.

No differences were found between immediate pushing and passive descent in terms of the rate of cesarean birth, lacerations, or episiotomies.

WHAT QUESTIONS REMAIN UNANSWERED?

Are there any conditions under which active pushing should be used? Are there differences in these findings when women do not use epidural analgesia?

WHAT IS BEST PRACTICE?

Passive descent should be used during birth to safely and effectively increase spontaneous vaginal births, decrease instrument-assisted birth, and shorten pushing time.

CRITICAL THINKING

How can the nurse help the mother recognize the urge to push at an effective time when epidural analgesia is in place?

References

Brancato, R., Church, S., & Stone, P. (2008). A meta-analysis of passive descent versus immediate pushing in nulliparous women with epidural analgesia in the second stage of labor. *Journal of Gynecological and Neonatal Nursing, 37,* 4–12. doi:10.1111/J.1552-6909.2007.00205.x

Crowning occurs when the fetal head is encircled by the external opening of the vagina (introitus) and means birth is imminent. Some women feel acute, increasingly severe pain and a burning sensation as the perineum distends. The woman may continue to fear that she will tear apart. The nurse needs to instruct the woman to "push through the pain and burning."

Usually, a childbirth-prepared woman feels relieved that the acute pain she felt during the transition phase is over. She also may be relieved that the birth is near and she can now push. Some women feel a sense of control now that they can be actively involved. Others, particularly those without childbirth preparation, may become frightened. They tend to fight each contraction and any attempt of others to persuade them to push with contractions. The woman may feel she has lost control and become embarrassed and apologetic, or she may demonstrate extreme irritability toward the staff or her supporters in an attempt to regain control over external forces against which she feels helpless. Such behavior may be frightening and disconcerting to her support persons. The nurse needs to provide reassurance to the support person(s) that this is a common reaction.

Spontaneous Birth (Vertex Presentation)

As the head distends the vulva with each contraction, the perineum becomes extremely thin, and the anus stretches and protrudes. As extension occurs under the symphysis pubis, the head is born. When the anterior shoulder meets the underside of the symphysis pubis, a gentle push by the mother aids in birth of the shoulders. The body then follows (Figure 22-11 ■).

Positional Changes of the Fetus

For the fetus to pass through the birth canal, the fetal head and body must adjust to the maternal pelvis by certain positional changes. These changes, called **cardinal movements** or mechanisms of labor, are described in the order in which they occur (Figure 22-12 ■).

DESCENT Descent is thought to occur because of four forces: (1) pressure of the amniotic fluid, (2) direct pressure of the fundus of the uterus on the breech of the fetus, (3) contraction of the abdominal muscles, and (4) extension and straightening of the fetal body. The head enters the inlet in the occiput transverse or oblique position because the pelvic inlet is widest from side to side. The sagittal suture is an equal distance from the maternal symphysis pubis and sacral promontory.

FLEXION Flexion occurs as the fetal head descends and meets resistance from the soft tissues of the pelvis, the musculature of the pelvic floor, and the cervix. As a result of the resistance, the fetal chin flexes downward onto the chest.

INTERNAL ROTATION The fetal head must rotate to fit the diameter of the pelvic cavity, which is widest in the anteroposterior diameter. As the occiput of the fetal head meets resistance from the levator ani muscles and their fascia, the occiput rotates from left to right, and the sagittal suture aligns in the anteroposterior pelvic diameter.

Figure 22-11 ■ The birth sequence.

Source: © Stella Johnson (www.stellajohnson.com).

EXTENSION The resistance of the pelvic floor and the mechanical movement of the vulva opening anteriorly and forward assist with extension of the fetal head as it passes under the symphysis pubis. With this positional change the occiput, then brow and face, emerge from the vagina.

RESTITUTION The shoulders of the infant enter the pelvis obliquely and remain oblique when the head rotates to the anteroposterior diameter through internal rotation. Because of this rotation the neck becomes twisted. Once the head emerges and is free of pelvic resistance the neck untwists, turning the head to one side (restitution), and aligns with the position of the back in the birth canal.

EXTERNAL ROTATION As the shoulders rotate to the anteroposterior position in the pelvis, the head is turned farther to one side (external rotation).

EXPULSION After the external rotation and through expulsive efforts of the laboring woman, the anterior shoulder meets the

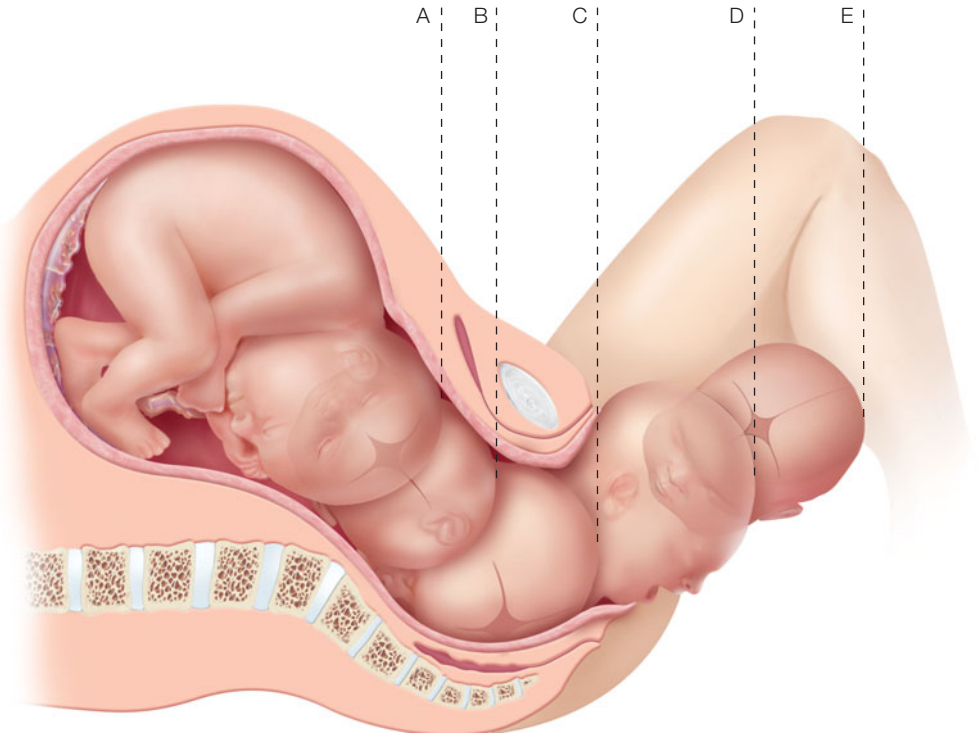

Figure 22-12 ■ Mechanisms of labor. A. and B. Descent. C. Internal rotation. D. Extension. E. External rotation.

undersurface of the symphysis pubis and slips under it. As lateral flexion of the shoulder and head occurs, the anterior shoulder is born before the posterior shoulder. The body follows quickly.

Third Stage

The third stage of labor is defined as the period of time from the birth of the infant until the completed delivery of the placenta.

Placental Separation

After the infant is born, the uterus contracts firmly, diminishing its capacity and the surface area of placental attachment. The placenta begins to separate because of this decrease in surface area. This separation is accompanied by bleeding, leading to the formation of a hematoma between the placental tissue and the remaining decidua. This hematoma accelerates the separation process. The membranes are the last to separate. They are peeled off the uterine wall as the placenta descends into the vagina.

Signs of placental separation usually appear around 5 minutes after birth of the infant, but can take up to 30 minutes to manifest. These signs are (1) a globular-shaped uterus, (2) a rise of the fundus in the abdomen, (3) a sudden gush or trickle of blood, and (4) further protrusion of the umbilical cord out of the vagina.

Placental Delivery

When the signs of placental separation appear, the woman may bear down to aid in placental expulsion. If this fails and the certified nurse-midwife or physician has ascertained that the fundus is firm, gentle traction may be applied to the cord while pressure is exerted on the fundus. The weight of the placenta as it is guided into the placental pan (a basin that holds the placenta once it is expelled) aids in the removal of the membranes from the uterine wall. A placenta is considered to be *retained* if more than 30 minutes have elapsed from completion of the second stage of labor.

If the placenta separates from the inside to the outer margins, it is expelled with the fetal (shiny) side presenting (Figure 22-13A ■). This is known as the *Schultze mechanism* of placental delivery or, more commonly, *shiny Schultze*. If the placenta separates from the outer margins inward, it will roll up and present sideways with the maternal surface delivering first. This is known as the *Duncan mechanism* of placental delivery and is commonly called *dirty Duncan* because the placental surface is rough (Figure 22-13B ■). Also see Figures 11-11 and 11-12 ∞ on page 228.

Nursing and medical interventions during the third stage of labor are discussed in chapter 24 ∞.

Fourth Stage

The fourth stage of labor is the time from 1 to 4 hours after birth in which physiologic readjustment of the mother's body begins. With the birth, hemodynamic changes occur. Blood loss at birth ranges from 250 to 500 ml. With this blood loss and the easing of pressure exerted by the pregnant uterus on the surrounding vessels, blood is redistributed into venous beds. This results in a moderate drop in both systolic and diastolic blood pressure, increased pulse pressure, and moderate tachycardia (Cunningham et al., 2010).

The uterus remains contracted and is in the midline of the abdomen. The fundus is usually midway between the symphysis pubis and umbilicus. Its contracted state constricts the vessels at the site of placental implantation. Immediately after birth of the placenta, the cervix is widely spread and thick.

Nausea and vomiting experienced during transition usually cease. The woman may be thirsty and hungry. She may

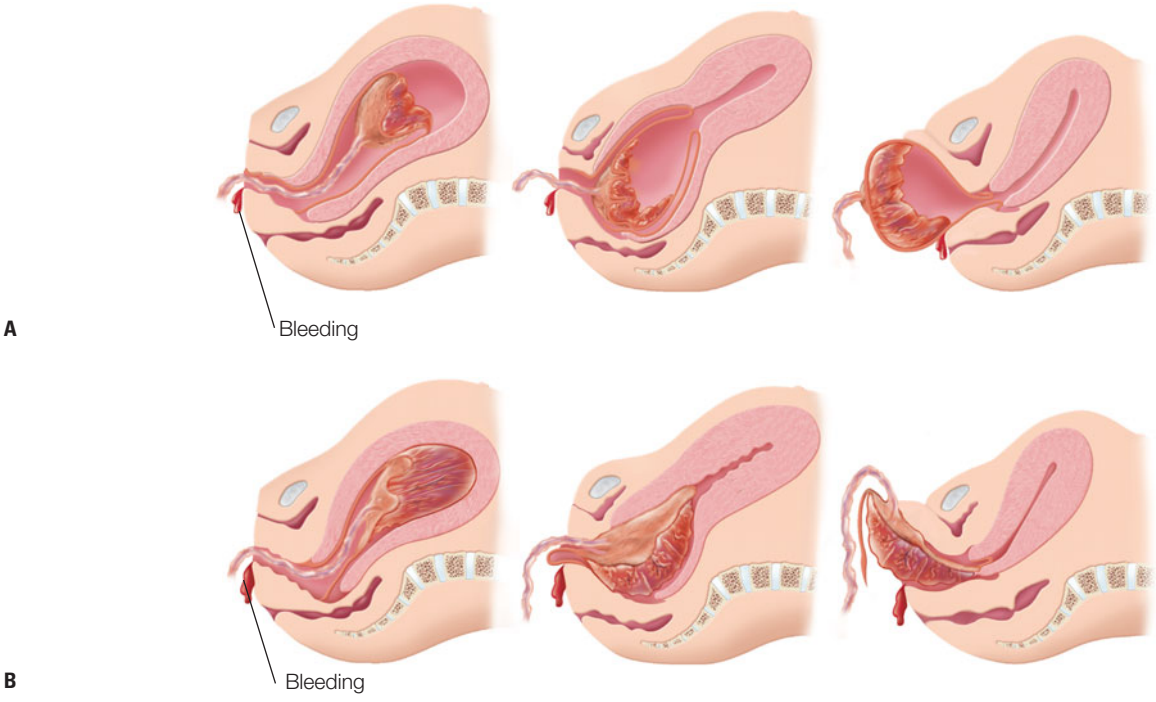

Figure 22-13 ■ Placental separation and expulsion. A. Schultze mechanism. B. Duncan mechanism.

experience a shaking chill, which is thought to be associated with the ending of the physical exertion of labor. The bladder is often hypotonic due to trauma during the second stage and/or the administration of anesthetics that may decrease sensations. Hypotonic bladder leads to urinary retention. Nursing care during this stage is discussed in chapter 24 ∞.

> *"I have had the privilege of practicing nursing in the birthing area for many years. In my head I know all the factors that must work together to bring this new life into the world. But it is in my heart and in working with and watching the laboring woman (and her partner if she has one) that I truly believe each labor and birth is a miracle. I, along with these parents, get to participate in a moment of time that will never occur again for any of us. I will never tire of this and will never get enough."*

Maternal Systemic Response to Labor

The labor process affects nearly every major body system. Each system adapts to these changes through various compensation mechanisms.

Cardiovascular System

The woman's cardiovascular system is stressed both by the uterine contractions and by the pain, anxiety, and apprehension the woman experiences. In pregnancy, the resting pulse rate increases by 10 to 18 beats per minute (Gabbe et al., 2007). During labor there is a significant increase in cardiac output. Each strong contraction greatly decreases or completely stops the blood flow in the branches of the uterine artery that supply the intervillous space (in the placenta). This leads to a redistribution of about 300 to 500 ml of blood into the peripheral circulation and an increase in peripheral resistance, resulting in increased systolic and diastolic blood pressure, a slowing of the pulse rate, and an increase of about 30% in cardiac output (Cunningham et al., 2010).

Maternal position also affects cardiac output, blood pressure, and pulse. When the laboring woman turns to a side-lying position, cardiac output increases by about 22%, the pulse rate decreases by about 6 beats per minute, and stroke volume increases by 27%. When the woman is supine, cardiac output increases 25%, stroke volume increases 33%, pulse pressure increases more than 26%, blood pressure rises significantly, and pulse rate decreases by 15%.

There is an additional effect on hemodynamics during the bearing-down efforts in the second stage. When the laboring woman holds her breath and pushes against a closed glottis (Valsalva maneuver), intrathoracic pressure rises. As intrathoracic pressure increases, the venous return is interrupted, increasing venous pressure. In addition the blood in the lungs is forced into the left atrium, which leads to a transient increase in cardiac output, blood pressure, and pulse pressure, and causes bradycardia. As venous return to the lungs continues to be diminished while the breath is held, a decrease in blood pressure, pulse pressure, and cardiac output occurs.

When the next breath is taken (Valsalva maneuver is interrupted), the intrathoracic pressure is decreased. Venous return increases, refilling the pulmonary bed and resulting in recovery of the cardiac output and stroke volume. This process is repeated with each pushing effort.

Care Plan Activity: Teenage Patient in Uncomplicated Labor

Immediately after birth, cardiac output peaks with an 80% increase over prelabor values. Then in the first 10 minutes it decreases 20% to 25%. Cardiac output further decreases in the first hour after the birth. However, these decreases still leave the woman with an elevated cardiac output for at least 24 hours after the birth (Cunningham et al., 2010).

Blood Pressure

As a result of increased cardiac output, systolic blood pressure rises during uterine contractions. In the first stage, systolic pressure may increase by 35 mm Hg, and there may be further increases in the second stage during pushing efforts. Diastolic pressure also increases by about 25 mm Hg in the first stage and 65 mm Hg in the second stage. These increases begin just before the uterine contraction, with a return to baseline as soon as the contraction ends (Cunningham et al., 2010). Blood pressure may also rise as a result of fear, apprehension, and pain (Gabbe et al., 2007).

Blood pressure may drop precipitously when the woman lies in a supine position and experiences aortocaval compression. In addition to hypotension there is an increase in the pulse rate, diaphoresis, nausea, weakness, and air hunger. These changes are attributed to the decreased cardiac output and a subsequent drop in stroke volume.

Women with hydramnios, women with multiple gestation, and obese women have the highest risk of developing aortocaval compression. Other predisposing factors include hypovolemia, dehydration, hemorrhage, metabolic acidosis, administration of narcotics (which results in vasodilation and inhibits compensatory mechanisms), and administration of epidural anesthesia, which results in *sympathetic blockade* (blocking of the sympathetic nervous system, leading to vasodilation and hypotension).

Fluid and Electrolyte Balance

Profuse perspiration (diaphoresis) occurs during labor. Hyperventilation also occurs, altering electrolyte and fluid balance from insensible water loss. The muscle activity elevates the body temperature, which increases sweating and evaporation from the skin. As the woman responds to the work of labor, the rise in the respiratory rate increases the evaporative water volume because each breath of air must be warmed to the body temperature and humidified. With the increased evaporative water volume, maintaining adequate oral fluids/hydration is important. Parenteral intravenous fluids may be used to maintain fluid and electrolyte balance.

Respiratory System

Oxygen demand and consumption increase at the onset of labor because of the presence of uterine contractions. Approximately 50% of the increased oxygen is used by the placenta, the uterus, and the fetus (Gabbe et al., 2007). As anxiety and pain from uterine contractions increase, hyperventilation frequently occurs. With hyperventilation there is a fall in $PaCO_2$, and respiratory alkalosis results (Cunningham et al., 2010).

As labor progresses and contractions become more frequent, stronger, and prolonged, the workload, tension, and anxiety of the woman continue to change. A mild increase in the respiratory rate is normal in labor and is related to the increase in metabolism (Gabbe et al., 2007).

By the end of the first stage most women have developed a mild metabolic acidosis compensated by respiratory alkalosis. As she pushes in the second stage of labor, the woman's $PaCO_2$ levels may rise along with blood lactate levels (due to muscular activity), and mild respiratory acidosis occurs. By the time the baby is born (end of second stage), there is metabolic acidosis uncompensated by respiratory alkalosis (Cunningham et al., 2010).

The changes in acid–base status that occur in labor are quickly reversed in the fourth stage because of changes in the woman's respiratory rate. Acid–base levels return to pregnancy levels by 24 hours after birth, and nonpregnant values are attained a few weeks after birth.

Renal System

During labor there is an increase in maternal renin, plasma renin activity, and angiotensinogen. This elevation is thought to be important in the control of uteroplacental blood flow during birth and the early postpartal period (Cunningham et al., 2010).

Polyuria is common during labor. This results from the increase in cardiac output, which causes an increase in the glomerular filtration rate and renal plasma flow. Slight proteinuria occurs in one half to one third of women in labor (Gibbs, Karlan, Haney, et al., 2008).

Structurally, the base of the bladder is pushed forward and upward when engagement occurs. The pressure from the presenting part may impair blood and lymph drainage from the base of the bladder, leading to edema of the tissues (Cunningham et al., 2010). Hematuria may be present as a result of trauma to the lower urinary tract.

Gastrointestinal System

During labor, gastric motility and absorption of solid food are reduced. Gastric emptying time is prolonged, and gastric volume (amount of contents that remain in the stomach) remains over 25 ml, regardless of the time the last meal was taken. This is even more marked in women who have received analgesia agents (Cunningham et al., 2010). These women may be at risk for aspiration should general anesthesia need to be used. During labor, anaerobic and aerobic carbohydrate metabolism rise due to an increase in skeletal muscle activity and maternal anxiety (Gabbe et al., 2007).

The fluid requirements of women in labor have not been clearly established. In some instances oral hydration is the primary goal. In other situations a saline lock may be inserted so that intravenous access is available if needed. If intravenous fluids are used, it is important to remember that when hypertonic glucose infusions are used, there is an increase in maternal blood glucose; this can lead to fetal hyperglycemia and hyperinsulinemia and to hypoglycemia in the newborn.

Immune System and Other Blood Values

The white blood cell (WBC) count increases to 25,000/mm^3 to 30,000/mm^3 during labor and early postpartum (Gibbs et al., 2008). The change in WBC count is due mostly to increased neutrophils resulting from a physiologic response to stress. The

increased WBC count makes it difficult to identify the presence of an infectious process.

Maternal blood glucose levels decrease because glucose is used as an energy source during uterine contractions. The decreased blood glucose levels lead to a decrease in insulin requirements (Cunningham et al., 2010). Glucose levels can drop significantly during a prolonged or difficult labor.

Pain

Pain during labor comes from a complexity of physical causes. Each woman will experience and cope with pain differently. Multiple factors affect a woman's reaction to labor pain.

Pain During Labor

The pain associated with the first stage of labor is unique in that it accompanies a normal physiologic process. Even though perception of the pain is determined to some extent by cultural patterning, there is unquestionably a physiologic basis for pain during labor. Pain during the first stage of labor arises from (1) dilatation of the cervix, (2) hypoxia of the uterine muscle cells during contraction, (3) stretching of the lower uterine segment, and (4) pressure on adjacent structures. The primary source of pain is dilatation or stretching of the cervix. Nerve impulses travel through the uterine plexus, to the pelvis through hypogastric plexuses, and then into the lumbar sympathetic chain (Figure 22-14 ■). They enter the spinal cord through the posterior roots of the 10th through 12th thoracic and 1st lumbar nerves.

As with other visceral pain, pain from the uterus is also directly referred to the dermatomes supplied by the 10th through 12th thoracic nerves. The areas of referred pain include the lower abdominal wall and the areas over the lower lumbar region and the upper sacrum (Figure 22-15 ■).

During the second stage of labor, pain is due to (1) hypoxia of the contracting uterine muscle cells, (2) distention of the vagina and perineum, and (3) pressure on adjacent structures including the lower back, buttocks, and thighs. The nerve impulses from the vagina and perineum are transmitted by way of

(This item omitted from WebBook edition)

Figure 22-14 ■ Pain pathway from uterus to spinal cord. Nerve impulses travel through the uterine plexus; pelvic plexus; lower, middle, and superior hypogastric plexuses; and lumbar sympathetic chain. They enter the neuroaxis through the 10th, 11th, and 12th thoracic and 1st lumbar spinal segments.

(This item omitted from WebBook edition)

Figure 22-15 ■ Area of reference of labor pain during the first stage. Pain is most intense in the darker colored areas.

(This item omitted from WebBook edition)

Figure 22-16 ■ Distribution of labor pain during the later phase of the first stage and early phase of the second stage. The darkest colored areas indicate the location of the most intense pain; moderate color, moderate pain; and light color, mild pain. The uterine contractions, which at this stage are very strong, produce intense pain.

the pudendal nerve plexus and enter the spinal cord through the posterior roots of the 2nd through 4th sacral nerves. The area of pain increases as shown in Figure 22-16 ■.

Pain during the third stage results from uterine contractions and cervical dilatation as the placenta is expelled. Sensations of pain are felt above the symphysis pubis bone in the perineal area and in the lower back (Figure 22-17 ■). The mechanism for the transmission of nerve impulses is the same as for the first stage of labor. The third stage of labor is short, and after this phase anesthesia is needed primarily for episiotomy repair.

(This item omitted from WebBook edition)

Figure 22-17 ■ Distribution of labor pain during the later phase of the second stage and actual birth. The perineal component is the primary cause of discomfort. Uterine contractions contribute much less.

Factors Affecting Response to Pain

Many factors affect the individual's perception of pain impulses. Some psychologic and environmental influences particularly appropriate to labor are discussed here.

Preparation for childbirth has been shown to reduce the need for analgesia during labor. Preparing for labor and birth through reading, talking with others, or attending a childbirth preparation class frequently has positive effects for the laboring woman and her partner. The woman who knows what to expect and what techniques she may use to increase comfort tends to be less anxious during the labor. A tour of the birthing center and an opportunity to see and feel the environment also help reduce anxiety, because during admission (especially with the first child) many new things are happening and they seem to occur all at once. The more the woman and her partner learn during classes and through their own efforts, the more likely they will reduce some anxiety.

Individuals tend to respond to painful stimuli in the way that is acceptable in their culture. In some cultures, it is natural to communicate pain, no matter how mild, whereas members of other cultures stoically accept pain out of fear or because it is expected. Nurses need to be aware of cultural norms and demonstrate culturally sensitive care to women and their families in the intrapartum setting (Vedam, Goff, & Marnin, 2007).

Families will react to the healthcare system based on their own cultural beliefs. Nurses need to identify specific cultural norms with each individual family so appropriate care can be provided. Whenever possible, requests that include the family's cultural preferences should be incorporated into the woman's care. Nurses should avoid making generalizations about specific cultures. Instead, individual preferences and beliefs should be explored.

Another factor that may influence response to pain is *fatigue* and *sleep deprivation.* The fatigued woman has less energy and ability to use such strategies as distraction or imagination to deal with pain. As a result, she may lose her ability to cope with labor and choose analgesics or other medications to relieve the discomfort.

The woman's *previous experience* with pain also affects her ability to manage current and future pain. Those who have had experience with pain seem more sensitive to painful stimuli than those who have not.

Anxiety can affect a woman's response to pain. Unfamiliar surroundings and events can increase anxiety, as does separation from family and loved ones. The woman's anticipation of discomfort and concerns about whether she can cope with the contractions may also increase her anxiety level. It is not uncommon for laboring women to worry about their partners or other family members. Reassurance from family members that things are being "taken care of at home" can help.

Both attention and distraction have an influence on the perception of pain. When pain sensation is the focus of attention, the perceived intensity is greater. A sensory stimulus such as a backrub can be a distraction that focuses the woman's attention on the stimulus rather than the pain. The nurse can offer suggestions to support persons on interventions to initiate physical distractions for the laboring woman.

As part of the culture of health care, nursing and medical professionals have their own (collective and individual) expectations of the woman in labor and those who support her. In one setting, the woman may be expected to use a breathing technique and relaxation methods, whereas in another, most women receive an epidural block. Some nurses may believe that the woman and her support persons should take care of themselves and ask for assistance only if really necessary; other nurses may believe that frequent interaction and support are essential as long as the woman and her support persons are comfortable with the interaction.

The healthcare professional is most likely to interpret pain according to the norms of the healthcare culture, although various other cultures have different ways of responding to pain. The absence of crying and moaning does not necessarily mean that pain is absent, nor does the presence of crying and moaning necessarily mean that pain relief is desired at that moment. It is very important for the nurse to accept and respect the fact that the pain is whatever the woman says it is and to assist her in coping with it.

Fetal Response to Labor

When the fetus is normal, the mechanical and hemodynamic changes of normal labor have no adverse effects.

Heart Rate Changes

Fetal heart rate decelerations can occur with intracranial pressures of 40 to 55 mm Hg. The currently accepted explanation of this early deceleration is hypoxic depression of the central nervous system, which is under vagal control. The absence of these head compression decelerations (early decelerations) in some fetuses during labor is explained by the existence of a threshold that is reached more gradually in the presence of intact membranes and lack of maternal resistance. Early decelerations are harmless in the normal fetus.

Acid–Base Status in Labor

The blood flow to the fetus is slowed during the acme of the contraction, which leads to a slow decrease in the fetal pH. During the second stage, as uterine contractions become stronger and last longer and the woman pushes with each contraction, there is a more rapid decrease in fetal pH. There is also an increase in fetal base deficit and in $PaCO_2$ and a drop in fetal oxygen saturation. Persistent acid–base imbalance can lead to multiorgan dysfunction in the infant, including neurologic impairment.

Hemodynamic Changes

The adequate exchange of nutrients and gases in the fetal capillaries and intervillous spaces depends in part on the fetal blood pressure. Fetal blood pressure is a protective mechanism for the normal fetus during the anoxic periods caused by the contracting uterus during labor. The fetal and placental reserve is enough to see the fetus through these anoxic periods unharmed.

Behavioral States

The human fetus develops behavioral states between 36 and 38 weeks of gestation. The behavioral states seem to continue during labor even in the presence of uterine contractions. Two sleep states (quiet and active) are most prevalent, although

quiet and active awake states are occasionally observed. A decrease in fetal heart rate variability accompanies the quiet sleep state, and there is also a decrease in fetal breathing movements and other general body activity. The quiet sleep state generally lasts less than 40 minutes.

Fetal Sensation

Beginning at about 37 or 38 weeks' gestation (full term), the fetus is able to experience sensations of light, sound, and touch. Fetal hearing begins to develop at 23 to 24 weeks but is not considered reliable until 28 weeks (Blackburn, 2007). Even in utero, the fetus is sensitive to light and will move away from a bright light source. Additionally, the term baby is aware of pressure sensations during labor such as the touch of the caregiver during a vaginal exam or pressure on the head as a contraction occurs. Although the fetus may not be able to process this input, as the woman labors the fetus is experiencing the labor as well.

FOCUS YOUR STUDY

- Five factors that continually interact during labor and birth are the birth passage, the birth passenger (fetus), the relationship between the birth passage and the fetus, the physiologic forces of labor, and factors associated with the woman's psychosocial status.
- Four types of pelves have been identified, and each has a different effect on labor. The diameters of gynecoid and anthropoid pelves are usually large enough for labor and birth to progress normally. In the android and platypelloid types, the pelvic diameters are diminished (smaller than in gynecoid and anthropoid). Labor is more likely to be difficult (longer) and a cesarean birth is more likely.
- Important dimensions of the maternal pelvis include the diameters of the pelvic inlet, pelvic cavity, and pelvic outlet.
- The fetal head contains bones in the top portion (cranial vault) that are not fused. This allows them to overlap somewhat in response to the pressures on the fetal head during labor. The pressure and overlapping of the sutures, which are membranous spaces between the cranial bones, result in a change in the shape of the head called molding.
- Fetal attitude refers to the relation of the fetal parts to one another. The head is usually held in midline and not to one side or the other, and the extremities are usually flexed and held close to the body because there is little extra room within the uterine cavity.
- Fetal lie refers to the relationship of the cephalocaudal (head to sacral area) axis of the fetus to the maternal spine. The fetal lie is either longitudinal (both the maternal and fetal spines are vertical) or transverse (the fetal spine is at a right angle to the maternal spine).
- Fetal presentation is determined by the body part lying closest to the inlet of the maternal pelvis. In a longitudinal lie the fetal presentation is usually cephalic (head first) but may also be breech (buttocks or one or both feet first). In a transverse lie the fetal shoulder is usually closest to the pelvic inlet.
- Engagement of the presenting part occurs when the largest diameter of the fetal presenting part reaches or passes through the pelvic inlet.
- Station refers to the relationship of the presenting part to an imaginary line drawn between the maternal ischial spines, which are in the midpoint of the pelvic cavity. The fetal presenting part enters the pelvic inlet at what is termed about a –5 and descends toward the ischial spines, where it is called a 0 (zero) station. Further descent from 0 to +4 occurs as the presenting part descends below the ischial spines toward the vaginal opening.
- Fetal position is the relationship of a specified landmark on the presenting fetal part to the sides, front, or back of the maternal pelvis. Once the position is known, the positions of the fetal head and back can be determined.
- Each uterine contraction has an increment, acme, and decrement.
- Contraction frequency is the time from the beginning of one contraction to the beginning of the next contraction.

- Duration of contractions refers to the period of time from the beginning to the end of one contraction.
- Intensity of contractions refers to the strength of the contraction during acme. Intensity of contractions is termed mild, moderate, or strong.
- Labor stresses the coping skills of women. Women with prenatal education about childbirth usually report more positive responses to labor.
- Women with support persons tend to use their coping skills more effectively than those who lack support.
- Premonitory signs of labor include lightening, Braxton Hicks contractions, cervical softening and effacement, bloody show, sudden burst of energy, weight loss, and, sometimes, rupture of membranes.
- True labor contractions occur regularly with an increase in frequency, duration, and intensity. The contractions usually start in the back and radiate around the abdomen. The discomfort is not relieved by ambulation, rest, or warm tub baths. False labor contractions do not produce progressive cervical effacement and dilatation. They are irregular and do not increase in intensity. The discomfort may be relieved by ambulation, rest, or warm tub baths.
- Possible causes of labor onset include the progesterone withdrawal hypothesis, the prostaglandin hypothesis, and the corticotropin-releasing hormone hypothesis.
- There are four stages of labor and birth. The first stage is from beginning of true labor to complete dilatation of the cervix. The second stage is from complete dilatation of the cervix to birth. The third stage is from birth to expulsion of the placenta. The fourth stage is from expulsion of the placenta to a period of 1 to 4 hours after.
- The fetus accommodates to the maternal pelvis in a series of movements called the cardinal movements of labor, which include descent, flexion, internal rotation, extension, restitution, external rotation, and expulsion.
- Placental separation is indicated by lengthening of the umbilical cord, a small spurt of blood, change in uterine shape, and a rise of the fundus in the abdomen.
- The placenta is expelled by Schultze or Duncan mechanism. This is determined by the way it separates from the uterine wall.
- Maternal systemic responses to labor involve the cardiovascular, respiratory, renal, gastrointestinal, and immune systems. Cardiac output and blood pressure increase, as do oxygen demand and consumption. Polyuria is common, and gastric motility and absorption are reduced. The white blood cell count increases, and blood glucose levels decrease.
- Factors that affect the response to labor pain include education, cultural beliefs, fatigue and sleep deprivation, personal significance of pain, previous experience, anxiety, and the availability of coping techniques.
- The fetus is usually able to tolerate the labor process with no untoward changes.

CRITICAL THINKING IN ACTION

Source: George Dodson/Pearson Education.

Ann Nelson, a 28-year-old, G2, P0010 at 41 weeks' gestation, is admitted to the birthing unit where you are working. She is here for cervical ripening and induction of labor due to postdate pregnancy and decreased amniotic fluid volume. A review of her prenatal chart reveals a pertinent history of infertility (Clomid-induced pregnancy) and asthma (treated with inhalers on a PRN basis). The Doppler picks up a fetal heart rate of 120 beats/min. You place Ann on the electronic fetal monitor and obtain the following data: BP 126/76, T 98°F, P 82, R 16; vaginal exam reveals a 20% effaced cervix, 1 cm dilatation in the posterior position, and vertex at −2 station. The fetal monitor shows a fetal heart rate baseline of 120 to 128 with occasional variable decelerations, accelerations to 140 with fetal activity. No contractions are noted on the monitor or palpated. Ann asks you what to expect with "cervical ripening" using prostaglandin gel.

1. Discuss the action of prostaglandin gel.
2. Ann asks you why cervical ripening and induction of labor are recommended for her and her baby. How would you best respond to her?
3. Ann asks how she will know if she is getting contractions. How would you answer her?
4. Discuss the difference between mild, moderate, and strong contractions.
5. Describe the latent phase of labor.

CHAPTER 23

Intrapartum Nursing Assessment

Birth is the sudden opening of a window, through which you look out upon a stupendous prospect. For what has happened? A miracle. You have exchanged nothing for the possibility of everything.

—William MacNeile Dixon

LEARNING OUTCOMES

1. Summarize intrapartum physical, psychosocial, and cultural assessments necessary for optimum maternal-fetal outcome.
2. Discuss the outer limits of normal progress of each of the phases and stages of labor.
3. Compare the various methods of monitoring fetal heart rate and contractions, giving advantages and disadvantages of each.
4. Describe the procedure for performing Leopold's maneuvers and the information that can be obtained.
5. Differentiate between baseline and periodic changes in the fetal heart rate.
6. Examine the differences between fetal tachycardia and fetal bradycardia.
7. Discuss fetal heart rates and patterns using National Institute of Child Health and Human Development (NICHD) terminology.
8. Explain the steps to be performed in the systematic evaluation of fetal heart rate tracings.
9. Evaluate abnormal findings on a fetal heart rate tracing.
10. Explain the interventions that are indicated when a nonreassuring fetal heart rate pattern is identified.
11. Describe the steps used to perform fetal scalp stimulation.

KEY TERMS

Accelerations *582*
Baseline fetal heart rate (BL FHR) *578*
Baseline variability (BL VAR) *581*
Decelerations *583*
Early decelerations *584*
Electronic fetal monitoring (EFM) *564*
Fetal bradycardia *579*
Fetal tachycardia *578*
Intrauterine pressure catheter (IUPC) *566*
Late decelerations *584*
Leopold's maneuvers *569*
Palpation *564*
Prolonged decelerations *586*
Scalp stimulation *591*
Variable decelerations *586*

The labor process is a period of increased physiologic stress for the pregnant woman and her fetus. The physiologic events that occur during the intrapartum period require many changes and rapid adaptations; thus accurate and frequent assessment is crucial. The primary purpose of the intrapartum assessment is to collect the essential data needed to evaluate the response of the mother and fetus to the changes in labor and the well-being of the "maternal-fetal unit" throughout those changes. The nurse in the birth setting uses a wide variety of assessment skills, including observation, palpation, and auscultation, to provide care for two primary patients, the mother and her child. The expectant mother's partner or support person is also an important member of the birthing team, and assessments of the couple's coping, interactions, and teamwork are integral to the nurse's knowledge base. The nurse's physical presence with the laboring woman provides the best opportunity for ongoing assessment, even as the nurse quietly provides comfort measures and gently assists the "coach" in offering support.

In current practice, "hands-on" techniques can be augmented by the use of technology. For example, the nurse or clinician can use Doppler ultrasound (US) to listen to the fetal heart rate (FHR) or an electronic fetal monitor to assist in recording contractions and the FHR. No matter what technology is used, however, it is important that the nurse remember that "the machine" or "the test" only provides information; it cannot replace the human interaction and support that are provided by the nurse. In the birth setting that provides "high-touch" nursing care, the "high-tech" assessments are easily integrated to provide comprehensive, high-quality care.

This chapter discusses the assessments that are an important part of nursing care in the birth setting.

Maternal Assessment

The goal of a maternal assessment is to create an accurate database of information from which healthcare providers best formulate an optimal plan of care for a patient given her current clinical situation. Assessment of the intrapartal woman begins with a patient history and screening for intrapartal risk factors. Data collection includes a variety of data assessment methods: the prenatal record, admission interviews of the patient and family members to obtain historical data, a psychologic assessment, and the initial and ongoing assessments of the mother and fetus throughout labor.

Assessment and evaluation of the potential intrapartum patient may vary from patient to patient depending on the woman's condition and stage of labor. The professional guidelines for perinatal care state that pregnant women who present to the acute care setting should be evaluated in a timely manner. Women may often need to be triaged upon presentation to the obstetrical unit; thus, nursing staff may be required to perform intrapartal assessments in various phases to facilitate prompt and efficient care for all patients. For instance, initial evaluation of a pregnant woman who presents for admission may minimally include only the assessment of her vital signs, fetal heart rate (FHR), status of uterine contractions, and any abnormal symptoms or signs of distress such as vaginal bleeding, acute abdominal pain, temperature above 100.4°F, premature labor, premature rupture of membranes (PROM), hypertension, or nonreassuring fetal patterns (American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2007).

If a pregnant woman is suspected of being in labor or has ruptured membranes or vaginal bleeding, the nurse should promptly continue to assess and evaluate the mother and initiate appropriate treatment. If a woman is in early labor and presents without complications, the nurse may defer the complete physical assessment and admission of the mother once fetal well-being has been determined. Assessment and evaluation may be limited to the interval between the points of care of a woman who has received prenatal care, has recently been evaluated, and presents with no risk factors to the present admission. On the other hand, a woman who has received no prenatal care may require a complete assessment including history and physical, obstetrical evaluation, laboratory tests, ultrasound, and other indicated procedures as her condition warrants (AAP & ACOG, 2007). Regardless of status, the well-being of the mother and fetus are of primary concern, and it is the responsibility of the nursing and medical staff to obtain accurate and appropriate data regarding the patient and to provide appropriate services as needed.

Prenatal Record

According to perinatal guidelines, when a pregnant woman approaches approximately 36 weeks' gestation, a copy of the prenatal record should be available at the acute care facility so that the medical record is accessible to members of the healthcare delivery team. If the prenatal record is available, it can provide the foundation for the intrapartum assessment. Health conditions, risk factors, abnormal test results, and ongoing assessments that have been completed during the course of the pregnancy are often useful information in determining patient care needs. Information contained in the prenatal record should be verified if possible to avoid the possibility of conflicts during subsequent patient interviews.

Historical Data

During assessment interviews, the pregnant patient is likely to be the primary source of information. Often her partner or another family member may be present and capable of providing information in the event that the mother cannot concentrate or participate in the interview because of her physical state or stage of labor. The patient's privacy must still remain a concern for the nurse in every circumstance, and every measure must be taken to safeguard it and the patient's right to confidentiality.

The historical data is the foundation for the intrapartum assessment. The historical or background data include the patient's demographic and socioeconomic information; medical, surgical, family, obstetrical, and gynecological histories; psychosociocultural assessments; and physical examination

Through the Eyes of a Nurse
Signs and Symptoms of Labor

Family's Experience

At the prenatal visit, the father of the baby expresses concerns about recognizing true labor signs. "She has been having so many of these Braxton Hicks contractions, I am afraid we won't know if it is really labor and she will have the baby at home! Is it that different? I keep having a reoccurring dream that she has the baby at home and we're all alone!"

Nurse's Response

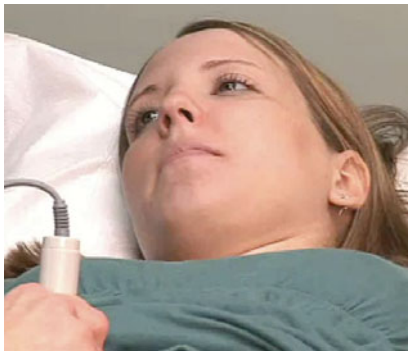
"Many couples worry that the baby will come quickly and will be born at home, but this is quite rare. The contractions (Braxton Hicks) that she is having now are for the most part painless tightening although they can be more uncomfortable when you get closer to the due date. They are common and do not have any particular pattern to them.

"True labor is marked by regular contractions that result in cervical change. The only way to know if you are having cervical change is to be examined. Once your contractions become regular and painful, you will come to the hospital where we will monitor your contraction pattern and examine your cervix.

"You will also need to come in to the birth setting if your water breaks or if you have any vaginal bleeding or a decrease in the baby's movement patterns."

Nurse's Actions and Rationale

The nurse reassures the couple that labor is usually recognized and that there usually is adequate time to get to the birth setting. The nurse should review the signs of labor and danger signs and advise the couple when they should come to the birth setting. A written information sheet is helpful and allows the couple to review the information at home.



(Simpson & Creehan, 2007). Relevant data include the following (Cunningham et al., 2010):

- Demographic information
  - Name and age
  - Attending obstetrician or certified nurse-midwife (CNM)
  - Pediatrician/family physician
- Socioeconomic factors
  - Housing, transportation
  - Ability to provide for the new baby
  - Support system
- Psychosocial assessment
  - Cultural factors
  - Resources and support systems
  - Domestic violence screening
  - Substance abuse/exposure
- Medical and surgical histories
  - History of previous illness, such as tuberculosis, heart disease, diabetes, convulsive disorders, immune system abnormalities, hematologic disorders, thyroid disorders, gastrointestinal abnormalities, asthma, sickle cell anemia, Tay-Sachs disease, psychologic disorders, and other inherited disorders
  - Surgeries
- Family history
  - Genetic disorders, medical conditions, psychiatric conditions
- Obstetrical history
  - Past pregnancies
    - Complications during pregnancy (e.g., preeclampsia/eclampsia, gestational diabetes, anemia, hyperemesis, hydramnios or oligohydramnios, placenta previa)
    - Labor complications (e.g., dystocia [malpresentation, cephalopelvic disproportion (CPD), macrosomia, failure to progress], precipitous or prolonged labor, prolonged pushing, hemorrhage, placenta abruption or accreta, cord prolapse, embolism, mechanical delivery [forceps or vacuum], pain management [epidural or medications], episiotomy/laceration)
    - Postpartum complications (e.g., hemorrhage, infection, thrombus, postpartum depression, difficulty breastfeeding)
    - High-risk factors
    - Previous abortions, term and preterm infants, number of living children, neonatal deaths
    - Mode of birth
  - Current pregnancy
    - Gravidity, parity
    - High-risk factors
    - Blood type; Rh factor; results of serology testing; complete blood count (CBC); glucose testing; screens for hepatitis, syphilis, rubella, chlamydia, gonorrhea, and group beta strep; quadruple screen, and results of any genetic diagnostic (nuchal translucency testing, chorionic villus sampling, amniocentesis), and specialized testing (Tay-Sachs, cystic fibrosis, sickle cell)
    - Allergies to medications, foods, or substances
    - Drug and alcohol consumption and smoking during pregnancy
    - Elevated blood pressure, bleeding problems, recurrent urinary tract infection
    - Medications used during the pregnancy, including prescription medication, over-the-counter medications, and herbal supplements
    - Method chosen for infant feeding
    - Type of prenatal education (childbirth preparation classes)
    - Woman's preferences regarding labor and birth, such as no episiotomy, no analgesics or anesthetics, or the presence/participation of the father or others at the birth
  - Gestational age assessment
  - Fetal activity
  - Leopold's maneuvers
  - Fetal positioning
- Clinical assessment
  - Maternal vital signs
  - Maternal weight, height, and weight gain this pregnancy
  - Nutritional status
  - Uterine activity
    - Contraction assessment
      - Onset, duration, frequency of uterine contractions
    - Fetal response to uterine contractions
  - Membrane status
    - Status of membranes, color of amniotic fluid
    - Date and time of rupture
  - Vaginal examination
    - Vaginal bleeding and discharge
    - Cervical exam
- Biochemical examinations during pregnancy
  - Laboratory studies
    - CBC, blood type, and Rh and antibody screen
    - Toxicology screening (if ordered)
    - Blood glucose screening
    - Urine for protein and sugar
  - Infectious disease evaluation
    - Chlamydia, gonorrhea, group beta strep, hepatitis B, rubella, syphilis
    - Optional infectious disease evaluation: cytomegalovirus, tuberculosis, trichomonas, HIV, hepatitis A and C, herpes simplex virus
- Fetal assessment
  - Gestational age assessment
    - Last menstrual period (LMP)
    - Fetal movement
    - Ultrasound exams for dating
  - Fetal activity
    - Fetal movement by maternal report
    - Fetal movement by palpation

Intrapartum High-Risk Screening

Screening for intrapartum high-risk factors is an integral part of assessment of the normal laboring woman. While obtaining the history, the nurse notes the presence of any factors that may be associated with a high-risk condition (Simpson & Creehan, 2007). For example, the woman who reports a physical symptom such as intermittent bleeding needs further assessment to rule out abruptio placentae or placenta previa before the admission process continues. In addition to identifying the presence of a high-risk condition, the nurse must recognize the implications of the condition for the laboring woman and her fetus. For example, in the case of an abnormal fetal presentation, the nurse understands that the labor may be prolonged, prolapse of the umbilical cord may be more likely, and there is a greater possibility of a cesarean birth.

Although physical conditions are frequently listed as the major factors that increase risk in the intrapartum period, psychosocial and cultural variables such as poverty, nutrition, the amount of prenatal care, and cultural beliefs regarding pregnancy can also precipitate a high-risk situation in the intrapartum period. Women who suffer from post-traumatic stress disorder (PTSD) or depression may be at increased risk for some intrapartal complications (Lev-Wiesel, Chen, Daphna-Tekoah, & Hod, 2009). The nurse should begin gathering data about these psychosocial and cultural factors as the woman enters the birthing area.

Communication problems can also affect the course of labor, as well as the nurse's ability to provide support and education. Thus, the nurse observes the communication pattern between the woman and her support person(s) and their responses to admission questions and initial teaching. If the nurse or other birthing room staff does not speak the primary language of the woman and her support person(s) or if the woman is hearing impaired, an appropriate interpreter should be obtained so that the patient can make informed decisions. (See further discussion in appendices C ∞, D ∞, and E ∞). Communication may also be affected by cultural standards regarding when it is acceptable to speak, who should ask questions, or whether it is acceptable for the woman to let others know if she is experiencing discomfort (Spector, 2009).

An intimate partner violence (IPV) assessment should be performed on all women throughout the pregnancy and at admission to the intrapartum unit. Since women with a history of IPV are at greater risk for certain adverse events, such as preterm labor, low birth weight, neonatal admissions, and infant death, an assessment of IPV is essential (New York City Department of Health and Mental Hygiene, 2010). Victims of IPV are also more likely to experience an unintended pregnancy and are more at risk for depression and postpartum depression (New York City Department of Health and Mental Hygiene, 2010).

A partial list of intrapartum risk factors appears in Table 23-1. The factors precede the Intrapartum Assessment Guide because they must be kept in mind during the assessment.

Intrapartum Physical and Psychosociocultural Assessment

A physical examination is part of the admission procedure and part of the ongoing care of the patient. Although the intrapartum physical assessment is not as complete and thorough as the initial prenatal physical examination (see chapter 15 ∞), it does involve assessment of some body systems and the actual labor process. The Intrapartum Assessment Guide on pages 560–563 provides a framework that the maternity nurse can use when examining the laboring woman.

The physical assessment includes assessments performed immediately on admission as well as ongoing assessments. When labor is progressing very quickly, the nurse may not have time for a complete assessment. In this case, the critical physical assessments would include maternal vital signs, labor status, fetal status, and laboratory findings. Psychologic disorders can also affect the intrapartum course. For example, the woman suffering from clinical depression may exhibit apathy, lack of energy, fear or hopelessness about the outcome of labor, or increased physical symptoms (Kamysheva, Skouteris, Wertheim, et al., 2009). The woman with a panic disorder may have short-lived, unpredictable episodes of intense anxiety, whereas the woman with a generalized anxiety disorder may experience continual and excessive anxiety or worrying. The woman with obsessive-compulsive disorder may have irrational impulses that are relieved only with performing a ritualistic behavior, such as repetitive hand washing. Psychosis is one of the most disabling psychiatric disorders, and the woman may experience hallucinations and delusions. Women with acute psychosis typically require inpatient hospitalization.

Pregnancy further complicates psychiatric disorders because many of the medications used to treat the symptoms are contraindicated in pregnancy (ACOG, 2008). For these reasons, the woman with a psychologic disorder may require additional support from the nurse.

Assessment of psychosocial history is a critical component of intrapartum nursing assessment. Because of the prevalence of physical and sexual assault against women in our society (see chapter 9 ∞), the nurse needs to consider the possibility that the woman may have experienced such violence at some point in her life. If this is the case, she may be anxious about the labor process, or anxiety may arise during labor. Therefore, it is essential to review the woman's prenatal record and any other available records for information that may indicate abuse.

The cultural assessment provides a starting point for a plan that honors the values and beliefs of the laboring woman (Spector, 2009). Frequently, however, the nurse feels uncertain about what to ask or consider, perhaps because there has been no personal opportunity to become aware of varying cultural values and beliefs. It is important to remember that despite one's cultural background, variations in different individuals and families can vary dramatically. Some individuals may not embrace cultural beliefs that are inherent in their culture. The cultural assessment section of the assessment guide (see pages 562–563) helps to encourage cultural sensitivity in the nurse (Spector, 2009).

TABLE 23-1 Intrapartum High-Risk Factors

FACTOR	MATERNAL IMPLICATION	FETAL-NEONATAL IMPLICATION
Abnormal presentation	↑ Incidence of cesarean birth ↑ Incidence of prolonged labor ↑ Incidence of fibroids	↑ Incidence of placenta previa Prematurity ↑ Risk of congenital abnormality Neonatal physical trauma ↑ Risk of intrauterine growth restriction (IUGR)
Multiple gestation	↑ Uterine distention → ↑ risk of postpartum hemorrhage ↑ Risk of cesarean birth ↑ Risk of preterm labor	Low birth weight Prematurity ↑ Risk of congenital anomalies Feto-fetal transfusion
Hydramnios	↑ Discomfort ↑ Dyspnea ↑ Risk of preterm labor Edema of lower extremities/varicosities	↑ Risk of esophageal or other high alimentary tract atresias ↑ Risk of central nervous system (CNS) anomalies (myelocele) ↑ Risk of TORCH (toxoplasmosis, rubella, cytomegalovirus, herpes virus hominis type 2) infections ↑ Risk of prolapse cord
Oligohydramnios	Maternal fear of "dry birth"	↑ Incidence of congenital anomalies ↑ Incidence of renal lesions ↑ Risk of intrauterine growth restriction (IUGR) ↑ Risk of fetal acidosis ↑ Risk of cord compression Postmaturity
Meconium staining of amniotic fluid	↑ Psychologic stress due to fear for baby	↑ Risk of fetal asphyxia ↑ Risk of meconium aspiration ↑ Risk of pneumonia due to aspiration of meconium
Premature rupture of membranes (PROM)	↑ Risk of infection (chorioamnionitis) ↑ Risk of preterm labor ↑ Anxiety/fear for the baby Prolonged hospitalization ↑ Incidence of tocolytic therapy	↑ Perinatal morbidity Prematurity ↓ Birth weight ↑ Risk of respiratory distress syndrome (RDS) Prolonged hospitalization
Induction of labor	↑ Risk of uterine rupture ↑ Length of labor if cervix not ready ↑ Anxiety	Prematurity if gestational age not assessed correctly ↑ Risk of hypoxia
Abruptio placentae/placenta previa	Hemorrhage Uterine atony ↑ Incidence of cesarean birth ↑ Maternal morbidity	Fetal hypoxia/acidosis Fetal exsanguination ↑ Perinatal mortality
Failure to progress in labor	Maternal exhaustion ↑ Incidence of augmentation of labor ↑ Incidence of cesarean birth	Fetal hypoxia/acidosis Intracranial birth injury
Precipitous labor (less than 3 hours)	Perineal, vaginal, cervical lacerations ↑ Risk of postpartum hemorrhage	Neonatal tentorial (brain) tears Trauma—neural or tissue, cephalohematoma
Prolapse of umbilical cord	↑ Fear for baby Cesarean birth → emergent	Acute fetal hypoxia/acidosis
Fetal heart decelerations	↑ Fear for baby ↑ Risk of cesarean birth, forceps, vacuum Continuous electronic monitoring and intervention in labor	Tachycardia, chronic asphyxic insult, bradycardia Acute asphyxic insult Chronic hypoxia Congenital heart block
Uterine rupture	Hemorrhage Cesarean birth/hysterectomy ↑ Risk of morbidity/mortality	Fetal anoxia Fetal hemorrhage ↑ Neonatal morbidity and mortality
Postdates (greater than 42 weeks)	↑ Anxiety ↑ Incidence of induction of labor ↑ Incidence of cesarean birth ↑ Use of technology to monitor fetus ↑ Risk of shoulder dystocia	Postmaturity syndrome ↑ Risk of fetal-neonatal mortality and morbidity ↑ Risk of antepartum fetal death ↑ Incidence/risk of large baby ↑ Hypoglycemia
Diabetes	↑ Risk of hydramnios ↑ Risk of hypoglycemia or hyperglycemia ↑ Risk of preeclampsia	↑ Risk of malpresentation ↑ Risk of macrosomia ↑ Risk of intrauterine growth restriction (IUGR) ↑ Risk of respiratory distress syndrome (RDS) ↑ Hypoglycemia, polycythemia ↑ Birth trauma ↑ Risk of congenital anomalies
Preeclampsia	↑ Abruptio placentae ↑ Risk of seizures ↑ Risk of stroke ↑ Risk of HELLP	↑ Risk of small-for-gestational-age (SGA) baby ↑ Risk of preterm birth ↑ Risk of mortality
AIDS/STD	↑ Risk of additional infections	↑ Risk of transplacental transmission

ASSESSMENT GUIDE Intrapartum—First Stage of Labor

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
VITAL SIGNS		
Blood Pressure (BP): less than or equal to 135 systolic and less than or equal to 85 diastolic in adult 18 years of age or older or no more than 15–20 mm Hg rise in systolic pressure over baseline BP during early pregnancy	High blood pressure (essential hypertension, gestational hypertension, preeclampsia, renal disease, apprehension, anxiety or pain) Low blood pressure (supine hypotension) Hemorrhage/hypovolemia Shock Drugs	Evaluate history of preexisting disorders and check for presence of other signs of preeclampsia. Do not assess during contractions; implement measures to decrease anxiety and reassess. Turn woman on her side and recheck BP. Provide quiet environment. Have oxygen (O_2) available.
Pulse: 60–90 beats/min	Increased pulse rate (excitement or anxiety, cardiac disorders, early shock, drug use)	Evaluate cause, reassess to see if rate continues; report to physician/CNM.
Respirations: 12–24/min (or pulse rate divided by 4)	Marked tachypnea (respiratory disease), hyperventilation in transition phase Decreased respirations (Narcotics)	Assess between contractions; if marked tachypnea continues, assess for signs of respiratory disease or respiratory distress.
	Hyperventilation (anxiety/pain)	Encourage slow breaths if woman is hyperventilating.
Pulse oximetry 95% or greater	Less than 90%: hypoxia, hypotension, hemorrhage	Apply O_2; notify physician/CNM.
Temperature: 36.2–37.6°C (98–99.6°F)	Elevated temperature (infection, dehydration, prolonged rupture of membranes, epidural regional block)	Assess for other signs of infection or dehydration.
WEIGHT		
25–35 lb greater than prepregnant weight if BMI is 18.5–24.9; 28–40 lb greater if BMI is below 18.5; 15–25 lb greater if BMI is 25–29.9; 37–54 lb greater if multiple gestation	Weight gain greater than 35 lb (fluid retention, obesity, large infant, diabetes mellitus, preeclampsia); weight gain less than 15 lb (small for gestational age [SGA], substance abuse, psychosocial problems)	Assess for signs of edema. Evaluate dietary patterns. Assess for substance abuse and eating disorders.
LUNGS		
Normal breath sounds, clear and equal	Rales, rhonchi, friction rub (infection), pulmonary edema, asthma	Reassess; refer to physician/CNM
FUNDUS		
At 40 weeks' gestation located just below xiphoid process	Uterine size not compatible with estimated date of birth (small [SGA] or large [LGA] for gestational age, molar pregnancy, hydramnios, multiple pregnancy, placental/fetal anomalies, malpresentation)	Reevaluate history regarding pregnancy dating. Refer to physician for additional assessment.
EDEMA		
Slight amount of dependent edema	Pitting edema of face, hands, legs, abdomen, sacral area (preeclampsia)	Check deep tendon reflexes for hyperactivity; check for clonus; refer to physician.
HYDRATION		
Normal skin turgor, elastic	Poor skin turgor (dehydration)	Assess skin turgor; refer to physician for deviations. Provide fluids per physician/CNM orders.
PERINEUM		
Tissues smooth, pink color (see Prenatal Initial Physical Assessment Guide, chapter 15 ∞)	Varicose veins of vulva, herpes lesions/genital warts	Note on patient record need for follow-up in postpartum period; reassess after birth; refer to physician/CNM.
Clear mucus; may be blood tinged with earthy or human odor.	Profuse, purulent, foul-smelling drainage	Suspected gonorrhea or chorioamnionitis; report to physician; initiate care to newborn's eyes; notify neonatal nursing staff and pediatrician.
Presence of small amount of bloody show that gradually increases with further cervical dilatation	Hemorrhage	Assess BP and pulse, pallor, diaphoresis; report any marked changes. Standard precautions.
LABOR STATUS		
Uterine Contractions (UC): regular pattern	Failure to establish a regular pattern, prolonged latent phase Hypertonicity Hypotonicity Dehydration	Evaluate whether woman is in true labor; ambulate if in early labor. Evaluate patient status and contractile pattern; oxygen, stop pitocin; terbutaline. Obtain a 30-minute electronic fetal monitoring (EFM) strip. Notify physician or CNM. Provide hydration.
Cervical Dilatation: progressive cervical dilatation from size of fingertip to 10 cm (see Procedure 23-1)	Rigidity of cervix (frequent cervical infections, scar tissue, failure of presenting part to descend)	Evaluate contractions, fetal engagement, position, and cervical dilatation. Inform patient of progress.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial nursing intervention.

ASSESSMENT GUIDE Intrapartum—First Stage of Labor continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
LABOR STATUS (continued)		
Cervical Effacement: progressive thinning of cervix (see Procedure 23-1)	Failure to efface (rigidity of cervix, failure of presenting part to engage); cervical edema (pushing effort by woman before cervix is fully dilated and effaced, trapped cervix)	Evaluate contractions, fetal engagement and position. Notify physician/CNM if cervix is becoming edematous; work with woman to prevent pushing until cervix is completely dilated. Keep vaginal exams to a minimum.
Fetal Descent: progressive descent of fetal presenting part from station −5 to +4 (see Figure 23-4 in Procedure 23-1)	Failure of descent (abnormal fetal position or presentation, macrosomic fetus, inadequate pelvic measurements)	Evaluate fetal position, presentation, and size.
Membranes: may rupture before or during labor	Rupture of membranes more than 12–24 hours before initiation of labor	Assess for ruptured membranes using Nitrazine test tape before doing vaginal exam. Follow standard precautions. Instruct woman with ruptured membranes to remain on bed rest if presenting part is not engaged and firmly down against the cervix. Keep vaginal exams to a minimum to prevent infection. When membranes rupture in the birth setting **immediately assess FHR** to detect changes associated with prolapse of umbilical cord (FHR slows).
Findings on Nitrazine Test Tape: Membranes probably intact yellow pH 5.0 olive pH 5.5 olive green pH 6.0	False-positive results may be obtained if large amount of bloody show is present, previous vaginal examination has been done using lubricant, infection is present, or tape is touched by nurse's fingers.	Assess fluid for consistency, amount, odor; assess FHR frequently. Assess fluid at regular intervals for presence of meconium staining. Follow standard precautions while assessing amniotic fluid.
Membranes probably ruptured blue-green pH 6.5 blue-gray pH 7.0 deep blue pH 7.5		Teach woman that amniotic fluid is continually produced (to allay fear of "dry birth"). Teach woman that she may feel amniotic fluid trickle or gush with contractions. Change Chux pads often.
Amniotic fluid clear, with earthy or human odor, no foul-smelling odor	Greenish amniotic fluid (nonreassuring fetal status) Bloody fluid (vasoprevia, abruptio placentae)	Assess FHR; do vaginal exam to evaluate for prolapsed cord; apply fetal monitor for continuous data; report to physician/CNM.
	Strong or foul odor (amnionitis)	Take woman's temperature and report to physician/CNM.
FETAL STATUS		
FHR: 110–160 beats/min Tachycardia Bradycardia	Less than 110 or greater than 160 beats/min (nonreassuring fetal status); abnormal patterns on fetal monitor: decreased variability, late decelerations, variable decelerations, absence of accelerations with fetal movement	Initiate interventions based on particular FHR pattern.
Presentation: Cephalic, 97% Breech, <3% Shoulder, <1%	Face, brow, breech, or shoulder presentation	Report to physician; after presentation is confirmed as face, brow, breech, or shoulder, woman may be prepared for cesarean birth.
Position: left-occiput-anterior (LOA) most common	Persistent occipital-posterior (OP) position; transverse arrest	Carefully monitor maternal and fetal status. Reposition mother side-lying or hands/knee to promote rotation of fetal head.
Activity: fetal movement	Tachysystole (more than 5 contractions in 10 minutes) (may precede fetal hypoxia)	Carefully evaluate FHR; apply fetal monitor.
	Complete lack of movement (nonreassuring fetal status or fetal demise)	Carefully evaluate FHR; apply fetal monitor. Report to physician/CNM.
LABORATORY EVALUATION		
Hematologic Tests ***Hemoglobin:*** 12–16 g/dl	Less than 11 g/dl (anemia, hemorrhage, sickle cell disorders, pernicious anemia)	Evaluate woman for problems due to decreased oxygen-carrying capacity caused by lowered hemoglobin.
CBC *Hematocrit:* 38%–47% *RBC:* 4.2–5.4 million/mm^3 *WBC:* 4500–11,000/mm^3, although leukocytosis to 20,000/mm^3 is not unusual *Platelets* 150,000–400,000/mm^3	Presence of infection or blood dyscrasias, loss of blood (hemorrhage, disseminated intravascular coagulation [DIC])	Evaluate for other signs of infection or for petechiae, bruising, or unusual bleeding.

*Possible causes of alterations are identified in parentheses.

†This column provides guidelines for further assessment and initial nursing intervention.

(continued)

ASSESSMENT GUIDE Intrapartum—First Stage of Labor continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
LABORATORY EVALUATION (continued)		
Serologic Testing Serologic test for syphilis (STS) or Rapid Plasma Reagent (RPR) test: nonreactive Rh Rh negative	Positive reaction (see chapter 15 ∞, Initial Prenatal Physical Assessment Guide)	For reactive test notify newborn nursery and pediatrician.
	Rh-positive fetus in Rh-negative woman or O+ woman	Assess prenatal record for titer levels during pregnancy. Obtain cord blood for direct Coombs' at birth.
Urinalysis: Glucose: negative	Glycosuria (low renal threshold for glucose, diabetes mellitus)	Assess blood glucose; test urine for ketones; ketonuria and glycosuria require further assessment of blood sugars.‡
Ketones: negative	Ketonuria (starvation ketosis)	Assess nutritional status.
Proteins: negative	Proteinuria (urine specimen contaminated with vaginal secretions, fever, infection, kidney disease); proteinuria of 2+ or greater found in uncontaminated urine may be a sign of ensuing preeclampsia	Instruct woman in collection technique; incidence of contamination from vaginal discharge is common. Report any increase in proteinuria to physician/CNM.
Red blood cells: negative	Blood in urine (calculi, cystitis, glomerulonephritis, neoplasm)	Assess collection technique (may be bloody show).
White blood cells: negative	Presence of white blood cells (infection in genitourinary tract)	Assess for signs of urinary tract infection.
Casts: none	Presence of casts (nephrotic syndrome)	
Nitrites	Infection	Assess for signs of urinary tract infection.
Cultural Assessment§	**Variations to Consider**	**Nursing Responses to Data†**
Cultural influences determine customs and practices regarding intrapartal care.	Individual preferences may vary.	
Ask the following questions: Who would you like to remain with you during your labor and birth?	She may prefer only her coach to remain or may also want family and/or friends.	Provide support for her wishes by encouraging desired people to stay. Provide information to others (with the woman's permission) who are not in the room.
What would you like to wear during labor?	She may be more comfortable in her own clothes.	Offer supportive materials such as Chux if needed to protect her own clothing. Avoid subtle signals to the woman that she should not have chosen to remain in her own clothes. Have other clothing available if the woman desires. If her clothing becomes contaminated, it will be simple to place it in a plastic bag.
What activity would you like during labor?	She may want to ambulate most of the time, stand in the shower, sit in the whirlpool bath, sit on a chair/stool/birthing ball, remain on the bed, and so forth.	Support the woman's wishes; provide encouragement and complete assessments in a manner so her activity and positional wishes are disturbed as little as possible.
What position would you like for the birth?	She may feel more comfortable in lithotomy with stirrups and her upper body elevated, or side-lying or sitting in birthing bed, or standing, or squatting, or on hands and knees.	Collect any supplies and equipment needed to support her in her chosen birthing position. Provide information to the coach regarding any changes that may be needed based on the chosen position.
Is there anything special you would like?	She may want the room darkened or to have curtains and windows open, music playing, a Leboyer birth, her coach to cut the umbilical cord, to save a portion of the umbilical cord, to save the placenta, to videotape the birth, and so forth.	Support requests, and communicate requests to any other nursing or medical personnel (so requests can continue to be supported and not questioned). If another nurse or physician does not honor the request, act as advocate for the woman by continuing to support her unless her desire is truly unsafe.
Ask the woman if she would like fluids, and ask what temperature she prefers.	She may prefer clear fluids other than water (tea, clear juice). She may prefer iced, room-temperature, or warmed fluids. See institution policy regarding oral intake in labor.	Provide fluids as desired.
Observe the woman's response when privacy is difficult to maintain and her body is exposed.	Some women do not seem to mind being exposed during an exam or procedure; others feel acute discomfort.	Maintain privacy and respect the woman's sense of privacy. If the woman is unable to provide specific information, the nurse may draw from general information regarding cultural variation: Southeast Asian women may not want any family member in the room during exam or procedures. Her partner may not be involved with coaching activities during labor or birth. Muslim women may need to remain covered during the labor and birth and avoid exposure of any body part. The husband may need to be in the room but remain behind a curtain or screen so he does not view his wife at this time.
If the woman is to breastfeed, ask if she would like to feed her baby immediately after birth.	She may want to feed her baby right away or she may want to wait a little while.	

§These are only a few suggestions. We do not mean to imply that this is a comprehensive cultural assessment; rather, it is a tool to encourage cultural sensitivity.

*Possible causes of alterations are identified in parentheses.

†This column provides guidelines for further assessment and initial nursing intervention.

‡Glycosuria should not be discounted. The presence of glycosuria necessitates follow-up.

ASSESSMENT GUIDE Intrapartum—First Stage of Labor continued

Psychosocial Assessment	Variations to Consider	Nursing Responses to Data†
PREPARATION FOR CHILDBIRTH		
Woman has some information regarding process of normal labor and birth.	Some women do not have any information regarding childbirth.	Add to present information base.
Woman has breathing and/or relaxation techniques to use during labor.	Some women do not have any method of relaxation or breathing to use, and some do not desire them.	Support breathing and relaxation techniques that patient is using; provide information if needed.
Woman and support person have done extensive preparation for childbirth (Bradley Classes, Lamaze).	Some women have strong opinions regarding labor and birth preparation.	Support woman's wishes to participate in her birth experience; support birth plan.
RESPONSE TO LABOR		
Early or Latent Phase: (0–3 cm) relaxed, excited, anxious for labor to be well established	May cope well or feel unable to cope with contractions because of fear, anxiety, or lack of information.	Provide support and encouragement; establish trusting relationship.
Active Phase: (4–7 cm) becomes more intense, begins to tire	May remain quiet and without any sign of discomfort or anxiety, may insist that she is unable to continue with the birthing process.	Provide support and coaching if needed.
Transitional Phase: (8–10 cm) feels tired, may feel unable to cope, needs frequent coaching to maintain breathing patterns		
Coping Mechanisms: Ability to cope with labor through use of support system, breathing, relaxation techniques, and comfort measures including frequent position changes in labor, warm water immersion, and massage	May feel marked anxiety and apprehension, may not have coping mechanisms that can be brought into this experience, or may be unable to use them at this time.	Support coping mechanisms if they are working for the woman; provide information and support if she exhibits anxiety or needs alternative to present coping methods.
	Survivors of sexual abuse may demonstrate fear of IVs or needles, may recoil when touched, may insist on a female caregiver, may be very sensitive to body fluids and cleanliness, and may be unable to labor lying down. May show extreme distress with vaginal examinations.	Encourage participation of coach/significant other if a supportive relationship seems apparent. Establish rapport and a trusting relationship. Provide information that is true and offer your presence.
ANXIETY		
Some anxiety and apprehension is within normal limits.	May show anxiety through rapid breathing, nervous tremors, frowning, grimacing, clenching of teeth, thrashing movements, crying, increased pulse and blood pressure.	Provide support, encouragement, and information. Teach relaxation techniques; support controlled breathing efforts. May need to provide a paper bag to breathe into if woman says her lips are tingling. Note FHR.
SOUNDS DURING LABOR		
	Some women are very quiet; others moan or make a variety of noises.	Provide a supportive environment. Encourage woman to do what feels right for her.
SUPPORT SYSTEM		
Physical intimacy between mother and father (or mother and support person/doula): caretaking activities such as soothing conversation, touching	Some women would prefer no contact, others may show clinging behaviors.	Encourage caretaking activities that appear to comfort the woman; encourage support for the woman; if support is limited, the nurse may take a more active role.
Support person stays in close proximity	Limited interaction may come from a desire for quiet.	Encourage support person to stay close (if this seems appropriate).
Relationship between mother and father (or support person): involved interaction	The support person may seem to be detached and maintain little support, attention, or conversation.	Support interactions; if interaction is limited, the nurse may provide more information and support.
		Ensure that coach/significant other has short breaks, especially/prior to transition.
		†This column provides guidelines for further assessment and initial nursing intervention.

The final section of the guide addresses psychosocial factors. The laboring woman's psychosocial status is an important part of the total assessment. The woman has previous ideas, knowledge, and fears about childbearing. The adequacy of resources, such as housing, transportation, utilities, and access to social services, should also be questioned. By assessing her psychosocial status, the nurse can meet the woman's needs for information and support. The nurse can then support the woman and her partner; in the absence of a partner, the nurse may become the support person.

Evaluating Labor Progress

Intrapartum nursing care requires competent assessment and clinical skills and a comprehensive knowledge of maternal-fetal anatomy and the physiology of the labor process. An ongoing,

accurate assessment of both the mother and fetus and their responses to labor is necessary to provide the data required to make sound clinical judgments and provide appropriate care. Labor can be monitored in a number of ways, each having its own benefits and limitations. If a "low technology" approach is desired, a nurse can monitor uterine contractions and the FHR intermittently using techniques such as palpation and auscultation. However, if the clinical situation demands, as in the case of a high-risk pregnancy, the laboring woman may be monitored electronically. External devices (tocodynanometer and ultrasound) or internal devices (intrauterine pressure catheter and fetal scalp electrode) may be used when a continuous graphic data record is needed to evaluate the mother and fetus during labor.

The method of monitoring during labor may vary, depending on the presence of risk factors at admission, the preferences of the woman and healthcare provider, and the institution's policies (AAP & ACOG, 2007; ACOG, 2005). If intermittent monitoring is used, the nurse must perform a "hands-on" assessment, including auscultation of fetal heart tones (FHT) and palpation of uterine contractions (UC). If continuous **electronic fetal monitoring (EFM)** is used, the amount of physical "hands-on" care may vary depending on whether an internal or external mode of monitoring is used. EFM provides a continuous tracing of the FHR.

Professional associations, such as American College of Obstetricians and Gynecologists (ACOG) and Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN), and individual healthcare institutions generally set the guidelines for the level of intrapartum monitoring. The frequency of the maternal-fetal assessment and documentation depends on the mother's stage of labor and the presence of risk factors. When EFM is used, ACOG recommends that the nurse or physician review EFM data frequently. For low-risk pregnancies, FHR tracings can be reviewed every 30 minutes in first stage labor and every 15 minutes in second stage labor. The FHR tracings of high-risk pregnancies should be reviewed more frequently—every 15 minutes in first stage labor and every 5 minutes in second stage labor. Periodic documentation should accompany each review of the FHR tracing. See Table 23-2 for the frequency of recommended assessments and documentations.

The recommended frequency of FHR tracing assessment and documentation is only a guideline for practice. At times, the nurse may find it necessary to monitor the FHR more frequently. Certain clinical events such as vaginal exams, rupture of membranes, abnormal uterine activity patterns, administration of medications, or procedures such as epidurals, amniocentesis, external versions, and other events have the potential to adversely affect the FHR tracing. It is beneficial to assess the FHR tracing before and after such events or anytime a nonreassuring FHR tracing is detected (Simpson & Creehan, 2007).

TABLE 23-2 Frequency of Maternal-Fetal Assessment and Documentation

	FIRST STAGE	SECOND STAGE
Low risk	Every 30 minutes	Every 15 minutes
High risk	Every 15 minutes	Every 5 minutes

Sources: Data from AAP & ACOG, 2007; Macones, Hankins, Spong, Hauth, & Moore, 2008.

Since its introduction into clinical practice in the late 1960s, EFM has continuously been researched and evaluated in regard to its ability to improve fetal outcomes and reduce morbidity and mortality. In the beginning, EFM was used in high-risk pregnancies, because it was thought that electronic assessment was far more accurate and valuable for diagnosing nonreassuring fetal status in labor. It was believed that continuous fetal monitoring could identify nonreassuring fetal status earlier, facilitate earlier interventions, and prevent fetal morbidity and mortality. Researchers originally thought EFM could prevent cerebral palsy, which was thought to be caused by neurologic damage from nonreassuring fetal status (Cunningham et al., 2010). Today's research does not support these earlier suppositions.

In 2002, 85% of all labors were monitored electronically, making EFM the most prevalent assessment procedure in maternal-fetal health care (Janet, 2009). However, despite its widespread use, research has failed to show that it has significantly improved the outcomes at birth. Multiple controlled random trials have failed to show that EFM is beneficial over intermittent auscultation in preventing neonatal morbidity and mortality (ACOG, 2005; AWHONN, 2008a; Cunningham et al., 2010). Intermittent assessment of the maternal-fetal couplet labor is generally considered to be as appropriate an assessment technique as electronic monitoring, especially for low-risk pregnancies when proper technique and 1:1 nurse-to-patient ratio are used (AWHONN, 2008b).

Uterine Activity Assessment

Monitoring uterine activity throughout labor is essential and provides data regarding the labor progress and fetal well-being. Numerous internal and external factors affect maternal and fetal well-being. Uterine contractions (UCs) interrupt the flow of blood to the placenta and reduce the amount of oxygen immediately available to the fetus. Decreased oxygen and blood flow directly affect the FHR. The pattern and intensity of contractions have a direct effect on the duration and progress of labor and the ability of the fetus to adapt to the intrapartal process.

UCs occur in wavelike patterns. Beginning at the fundus (top or apex of the uterus), the UC progresses downward through the lower segments of the uterus and is then followed by a similar wave of relaxation. The contraction of the upper uterine segment increases intrauterine pressure and leads to cervical dilatation and effacement and the descent of the fetus. During and between UCs, the fundus changes shape and firmness, reflecting the intensity of the UC. By monitoring the changes in the fundus, the nurse can determine the timing and intensity of the UC and the resting tone of the uterus between contractions (AWHONN, 2008a). The intensity and frequency of the UC varies from woman to woman and labor to labor. Three methods of monitoring UCs are currently used: palpation, external electronic monitoring with a tocodynanometer, and internal electronic monitoring with an intrauterine pressure catheter. Each method is discussed in the following sections.

PALPATION **Palpation** is the technique of assessing a UC by touch. To assess UCs, the nurse places the fingertips of one hand on the top of the uterus. Hand placement is usually on the

fundus, but the location may vary based on maternal or fetal position, uterine size and shape, or maternal body composition. Gentle pressure is applied to the abdomen until the firmness of the underlying uterine wall is felt.

The *frequency* of the contractions is measured from the beginning of one contraction to the beginning of the next. The length of the contraction, referred to as the *duration,* is measured from the beginning of the contraction, when the muscle begins to tense, to the end of the same contraction, when the muscle is completely relaxed. Uterine resting tone is determined between UCs, when optimum uterine relaxation is achieved (Cunningham et al., 2010).

During the acme (peak) of the contraction, intensity can be evaluated subjectively by estimating the firmness of the fundus. It can be useful to compare the contraction to the firmness of a nose, chin, or forehead. A tense fundus that is easily indented (tip of the nose) is considered mild intensity. When the fundus becomes firm and difficult to indent with the fingertips (chin), the strength of the UC is considered moderate. The fundus that is hard and cannot be indented (forehead) is classified as strong (Cunningham et al., 2010). The nurse should assess successive contractions to provide reliable data. Table 23-3 compares contraction characteristics in different phases of labor. Direct uterine palpation is used with intermittent auscultation of the fetal heart or in conjunction with continuous EFM. The frequency of palpation depends on the risk status of the mother and fetus and the stage of labor along with the quality of contraction tracing from an internal or external monitor (Cunningham et al., 2010).

Palpation has its capabilities, benefits, and limitations. Palpation allows the nurse to assess relative frequency, duration, and subjective strength of the contraction and uterine resting tone. UC assessment by palpation is beneficial over electronic monitoring because it (1) is noninvasive and does not increase the risk for infection or patient injury; (2) is readily accessible, requiring no equipment; (3) increases the "hands-on" care of the patient that can be reassuring to her; and (4) allows the mother freedom from restricting and sometimes uncomfortable abdominal belts, thus permitting her to move freely and ambulate if her condition permits. Palpation is limited because it does not provide actual quantitative measure of uterine pressure; thus subjective differences between nurses and nurse-to-patient interpretations may exist. Palpation offers no permanent record, which can hinder interpretation by others. Maternal size and increased adipose tissue from obesity and maternal positioning may prevent direct palpation of the fundus. The limitations of palpation may outweigh the benefits in some clinical situations, and electronic monitoring may be a more appropriate choice for uterine assessment (Cunningham et al., 2010).

TABLE 23-3 Contraction and Labor Progress Characteristics

Contraction Characteristics	
Early/Latent phase:	Every 10–30 min × 20–40 sec; mild, progressing to moderate
	Every 3–7 min × 30–40 sec; moderate
Active phase:	Every 2–5 min × 40–60 sec; moderate to strong
Transition phase:	Every 1 1/2–2 min × 60–90 sec; strong
Labor Progress Characteristics	
Primipara:	1.2 cm/hr dilatation 1 cm/hr descent At least 2 hr in second stage if progress is made; up to 3 hr
Multipara:	1.5 cm/hr dilatation 2 cm/hr descent Less than 30 minutes in second stage

Source: Cunningham et al., 2010.

ELECTRONIC MONITORING WITH EXTERNAL TOCODYNAMOMETER Electronic monitoring of uterine contractions can be done externally by using a tocodynamometer or tocotransducer (toco). A toco is a pressure-monitoring device that is placed on the maternal abdomen at or near the fundus (the area of greatest contractility) and held in place with an elastic belt, belly band, or other adhesive material (Figure 23-1 ■). By placing the toco over a fetal part in the fundus rather than a pocket of amniotic fluid, a better contraction tracing can be obtained (Cunningham et al., 2010). As the uterus contracts, pressure exerted against the toco is amplified and transmitted to the EFM and recorded on graph paper.

The procedure for applying the tocotransducer begins with palpation of the uterus to locate the fundus. The toco monitors uterine activity transabdominally by detecting changes in the abdominal wall and converting the fundal movement into electronic impulses. The toco can be used to assess UCs for *frequency* (timing) and *duration* (length). However, it cannot determine UC intensity (strength). The displayed numbers and graph tracing for UC intensity are arbitrary and are influenced by how tightly the belt is applied around the maternal abdomen and/or the maternal position. Palpation must be used to assess UC intensity when the external toco monitor is used. When the belt is tight enough, the nurse should be able to note the beginning of contractions on the monitor just before or at the same time the woman begins to feel them (Cunningham et al., 2010).

Figure 23-1 ■ Woman in labor with external monitor applied. The tocodynamometer placed on the uterine fundus is recording uterine contractions. The lower belt holds the ultrasonic device that monitors the fetal heart rate. The belts can be adjusted for comfort.

Case Study: Maternal Assessment During Labor

Figure 23-2 ■ The beltless tocodynamometer system features remote telemetry.

Source: Courtesy of Hewlett-Packard Company.

A beltless tocodynamometer system featuring remote telemetry is available. This system consists of an adhesive transducer that is applied to the most prominent part of the woman's abdomen with a double-sided adhesive film. The nonbelted tocodynamometer tends to be preferred by the laboring woman because it allows more freedom of movement, is easily applied, needs readjustment only infrequently, and generally is more convenient (Figure 23-2 ■). It enables upright positions, which promote fetal descent by gravity, as well as ambulation, which can shorten the labor course and increase comfort for the laboring woman (Cunningham et al., 2010).

The advantages to using a toco for assessing uterine contractions are that it is noninvasive, easy to place, and may be used both before and following rupture of membranes. Because it is noninvasive, it can be used intermittently to allow the woman to ambulate, shower, or use a whirlpool bath. The toco also provides a permanent, continuous recording of the duration and frequency of contractions for future evaluation. Placement of the tocotransducer influences the accuracy of the uterine graphic tracing (Cunningham et al., 2010). As with any type of technology, no toco is flawless, and the monitor cannot fill the role of the nurse. The nurse should routinely palpate the intensity of the contractions and the relaxation of the uterus between contractions and compare the assessment with data recorded by the monitor. Another disadvantage is that sometimes the belt may become uncomfortable because it must be worn snugly to monitor UCs accurately. The belt may require frequent readjustment as the mother changes position. The mother may also feel inhibited to move or as though she needs to remain in one position so as not to disturb the belt.

> "Trying to figure out if I was in labor was quite a task. Here I was, a birthing room nurse, and I couldn't decide if my contractions were the real thing. I timed them, and about the time I decided this was it, they would slow down. How exasperating not to know! It was so hard on me. But now I see that all women are in this spot. They want so much to be right, and we often treat them as if they should be able to sense when it's the real thing. I'd like the birthing room nurses to remember this."

ELECTRONIC MONITORING BY INTERNAL PRESSURE CATHETER Electronic monitoring of UCs can be done internally by using an **intrauterine pressure catheter (IUPC)**. The IUPC is a catheter that is inserted into the uterine cavity through the cervical os. With correct placement in the uterus, usually in the area of the fetal small parts (arms or legs), the catheter reflects the pressure inside the uterine cavity. As the pressure changes in the uterus, the changes are relayed through a transducer to the fetal monitor, producing a tracing on the graph paper. The IUPC can measure the resting tone of the uterus between contractions and the actual amount of intrauterine pressure during contractions, referred to as UC intensity (Cunningham et al., 2010).

IUPCs can be one of two types: fluid-filled catheters and solid-tipped catheters. Fluid-filled catheters are a single-lumen catheter connected to a pressure-sensitive diaphragm outside the uterus. As intrauterine pressure changes, the column of fluid in the catheter fluctuates and exerts pressure on the diaphragm, sending signals to the transducer and fetal monitor. The solid-tipped catheter uses more recent technology in that the catheter contains a solid-state micropressure transducer (electronic sensor) at its tip, and the catheter that is inserted directly into the uterine cavity through the cervical os. The catheter is then connected by a cable to the EFM. The catheter also incorporates a second lumen, permitting amnioinfusion while simultaneously providing accurate monitoring of intrauterine pressure (Figure 23-3 ■) (Cunningham et al., 2010). Regardless of the type of catheter, fluid filled or solid tipped, the IUPC can be used only after membranes are ruptured and the patient has adequate cervical dilation, usually 3 centimeters or more (Cunningham et al., 2010).

The IUPC has several benefits over an external tocotransducer or palpation. Because the IUPC is inserted directly into the uterus, it provides near-exact pressure measurements for contraction intensity and uterine resting tone. The increased sensitivity of the IUPC allows for very accurate timing of UCs, thus making it extremely useful in cases when the provider needs closer uterine monitoring. The IUPC may be the preferred method of monitoring when it is particularly important to avoid tachysystole and possible uterine rupture in women with a previous history of cesarean birth who are attempting a vaginal birth after cesarean (VBAC) and are receiving oxytocin. If the woman's labor is prolonged, internal monitoring can be used to accurately assess the frequency and strength of contractions. If a nonreassuring FHR tracing is present, internal monitoring with IUPC and fetal scalp electrode may be essential to correlate UC timing and FHR pattern response. IUPCs are also preferred when amnioinfusion is indicated, such as in cases with meconium-stained amniotic fluid (Wiederman, Saugstad, Branes-Powell, et al., 2008). The IUPC provides a permanent record of the uterine

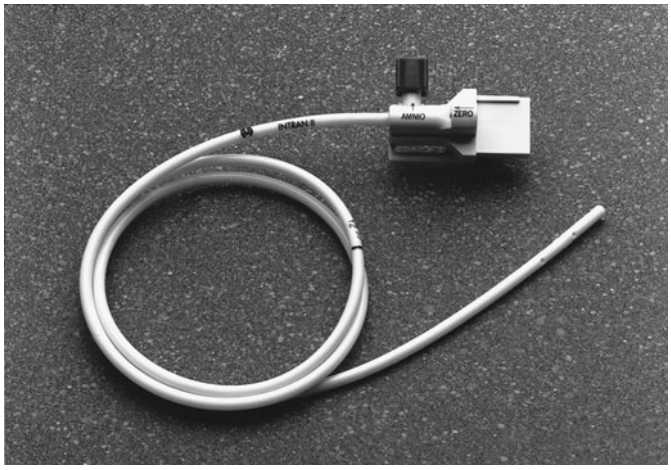

Figure 23-3 ■ INTRAN Plus intrauterine pressure catheter. There is a micropressure transducer (electronic sensor) located at the tip of the catheter and a port for amnioinfusion at the distal end of the catheter.

Source: Photographer, Elena Dorfman.

activity for future analysis and documentation, making it useful in patient care decision making.

However, with all of its benefits, the IUPC has its limitations and risks. Use of IUPCs is limited by the clinical situation. Membranes must be ruptured and adequate cervical dilation must be achieved for insertion. The procedure is invasive and increases the risk of uterine infection or uterine perforation or trauma. When an intrauterine catheter is used, there is a 1% risk of infection, but this seems to depend on the duration of ruptured membranes and length of labor (Cheng & Caughley, 2009). Invasive equipment like the IUPC is contraindicated in cases when active infections can be transmitted vertically through the cervix into the uterus to the fetus. Insertion of an IUPC with a low-lying placenta can result in placenta puncture, which can cause hemorrhage and nonreassuring fetal status (Cunningham et al., 2010). IUPCs also require proper insertion and zeroing procedures; thus, competency in insertion technique and equipment maintenance and troubleshooting is essential.

Cervical Assessment

Cervical dilatation and effacement are evaluated directly by vaginal examination (see Procedure 23-1: Performing an Intrapartum Vaginal Examination). The vaginal examination can also provide information regarding fetal position, station of the presenting part, and membrane status (intact or ruptured). To assist in evaluating membrane status, the nurse assesses for the presence of amniotic fluid (Procedure 23-2: Assessing for Amniotic Fluid).

PROCEDURE 23-1 Performing an Intrapartum Vaginal Examination

NURSING ACTION

Preparation

- Explain the procedure, the indications for the exam, what the exam may feel like, and that it may cause discomfort.
- Assess for latex allergies.
- Position the woman with her thighs flexed and abducted. Instruct her to put the heels of her feet together. Drape the woman with a sheet, leaving a flap to access the perineum.

  Rationale: *This position provides access to the woman's perineum. The drape ensures privacy.*
- Encourage the woman to relax her muscles and legs.
- Inform the woman before touching her. Be gentle.

  Rationale: *Relaxation decreases muscle tension and increases comfort.*

CLINICAL TIP

Use nonlatex gloves if the woman has a latex allergy.

EQUIPMENT AND SUPPLIES

Clean disposable gloves if membranes not ruptured
Sterile gloves if membranes ruptured
Lubricant
Nitrazine test tape
Slide
Sterile cotton-tipped swab (Q-tip)

Before the Procedure: Test for Fluid Leakage

If fluid leakage has been reported or noted, use Nitrazine test tape and Q-tip with slide for fern test before performing the exam (see Procedure 23-2).

Procedure: Clean Gloves (Sterile if membranes ruptured)

CLINICAL TIP

Digital examination may be deferred if the woman has ruptured membranes but is not in active labor (AAP & ACOG, 2007).

1. Pull glove onto dominant hand.

   Rationale: *Single glove is worn when membranes are intact. If a sterile exam is needed, both hands will be gloved with sterile gloves.*
2. Using your gloved hand, position the hand with the wrist straight and the elbow tilted downward. Insert your well-lubricated second and index fingers of the gloved hand gently into the vagina until they touch the cervix. Use care when positioning your hand.

   Rationale: *This position allows the fingertips to point toward the umbilicus and find the cervix.*
3. If the woman verbalizes discomfort, acknowledge it and apologize. Pause for a moment and allow her to relax before progressing.

   Rationale: *This validates the woman's discomfort and helps her feel more in control.*

(continued)

PROCEDURE 23-1 Performing an Intrapartum Vaginal Examination continued

4. To determine the status of labor progress, perform the vaginal examination during and between contractions.

   Rationale: *Cervical effacement, dilatation, and fetal station are affected by the presence of a contraction.*

5. Palpate for the opening, or a depression, in the cervix. Estimate the diameter of the depression to identify the amount of dilatation (Figure 23-4 ■).

   Rationale: *Allows determination of effacement and dilatation.*

6. Determine the status of the fetal membranes by observing for leakage of amniotic fluid. If fluid is expressed, test for amniotic fluid.

   Rationale: *Determine the presenting part is necessary to assess the position of the fetus and to evaluate fetal descent.*

7. Palpate the presenting part (Figure 23-5 ■).
8. Assess the fetal descent (Figure 23-6 ■) and station by identifying the position of the posterior fontanelle in relation to the ischial spines.
9. Record findings on woman's chart and on fetal monitor strip if fetal monitor is being used.

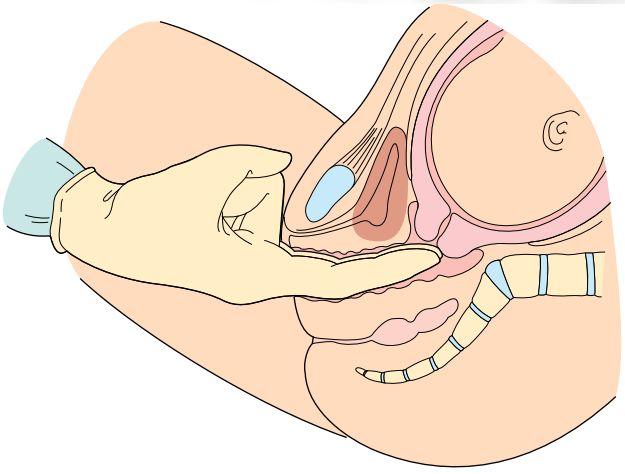

Figure 23-4 ■ To gauge cervical dilatation, the nurse places the index and middle fingers against the cervix and determines the size of the opening. Before labor begins, the cervix is long (approximately 2–5 cm), the sides feel thick, and the cervical canal is closed, so an examining finger cannot be inserted. During labor, the cervix begins to dilate, and the size of the opening progresses from 1 cm to 10 cm in diameter.

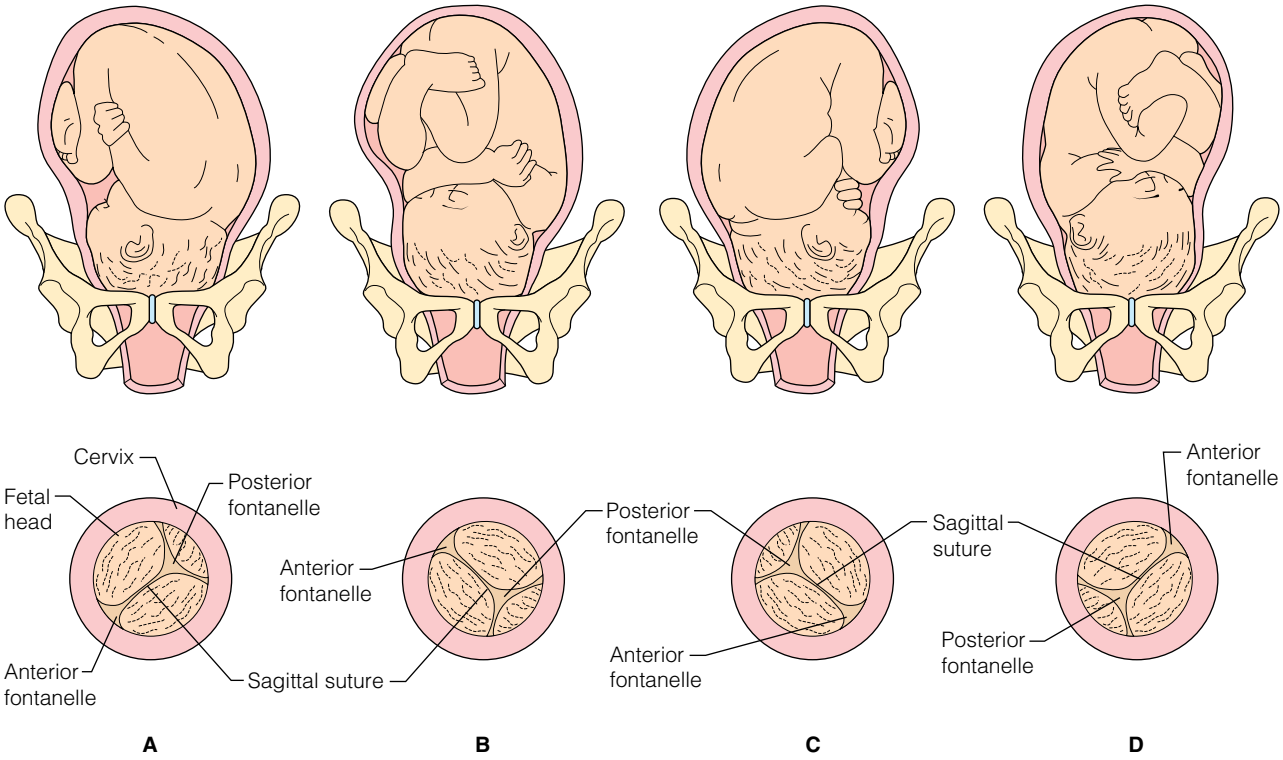

Figure 23-5 ■ Palpation of the presenting part (the portion of the fetus that enters the pelvis first). A. Left occiput anterior (LOA). The occiput (area over the occipital bone on the posterior part of the fetal head) is in the left anterior quadrant of the woman's pelvis. When the fetus is in LOA, the posterior fontanelles (located just above the occipital bone and triangular in shape) are in the upper left quadrant of the maternal pelvis. B. Left occiput posterior (LOP). The posterior fontanelle is in the lower left quadrant of the maternal pelvis. C. Right occiput anterior (ROA). The posterior fontanelle is in the upper right quadrant of the maternal pelvis. D. Right occiput posterior (ROP). The posterior fontanelle is in the lower right quadrant of the maternal pelvis.

Note: The anterior fontanelle is diamond shaped. Because of the roundness of the fetal head, only a portion of the anterior fontanelle can be seen in each of the views, so it appears to be triangular in shape.

PROCEDURE 23-1 Performing an Intrapartum Vaginal Examination continued

Documentation

Document that the procedure was explained to the patient, and that the woman verbalized understanding and provided consent before the vaginal examination. The woman's reaction and how the procedure was tolerated should be documented. The findings of the examination should be clearly documented using a facility-appropriate documentation form.

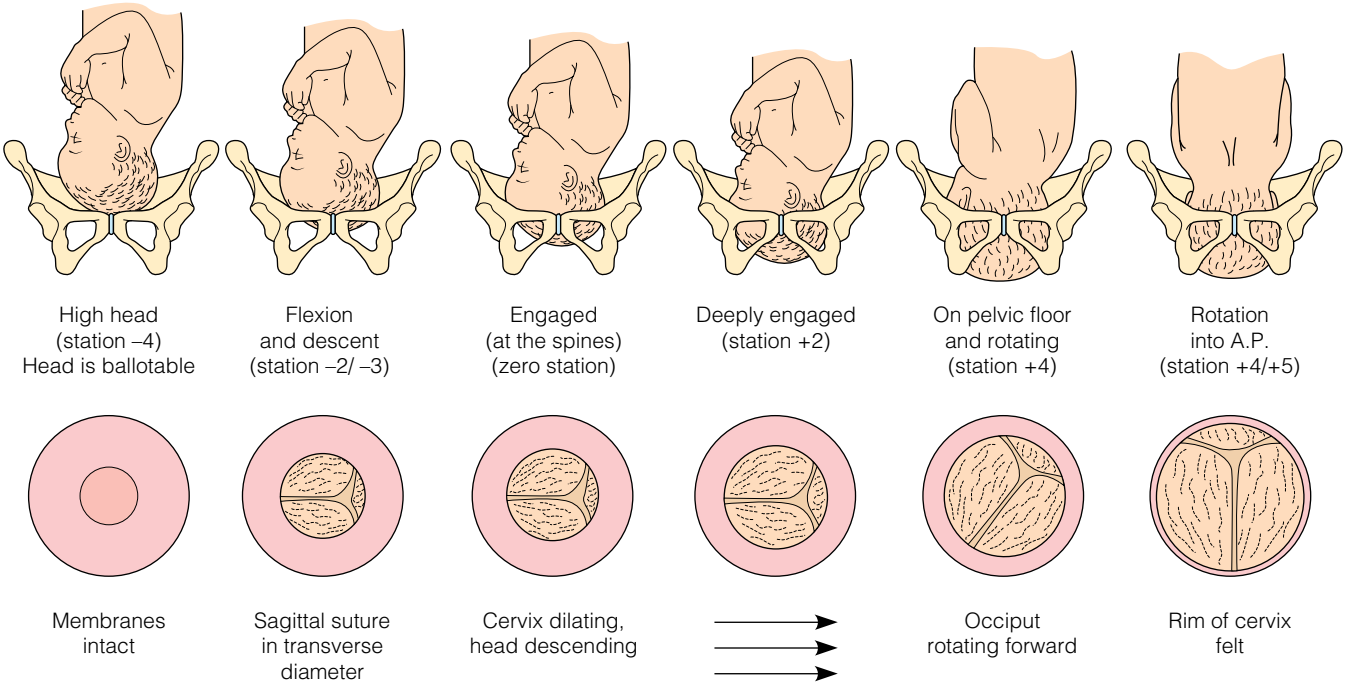

Figure 23-6 ■ Descent of the fetus through the maternal pelvis can be assessed by determining station (the relationship of the presenting part to an imaginary line between the maternal ischial spines). As the fetus moves downward, cardinal movements occur (see chapter 22 ∞). The nurse assesses the station and identifies the cardinal movements by determining the position of the posterior fontanelle. The upper panels depict the fetal head progressing downward through the pelvis. From left to right, the first four views depict descent and flexion of the fetal chin onto the fetal chest. In the last two views, internal rotation occurs. Each view also depicts downward movement of the fetal head through the maternal pelvis as measured by the change in station. The lower panels depict the cervix, which is still rather thick (little effacement has occurred). The amniotic membranes are still intact over the fetal head. When the fetus is at –4 station, the fetal head is ballotable (when it is touched by the examining nurse's finger, the head floats upward and resettles downward). In the second view, note the thinner cervix (which indicates that more effacement has occurred). The sagittal suture and posterior fontanelle can be palpated. The next two views depict further effacement and descent of the fetal head from 0 station to +2. The last two views depict continuing effacement and position that would be felt on vaginal examination of the presenting part while the fetal head is completing internal rotation.

Fetal Assessment

A complete intrapartum fetal assessment requires determination of the fetal position and presentation and evaluation of the fetal status.

Determination of Fetal Position and Presentation

Fetal position is determined in several ways, including the following:

- Inspection of the woman's abdomen
- Palpation of the woman's abdomen (Leopold's maneuvers)
- Vaginal examination to determine the presenting part
- Ultrasound (US)

Inspection

The nurse should observe the woman's abdomen for size and shape. The lie of the fetus should be assessed by noting whether the uterus projects up and down (longitudinal lie) or left to right (transverse lie) (Cunningham et al., 2010).

Palpation: Leopold's Maneuvers

Leopold's maneuvers are a systematic way to evaluate the maternal abdomen (Figure 23-7 ■). Frequent practice increases the examiner's skill in determining fetal position by palpation. Leopold's maneuvers may be difficult to perform on an obese woman or on a woman who has excessive amniotic fluid (hydramnios) (Cunningham et al., 2010).

Care should be taken to ensure the woman's comfort during Leopold's maneuvers. The woman should have recently emptied

PROCEDURE 23-2 Assessing for Amniotic Fluid

NURSING ACTION

Preparation

- Explain the procedure, indications for the procedure, what the woman will feel, and information that may be obtained.
- Determine whether she has noted the escape of any fluid from her vagina.

Equipment and Supplies

Nitrazine test tape

Sterile speculum

A glass slide and a sterile cotton-tipped swab (Q-tip)

Sterile syringe

Microscope

Procedure: Sterile Gloves

1. Complete this test before doing an examination that requires the use of lubricant.
2. Put on sterile gloves. With one gloved hand, spread the labia, and with the other gloved hand place a small section of Nitrazine tape (approx. 2 in. long) against the vaginal opening. Take care not to touch the tape with bare fingers before the test.

   Rationale: *Contamination of the Nitrazine test tape with lubricant can make the test unreliable. Enough fluid needs to be placed on the test tape to make it wet.*
3. Compare the color on the test tape to the guide on the back of the Nitrazine test tape container to determine test results.

   Rationale: *Amniotic fluid is alkaline, and an alkaline fluid turns the Nitrazine test tape a dark blue. If the test tape remains a beige color, the test is negative for amniotic fluid.*
4. Amniotic fluid may also be obtained by speculum exam. This is indicated in preterm premature rupture of membranes. If fluid is present in sufficient amount to draw some into a syringe, a small amount should be collected, or the pool of fluid in the posterior vagina can be obtained with a sterile cotton swab. A small amount of fluid is placed on a glass slide, allowed to dry, and then examined under the microscope or sent to the lab. A fern pattern confirms the presence of amniotic fluid. See Figure 12-4 on page 249 for an example of fern.

   Rationale: *Obtaining a specimen by speculum examination reduces the contamination of the fluid with other substances such as blood and cervical mucus and reduces the chance of infection for the woman who is not actively laboring.*

Documentation

Record the findings on the labor record. Documentation of the status of membranes should include whether they are intact or ruptured. Other characteristics, such as color, odor, and amount of fluid present, should also be recorded, along with the time of rupture.

her bladder and should lie on her back with her abdomen uncovered. To aid in relaxation of the abdominal wall, the shoulders should be raised slightly on a pillow and the knees drawn up a little. The procedure should be completed between contractions. The examiner's hands should be warm. The order in which Leopold's maneuvers are performed may vary from one clinician to another.

While inspecting and palpating the maternal abdomen, the nurse should consider the following questions:

- Is the fetal lie longitudinal or transverse?
- What is in the fundus? Am I feeling buttocks or head?
- Where is the fetal back?
- Where are the small parts or extremities?
- What is in the inlet? Does it confirm what I found in the fundus?
- Is the presenting part engaged, floating, or dipping into the inlet? (See Figure 22-6 on page 534).
- Is there fetal movement?
- How large is the fetus (appropriate, large, or small for gestational age)?
- Is there one fetus or more than one?
- Is fundal height proportionate to the estimated gestational age?

Leopold's Maneuvers

FIRST MANEUVER While facing the woman, the nurse palpates the upper abdomen with both hands (see Figure 23-7A). The nurse determines the shape, size, consistency, and mobility of the form that is found. The fetal head is firm, hard, and round and moves independently of the trunk. The breech feels softer and symmetric and has small bony prominences; it moves with the trunk.

SECOND MANEUVER After ascertaining whether the head or the buttocks occupies the fundus, the nurse tries to determine the location of the fetal back and notes whether it is on the right or left side of the maternal abdomen. Still facing the woman, the nurse palpates the abdomen with deep but gentle pressure, using the palms (see Figure 23-7B). The right hand should be steady while the left hand explores the right side of the uterus. The nurse then repeats the maneuver, probing with the right hand and steadying the uterus with the left hand. The fetal back should feel firm and smooth and should connect what was found in the fundus with a mass in the inlet. Once the back is located, the nurse validates the finding by palpating the fetal extremities (small irregularities and protrusions) on the opposite side of the abdomen.

THIRD MANEUVER Next, the nurse should determine what fetal part is lying above the inlet by gently grasping the lower portion of the abdomen just above the symphysis pubis with the thumb and fingers of the right hand (see Figure 23-7C). This maneuver yields the opposite information from what was found in the fundus and validates the presenting part. If the head is presenting and is not engaged, it may be gently pushed back and forth.

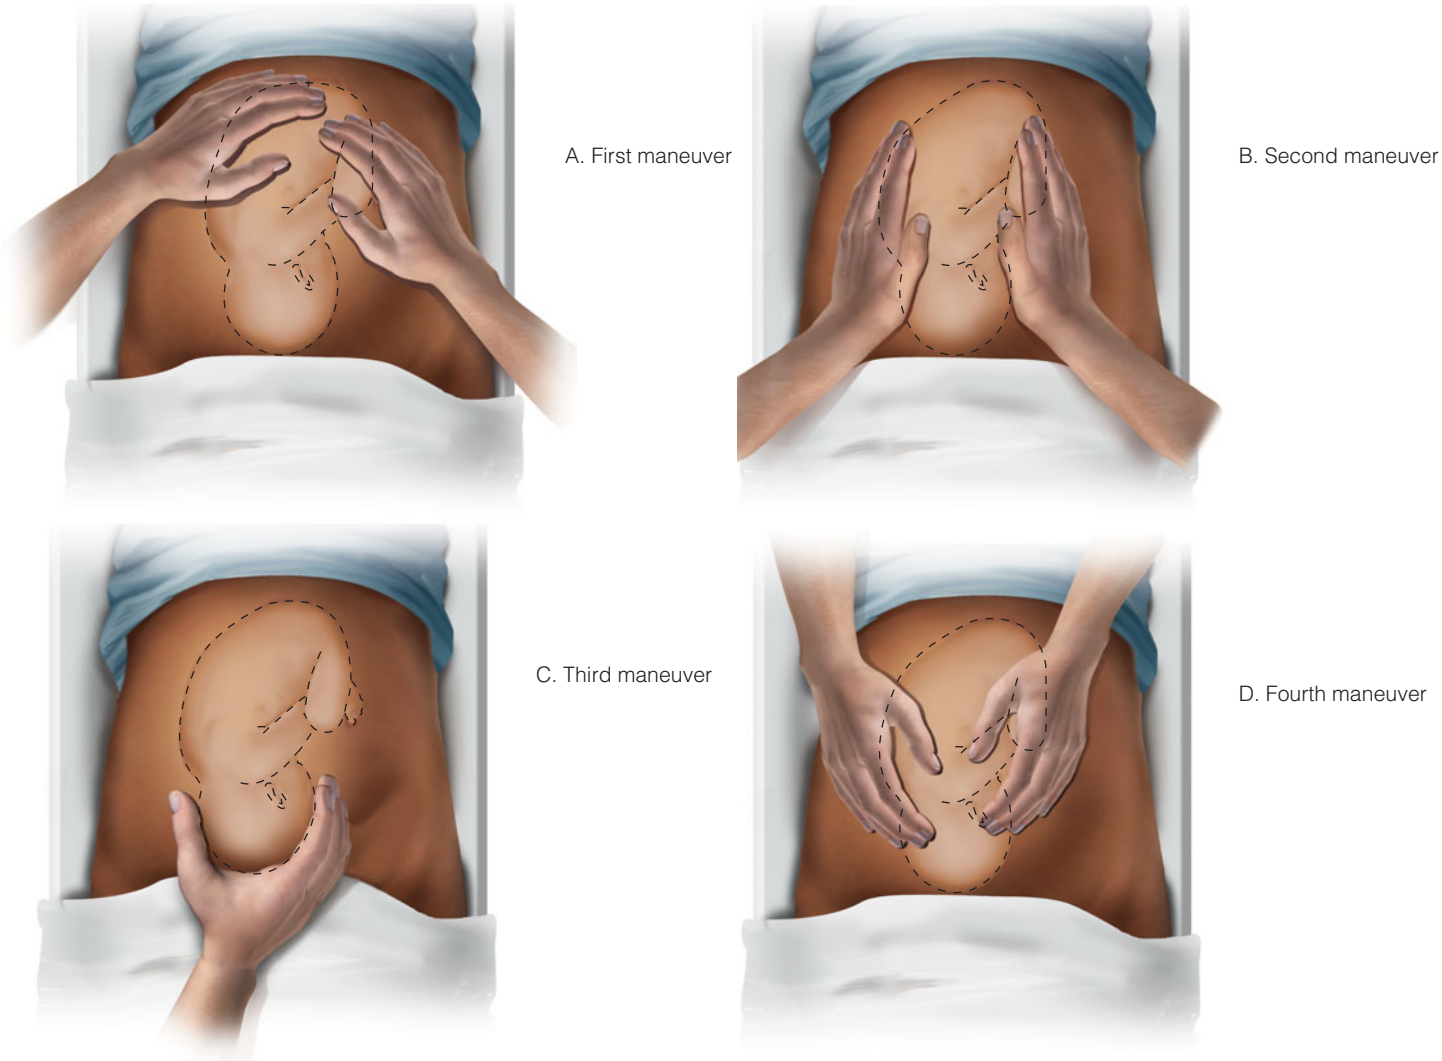

Figure 23-7 ■ Leopold's maneuvers for determining fetal head position, presentation, and lie.

Note: Some practitioners may perform the sequence differently. Many nurses do the fourth maneuver first to identify the part of the fetus in the pelvic inlet.

FOURTH MANEUVER For this portion of the examination, the nurse faces the woman's feet and attempts to locate the cephalic prominence or brow. Location of this landmark assists in assessing the descent of the presenting part into the pelvis. The fingers of both hands are moved gently down the sides of the uterus toward the pubis (see Figure 23-7D). The cephalic prominence (brow) is located on the side where there is greatest resistance to the descent of the fingers toward the pubis. It is located on the opposite side from the fetal back if the head is well flexed. However, when the fetal head is extended, the occiput is the first cephalic prominence felt, and it is located on the same side as the back. Therefore, when completing the fourth maneuver, if the nurse finds that the first cephalic prominence palpated is on the same side as the back, the head is not flexed. If the first prominence found is opposite the back, the head is well flexed (Cunningham et al., 2010).

Vaginal Examination

The vaginal examination reveals information regarding the fetus such as presentation, position, station, degree of flexion of the fetal head, and any swelling that may be present on the fetal scalp (caput succedaneum).

CLINICAL TIP

If you are having difficulty reaching the posterior cervix, ask the woman to place her fists under her buttocks or use a bedpan to facilitate a pelvic tilt, which will make the cervix more accessible.

Ultrasound

Real-time ultrasound (US) is frequently available in the birth setting. It may be used to assess fetal lie, presentation, and position; obtain measurements of biparietal diameter to estimate gestational age; assess for anomalies when a vaginal examination reveals suspicious findings; and assess placement of the placenta. Ultrasound is often helpful to pinpoint the fetal heart location when the nurse is having difficulty finding it, such as in cases where there are multiple fetuses. It can also be used to diagnose a fetal demise (Cunningham et al., 2010). (See

chapter 21 ∞ for further discussion of the use of ultrasound for fetal assessment.)

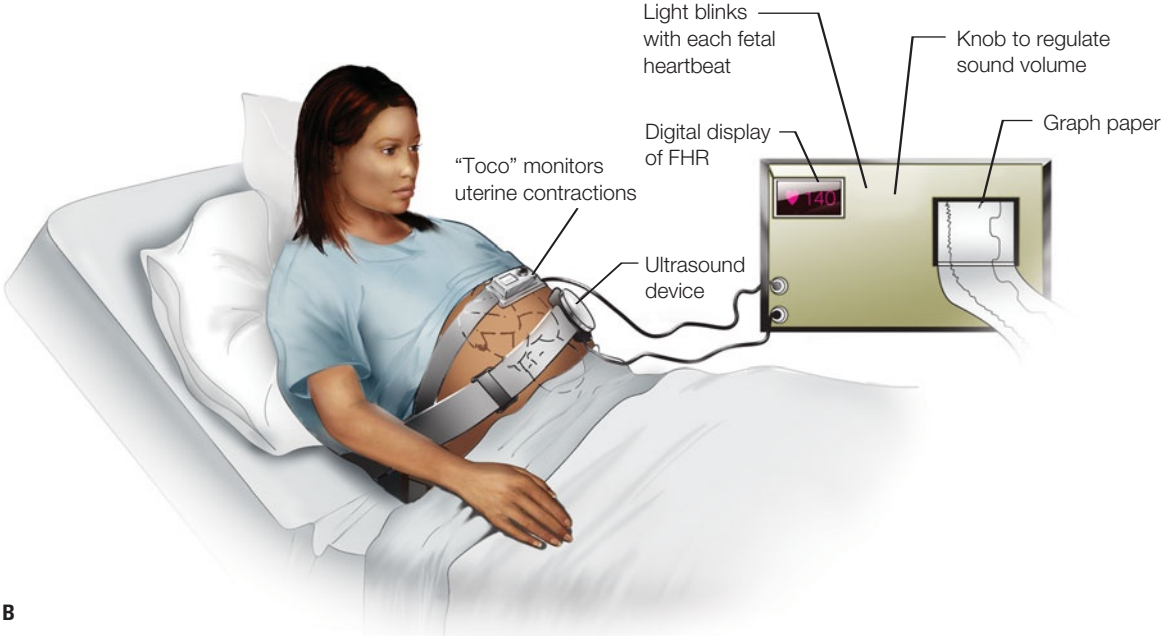
Auscultation of Fetal Heart Rate

Auscultation is the direct auditory monitoring and interpretation of the fetal heart in utero. The number of fetal heart beats per minute (beats/min) is referred to as the fetal heart rate (FHR). Auscultation uses a handheld instrument, such as a fetoscope or ultrasound Doppler, to listen to and count the FHR (Figure 23-8 ■). Each instrument uses slightly different technology. Fetoscopes magnify actual fetal heart sounds, whereas Dopplers use ultrasound to convert fetal myocardial movement into sound waves that are then amplified and sent through a speaker from which the heart rate can be counted. Some Dopplers display a digital readout in addition to the audible sound produced.

Before listening to the FHR the first time, the nurse may choose to perform Leopold's maneuvers to determine the probable location to best hear the FHR. The FHR is heard most clearly at the fetal back (Cunningham et al., 2010) (Figure 23-9 ■). Thus, in a cephalic presentation, the FHR is best heard in the lower quadrant of the maternal abdomen. In a breech presentation it is heard at or above the level of the maternal umbilicus. In a transverse lie the FHR may be heard best just above or just below the umbilicus. As the presenting part descends and rotates through the maternal pelvis during labor, the FHR tends to descend and move toward the midline. In some instances, the monitor may track the maternal heart rate instead of the FHR. However, the nurse can avoid the error by comparing the maternal pulse with the FHR.

After the FHR is located, it is usually counted for 30 to 60 seconds to obtain the number of beats per minute. The nurse should

A



B

Figure 23-8 ■ A. The nurse uses a Doppler to assess the fetal heart rate. Doppler monitors can be used for intermittent labor monitoring or in the outpatient or community setting. When the fetal heart rate is picked up by the electronic monitor, the sound of the heartbeat can be heard by all persons in the room. B. Electronic monitoring by external technique. The ultrasound device is placed over the area of the fetal back and transmits information about the FHR. The tocodynamometer ("toco") is placed over the uterine fundus to provide information used to monitor uterine contractions. Information from both devices is transmitted to the electronic fetal monitor. The FHR is shown in a digital display (as a blinking light), on the special monitor paper, and audibly (by adjusting a knob on the monitor). The uterine contractions are displayed on the special monitor paper as well.

Source: (A) Photographer, Elena Dorfman.

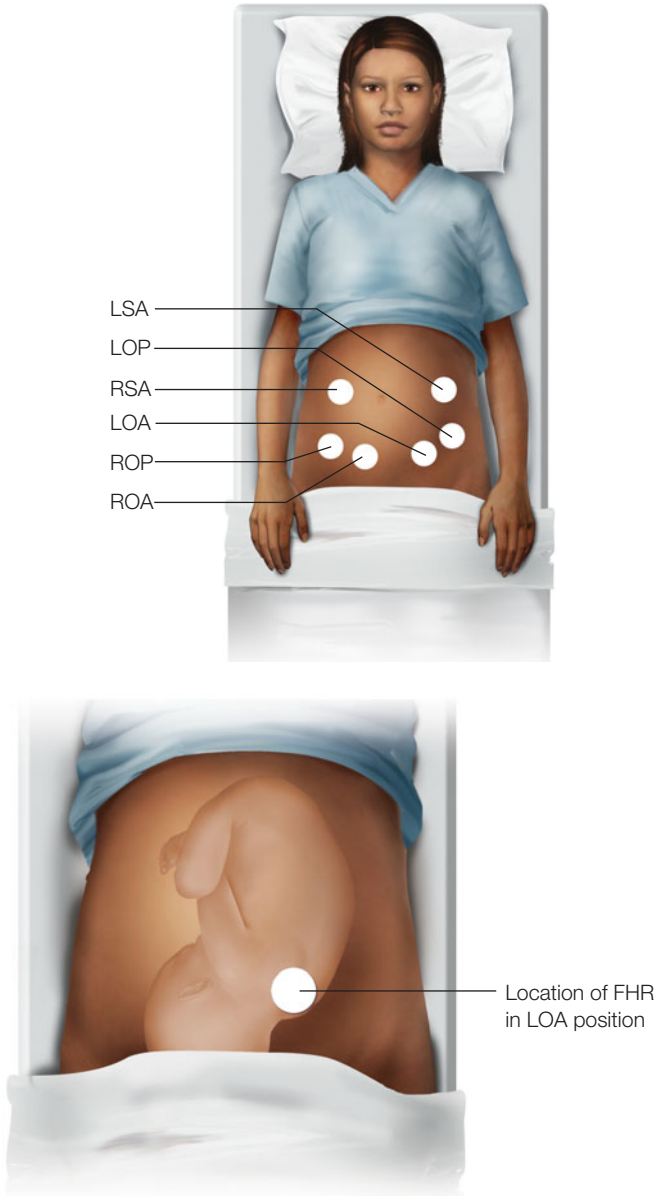


Figure 23-9 ■ Location of FHR in relation to the more commonly seen fetal positions. The FHR is heard more clearly over the fetal back.

listen before, during, and just after a contraction to detect any abnormal heart rate, especially if the FHR is over 160 (tachycardia), under 110 (bradycardia), or if irregular beats (such as a deceleration) are heard (Cunningham et al., 2010). Listening through a contraction may be difficult because of maternal movement or a muffling of the FHR sounds. It is especially important to listen during and after the contraction to detect any deceleration that might occur. It is also important to listen immediately after each contraction when the woman is pushing during second stage, because fetal bradycardia frequently occurs as pressure is exerted on the fetal head during descent. See Procedure 23-3: Auscultation of Fetal Heart Rate and Table 23-4 for guidelines regarding how often to auscultate FHR.

Auscultation has been used for many years and remains a very valuable assessment technique even though it uses less technology than electronic fetal monitoring (EFM). Research

TABLE 23-4 Frequency of Auscultation: Assessment and Documentation

LOW-RISK PATIENTS	HIGH-RISK PATIENTS
First stage of labor every 30 min	First stage of labor every 15 min
Second stage of labor every 15 min	Second stage of labor every 5 min

Labor Events

Assess FHR before:
Initiation of labor-enhancing procedures (e.g., artificial rupture of membranes)
Periods of ambulation
Administration of medications
Administration or initiation of analgesia/anesthesia

Assess FHR following:
Rupture of membranes
Recognition of abnormal uterine activity patterns, such as increased basal tone or tachysystole
Evaluation of oxytocin (maintenance, increase, or decrease of dosage)
Administration of medications (at time of peak action)
Expulsion of enema
Urinary catheterization
Vaginal examination
Periods of ambulation
Evaluation of analgesia and/or anesthesia (maintenance, increase, or decrease of dosage)

and standards have shown that intermittent auscultation is equally effective for monitoring the FHR as EFM when a 1:1 nurse-to-patient ratio is maintained and the pregnant patient remains low risk. Low-risk status has been defined as "no pregnancy risk factors, no meconium stained fluid, normal labor patterns, and labor without augmentation or induction" (Cunningham et al., 2010). Outside these parameters, intermittent auscultation may not be appropriate and should not be used to assess high-risk pregnancies (Cunningham et al., 2010).

Auscultation is a learned skill and requires practice and knowledge of its benefits and limitations as an assessment tool. It has many advantages that make it a preferred method of monitoring by both mothers and nurses. Auscultation uses minimum instrumentation, is portable, and allows for maximum maternal movement; thus it is convenient and economical. Its disadvantages include the limited data this technique can provide compared with EFM. Only the baseline FHR (BL or BL FHR), rhythms of the FHR, and obvious increases and decreases can be monitored. Auscultation also does not provide a permanent record, thus making interpretation of the FHR impossible in the future or by another care provider. Identifying patterns and nonreassuring FHR is difficult and requires training. Auscultation must be practiced to ensure accurate interpretation of data.

Identifying UCs and the FHR simultaneously is necessary to determine patterns in the FHR and the relationship between the FHR and the UC. Auscultation does not allow for the detection of small changes in the FHR and cannot determine baseline variability (BL VAR). It may also be limited by maternal obesity and movement by the mother and fetus (Simpson & Creehan, 2007). In such instances, it may be essential to monitor using electronic means, regardless of the patient's risk status.

PROCEDURE 23-3 Auscultation of Fetal Heart Rate

NURSING ACTION

Preparation

- Explain the procedure, the indications for it, and the information that will be obtained.
- Uncover the woman's abdomen.

Equipment and Supplies

Doppler device

Ultrasonic gel

Procedure

CLINICAL TIP

The fetal heart rate (FHR) is heard most clearly through the fetal back. Locate the fetal back using Leopold's maneuvers.

1. To use the Doppler:
   - Place ultrasonic gel on the diaphragm of the Doppler. Gel is used to maintain contact with the maternal abdomen and enhances conduction of sound.
   - The diaphragm should be warmed prior to using the Doppler.
   - Place the Doppler diaphragm on the woman's abdomen halfway between the umbilicus and symphysis and in the midline. You are most likely to hear the FHR in this area. Listen carefully for the sound of the fetal heartbeat.
2. Check the woman's pulse against the fetal sounds you hear. If the rates are the same, reposition the Doppler and try again.

   Rationale: *If the rates are the same, you are probably hearing the maternal pulse and not the FHR.*
3. If the rates are not similar, count the FHR for 1 full minute. Note that the FHR has a double rhythm and only one sound is counted.
4. If you do not locate the FHR, move the Doppler laterally (see Figure 23-8A).
5. Auscultate the FHR between, during, and for 30 seconds following a uterine contraction (UC).
6. Frequency recommendations:
   - Low-risk women: Every 30 minutes during the first stage, and every 15 minutes in the second stage.
   - High-risk women: Every 15 minutes during the first stage, and every 5 minutes in the second stage.

   Rationale: *This evaluation provides the opportunity to assess the fetal status and response to labor.*

Documentation

Document that the procedure was explained to the woman and that she verbalized understanding. The location of the FHR, FHR baseline, changes in FHR that occur with contractions, and presence of accelerations or decelerations should be included. Other characteristics should include variability, maternal position, type of device used, uterine activity, maternal pulse, and nursing interventions that were performed.

The Fetoscope

The fetoscope is an older assessment tool; however, some clinicians prefer it because it is "natural" and does not rely on ultrasound.

To use the fetoscope:

- The bell should be warmed prior to using the fetoscope.
- Place the fetoscope earpieces in your ears and the device support against your forehead; use the handpiece to position the bell of the fetoscope on the mother's abdomen.
- Place the diaphragm halfway between the umbilicus and symphysis and in the midline. *You are most likely to hear the FHR in this area.*
- Without touching the fetoscope, listen carefully for the FHR.

Monitoring a Fetal Heart Rate

Electronic Fetal Monitoring

Electronic fetal monitoring (EFM) provides a continuous tracing of the fetal heart rate (FHR), allowing characteristics of the FHR to be observed and evaluated (see Procedure 23-4: Electronic Fetal Monitoring and Figure 23-8B). EFM requires advanced assessment and clinical judgment skills, regardless of the setting in which it is used. Therefore, a licensed, experienced healthcare professional should perform each aspect of fetal heart monitoring (FHM), consistent with their state or provincial scope of practice. AWHONN (2008b) maintains that fetal heart monitoring includes: (1) application of fetal monitoring components; (2) intermittent auscultation; (3) ongoing monitoring and interpretation of FHR data; (4) initial assessment of the laboring woman and fetus; and (5) ongoing clinical interventions and evaluations of the woman and fetus.

Initiation of monitoring and ongoing clinical evaluation should only be performed by healthcare professionals who have education and skills validation in FHM and in the care of the laboring woman. AWHONN regards these healthcare professionals with expertise in fetal monitoring as: (1) registered nurses; (2) certified nurse midwives (CNMs), certified midwives (CMs), and registered midwives (RMs [Canada]); (3) other advanced practice nurses such as nurse practitioners and clinical nurse specialists; (4) physicians; and (5) physician assistants (PAs) (2008b).

In the late 1990s, standardized definitions for FHR tracings were proposed (National Institute of Child Health and Human Development [NICHD], 1997) in an effort to resolve controversy surrounding the benefits of EFM, the primary interpretation of FHR patterns, and appropriate interventions for nonreassuring tracings (Cunningham et al., 2010). In 2004, the

Monitor

Two elastic monitor belts

Tocodynamometer ("toco")

Ultrasound transducer

Ultrasound gel

Procedure

CLINICAL TIP

Evaluating the FHR tracing provides information about fetal status and response to the stress of labor. The presence of reassuring characteristics is associated with good fetal outcomes. Rapid identification of nonreassuring characteristics allows prompt interventions and the opportunity to determine the fetal response to the interventions.

1. Turn on the monitor.
2. Place the two elastic belts around the woman's abdomen.
3. Place the "toco" over the uterine fundus off the midline on the area palpated to be most firm during contractions. Secure it with one of the elastic belts.

   Rationale: *The uterine fundus is the area of greatest contractility.*
4. Note the uterine contraction (UC) tracing. The resting tone tracing (that is, without a UC) should be recording on the 10 or 15 mm Hg pressure line. Adjust the line to reflect that reading.

   Rationale: *If the resting tone is set on the zero line, there often is a constant grinding noise.*
5. Apply the ultrasonic gel to the diaphragm of the ultrasound transducer.

   Rationale: *Ultrasonic gel is used to maintain contact with the maternal abdomen. The ultrasonic beam is directed toward the fetal heart.*
6. Place the diaphragm on the maternal abdomen in the midline between the umbilicus and the symphysis pubis.
7. Listen for the FHR, which will have a whiplike or galloping sound. Move the diaphragm laterally if necessary to obtain a stronger sound (see Figure 23-9).
8. When the FHR is located, attach the second elastic belt snugly to the transducer.

   Rationale: *Firm contact is necessary to maintain a steady tracing.*
9. Place the following information on the beginning of the fetal monitor paper: date, time, woman's name, gravida, para, membrane status, and name of physician or certified nurse-midwife.

Note: *Each birthing unit may have specific guidelines about additional information to include.*

Documentation

Document that the procedure was explained to the woman and that she verbalized understanding. In addition, document the maternal position, the type of device used and location of the FHR. The record of both the FHR and uterine activity should be of adequate quality for visual interpretation. A full description of the electronic fetal monitor tracing requires a qualitative and quantitative description of: (1) uterine contraction characteristics (duration, frequency, strength), (2) baseline FHR, (3) baseline FHR variability, (4) presence of accelerations, (5) periodic or episodic decelerations, and (6) changes or a trend of FHR patterns over time (Macones, Hankins, Spong, Hauth, & Moore, 2008).

Further documentation should include maternal pulse and blood pressure, presence of fetal movement, and any interventions and/or procedures performed including fetal response to the interventions.

Example: 8-3-10 BL FHR 135–140. Minimal FHR baseline variability noted. Late decelerations noted with decrease of FHR to 130 beats/min for 20 sec with each UC. UC every 3 min × 50–60 sec of moderate intensity by palpation. Patient turned to left side. No further deceleration with three subsequent UCs. Two accelerations of 20 beats/min × 20 sec noted with fetal movement. Patient instructed to remain on left side. B. Burch, RNC

Joint Commission on Accreditation of Healthcare Organizations (JCAHO) recommended standardized and consistent use of fetal monitoring terminology among all healthcare professionals and the development of clear guidelines for fetal monitoring of potential high-risk patients. In response, in May 2005, ACOG issued a bulletin that reviewed FHR assessment terminology and described the management of nonreassuring FHR patterns (ACOG, 2005). At the same time, AWHONN revised its fetal monitoring courses to incorporate the standardized terminology. In December 2005, ACOG modified its May bulletin to match AWHONN guidelines and NICHD terminology.

Subsequently, the Royal College of Obstetricians and Gynaecologists (RCOG) of the United Kingdom and the Society of Obstetricians and Gynaecologists of Canada (SOGC) convened expert groups to assess the evidence-based use of electronic fetal monitoring (EFM) (Liston, Sawchuck, & Young, 2007).

These groups produced consensus documents with more specific recommendations for FHR pattern classification and intrapartum management actions (Liston et al., 2007; RCOG, 2008). In addition, new interpretations and definitions have been proposed, including terminology and new interpretative systems using three and five tiers (Liston et al., 2007; Parer & Ikeda, 2007; RCOG, 2008). Recently, NICHD, ACOG, and the Society for Maternal-Fetal Medicine (SMFM) jointly sponsored a workshop focused on EFM. The goals of this workshop were to (1) review and update the definitions for FHR pattern categorization, (2) assess existing classification systems for interpreting specific FHR patterns and to make recommendations about a system for use in the United States, and (3) make recommendations for research priorities for EFM. This chapter reflects the most recent guidelines at the time of this book's publication instituted by ACOG, AWHONN, and NICHD for FHR tracings.

Indications for Electronic Fetal Monitoring

ACOG states that the frequency of FHR monitoring used during labor should be based on risk factors (Barclay, 2009). Although there is as yet no standardized list, Table 23-5 identifies some common indications for EFM.

TABLE 23-5 Possible Indications for Electronic Fetal Monitoring

Fetal Factors

Decreased fetal movement
Abnormal auscultatory FHR
Meconium passage
Abnormal presentations/positions
Intrauterine growth restriction (IUGR) or small-for-gestational-age (SGA) fetus
Postdates (greater than 41 weeks)
Multiple gestation

Maternal Factors

Fever
Infections
Preeclampsia
Disease conditions (e.g., hypertension, diabetes)
Anemia
Rh alloimmunization
Previous perinatal death
Grand multiparity
Previous cesarean birth
Borderline/contracted pelvis

Uterine Factors

Dysfunctional labor
Failure to progress in labor
Oxytocin induction/augmentation
Uterine anomalies

Complications of Pregnancy

Prolonged rupture of membranes
Premature rupture of membranes
Preterm labor
Marginal abruptio placentae
Partial placenta previa
Occult/frank prolapse of cord
Amnionitis

Regional Anesthesia

Elective Monitoring

External Monitoring

Application: Fetal Monitoring

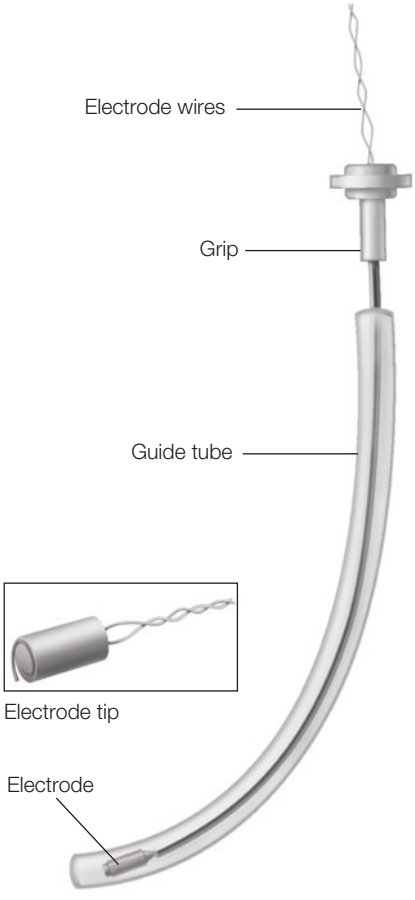
Electronic monitoring of the FHR can be done externally by using an ultrasound (US) transducer. The US transducer is a Doppler device with computerized logic to interpret and count the Doppler signals (Cunningham et al., 2010). The US transducer is placed on the maternal abdomen over the fetal back (as determined by Leopold's maneuvers), where the FHR is usually the loudest, and is held in place with an elastic belt. A water-soluble gel is applied to the underside of the transducer to aid in conduction of the fetal heart sounds. The US transducer then emits ultrasonic beams that reflect off the moving fetal myocardium and return to the transducer. The transducer receives the signal and interprets it before amplifying it in the fetal monitor and recording it on graph paper. The US image can be influenced by other moving structures in the maternal abdomen, such as maternal arterial blood flow and maternal or fetal movement. Interference is generally filtered out; however, on occasion the maternal heart rate is detected by the US transducer and must be distinguished from the FHR by comparing the signal with the maternal pulse.

The external US transducer can be more beneficial than auscultating the FHR because it produces a continuous graphic recording. The US transducer can show the baseline (BL), baseline variability (BL VAR), and changes in the FHR. It is noninvasive and does not require rupture of membranes or minimal cervical dilation. FHR monitoring by US transducer is limited because it is susceptible to interference from maternal and fetal movement, as discussed earlier, and may produce a weak signal (Simpson & Creehan, 2007). The tracing may become sketchy and difficult to interpret. Repeating the procedure for US placement usually remedies the weak signal and tracing.

Internal Monitoring

Internal fetal monitoring is accomplished with a fetal scalp electrode (FSE), a fine surgical spiral wire, attached to the fetal scalp. The FSE is the most precise method of monitoring because it is a direct electrocardiogram (ECG) of the FHR and produces the most accurate FHR tracing. The FSE is attached to the fetus during a vaginal exam. Once in place, the electrode is connected to the fetal monitor. The monitor determines the time between fetal "R" waves in the "QRS" complex and calculates the findings into a FHR. The FHR is then recorded on graph paper.

For the spiral electrode to be inserted, the cervix must be dilated at least 2 cm, the presenting fetal part must be accessible by vaginal examination, and the membranes must be ruptured. Even though it is not possible to apply the electrode and catheter under strict sterile conditions, the procedure should be performed as aseptically as possible. After determining fetal position by vaginal examination, the examiner (physician or nurse) inserts the electrode, which is encased in a plastic guide, to the level of the internal cervical os and attaches it to the presenting part, being careful not to apply it to the face, suture



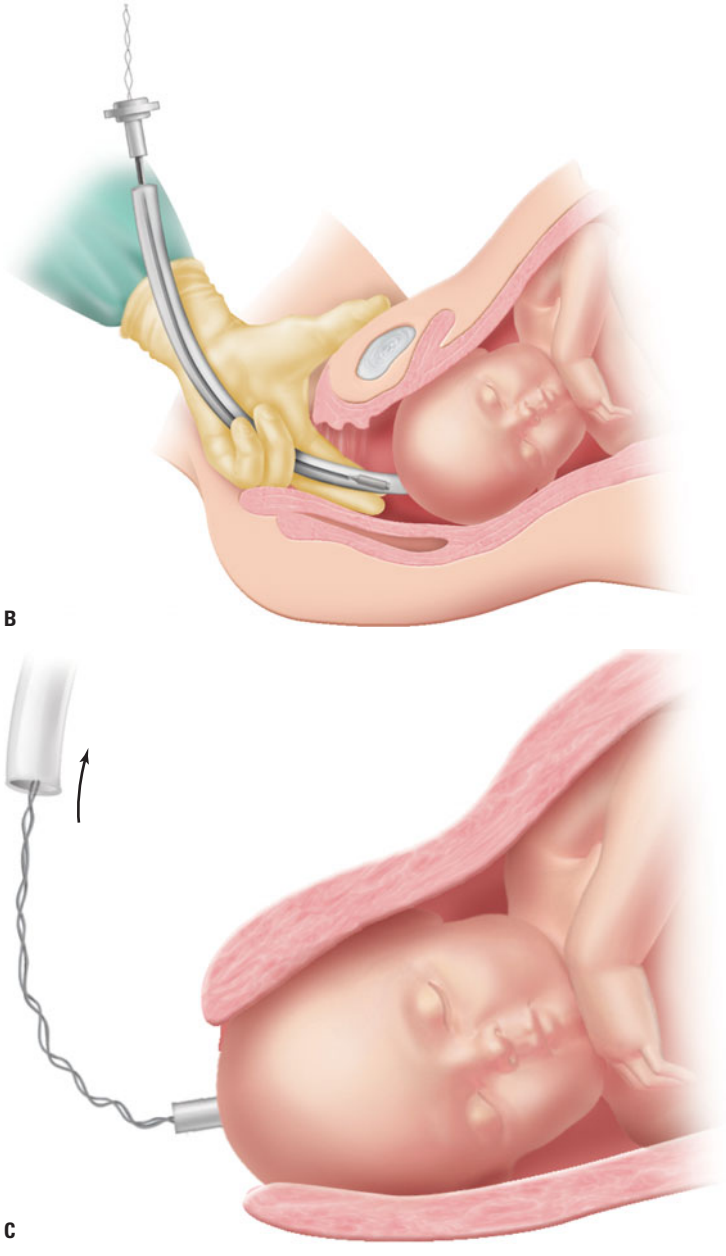


Figure 23-10 ■ Techniques for internal, direct fetal monitoring. A. Spiral electrode. B. Attaching the spiral electrode to the scalp. C. Attached spiral electrode with guide tube removed.

lines, fontanelles, cervix, or perineum if the fetus is in a breech presentation (Cunningham et al., 2010). The electrode is rotated clockwise until it is attached to the presenting part and is then disengaged from the guide tube (Figure 23-10 ■). The guide tube is removed, and the end wires are connected to a leg plate that is attached to the woman's thigh. The cable from the leg plate is connected to the monitor. Infections and injuries from internal electrodes and catheters are a small but actual risk. Although nurses in some facilities apply internal monitors, in many settings their application is limited to the physician or certified nurse-midwife (CNM).

Because the risk of transmission to the fetus is increased by the small puncture in the fetal scalp, use of internal scalp electrodes should be avoided if at all possible in the presence of known maternal infections such as HIV, hepatitis, or group B streptococcus. Also, women who have had internal monitors and subsequently given birth by cesarean are more likely to have postpartum infections (Chan & Johnson, 2008).The fetal scalp electrode is removed prior to birth. Fetal scalp monitors are also avoided in preterm infants because of the increased risk of ventricular hemorrhage (Cunningham et al., 2010).

The FHR tracing at the top of Figure 23-11 ■ was obtained by internal monitoring, and the uterine contraction tracing at the bottom was obtained by external monitoring. A comparison shows that the spiral electrode provides an instantaneous and continuous recording of FHR that is clearer than the data provided by external monitoring. Notice that the FHR shows variability (the tracing moves up and down instead of in a straight line), ranging between about 140 and 155 beats/min.

Telemetry

As discussed previously, FHR and uterine activity may also be monitored by a telemetry system. Equipment consists of US along with external uterine pressure transducers connected to a small battery-operated transmitter. Signals are transmitted to a receiver connected to a monitor that displays FHR and uterine activity data. A printout provides documentation. This system, which can be worn on a shoulder strap, allows the woman to ambulate, helping her to feel more comfortable and less confined during labor, yet provides for continuous monitoring.

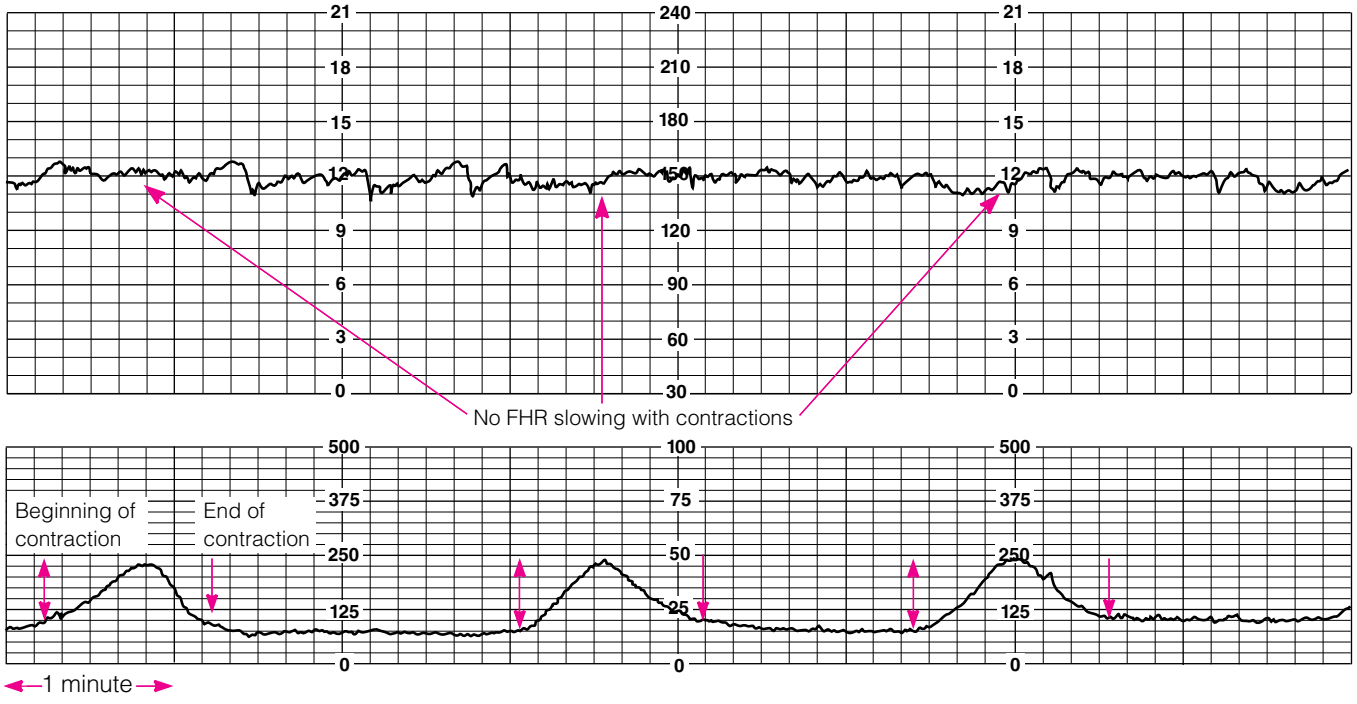

Figure 23-11 ■ Top: A FHR tracing obtained by internal monitoring. Normal FHR range is 110 to 160 beats/min. This tracing indicates a FHR range of 140 to 155 beats/min. Bottom: A uterine contraction tracing obtained by external monitoring. Each dark vertical line marks 1 minute, and each small rectangle represents 10 seconds. The contraction frequency is about every 3 minutes, and the duration of the contractions is 50 to 60 seconds.

Telemetry provides for direct as well as indirect monitoring of FHR, indirect monitoring of uterine pressure, and dual FHR monitoring of twins.

Fetal Heart Rate Patterns

When the fetal heart rate (FHR) is monitored electronically, the interval between two successive fetal heartbeats is continually measured. The rate is displayed as if the beats occurred at the same interval for 60 seconds (Cunningham et al., 2010). For example, if the interval between beats is 0.5 seconds per 60 seconds, then divide the interval time into the time frame. The rate for the full minute would then be 60 seconds/0.5 = 120 beats per minute (beats/min).

Fetal heart rate patterns are defined by the characteristics of baseline, variability, accelerations, and decelerations. The features of the FHR patterns are categorized as either baseline, periodic, or episodic. Periodic patterns are those associated with uterine contractions, and episodic patterns are those not associated with uterine contractions (Macones et al., 2008).

The definitions for FHR pattern categorization, jointly developed by NICHD, ACOG, and SMFM mentioned previously, have potential benefits. Standardized terminology minimizes variation among care providers and allows for accurate documentation of the fetal status in medical records. If everyone on the perinatal team communicates clearly, treatment can be initiated promptly and there may be a decreased risk of adverse outcomes (AWHONN, 2005). The FHR definitions and interpretive system was developed for consistent use by perinatal care providers in clinical practice and research (Macones et al., 2008).

Baseline Fetal Heart Rate

The **baseline fetal heart rate (BL FHR)** is determined by approximating the mean (average) FHR during a 10-minute period, rounded to increments of 5 beats/min (e.g., 125, 130, 135, 140). Accelerations, decelerations, and periods of marked FHR variability (>25 beats/min) are excluded. There must be at least 2 minutes of identifiable baseline segments (not necessarily contiguous) in any 10-minute window, or the baseline for that period is indeterminate, and the preceding 10-minute window must be used to determine the baseline (Macones et al., 2008). For example, if FHR over a period of 10 minutes fluctuates between 142 beats/min and 156 beats/min, the BL FHR would be documented as 150 beats/min with moderate variability.

The normal baseline (BL) rate ranges from 110 to 160 beats/min, depending on gestational age. As the gestational age of the fetus increases, the FHR decreases. The FHR decreases an average of 16 beats/min between 16 weeks' gestation and term. The slowing of the FHR occurs as the parasympathetic nervous system (PNS) matures and exerts control over the fetal heart activity (Cunningham et al., 2010).

Tachycardia

Fetal tachycardia is a BL FHR greater than 160 beats/min for at least a 10-minute period. The possible causes of tachycardia may be idiopathic, maternal, fetal, or a combination of maternal and fetal. Some of the most common causes are the following (Cunningham et al., 2010):

Maternal

- Fever (Metabolism of the fetus accelerates because of increased maternal temperature.)

RESEARCH EVIDENCE IN PRACTICE

Fetal Monitoring During Labor

CLINICAL QUESTION

What is the most effective method for monitoring fetal status during labor?

RESEARCH EVIDENCE

During labor, there are multiple ways to monitor fetal status as labor progresses. The fetus can be monitored externally using a special stethoscope or hand-held monitor, or the baby can be continuously assessed using cardiotocography (CTG) and assessing the baby's condition with an electrocardiogram (ECG). Also available is fetal pulse oximetry, which measures how much oxygen the baby's blood is carrying via a probe that sits inside the vagina during labor.

Several Cochrane Collaborative reviews critically appraised research related to these methods—continuous CTG, ECG, and fetal pulse oximetry—to determine the method that is most effective in producing desirable outcomes for mother and baby. The Cochrane Collaborative is a highly rigorous source of research evidence. Among these three reviews, randomized trials involving more than 54,000 women in labor were reviewed.

From an acceptability standpoint, CTG restricts movement of the mother and requires insertion of an internal electrode in the baby's head after rupture of the membranes. The fetal oximetry probe does not limit the mother's mobility.

Monitoring the baby's heart using an ECG plus CTG during labor helps mothers and babies when continuous electronic fetal heart rate monitoring is indicated. In other words, these monitoring methods are useful if monitoring is needed based on heart rate or rhythm irregularities in the fetus. The application of this type of monitoring must be considered in light of the limitations on the mother's mobility and the need for an invasive procedure during labor.

There was limited support for the use of fetal pulse oximetry when used in the presence of a nonreassuring ECG. The data revealed only a small reduction in the cesarean birth rate under these conditions. In general, continuous CTG and ECG were associated with increased cesarean birthrates and instrument-assisted births. None of the monitoring methods was associated with a reduction in cerebral palsy, infant mortality, or other measures of neonatal well-being.

WHAT QUESTIONS REMAIN UNANSWERED?

It is unclear whether any type of internal monitoring is needed when the mother and baby are low risk and no problems arise during labor. It does appear that monitoring is associated with a higher rate of instrumental or cesarean births, but this may be due to the risks that are associated with applying internal monitoring in the first place.

WHAT IS BEST PRACTICE?

Internal monitoring of fetal heart rate and rhythm using CTG is indicated for high-risk pregnancies or those in which fetal condition must be continuously assessed.

CRITICAL THINKING

What are the conditions under which the nurse should recommend internal monitoring methods? How is the assessment plan altered when internal monitoring is applied?

- Dehydration
- Anxiety
- Betasympathomimetic or sympathetic drugs, such as ritodrine, terbutaline, atropine, and isoxsuprine (These drugs have a cardiac stimulant effect.)
- Maternal hyperthyroidism (Thyroid-stimulating hormones may cross the placenta and stimulate the FHR.)
- Supraventricular tachycardia

Fetal

- Early fetal hypoxia (This leads to stimulation of the sympathetic nervous system (SNS) as the fetus compensates for reduced blood flow.)
- Asphyxia
- Fetal anemia (The heart rate increases as a compensatory mechanism to improve tissue perfusion.)
- Infection
- Prematurity
- Prolonged fetal stimulation

Tachycardia is considered a nonreassuring sign if it is accompanied by other FHR patterns such as late decelerations, severe variable decelerations, or decreased or absent variability. If tachycardia is associated with maternal fever, treatment may consist of antipyretics, cooling measures, and antibiotics (Cunningham et al., 2010). Fetal arrhythmia or dysrhythmia needs to be ruled out. The pediatrician should be notified, because tachycardia may cause heart failure in the newborn.

Intervention for tachycardia usually requires treatment of the underlying cause. Additional testing and monitoring may be used to further determine fetal well-being.

Bradycardia

Fetal bradycardia is by definition a FHR baseline less than 110 beats/min for at least a 10-minute period. The lower limits of the FHR have been debated in the past. A FHR as low as 90 beats/min with good variability has been classified as benign and reassuring. When bradycardia is accompanied by decreased variability or late decelerations, or both, it is considered ominous and a sign of advanced fetal compromise (Cunningham et al., 2010). The possible causes of bradycardia include the following (Cunningham et al., 2010):

- Stimulation of the vagus nerve (prolonged head compression as in early decelerations, application of the forceps or vacuum extractor, or prolonged scalp stimulation)
- Drugs that stimulate the PNS or block the SNS (anesthesia and regional analgesia)

- Maternal hypotension (Maternal hypotension results in decreased blood flow to the fetus.)
- Prolonged umbilical cord compression (Fetal baroreceptors are activated by cord compression, which produces vagal stimulation, and in turn decreases FHR.)
- Fetal dysrhythmia (This is associated with complete heart block in the fetus.)
- Hypoxemia or late fetal asphyxia (There is depression of myocardial activity.)
- Accidental monitoring of maternal pulse

Wandering Baseline

A *wandering baseline* is a smooth, meandering, unsteady BL that fluctuates in the normal BL range without variability (Cunningham et al., 2010). The possible causes of this type of BL may be a congenital defect or metabolic acidosis. Immediate interventions should be taken to enhance fetal oxygenation, and delivery should be anticipated (AWHONN, 2006).

Sinusoidal Fetal Heart Rate Pattern

A sinusoidal FHR pattern is defined as having a visually apparent, smooth, wavelike, undulating sine pattern in FHR baseline (Macones et al., 2008). The pattern has a series of cycles that are extremely smooth and regular (not necessarily identical) in amplitude and duration. It resembles a perfect letter "S" lying on its side. The FHR undulates in a sine pattern between 120 and 160 beats/min with variability amplitude of 5 to 15 beats/min. The pattern has a cycle frequency of 3–5/minute that persists for 20 minutes or more (Macones et al., 2008). Accelerations do not occur spontaneously, nor can they be induced (Figure 23-12 ■).

Sinusoidal patterns may be benign (pseudosinusoidal) or pathological (true sinusoidal) patterns. Pathologic sinusoidal patterns are indicative of nonreassuring fetal status and require immediate attention (Cunningham et al., 2010). The possible causes of a true sinusoidal pattern include the following (Cunningham et al., 2010):

- Fetal anemia
- Chronic fetal bleeding
- Fetal isoimmunization
- Twin-to-twin transfusion
- Umbilical cord occlusion
- Central nervous system (CNS) malformations

If the sinusoidal pattern is uncorrectable, interventions include immediate notification of the healthcare provider and expeditious delivery.

Arrhythmias and Dysrhythmias

Arrhythmias, a term often used interchangeably with *dysrhythmias,* are disturbances in the FHR pattern that are not associated with abnormal electrical impulse formation or conduction in the fetal cardiac tissue. An arrhythmic pattern demonstrates a normal P wave and QRS complexes (Tucker, Miller, & Miller, 2008). However, dysrhythmic FHR patterns may exhibit abnormal electrical impulse formation and/or conduction in the fetal cardiac tissues, resulting in abnormal P waves or QRS complexes, or both. Arrhythmic and dysrhythmic patterns get their names from the origin of the pattern, for example, sinus node variants, atrial node patterns, or ventricular patterns (Tucker, Miller, & Miller, 2008).

FHR dysrhythmias are estimated to occur in 2% to 14% of all pregnancies. Whereas 90% of dysrhythmias are benign, 10% can be life threatening and require the consultation of a neonatal or pediatric cardiology expert (Tucker, Miller, & Miller,

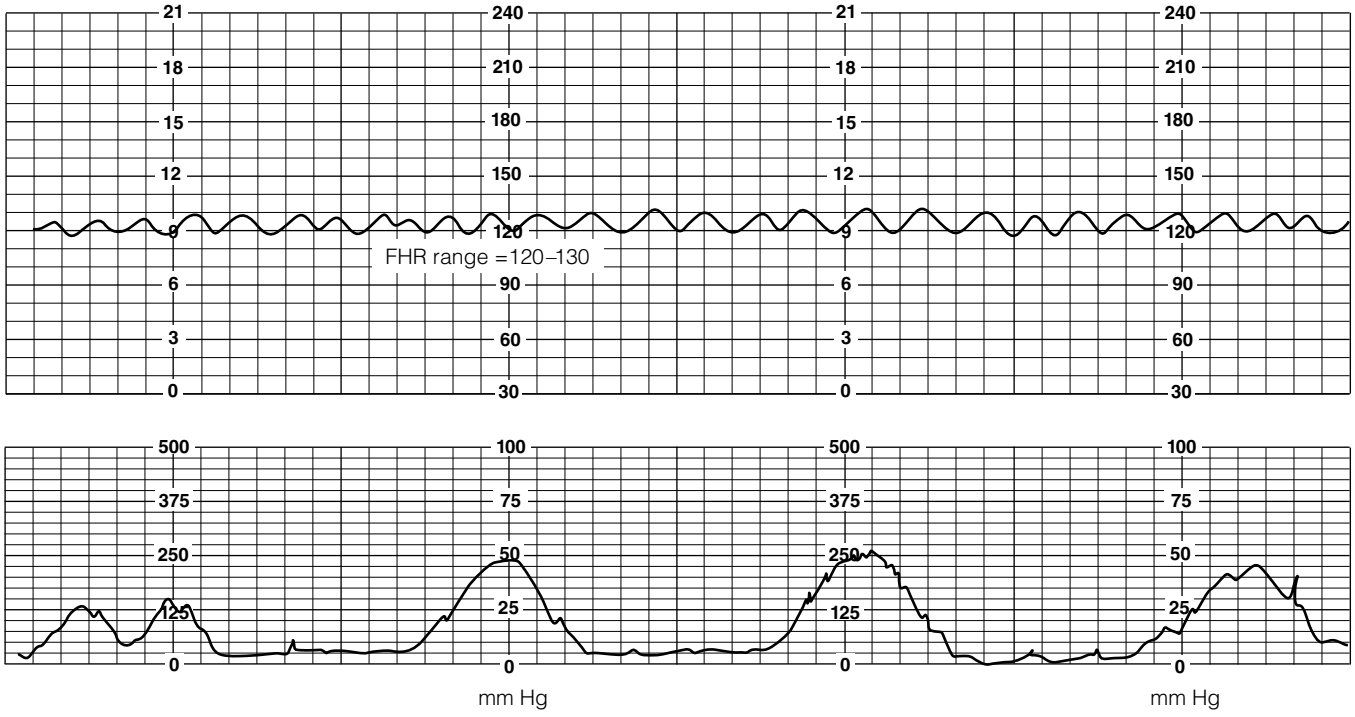

Figure 23-12 ■ Sinusoidal pattern. Note the undulating waveform evenly distributed between the 120 and 130 beats/min baseline. There is minimal variability.

TABLE 23-6 Common Causes of Various Types of Fetal Dysrhythmias

SINUS NODE VARIANTS	ATRIAL DYSRHYTHMIAS	VENTRICULAR DYSRHYTHMIAS
• Bradycardia	• Parasympathetic response to fetal hypoxemia	• Beta-blocker drugs
• Tachycardia	• Maternal ingestion of stimulants (e.g., caffeine, tobacco, alcohol, cocaine)	• Complete heart blocks (AV malformation)
• Marked sinus arrhythmia	• Abnormal reentry conduction	• Congenital heart disease
• Infections	• Cardiomyopathy	• Autoimmune disease (AV malformation)
• CNS disturbances	• Fetal-maternal placental hemorrhage	• Maternal collagen disorders (AV malformation)
	• Nonimmune hydrops fetalis	
	• Wolf-Parkinson White syndrome	
	• Cardiac structural abnormalities (e.g., atrial septal defect (ASD), ventricular septal defect (VSD), valve malformation)	

Sources: Data from AWHONN, 2004; Cunningham et al., 2010; Tucker, Miller, & Miller, 2008).

2008). For this reason, it is important to accurately diagnose abnormal FHR patterns and distinguish fetal arrhythmias from artifact and electrical interference. Fetal dysrhythmias can be difficult to diagnose, because detection of the fetal cardiac electrical activity is best accomplished by invasive or advanced monitoring techniques such as fetal scalp electrode, real-time ultrasound, Doppler velocimetry, fetal echocardiogram, and echocardiogram monitoring (e.g., M-Mode EchoCG, and Pulsed Doppler EchoCG) (Tucker, Miller, & Miller, 2008). With the exception of the fetal scalp electrode, more advanced and expensive diagnostic testing may not be readily available.

The most common causes of FHR dysrhythmias are discussed in Table 23-6.

Baseline Variability

Baseline variability (BL VAR) is a reliable indicator of fetal cardiac and neurological function and well-being. The opposing "push-pull" balancing between the sympathetic nervous system and the parasympathetic nervous system directly affects the FHR. ACOG, AWHONN, and NICHD define baseline variability (BL VAR) as baseline (BL) fluctuations in the baseline FHR that are irregular in amplitude and frequency. The fluctuations are visually quantified as the amplitude of the peak-to-trough in beats/min (Macones et al., 2008). Evaluation of BL VAR is based on visual assessment of the amplitude of the BL cycles (AWHONN, 2005). Variability is classified by ACOG, AWHONN, and NICHD as follows (Macones et al., 2008):

- Absent FHR variability—amplitude range undetected
- Minimal FHR variability—amplitude range detectable but 5 beats/min or less
- Moderate FHR variability—amplitude range of 6 to 25 beats/min
- Marked FHR variability—amplitude range greater than 25 beats/min

Figures 23-13 ■ and 23-14 ■ illustrate examples of each of these categories.

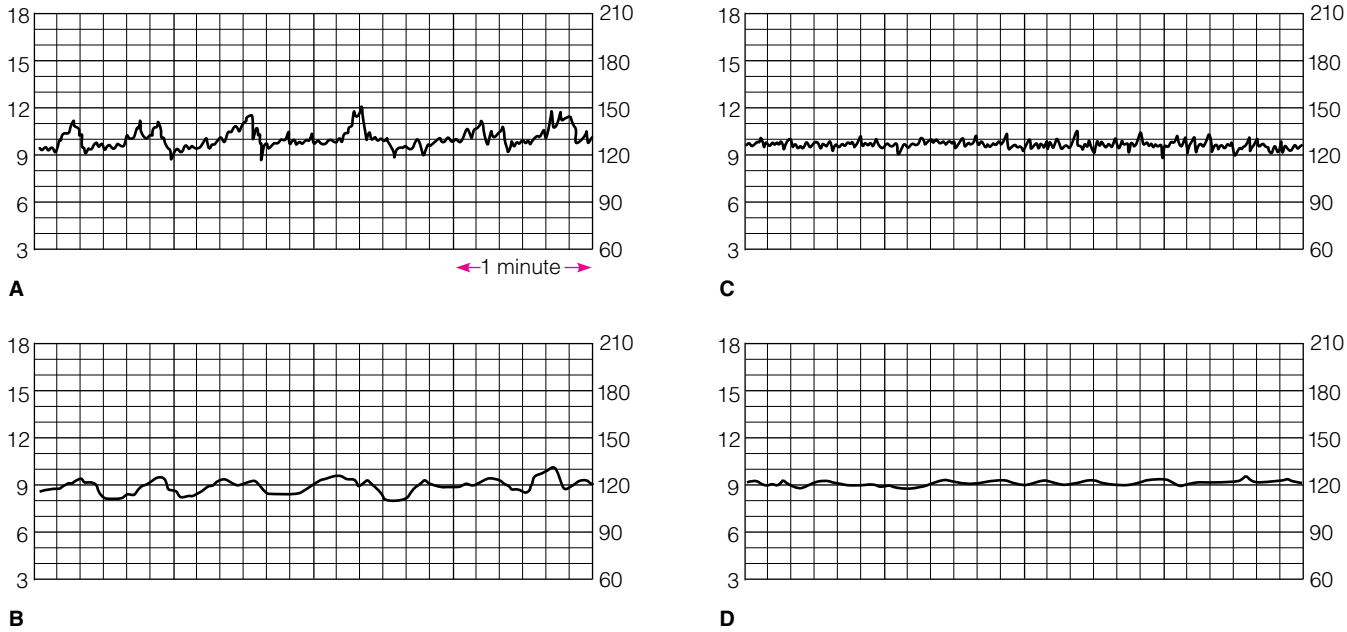

Figure 23-13 ■ A. and B. Moderate variability. C. Minimal variability. D. Absent variability.

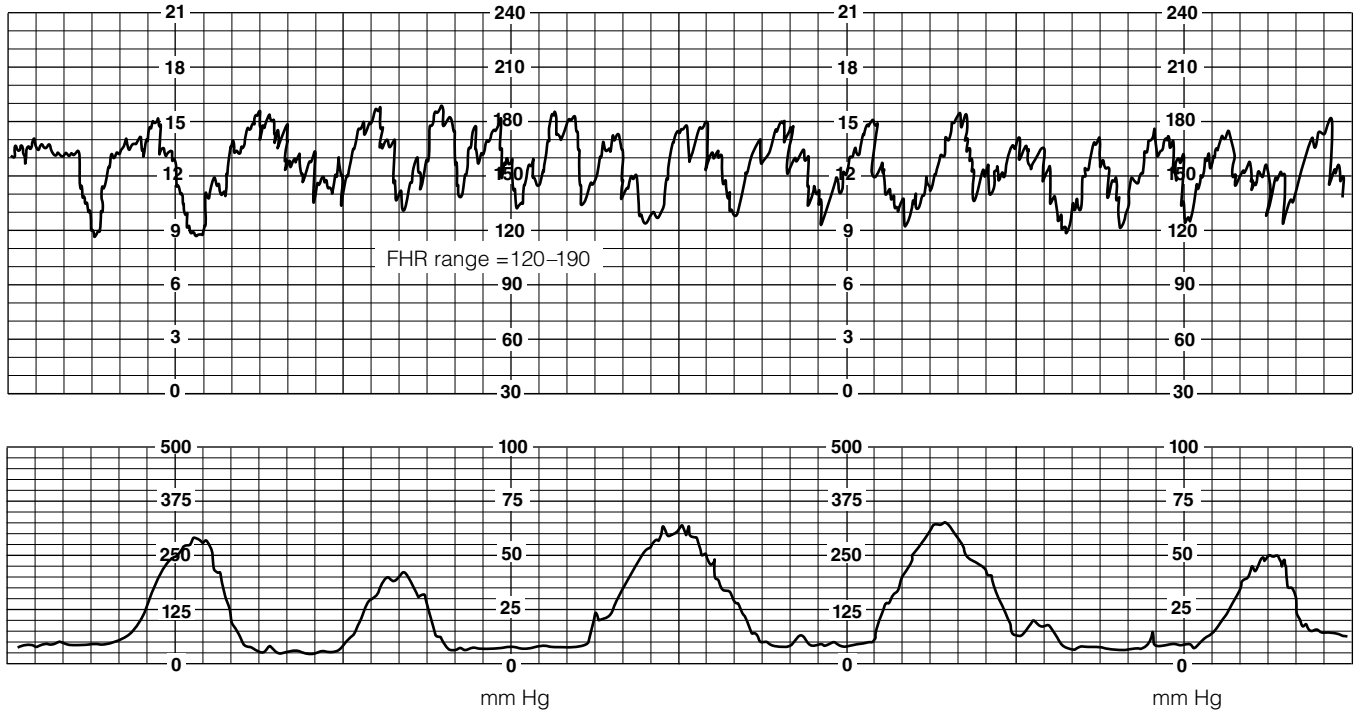

Figure 23-14 ■ Marked variability. FHR varies markedly between 120 and 190 beats/min. With this type of pattern, it is not possible to determine average baseline FHR because of the wide, marked variations.

Fetal Heart Rate Changes

In addition to changes in the average BL FHR range, the FHR may also exhibit intermittent or transient deviations or changes from the BL that are commonly referred to as accelerations and decelerations. These transient deviations or changes in BL are categorized as episodic or periodic. Episodic changes (formerly referred to as nonperiodic changes) are not associated with uterine contractions (UCs). Periodic changes occur with UCs. If a periodic change occurs with 50% or more of UCs in a 20-minute period, it is further categorized as a recurrent change or pattern (Cunningham et al., 2010).

The nurse must remember that it is very important to examine all changes in FHR in relation to the surrounding BL and uterine activity. A comprehensive evaluation of the maternal-fetal interaction facilitates effective and efficient treatment and fetal well-being.

Accelerations

An **acceleration**, also called an *accel*, is described as a visually apparent abrupt increase in the BL FHR, with an onset-to-peak of less than 30 seconds beginning at the most recent calculated BL. To be called an acceleration, the peak must be 15 beats/min or more and the acceleration must last 15 seconds or more from the onset to the return to BL. The duration of the acceleration is defined as the time from the initial change in FHR from the BL to the return of the FHR to the BL. At gestations of less than 32 weeks, accelerations are defined as having a peak of 10 beats/min or more and a duration of 10 seconds or more. A *prolonged acceleration* is any acceleration that lasts 2 minutes or more but less than 10 minutes in duration. Prolonged accelerations that last more than 10 minutes are defined as a baseline change (Macones et al., 2008).

As discussed earlier in this chapter, accelerations can be either episodic or periodic. *Episodic accelerations* are not associated with contractions and tend to be more peaked and abrupt. They are often associated with fetal movement, stimulation, or an environmental stimulus. Episodic accelerations are reassuring FHR patterns, whether or not they are accompanied by fetal movement. *Periodic accelerations* are associated with uterine contractions. When they occur on a repetitive basis, they may be smooth in configuration, multiphasic, and may precede variable decelerations (Cunningham et al., 2010). Various types of accelerations are displayed in Figure 23-15 ■.

Accelerations are generally associated with the stimulation of the autonomic nervous system (ANS), specifically the (SNS), which increases the FHR. If the heart rate increases with CNS stimulation, it usually indicates an intact fetal nervous system and fetal well-being. FHR accelerations can be associated with fetal movement, vaginal exams, application of a fetal scalp electrode, occiput posterior presentation and uterine contractions, fundal pressure, abdominal palpation, vibroacoustic stimulation (VAS), scalp stimulation, and other environmental stimuli (Tucker et al., 2008). Infants of extreme prematurity are less likely to accelerate because of their immature PNS. In fetuses of less than 32 gestational weeks, an acceleration of at least 10 beats/min for 10 seconds is reassuring (Cunningham et al., 2010). Fetuses suffering from intrauterine growth restriction (IUGR) experience fewer accelerations than normal, healthy, well-oxygenated fetuses. Medications administered to the mother may inhibit accelerations because of their effect on the SNS. Some of the drugs seen to affect fetuses are beta blockers and CNS depressants. Hypoxia is also a large con-

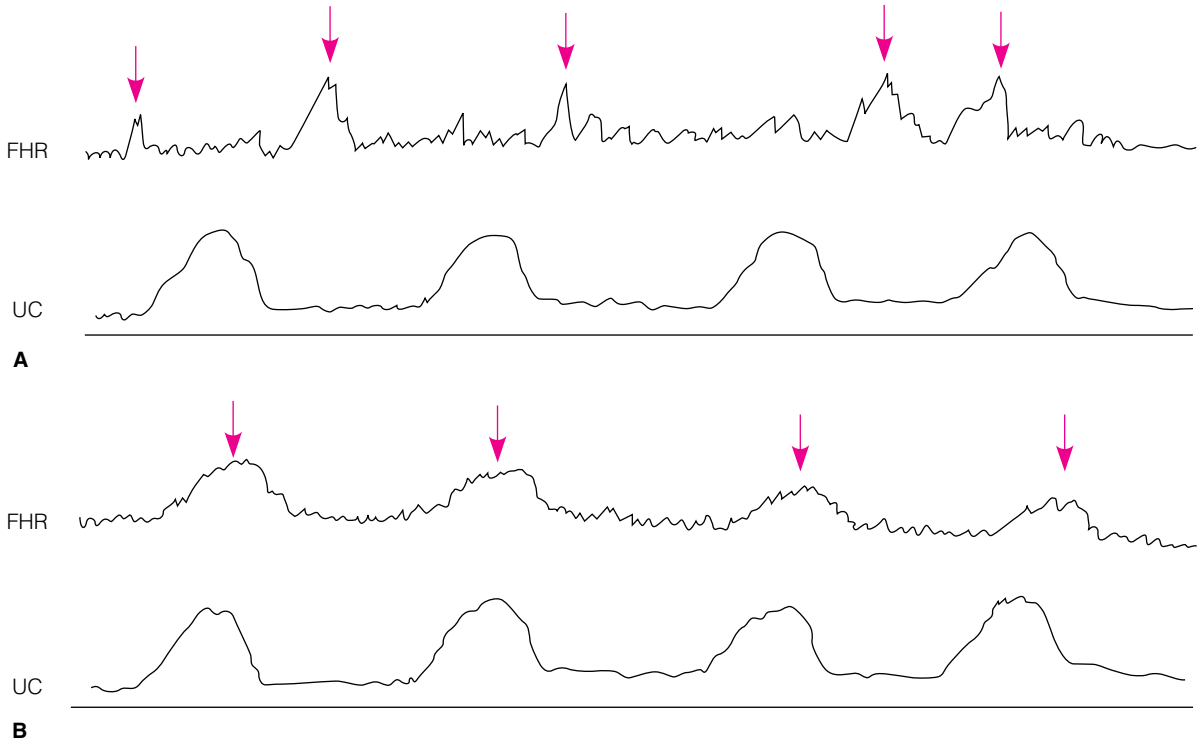

Figure 23-15 ■ Types of accelerations. A. Episodic accelerations. B. Periodic accelerations.

tributing factor to lack of accelerations and may be the first sign of a nonreassuring FHR tracing (Cunningham et al., 2010).

Accelerations are generally benign because they are associated with an intact fetal nervous system, lack of fetal hypoxia, and acidosis. The patterns are considered reassuring, thus no intervention is required (Cunningham et al., 2010; Tucker et al., 2008).

Decelerations

Decelerations, often referred to as *decels,* are generally defined as decreases in the FHR below the BL. Each deceleration has its own unique characteristics, etiology, and significance. Each deceleration consists of several components:

- ***Onset:*** point at which the deceleration leaves the BL FHR
- ***Descent:*** time from onset to nadir
- ***Nadir:*** lowest point of the deceleration
- ***Depth:*** the level (in beats per minute) a deceleration reaches its nadir
- ***Recovery:*** time from nadir to return to BL
- ***Duration:*** the total length of time from onset to return to BL

Decelerations are identified and classified as late, early, or variable based on specific characteristics of their shape, appearance, rate of descent, and timing in relationship to uterine contractions (Figure 23-16 ■). Variable decelerations may be accompanied by other characteristics, the clinical significance of which requires further research investigation. Macones et al. (2008) provide some examples of these characteristics including a slow return of the FHR after the end of the contraction, biphasic decelerations, tachycardia after variable deceleration(s), accelerations preceding and/or following a deceleration (sometimes called "shoulders" or "overshoots"), and fluctuations in the FHR in the trough of the deceleration. See Figure 23-17 ■.

Macones et al. (2008) describe characteristics of decelerations according to the 2008 NICHD Workshop Report on Electronic Fetal Monitoring: Update on Definitions, Interpretation, and Research Guidelines as follows:

Early Deceleration

- Visually apparent, usually symmetrical, gradual decrease and return of the FHR associated with a uterine contraction.
- A gradual FHR decrease is defined as one from the onset to the FHR nadir of 30 seconds or more.
- The decrease in FHR is calculated from the onset to the nadir of the deceleration.
- The nadir of the deceleration occurs at the same time as the peak of the contraction.
- In most cases the onset, nadir, and recovery of the deceleration are coincident with the beginning, peak, and ending of the contraction, respectively.

Late Deceleration

- Visually apparent, usually symmetrical, a gradual decrease and return of the FHR to BL, associated with a uterine contraction.
- A gradual FHR decrease is defined as from the onset to the FHR nadir of 30 seconds or more.
- The decrease in FHR is calculated from the onset to the nadir of the deceleration.
- The deceleration is delayed in timing, with the nadir of the deceleration occurring after the peak of the contraction.
- In most cases, the onset, nadir, and recovery of the deceleration occurs after the beginning, peak, and ending of the contraction, respectively.

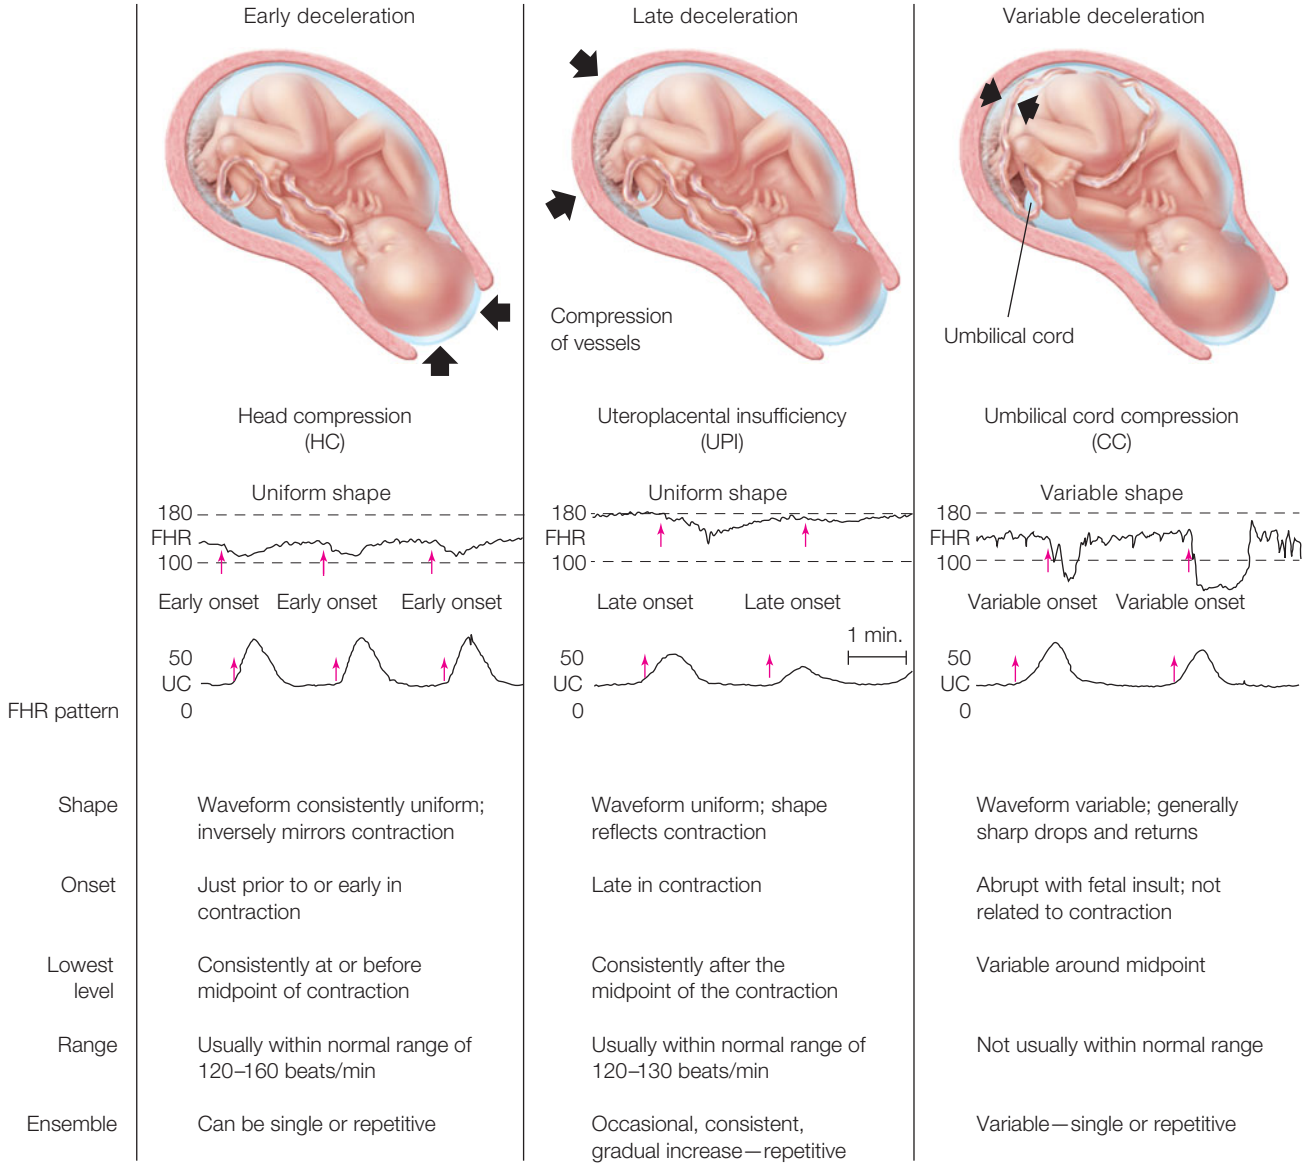

Figure 23-16 ■ Types and characteristics of early, late, and variable decelerations.

Source: Hon, E. (1976). An introduction to fetal heart rate monitoring *(2nd ed., p. 29). Los Angeles: University of Southern California School of Medicine.*

Variable Deceleration

- Visually apparent abrupt decrease in FHR.

An abrupt FHR decrease is defined as from the onset of the deceleration to the beginning of the FHR nadir of 30 seconds or less. The decrease in FHR is calculated from the onset to the nadir of the deceleration.

- The decrease in FHR is 15 beats/min or more, lasting 15 seconds or more but less than 2 minutes in duration.
- When variable decelerations are associated with uterine contractions, their onset, depth, and duration commonly vary with successive uterine contractions.

Early decelerations are a result of vagal nerve stimulation caused by fetal head compression that occurs during UCs (Figure 23-18 ■). They are usually uniform in shape and mirror the shape of the UC. The depth of the deceleration is rarely more than 30 to 40 beats/min (Cunningham et al., 2010) (Figure 23-19 ■). Early decels are not associated with loss of variability, tachycardia, or other FHR changes that are associated with fetal hypoxia, acidosis, or low Apgar scores. They are viewed as reassuring unless they are seen with the lack of descent of the fetal head into the pelvis (Cunningham et al., 2010).

Late decelerations, often referred to as *lates* or *late decels,* are due to uteroplacental insufficiency and are a result of decreased blood flow and/or oxygen transfer to the fetus through the intervillous space during contractions. Late decels may be one of two types: reflexive or myocardial. The pathophysiology of late decels is complicated and is not always understood (Cunningham et al., 2010).

When uteroplacental reserve is adequate, the fetus normally tolerates the transient stress of repetitive contractions. If a decrease in uteroplacental blood flow (for example, from maternal hypotension or excessive uterine activity) lowers the

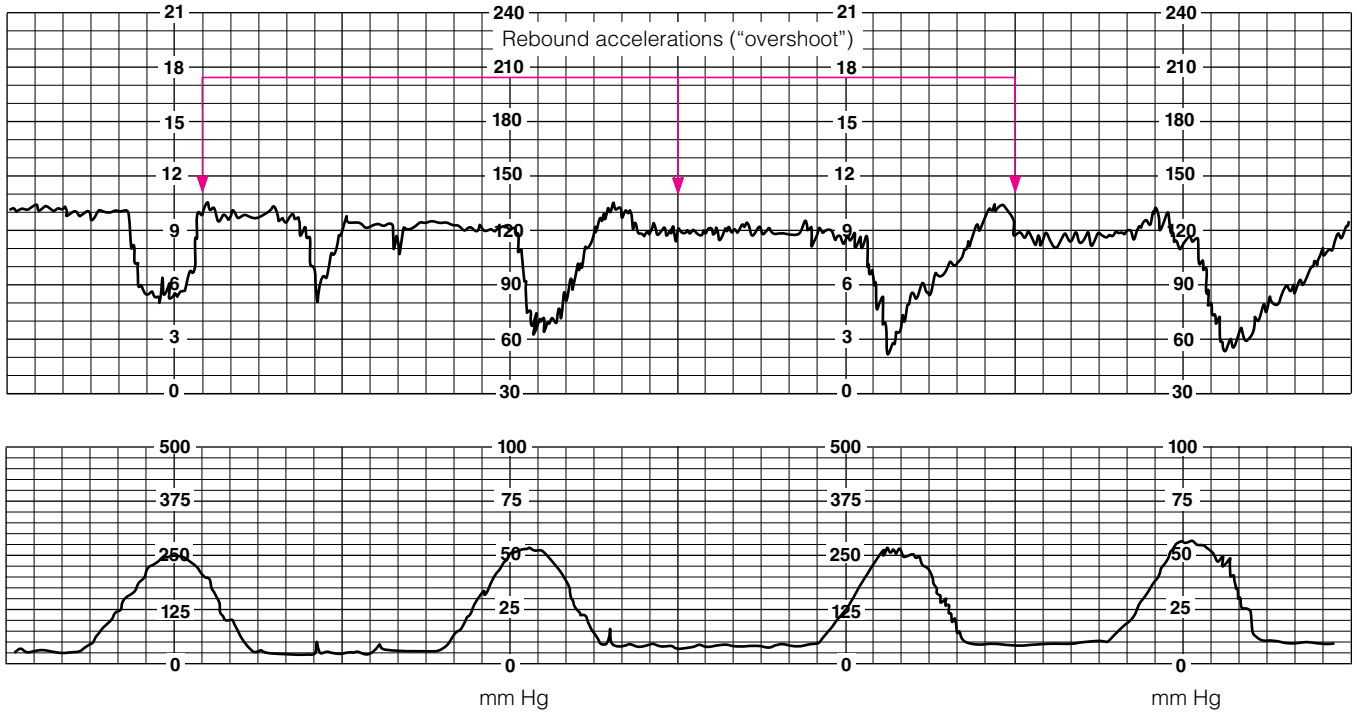

Figure 23-17 ■ Variable decelerations with overshoot. The timing of the decelerations is variable, and most have a sharp decline. A rebound acceleration (overshoot) occurs after most of the decelerations. Baseline FHR is 115 to 130 beats/min. Nadir of decelerations is 55 to 80 beats/min. Variability is minimal.

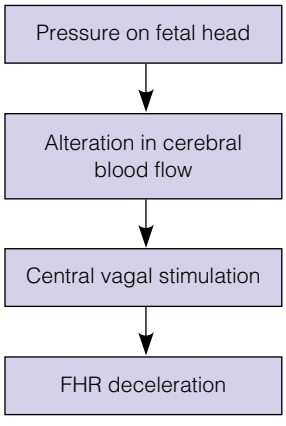

Figure 23-18 ■ Mechanism of early deceleration (head compression).

oxygen level in the intervillous space to a level lower than the oxygen level in the fetus, fetal chemoreceptors are stimulated and FHR decreases. This response to the lowered oxygen level is reflexive, because it is a normal physiologic chemical response to low oxygen levels in the blood. The delay in the FHR deceleration is due to the time it takes for the normal physiologic response of the neurologic system to respond to the lowered oxygen environment. This type of late decels is generally considered nonacidemic and is associated with moderate BL VAR. The BL VAR is the key to determining an intact fetal CNS and should always be considered when evaluating late decelerations and the level of intervention required (Cunningham et al., 2010).

In some cases, repetitive or chronic episodes of decreased oxygen in the intervillous space exist and the fetus experiences a chronic state of hypoxia that leads to metabolic acidosis. The fetal CNS is affected by the metabolic acidosis and progresses to myocardial depression. Late decelerations are produced by the myocardial depression (Tucker et al., 2008) (Figure 23-20 ■).

The decrease in heart rate resulting from late decelerations is usually shallow, typically 10 to 20 beats/min; however, it may approach 30 to 40 beats/min below the BL (Cunningham et al., 2010) (Figure 23-21 ■). The depth of the late deceleration is usually proportional to the strength of the UC; late decelerations are considered a nonreassuring sign. When they are repetitive and uncorrectable and associated with minimal or absent BL VAR and/or BL rate changes, they indicate fetal hypoxia and acidemia and require prompt attention and intervention. The objective of intervention is to improve fetal oxygenation and uteroplacental perfusion while assessing and eliminating the stressor as reflected by the deceleration (Cunningham et al., 2010). If this is not possible, immediate birth may be indicated.

Sometimes late or variable decelerations are due to the supine position of the laboring woman. In this case, the decrease in uterine blood flow to the fetus may be alleviated by raising the woman's upper trunk or turning her to the side to displace pressure of the gravid uterus on the inferior vena cava. If the woman remains flat on her back, the fetus will continue to have decelerations because of oxygen compromise. Immediate nursing interventions include changing the maternal position and increasing the administration of intravenous fluids. Oxygen should be provided to the mother via face mask if hypoxia is suspected, such as when there is absent or minimal variability. If oxytocin (Pitocin) is being administered, the infusion

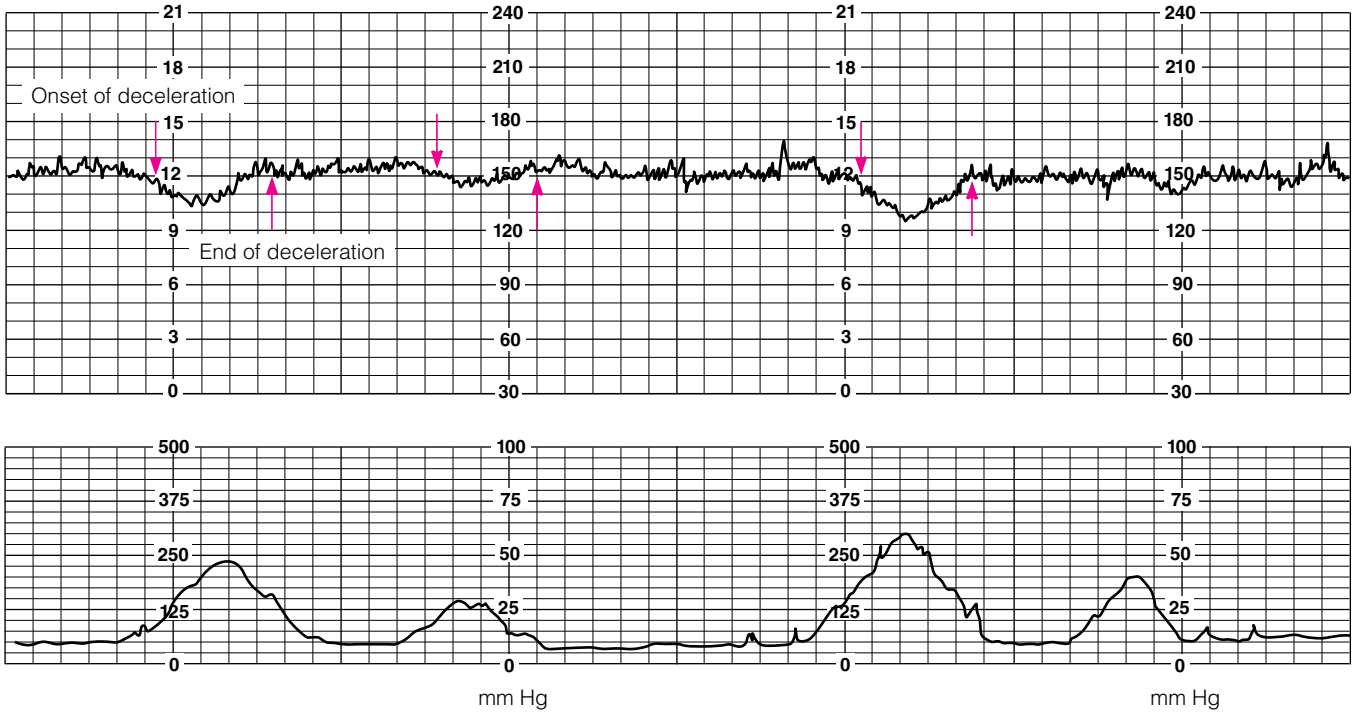

Figure 23-19 ■ Early decelerations. Baseline FHR is 150 to 155 beats/min. Nadir (lowest point) of decelerations is 130 to 145 beats/min.

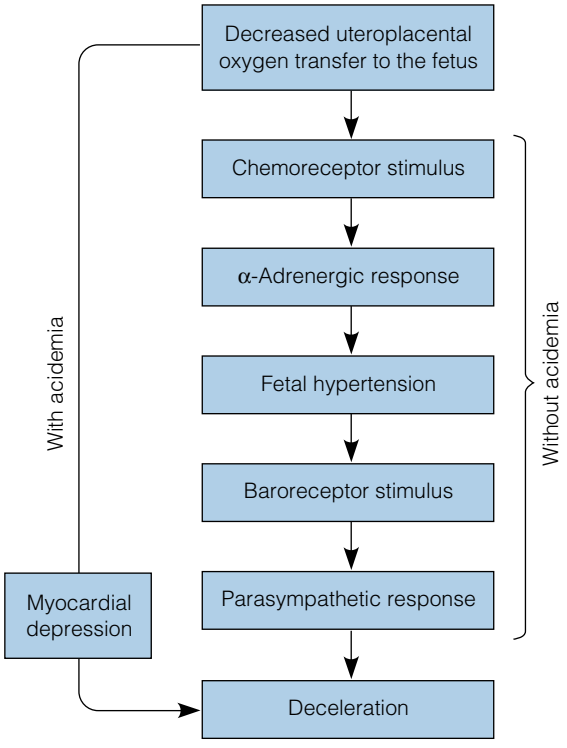

Figure 23-20 ■ Mechanism of late deceleration.

Source: Reprinted with permission from Freeman, R. K., & Garite, T. J. (1981). The physiologic basis of fetal monitoring. In Fetal heart rate monitoring *(p. 15). Copyright © 1981 Lippincott, Williams & Wilkins.*

should be stopped immediately until the FHR recovers or the physician or certified nurse-midwife (CNM) has instructed that the infusion be resumed. The physician or CNM should be notified immediately in the event that late decelerations occur.

Late decelerations normally occur within the normal heart range (110 to 160 beats/min) and may be quite obvious or very subtle and almost indistinguishable. Some fetuses at highest risk demonstrate a flat BL FHR with late decelerations that are barely noticeable (Cunningham et al., 2010).

EPISODIC OR PERIODIC DECELERATIONS Decelerations can be episodic or periodic. As discussed earlier in this chapter, episodic decelerations implies that the deceleration occurred without relationship to UCs. Episodic decelerations may occur without or between contractions and usually are the result of environmental stimuli, such as vaginal exams, rupture of membranes, the administration of regional anesthesia or medications, or other events (Cunningham et al., 2010). Also discussed earlier, periodic refers to decelerations that occur in direct association with UCs. Episodic or periodic decelerations are considered *repetitive* if they occur with 50% or more of UCs (Tucker et al., 2008).

EARLY OR LATE DECELERATIONS Periodic decelerations associated with UCs are also classified by their timing in respect to them. The etiology and clinical significance of each type of deceleration are unique. Clinical interventions and treatments are based on the systematic assessment of the FHR tracing and the overall evaluation of the mother, the fetus, and labor status. Deceleration characteristics and the discussion of their clinical significance and interventions are included in the following sections.

PROLONGED DECELERATIONS A **prolonged deceleration** is a visually apparent decrease in the FHR of 15 beats/min or more below the BL that lasts more than 2 minutes and less than 10 minutes from onset to return to BL (Figure 23-22 ■).

VARIABLE DECELERATIONS **Variable decelerations** are those that have a U or V shape and are typically associated with

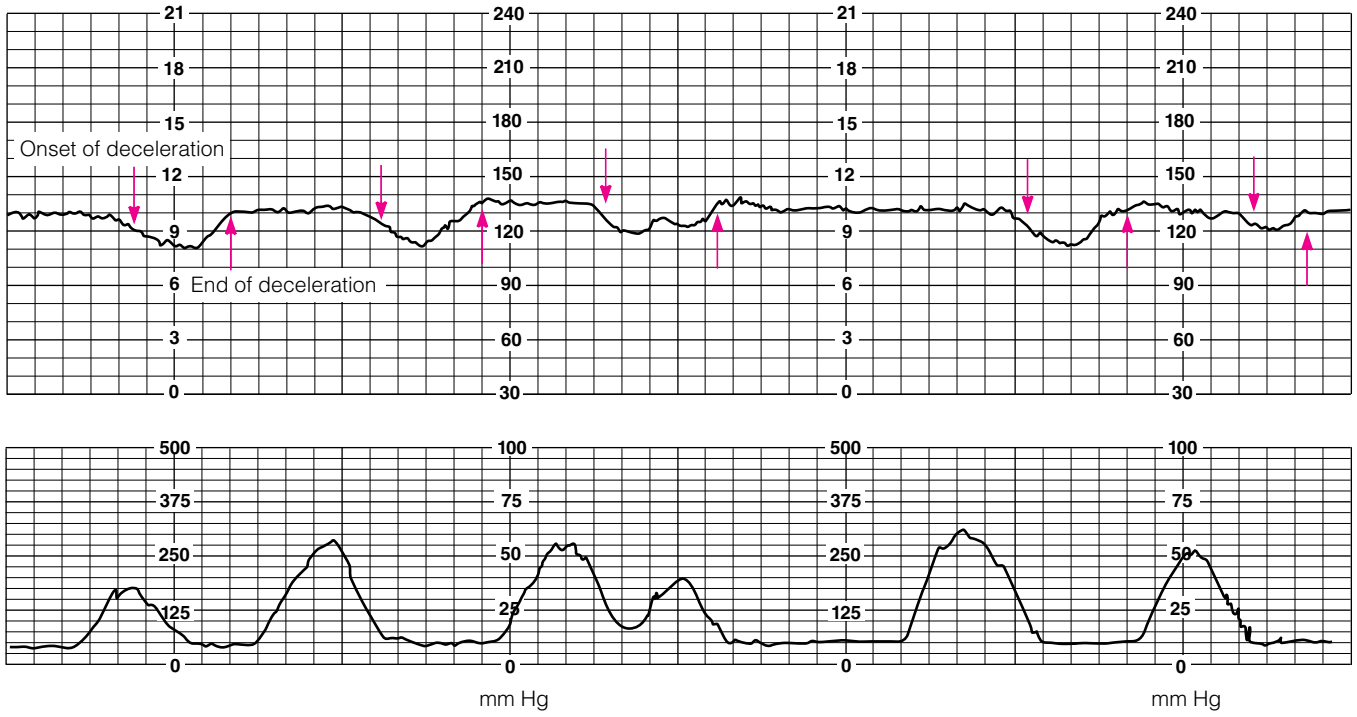

Figure 23-21 ■ Late decelerations. Baseline FHR is 130 to 148 beats/min. Nadir (lowest point) of decelerations is 110 to 120 beats/min. Absent variability.

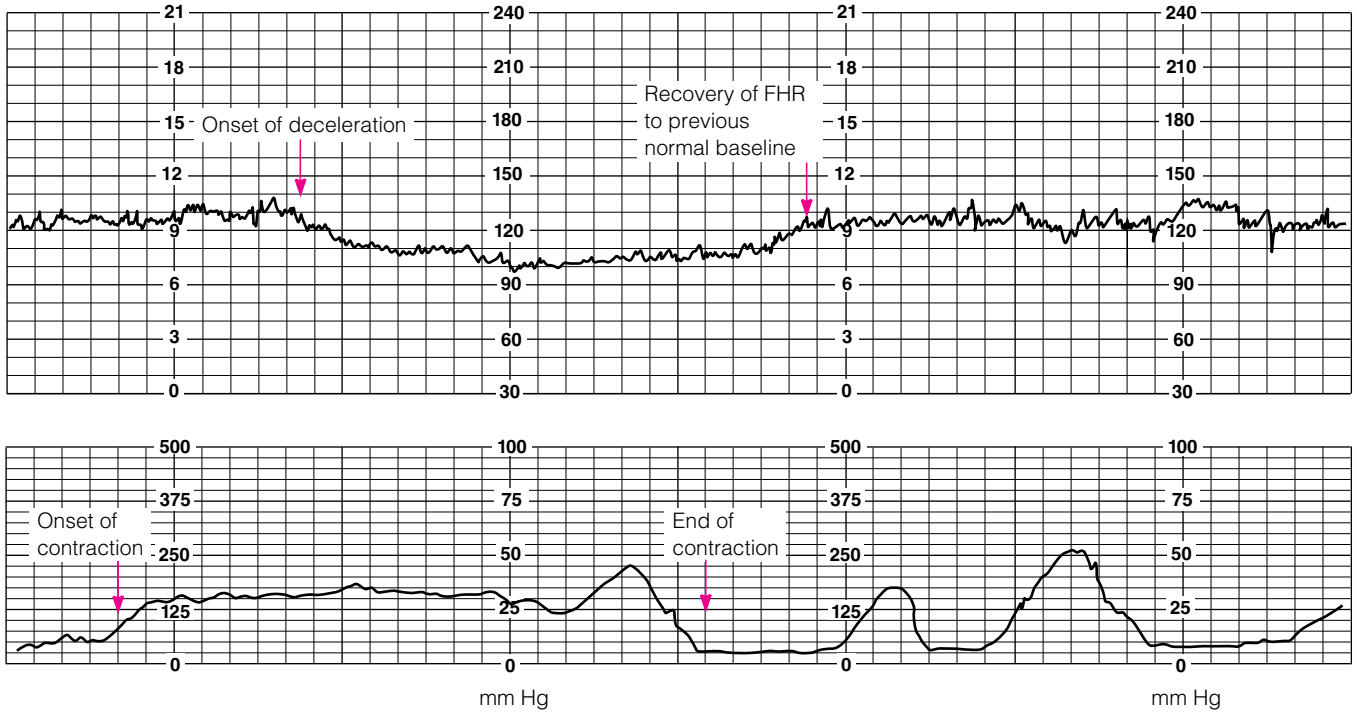

Figure 23-22 ■ The prolonged deceleration depicted lasts approximately 160 seconds.

Note: the prolonged contraction of 120 seconds. The deceleration begins after 80 seconds of uterine contraction. Note the beginning return of FHR 30 seconds after uterine tone returns to normal resting tone (contraction ends). Minimal variability is present despite the deceleration.

cord compression. They may vary somewhat in shape but have an abrupt onset and return to normal abruptly as well. They vary in intensity and duration and usually correlate to uterine contractions. They are thought to result from vagus nerve firing resulting from umbilical cord compression that occurs. They are usually not concerning unless the deceleration is less than 70 beats/min and lasts more than 60 seconds. In addition, if the variable is slow to return to baseline, it could be an indication

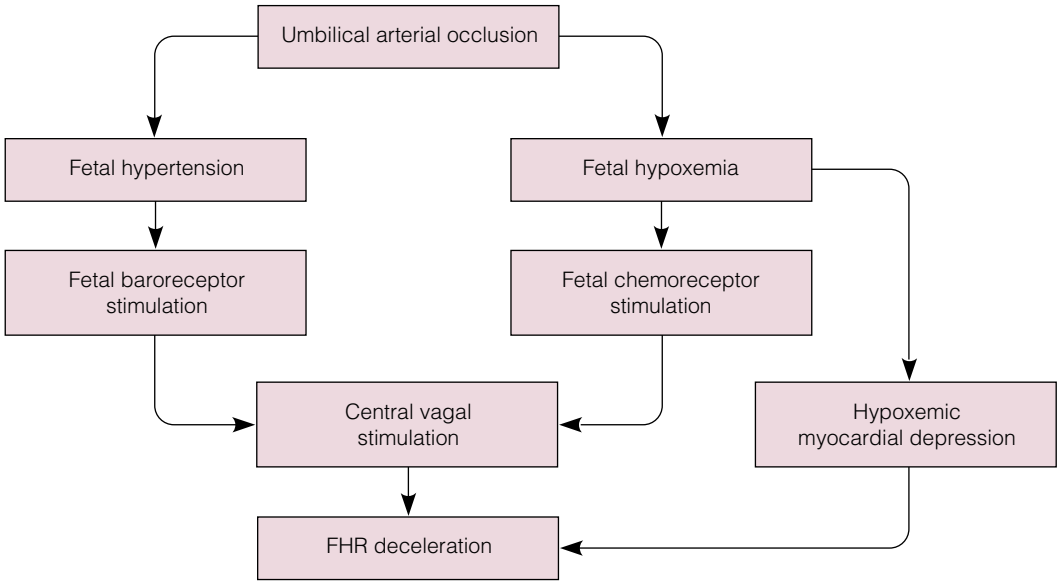

Figure 23-23 ■ Mechanism of variable deceleration.

of hypoxia and warrants intervention (Medical Library, 2010) (Figures 23-23 ■ and 23-24 ■).

Interpretation of Fetal Heart Rate Patterns

The effective nurse uses a systematic approach in evaluating FHR tracings to avoid interpreting findings on the basis of inadequate or erroneous data. With a systematic approach, the nurse can make a more accurate and rapid assessment; easily communicate data to the woman, physician or CNM, and staff; and have a universal language for documenting the woman's record. Evaluation of the electronic monitor tracing begins with a look at the uterine contraction pattern. To evaluate the contraction pattern, the nurse should:

1. Determine the uterine resting tone.
2. Assess the contractions:
   a. What is the frequency?
   b. What is the duration?
   c. What is the intensity (if internal monitoring)?

   The next step is to evaluate the FHR tracing.

1. Determine the baseline:
   a. Is the baseline within normal range?
   b. Is there evidence of tachycardia?
   c. Is there evidence of bradycardia?
2. Determine FHR variability:
   a. Is variability absent, minimal, or moderate? Is variability minimal or marked?
3. Determine whether a sinusoidal pattern is present.
4. Determine whether there are periodic changes.
   a. Are accelerations present?
   b. Is there a reassuring tracing or FHR pattern?
   c. Are decelerations present?
   d. Are they uniform in shape? If so, determine if they are early or late decelerations.
   e. Are they nonuniform in shape? If so, determine if they are variable decelerations.

After evaluating the FHR tracing for the factors listed, the nurse may categorize the tracing according to the Three-Tier Fetal Heart Rate Interpretation System below. The three-tier system for the categorization of FHR patterns is recommended by ACOG, AWHONN, and NICHD (Macones et al., 2008). Categorization of the FHR tracing evaluates the fetus at that point in time; tracing patterns can and will change. A FHR tracing may move back and forth between categories depending on the clinical situation and management strategies employed.

The Three-Tier Fetal Heart Rate Interpretation System (Macones et al., 2008).

Category I

Category I FHR tracings include all of the following:

- Baseline rate: 110–160 beats/min
- Baseline FHR variability: moderate
- Late or variable decelerations: absent
- Early decelerations: present or absent
- Accelerations: present or absent

Category II

Category II FHR tracings include all FHR tracings not categorized as Category I or Category III. Category II tracings may represent an appreciable fraction of those encountered in clinical care. Examples of Category II FHR tracings include any of the following:

- Baseline rate
  - Bradycardia not accompanied by absent baseline variability
  - Tachycardia

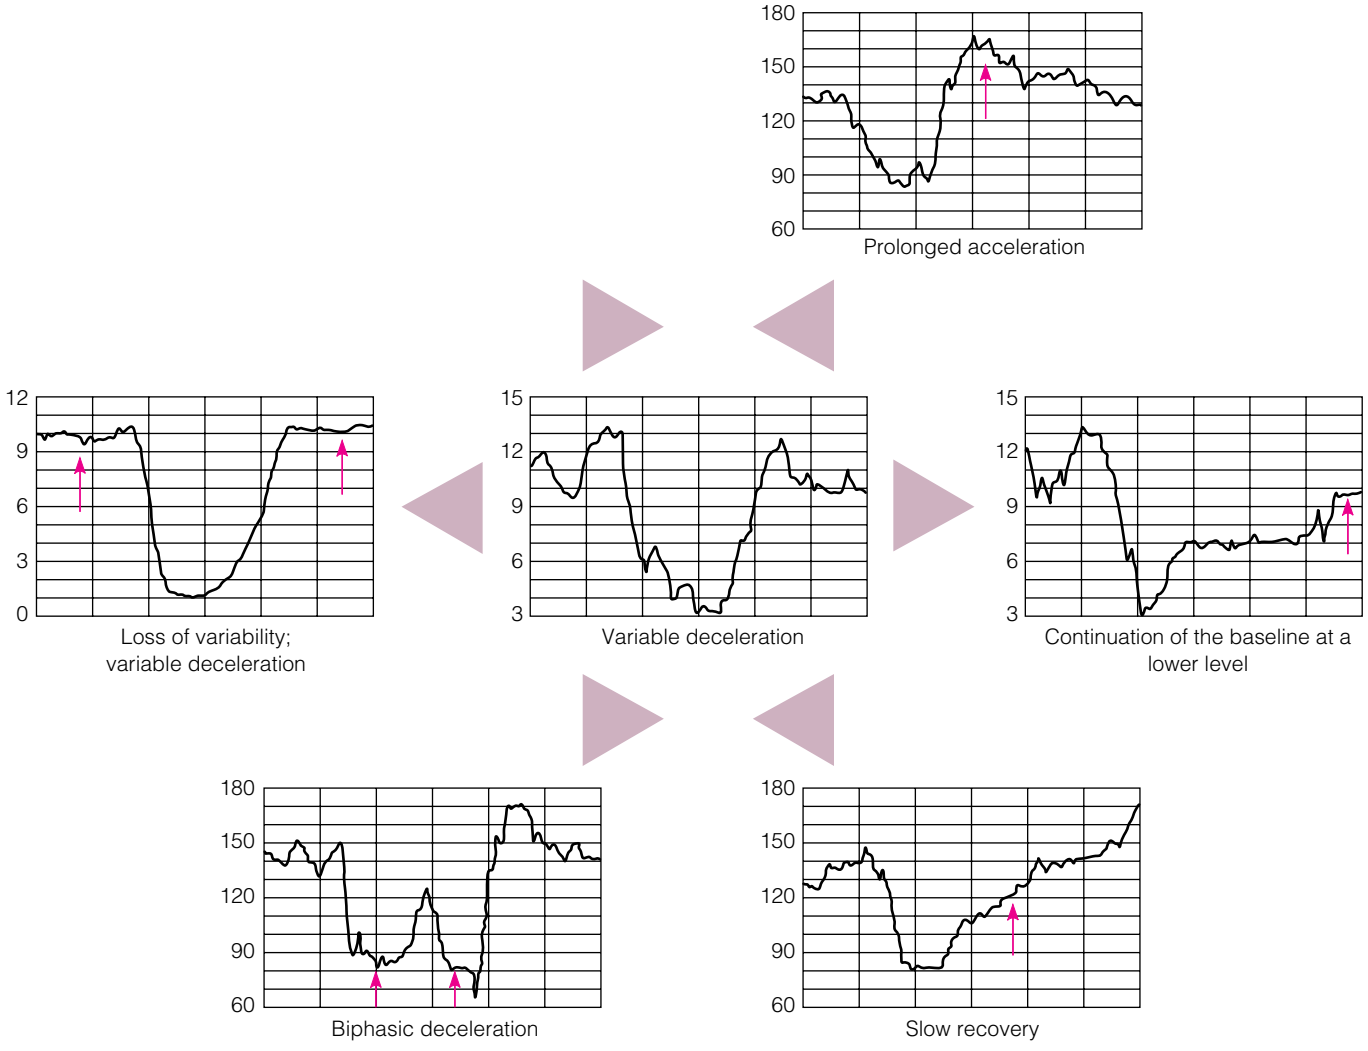

Figure 23-24 ■ Atypical variable decelerations. The presence of any of these types of variable decelerations strongly suggests fetal hypoxia, especially when variability is decreased.

Source: Reprinted with permission from Krebs, H. B., Petrie, R. E., & Dunn, L. J. (1983). Atypical variable decelerations. American Journal of Obstetrics & Gynecology, 145*(3), 298. Copyright © Elsevier, 1983.*

- Baseline FHR variability
  - Minimal baseline variability
  - Absent baseline variability not accompanied by recurrent decelerations
  - Marked baseline variability
- Accelerations
  - Absence of induced accelerations after fetal stimulation
- Periodic or episodic decelerations
  - Recurrent variable decelerations accompanied by minimal or moderate baseline variability
  - Prolonged deceleration of 2 minutes or more but less than 10 minutes
  - Recurrent late decelerations with moderate baseline variability
  - Variable decelerations with other characteristics, such as slow return to baseline, "overshoots," or "shoulders"

Category III

Category III FHR tracings include either:

- Absent baseline FHR variability and any of the following:
  - Recurrent late decelerations
  - Recurrent variable decelerations
  - Bradycardia
- Sinusoidal pattern

Category I FHR tracings are normal. They are strongly predictive of normal fetal acid–base status at the time of observation. The FHR tracings may be followed in a routine manner, and no specific action is required.

Category II FHR tracings are indeterminate. They are not predictive of abnormal fetal acid–base status, yet we do not have adequate evidence at present to classify these as Category I or Category III. Category II tracings require evaluation and continued surveillance and reevaluation, taking into account the entire associated clinical circumstances.

Category III FHR tracings are abnormal. They are predictive of abnormal fetal acid–base status at the time of observation. They require prompt evaluation. Depending on the clinical

situation, efforts to expeditiously resolve the abnormal FHR pattern may include, but are not limited to, provision of maternal oxygen, change in maternal position, discontinuation of labor stimulation, and treatment of maternal hypotension.

It is important to provide information to the laboring woman regarding the FHR pattern and the interventions that will help her fetus. Sharing information with the laboring woman reassures her that a potential or actual problem has been identified and that she is an active participant in the interventions. Occasionally, a problem arises that requires immediate intervention. In that case, the nurse can say something like, "It is important for you to turn on your side right now because the baby is having a little difficulty. I'll explain what is happening in just a few moments." This type of response lets the woman know that although an action needs to be accomplished rapidly, information will soon be provided. In the haste to act quickly, the nurse must not forget that it is the woman's body and her baby.

Labor and birth nurses must be skilled and competent in evaluating electronic FHR patterns and responding appropriately (Table 23-7). Competence can be maintained through frequent in-services, formal courses, and continuing education programs.

PROFESSIONALISM IN PRACTICE

FHR and Legal Responsibilities

Nurses caring for women during childbirth are legally responsible for correctly interpreting FHR patterns, initiating appropriate nursing interventions based on those patterns, and documenting the outcomes of those interventions.

TABLE 23-7 Guidelines for Management of Variable, Late, and Prolonged Deceleration Patterns

PATTERN	NURSING INTERVENTIONS
Variable decelerations Isolated or occasional Moderate	Report findings to physician/CNM and document in chart. Provide explanation to woman and partner. Change maternal position to one in which FHR pattern is most improved. Discontinue oxytocin if it is being administered and other interventions are unsuccessful. Perform vaginal examination to assess for prolapsed cord or change in labor progress. Monitor FHR continuously to assess current status and for further changes in FHR pattern.
Variable decelerations Severe and uncorrectable	Give oxygen if indicated. Report findings to physician/CNM and document in chart. Provide explanation to woman and partner. Prepare for probable cesarean birth. Follow interventions listed above. Prepare for vaginal birth unless baseline variability is decreasing or FHR is progressively rising—then cesarean, forceps, or vacuum birth is indicated. Assist physician with fetal scalp sampling if ordered. Prepare for cesarean birth if scalp pH shows acidosis or downward trend.
Late decelerations	Give oxygen if indicated. Report findings to physician/CNM and document in chart. Provide explanation to woman and partner. Monitor for further FHR changes. Maintain maternal position on left side. Maintain good hydration with intravenous (IV) fluids (normal saline or lactated Ringer's). Discontinue oxytocin if it is being administered and late decelerations persist despite other interventions. Administer oxygen by face mask at 7–10 L/min. Monitor maternal blood pressure and pulse for signs of hypotension; possibly increase flow rate of IV fluids to treat hypotension. Follow physician's orders for treatment for hypotension if present. Increase IV fluids to maintain volume and hydration (normal saline or lactated Ringer's). Assess labor progress (dilatation and station). Assist physician with fetal blood sampling: If pH stays above 7.25, physician will continue monitoring and resample; if pH shows downward trend (between 7.25 and 7.20) or is below 7.20, prepare for birth by most expeditious means.
Late decelerations with tachycardia or variability decreasing	Report findings to physician/CNM and document in chart. Maintain maternal position on left side. Administer oxygen by face mask at 7–10 L/min. Discontinue oxytocin if it is being administered. Assess maternal blood pressure and pulse. Increase IV fluids (normal saline or lactated Ringer's). Assess labor progress (dilatation and station). Prepare for immediate cesarean birth. Explain plan of treatment to woman and partner. Assist physician with fetal blood sampling (if ordered).
Prolonged decelerations	Perform vaginal examination to rule out prolapsed cord or to determine progress in labor status. Change maternal position as needed to try to alleviate decelerations. Discontinue oxytocin if it is being administered. Notify physician/CNM of findings/initial interventions and document in chart. Provide explanation to woman and partner. Increase IV fluids (normal saline or lactated Ringer's). Administer tocolytic if hypertonus noted and ordered by physician/CNM. Anticipate normal FHR recovery following deceleration if FHR previously normal. Anticipate intervention if FHR previously abnormal or deceleration lasts greater than 3 minutes.

Indirect Methods of Fetal Assessment

When there is a question regarding fetal status, indirect methods such as **scalp stimulation** (pressing on the fetal scalp with the examining fingers during a vaginal exam to elicit an acceleration of fetal heart rate [FHR]), *acoustic stimulation* (using a sound device placed against the maternal abdomen to elicit an acceleration in FHR), or stimulation by maternal abdominal palpation (patting or shaking the abdomen) can be used to assess the fetus. Ongoing scalp stimulation is not recommended and should not be used by nurses (Tucker, Miller, & Miller, 2008). When one of the indirect methods is used, the fetus who is not in any stress responds with an acceleration of the FHR, described as a reactive response (acceleration of 15 beats per minute (beats/min) amplitude with a duration of 15 seconds). Whereas reactivity is associated with fetal well-being, the absence of acceleration does not diagnose acidemia or predict fetal compromise (Tucker et al., 2008). Further observation and assessment measures are indicated.

Cord Blood Analysis at Birth

In cases in which significant abnormal FHR patterns have been noted before birth, amniotic fluid is meconium stained, or the infant is depressed at birth, umbilical cord blood may be analyzed immediately after birth to assess the infant's respiratory status. The cord is usually clamped before the infant takes his or her first breath to provide an evaluation of blood gas status before the infant interacts with the extrauterine environment, because values can change after only a few seconds of neonatal breathing.

An 8- to 10-inch segment of the umbilical cord is double-clamped and cut, and a small amount of blood is aspirated from one of the umbilical arteries (arterial blood seems to provide the most reliable indication of blood gas status and fetal tissue pH). Blood is collected in a heparinized syringe unless it is to be analyzed immediately; it should not be allowed to remain in the segment of cord longer than 30 minutes. Some clinicians may collect a segment of cord and send blood samples only if the Apgar score is below 7 at 5 minutes, as recommended by AAP and ACOG (2007). In this instance, values might be used to clarify the cause of a low Apgar score while minimizing any medical-legal exposure and expense. Determination of pH and base deficit values can differentiate whether fetal acidemia is due to hypoperfusion of the placenta or to cord compression.

FOCUS YOUR STUDY

- Intrapartum assessment includes attention to both physical and psychosociocultural parameters of the laboring woman, assessment of the fetus, and ongoing assessment for conditions that place the woman and her fetus at an increased risk.
- Birthing room nurses have responsibilities for recognizing and interrupting fetal monitoring patterns, notifying the physician or certified nurse-midwife (CNM) of problems, and initiating corrective and supportive measures when needed.
- Uterine contractions (UCs) may be assessed externally through palpation or by an electronic monitor. An intrauterine pressure catheter can be placed internally to measure uterine activity more accurately.
- A vaginal examination determines the status of cervical dilatation, effacement, and fetal presentation, position, and station.
- Fetal presentation can also be assessed by inspection, vaginal examination, or ultrasound (US).
- Leopold's maneuvers provide a systematic evaluation of fetal presentation and position.
- Indications for electronic fetal monitoring (EFM) include fetal, maternal, and uterine factors; presence of pregnancy complications; regional anesthesia; and elective monitoring.
- The fetal heart rate (FHR) may be assessed by auscultation or electronic fetal monitoring.
- Electronic fetal monitoring (EFM) is accomplished by indirect ultrasound or by direct methods that require the placement of a spiral electrode on the fetal presenting part.
- Variability refers to baseline (BL) fluctuations of 2 cycles per minute or greater in the FHR and it is classified by the

visually quantified amplitude of peak-to-trough in beats per minute.

- The normal range of FHR is 110 to 160 beats per minute.
- Baseline changes in the FHR include tachycardia, bradycardia, and variability.
- Tachycardia is defined as a rate of 160 beats per minute or more for at least a 10-minute segment of time.
- Bradycardia is defined as a rate of 110 beats per minute or less for at least a 10-minute segment of time.
- Baseline variability is an important parameter of fetal well-being.
- Periodic changes in the FHR from baseline include decelerations and accelerations. Accelerations are normally caused by fetal movement.
- Decelerations are categorized as early, late, or variable according to NICHD categories.
- Early decelerations are due to compression of the fetal head during contractions and are generally considered benign when they occur with ongoing fetal descent. They typically do not require intervention.
- Late decelerations are associated with uteroplacental insufficiency.
- Variable decelerations are associated with compression of the umbilical cord.
- Sinusoidal patterns are characterized by an undulant sine wave.

CRITICAL THINKING IN ACTION

Source: George Dodson/Pearson Education.

Cindy Bell, a 20-year-old gravida 2, para 1 at 40 weeks' gestation, presents to you in the birthing unit with contractions every 5 to 7 minutes. She is accompanied by her husband. Spontaneous rupture of membranes occurred 2 hours prior to admission. Cindy tells you that the fluid was colorless and clear. You orient Cindy and her family to the birthing room and perform a physical assessment, documenting the following data: vital signs are normal. A vaginal exam demonstrates the cervix is 75% effaced, 4 cm dilated with a vertex at –1 station in the LOP position. You place Cindy on an external fetal monitor. The fetal heart rate baseline is 140–147 with accelerations to 156; no decelerations are noted. Contractions are 5–6 minutes apart, moderate intensity and lasting 40–50 seconds. Cindy states she would like to stay out of bed as long as possible because lying down seems to make the contractions more painful, especially in her back.

1. Discuss the benefits of ambulation in labor.
2. Cindy would like her daughter to be present for the baby's birth. What would you discuss with her about the impact of having a young sibling present during labor and birth?
3. What fetal heart rate assessment will best ensure fetal well-being during the period Cindy is ambulating?
4. When a nonreassuring fetal heart pattern is detected, what remedial nursing intervention is carried out?
5. What are indications for continuous fetal monitoring in labor?

CHAPTER 24

The Family in Childbirth: Needs and Care

The moment our daughter was born, time seemed to stand still. We couldn't keep our eyes off of her. I remember vividly the first time I touched her tiny finger and stroked her cheek. Those moments together as a family are forever engraved in my memory.

LEARNING OUTCOMES

1. Identify nursing diagnoses specific to the first, second, third, and fourth stages of labor.
2. Describe factors that are assessed in the laboring woman during the admission process.
3. Discuss the components of a social history and its role in caring for the laboring woman.
4. Summarize the importance of incorporating family expectations and cultural beliefs into the nursing care plan.
5. Discuss nursing interventions to meet the care needs of the laboring woman and her partner during each stage of labor.
6. Describe nursing interventions for promoting the woman's comfort during each stage of labor.
7. Summarize immediate nursing care of the newborn following birth.
8. Discuss the components of care for the woman during the third stage of labor.
9. Discuss initial measures to help the woman and family integrate the newborn into family life.
10. Explore the nurse's role in providing sensitive care to adolescent parents.
11. Delineate management of a nurse-managed precipitous birth.

KEY TERMS

Apgar score *620*
Hyperventilation *611*
Precipitous birth *630*

It is time for a child to be born. The waiting is over; labor has begun. The dreams and wishes of the past months fade as the expectant family faces the reality of the tasks of childbearing and childrearing that are ahead.

The couple is about to undergo one of the most meaningful and stressful events in their life together. Physical and psychologic resources, coping mechanisms, and support systems will all be challenged. Despite months of childbirth education classes, the laboring woman may question her ability to cope with labor and to meet her own expectations of herself. The partner may wonder whether he will be able to provide the support his partner and newborn will need. They may worry about the baby's health. Although they look forward to the birth of their baby, they are entering an unfamiliar landscape where, even with prenatal preparation, unknown possibilities await them.

Some childbearing families may worry that they will not be provided with adequate care during labor due to lack of medical insurance or healthcare coverage. In 1986, the Emergency Medical Treatment and Labor Act (EMTLA) was passed by Congress to ensure that patients requiring emergency medical services, including women in labor, had access to medical services regardless of their ability to pay for services (U.S. Department of Health and Human Services, 2010).

Many childbearing families look to the nurse for support and guidance. Indeed, for laboring women who are admitted alone, the nurse may be their sole support. It is essential, therefore, to provide holistic care that addresses the patient's or couple's physiologic, psychologic, and comfort needs throughout the challenging and emotional process of labor and birth.

The previous two chapters present information that lays the foundation for this chapter. Chapter 22 ∞ presents a database of information regarding physiologic and psychologic changes during labor and birth, and chapter 23 ∞ discusses intrapartum assessment. This chapter discusses nursing care during labor and birth. The Clinical Pathway on pages 596–598 summarizes nursing care of the childbearing family in the first through fourth stages of labor and birth.

Nursing Diagnosis During Labor and Birth

In devising a plan of care for the intrapartum period, the nurse can develop a general plan that encompasses the whole process, from the beginning of labor through the fourth stage, or the nurse can develop a plan for each stage of labor and birth. The nurse's plan and actions are based on current findings from nursing and medical research. By providing evidence-based guided care, the nurse ensures that the woman and her family are appropriately cared for during their labor and birth. An overall plan presents an overview of the whole process, but it is usually general in nature. A plan of care that identifies nursing diagnoses for (at least) each stage provides an opportunity to identify more specific nursing interventions.

In the first stage of labor, nursing diagnoses that may apply include the following:

- ***Fear/Anxiety*** related to discomfort of labor and unknown labor outcome
- ***Health-Seeking Behaviors: Health Education Regarding Information About the Fetal Monitor*** related to an expressed desire to understand equipment used
- ***Compromised Family Coping*** related to labor process
- ***Acute Pain*** related to uterine contractions, cervical dilatation, and fetal descent
- ***Deficient Knowledge*** related to lack of information about normal labor process and comfort measures
- ***Fear/Anxiety*** related to unknown birth outcome and anticipated discomfort

Nursing diagnoses for the second and third stages may include the following:

- ***Acute Pain*** related to uterine contractions, birth process, and/or perineal trauma from birth
- ***Deficient Knowledge*** related to lack of information about pushing methods
- ***Ineffective Coping*** related to birth process
- ***Fear/Anxiety*** related to outcome of birth process

In the fourth stage, possible nursing diagnoses include the following:

- ***Acute Pain*** related to perineal trauma
- ***Deficient Knowledge*** related to lack of information about involutional process and self-care needs
- ***Readiness for Enhanced Family Processes*** related to incorporation of the newborn into the family

Nursing Care During Admission

Many families worry that they will not reach the birthing center in time for the birth or that cues indicating the onset of labor will be missed. Sometimes labor occurs so rapidly that birth is imminent upon admission. Usually, the family is advised to arrive at the birth setting at the beginning of the active phase of labor or when the following occur:

- Rupture of membranes (ROM)
- Decreased fetal movement
- Regular, frequent uterine contractions (UCs) (nulliparas, about 5 minutes apart for 1 hour; multiparas, 6 to 8 minutes apart for 1 hour)
- Any vaginal bleeding

If time permits and the family is not familiar with what will occur during labor, the nurse can provide information on admission. (See Patient Teaching: What to Expect During Labor.)

The family may be facing a number of unfamiliar procedures that are routine for healthcare providers. It is important to remember that each woman has the right to determine what happens to her body. Informed consent should be obtained before any procedure that involves touching the body.

Establishing a Positive Relationship

The initial interaction with the nurse and how it is perceived by the woman and her partner greatly influences the course

CLINICAL PATHWAY For Intrapartum Stages

Category	First Stage	Second and Third Stage	Fourth Stage Birth to 1 Hour Past Birth
Referral	Review prenatal record Advise CNM/physician of admission	Labor record for first stage	Report to recovery room nurse ■ ***Expected Outcomes*** Appropriate resources identified and utilized
Assessments	Admission assessments: Ask about problems since last prenatal visit; labor status (contraction frequency and duration), membrane status (intact or ruptured); coping level; support; woman's desires during labor and birth; ability to verbalize needs; laboratory testing (blood and UA) Intrapartal assessments: Cervical assessment: from 1 to 10 cm dilatation; nullipara (1.2 cm/h), multipara (1.5 cm/h) Cervical effacement: from 0% to 100%, multiparas may not fully efface prior to birth. Fetal descent: progressive descent from −4 to +4 Membrane assessment: intact or ruptured; when ruptured, Nitrazine positive, fluid clear, no foul odor Comfort level: woman states is able to cope with contractions Behavioral characteristics: facial expressions, tone of voice, and verbal expressions are consistent with comfort level and ability to cope Latent Phase: • BP, P, R q30min for low-risk women and q15min for high-risk women if in normal range (BP 90–135/60–85 or not greater than 30 mm Hg systolic or 15 mm Hg diastolic over baseline; pulse 60–90; respirations 12–24/min, quiet, easy) • Temp every 4h unless greater than 37.6°C (99.6°F) or membranes ruptured then q1h • Uterine contractions q30min for low-risk women and q15min for high-risk women (contractions q5–10min, 15–40 sec, mild intensity) • FHR q30min (for low-risk women) and q15min (for high-risk women) if reassuring (reassuring FHR has: baseline 110–160, variability present, average, accelerations with fetal movement, no late decelerations); if nonreassuring, position on side, start O_2, assess for hypotension, monitor continuously, discontinue Pitocin if infusing, notify CNM/physician Active Phase: • BP, P, R, q30min if WNL for low-risk women and q15min for high-risk women • Temp as above • Uterine contractions q15–30min: contractions q2–3min, 60 sec, moderate to strong • FHR q30min (for low-risk women) and q15min (for high-risk women) if reassuring; if nonreassuring institute interventions Transition: • BP, P, R, q30min • Uterine contractions q30min for low-risk women and q15min for high-risk women; contractions q2min, 60–75 sec, strong • FHR q30min for low-risk women and every 15 minutes for high-risk women if reassuring; if nonreassuring, see above	Second stage assessments: • BP, P, R q5–15min • Uterine contractions palpated continuously • FHR q15min (for low-risk women) and q5min (for high-risk women) if reassuring; if nonreassuring, monitor continuously Fetal descent: descent continues to birth Comfort level: woman states is able to cope with contractions and pushing Behavioral characteristics: response to pushing, facial expressions, verbalization Third stage assessments: • BP, P, R q5min • Uterine contractions, palpate occasionally until placenta is delivered, fundus maintains tone and contraction pattern continues to birth of placenta Newborn assessments: • Assess Apgar score of newborn • Respirations: 30–60, irregular • Apical pulse: 110–160 and somewhat irregular • Temperature: Skin temp above 36.5°C (97.8°F) • Umbilical cord: two arteries, one vein (if one artery, assess for anomalies and urine output) • Gestational age: 38–42 weeks	Immediate postbirth assessments of mother q15min for 1h: • BP: 90–135/60–85; should return to prelabor level • Pulse: slightly lower than in labor; range is 60–90 • Respirations: 12–24/min; easy; quiet • Temperature: 36.2–37.6°C (98–99.6°F) • Fundus firm, in midline, at the umbilicus • Lochia rubra; moderate amount; less than 2 pad/h; no free flow or passage of clots with massage • Perineum: sutures intact; no bulging or marked swelling; minimal bruising may be present; no c/o severe pain nor rectal pain • Bladder nondistended; spontaneous void of greater than 100 ml clear, straw-colored urine; bladder nondistended following voiding • If hemorrhoids present, no tenseness or marked engorgement; less than 2 cm diameter Comfort level: less than 3 on scale of 1 to 10 Energy level: awake and able to hold newborn Newborn assessments if newborn remains with parents: • Respirations: 30–60; irregular • Apical pulse: 110–160 and somewhat irregular • Temperature: skin temp above 36.5°C (97.8°F); skin feels warm to touch • Skin color noncyanotic • Mucus: small amount, clear, easily suctioned with bulb syringe without skin color change • Behavioral: newborn opens eyes widely if room is slightly darkened • Movements rhythmic; no hand tremors present ■ ***Expected Outcomes*** Findings indicate normal progression with absence of complications

CLINICAL PATHWAY For Intrapartum Stages continued

Category	First Stage	Second and Third Stage	Fourth Stage Birth to 1 Hour Past Birth
Teaching/ psychosocial	Establish rapport Orient to environment, expected assessments, and procedures Answer questions and provide information Orient to EFM if used Teach relaxation, visualization, and breathing pattern if needed Explain comfort measures available Assume advocacy role for woman/family during labor and birth	Orient to expected assessments and procedures Answer questions and provide information Explain comfort measures available Continue advocacy role	Explain immediate assessments and care after this first hour Teach self-massage of fundus and expected findings Instruct to call for assistance if mother desires to get OOB Begin newborn teaching; bulb syringe, positioning; maintaining warmth Assist parents in exploring their newborn Assist with first breastfeeding experience ***Expected Outcomes*** Patient and partner verbalize/demonstrate understanding of teaching
Nursing care management and report	Straight cath prn if bladder distended If regional block administered monitor BP, FHR, sensation per protocol Provide continuing status reports to CNM/physician Perform sterile vaginal examination as indicated	Indwelling catheter or straight cath prn if bladder distended Continue monitoring VS, FHR, and sensation if regional block has been given	Straight cath if bladder distended Monitor return of motor ability and sensation if regional block has been given Weigh perineal pads if lochia flow greater than 1 saturated pad in 15 min, presence of boggy uterus and clots; ↓ BP, ↑ P ***Expected Outcomes*** • Maternal/fetal well-being maintained and supported • Mother and newborn experience safe labor and birth • Family participates in process as desired
Activity	Encourage ambulation unless contraindicated Maintain bed rest immediately after administration of IV pain medication, or following regional block Woman rests comfortably between contractions	Position comfortably for birth Woman rests comfortably between pushing efforts and while awaiting birth of placenta	Position of comfort ***Expected Outcomes*** • Activity maintained as desired unless contraindicated • Comfort enhanced by positioning/ movement
Comfort	Institute comfort measures: ambulation, frequent position change, effleurage, focal point, patterned paced breathing, visualization, therapeutic touch, backrub, moist cloths to face, holding hand, words of encouragement, changing underpad, shower, whirlpool, staying with the woman/family, warmed blanket at back, sacral pressure Offer pain medication or administer if requested Assist with administration of regional block	Institute comfort measures: • Second stage: cool cloth to forehead, encouragement, coaching, help support legs while pushing, position of comfort for pushing and birth • Third stage: cool cloth to forehead, assist parents to see newborn, position mother to hold newborn, provide encouragement	Institute comfort measures: • Perineal discomfort: gently cleanse and apply ice pack; position to decrease pressure on perineum • Uterine discomfort; palpate fundus gently • Hemorrhoids: ice pack • General fatigue: position of comfort, encourage rest • Administer pain medication PRN ***Expected Outcomes*** Optimal comfort level maintained Active reduction of pain/discomfort achieved
Nutrition	Ice chips and clear fluids Evaluate for signs of dehydration	Ice chips and clear fluids	Regular diet if assessments are WNL Encourage fluids ***Expected Outcomes*** Nutritional needs met
Elimination	Voids at least q2h; urine clear, straw-colored, negative for protein Bladder nondistended May have bowel movement Monitor I&O with IVs	May void spontaneously with pushing May pass stool with pushing	Voids spontaneously ***Expected Outcomes*** Urinary bladder and bowel function unimpaired

(continued)

CLINICAL PATHWAY For Intrapartum Stages continued

Category	First Stage	Second and Third Stage	Fourth Stage Birth to 1 Hour Past Birth
Medications	Administer pain medication per woman's request	Local infiltration of anesthetic agent for birth by CNM/physician Pitocin 10–20 units IM, IVP per IV, tubing, or added to IV fluids	Continue Pitocin infusion Administer pain medication PRN ■ ***Expected Outcomes*** Comfort enhanced by pain-relieving techniques, administration of analgesia agent or an analgesic or anesthetic block
Discharge planning	Evaluate knowledge of labor and birth process Evaluate support system and need for referral after birth		Provide information if mother to be moved from LDR room Provide opportunity for parents to ask questions regarding newborn Evaluate knowledge of normal postpartum, newborn care ■ ***Expected Outcomes*** Mother and newborn transferred to low-risk postpartal and newborn care
Family involvement	Identify available support person(s) Recognize possible impact of culture on responses Observe interaction between woman and partner Create moment alone with woman to identify possible abuse Assess current parenting skills	Provide opportunities for woman and support person(s) to watch newborn assessments Perform newborn assessment on mother's abdomen/chest if possible	Provide opportunity for parents to be with baby Encourage skin-to-skin contact Darken room to encourage eye-to-eye contact Provide quiet time for new family Parenting: demonstrates early culturally expected parenting behaviors ■ ***Expected Outcomes*** • Incorporation of newborn into family • Family verbalizes comfort with newborn care
Date			

Abbreviations: CNM, certified nurse-midwife; BP, blood pressure; FHR, fetal heart rate; LTV long-term variability; WNL, within normal limits; VS, vital signs; EFM, electronic fetal monitoring; IV, intravenous; I&O, intake and output; IM, intramuscularly; IVP, intravenous push; LDR, labor, delivery, and recovery; OOB, out of bed; UA, urinary analysis; PRN, as needed

of her hospital stay. For some women, the hospital environment itself can be perceived as cold, impersonal, and technical and can produce anxiety or emotional stress. If the family is greeted in a brusque, harried manner, they are less likely to look to the nurse for support. A calm, pleasant manner, in contrast, indicates to the family that they are important. It helps instill in the couple a sense of confidence in the staff's ability to provide quality care and ensure safety during this critical time.

It is important to establish rapport and to create an environment in which the family feels free to ask questions. The support and encouragement of the nurse in maintaining a caring environment begins with the initial admission but needs to be attended to with all subsequent actions. Before completing assessments, the nurse may provide the opportunity for questions and may explain the environment and the procedures that will be a part of the labor and birthing care. In many hospitals, the admission process also includes signing an informed consent for treatment, and the patient is given information on arranging advance directives or instructions about her wishes if she were to become critically ill. In all cases, an identification bracelet and a bracelet that lists all known drug allergies are attached to her wrist.

Another important aspect of the initial contact is communicating in the woman and family's primary language. In addition to having interpreters available for Hispanic, Korean, Vietnamese, and other patients who do not speak English fluently, the nurse must consider the special needs of the deaf woman or family. There are more than 400,000 Americans who have a bilateral hearing loss, so there is a good chance that the nurse will work with a deaf expectant mother, father, grandparents, or siblings at some point. Table 24-1 provides suggestions for communicating more effectively with a woman or support person who is deaf.

Culture plays a major role in how a woman and her family view the labor and birth process. Trends in American culture are moving toward a shared partnership model between the woman and her partner in which the partner is actively involved in the birth process and often stays with the mother throughout the labor and birth. In contrast, Iranian and Turkish women are less likely to have their partner with them in the labor and birth setting. Instead, this is primarily the role of elder women family members and female friends (Ozsoy & Katabi, 2008).

PATIENT TEACHING What to Expect During Labor

ASSESSMENT As the woman is admitted into the birthing area, assess the woman's knowledge regarding the childbirth experience. Her knowledge base will be affected by previous births, attendance at childbirth education classes, and the amount of information she has been able to gather during her pregnancy by asking questions or reading. You may also assess the factors that affect communication and anxiety level. Assess labor progress to determine what to teach and the time available for teaching. If the woman is in early labor and she needs additional information, proceed with teaching.

NURSING DIAGNOSIS The key nursing diagnosis will probably be ***Deficient Knowledge*** related to lack of information about nursing care during labor.

NURSING PLAN AND IMPLEMENTATION The teaching plan will focus on the assessments and support the woman will receive during labor.

PATIENT GOALS At the completion of teaching, the woman will be able to:

- Verbalize the assessments the nurse will complete during labor
- Discuss the support and comfort measures that are available

TEACHING PLAN

Content	Teaching Method
■ Describe aspects of the admission process, including:	Provide information on the basic assessment and care activities.
■ Taking an abbreviated history	Allow time for questions and discussion as labor progress permits.
■ Physical assessment (maternal vital signs [VS], fetal heart rate [FHR], contraction status, status of membranes)	
■ Assessment of uterine contractions (frequency, duration, intensity)	
■ Orientation to surroundings	
■ Introductions to other support staff	
■ Determination of woman's and family support person's expectations of the nurse	
■ Present aspects of ongoing physical care, such as when to expect assessment of material VS, FHR, and contractions.	
■ If the electronic fetal monitor is used, describe how it works and the information it provides. Orient the woman to the sights and sounds of the monitor. Explain what "normal" data will look like and what characteristics are being watched for.	Demonstrate the fetal monitor.
■ Be sure to note that assessments will increase as the labor progresses, especially during the transition phase (usually the time the woman would like to be left alone) to help keep the mother and baby safe by noting deviations from normal course.	
■ Describe the vaginal examination and the information it elicits.	Use a cervical dilatation chart to illustrate the amount of dilatation.
■ Review comfort techniques that may be used in labor and ascertain what the woman thinks will promote comfort.	Focus on open discussion.
■ Review the breathing techniques the woman has learned so that you will be able to support her technique.	Ask the woman to demonstrate the techniques she has learned.
■ Review comfort and support measures, such as positioning, backrub, effleurage, touch, distraction techniques, and ambulation.	Focus on open discussion.
■ If the woman is in early labor, offer her a tour of the birthing area.	Provide a tour of birthing area, explaining equipment and routines. Include the woman's partner.

Evaluation

At the end of this teaching session, the woman will be able to describe the assessments that will occur during her labor and to discuss comfort and support measures that may be used.

Documentation

Documentation of patient teaching should include the teaching information discussed, the patient's verbalization of understanding, and specific interventions or warning signs that were given, along with the patient's understanding of follow-up, if needed in the future.

TABLE 24-1 Improving Communication with a Deaf Woman or Support Person

- Determine how the deaf individual prefers to communicate: speech reading (lip reading), sign language, pantomime, writing, or a combination of methods.
- If speech reading is used, face the person directly, speak with a natural tone and rhythm (exaggerated pronunciation may distort lip movements), and keep your hands away from your face. Do not chew gum.
- Use gestures and pantomime if necessary to enhance your speech.
- Do not assume written communication is the most effective approach. Writing carries a great potential for miscommunication and should not be forced unless the deaf person requests it.
- Most deaf individuals in the United States use American Sign Language (ASL) (see appendix E ∞). If the woman signs, call a professional ASL interpreter.
- Use a family member as an interpreter only until the professional interpreter arrives. Family members may not interpret all that is said or may add additional information. Professional ASL interpreters are bound by a code of ethics to maintain strict confidentiality, to transmit accurate messages, and to refrain from editing or adding information.
- Keep the woman's dominant hand and arm free for signing.
- Explain any procedures before they are needed.
- Look at the deaf individual, not the interpreter, when speaking.
- Speak in first person to the patient.
- Be alert for signs of "smiling and nodding." Often, when a deaf person does not understand something, the person will simply smile and nod. If that occurs, assess the person's understanding by asking the person to repeat the information to you.

Source: Adapted from Shelp, S. G. (1997). Your patient is deaf, now what? RN, 60*(2), 37–38, 40. Reprinted by permission of Medical Economics. Montvale, NJ.*

Labor Assessment

Following the initial greeting, the woman may either be taken into a labor assessment area (sometimes called a *triage area*) for evaluation or admitted directly into a birthing room. Some couples prefer to remain together during the admission process, and others prefer to have the partner or support person wait outside. The nurse should ask the woman's preference whenever possible. As the nurse helps the woman undress and get into a hospital gown, the nurse can begin to develop rapport and establish the nursing database. The labor and birth nurse can obtain essential information regarding the woman and her pregnancy. By doing an admission history, the nurse can initiate any immediate interventions needed and establish individualized priorities. The nurse is then able to make effective nursing decisions regarding intrapartal care:

- Is the woman in labor or is she a candidate to be sent home with a clear understanding of when to return?
- Are there factors that put the laboring woman or the fetus at risk?
- Should ambulation or bed rest be encouraged?
- Is more frequent monitoring needed?
- What does the woman or couple want during labor and birth?
- Who will be with the laboring woman for social support?

The woman is made comfortable. If she wants to rest in bed, a side-lying or semi-Fowler's position rather than a supine position is most comfortable and avoids supine hypotensive syndrome (vena caval syndrome).

After obtaining the essential information from the woman and her prenatal records from her certified nurse-midwife (CNM) or physician, the nurse begins the intrapartal assessment (chapter 23 ∞ discusses intrapartal assessment in depth).

As the assessments begin, the nurse auscultates the fetal heart rate (FHR). (Detailed information on monitoring FHR is presented in chapter 21 ∞.) The woman's blood pressure, pulse, respirations, and oral temperature are assessed. Contraction status (frequency, duration, and intensity), cervical dilatation and effacement, and fetal presentation and station are determined. If the woman is a nullipara in the early latent phase (for example, contractions are 10 to 30 minutes apart, with mild intensity and very little discomfort; cervix is long and thick, with dilatation of 1 to 2 cm; membranes are intact) she may be sent home to ambulate and rest in her own surroundings or directed to remain in a birthing center area and ambulate. When further progress is documented, she is admitted. Women who are admitted in the latent phase are more likely to have a longer duration of labor, increased use of epidural analgesia for pain, and increased use of oxytocin to augment labor than women who are clearly in the active phase at admission.

After the vaginal examination, the nurse shares the findings with the couple. If there are signs of advanced labor (frequent contractions, advanced cervical dilatation, and/or an urge to bear down), the physician or CNM is notified immediately, and actions are taken to prepare for the birth. If there are signs of excessive bleeding upon admission or if the woman reports episodes of painless bleeding in the last trimester, placenta previa may be present; in such cases, vaginal examination is not performed because it may stimulate copious bleeding.

Results of FHR assessment, uterine contraction evaluation, and the vaginal examination help determine whether the rest of the admission process can proceed at a more leisurely pace or whether additional interventions have higher priority. For example, an FHR of 110 beats per minute (beats/min) on auscultation indicates that an electronic fetal monitor (EFM) should be applied immediately to obtain additional data. The woman's vital signs will then be assessed immediately (Table 24-2).

Depending on how rapidly labor is progressing, the nurse notifies the CNM or physician before or after completing the admission procedures. If high-risk or emergency data are identified, the nurse immediately reports the findings to the CNM or physician; otherwise all assessment data should be gathered before initiating contact with the healthcare provider (Carolan, 2009). The report should include the following information: cervical dilatation and effacement, station, presenting part, status of the membranes, contraction pattern, FHR, vital signs that are not in the normal range, the woman's wishes, and her response to labor.

Collecting Laboratory Data

After admission data are obtained, multiple laboratory tests are performed to provide more extensive physiologic data that are

TABLE 24-2 Indicators of Normal Labor Process on Admission

INDICATOR	NORMAL CHARACTERISTICS
Uterine contractions	Frequency of not less than 2 minutes Duration of less than 75 seconds Uterine relaxation between contractions Most intense discomfort only with contractions (Some women, especially those with occiput posterior position, complain of less intense lower abdominal and/or back pain between contractions.)
Fetal heart rate	Rate 110–160 with average variability Absence of late decelerations
Maternal vital signs	BP below +140/90 or less than +30/+15 above prepregnancy readings Pulse 60–100 Temperature between 97.8°F and 99.6°F (36.5°C and 37.5°C)
If membranes ruptured	Fluid clear without odor

used to determine appropriate care for the woman and her fetus. A clean-voided midstream urine specimen is usually collected. The woman with intact membranes may collect her specimen in the bathroom. The nurse can test the woman's urine for the presence of protein, ketones, glucose, and leukocytes by using a dipstick before sending the sample to the laboratory. This procedure is especially important if nondependent edema or elevated blood pressure is noted on admission. Proteinuria of +1 or more may be a sign of preeclampsia. Glycosuria is found frequently in pregnant women because of the increased glomerular filtration rate in the proximal tubules and the inability of these tubules to increase glucose reabsorption. However, it may also be associated with gestational diabetes and should not be discounted. Leukocytes can be found in the urine when bacteria are present. The presence of a urinary tract infection can contribute to uterine irritability, pelvic pressure, and back pain, all symptoms that can be mistaken for labor.

Laboratory tests can be performed in the outpatient setting before admission but are most commonly done at the time of admission in the birthing center. Hemoglobin and hematocrit values help determine the oxygen-carrying capacity of the circulatory system and the ability of the woman to withstand blood loss at birth. Elevation of the hematocrit indicates hemoconcentration of blood, which occurs with edema or dehydration. A low hemoglobin, in the absence of other evidence of bleeding, suggests anemia. Blood may be typed and crossmatched if the woman is in a high-risk category, has active bleeding, or has a history of blood disorders. A serology test for syphilis is obtained if one has not been done in the last 3 months or if an antepartal serology result was positive. The Centers for Disease Control and Prevention (CDC) recommends that all women undergo voluntary screening for HIV during pregnancy. Women who have not been screened during the pregnancy should be screened for HIV in the intrapartum setting once consent has been obtained (Udeh, Udeh, & Graves, 2008).

Social Assessment

Once initial physical assessments are performed, the nurse can then take a detailed social history that provides a comprehensive view of both the woman's social habits and psychologic factors that may affect her birth experience. The presence of certain risk factors—including family violence or sexual assault (see chapter 9 ∞); use of drugs, alcohol, or tobacco; and presence of sexually transmitted infections—can influence a

RESEARCH EVIDENCE IN PRACTICE

Routine Perineal Shaving on Admission in Labor

CLINICAL QUESTION

Does routine perineal shaving on admission in labor provide any benefit for the mother?

RESEARCH EVIDENCE

In some parts of the world, women may have their pubic hair shaved with a razor when they are admitted to the hospital to give birth. This is based on the belief that shaving reduces the risk of infection if the perineum tears or if an episiotomy is necessary. It is thought that shaving may make suturing of lacerations easier and may help with instrument-assisted births.

The Cochrane Collaborative sponsored a review of the research evidence regarding the effects of perineal shaving. The Cochrane Database of Systematic Reviews is a source of high quality, research-based evidence.

The review found no benefit from routine perineal shaving. Controlled trials involving more than 1000 women were reported in this review. Each used antiseptic skin preparation and compared perineal shaving with simply cutting hairs on the vulva to less than a centimeter. No differences were found between the women who were shaved and those who were not. While there were no differences in wound infection, the incidence of open wounds, and ease of suturing, there were differences in complaints in the weeks following the birth. Women who had their perineum shaved complained of irritation, redness, multiple superficial scratches from the razor, and burning and itching of the vulva.

WHAT QUESTIONS REMAIN UNANSWERED?

Does it remain necessary to clip the hair of the vulva and perineum? Is the simple application of antiseptic as effective as clipping the hair? Is shaving effective in developing countries where antiseptic may not be available?

WHAT IS BEST PRACTICE?

The application of antiseptic and clipping of longer hairs in the perineum is as effective as shaving, without the complaints that accompany regrowth of pubic hair.

CRITICAL THINKING

How can the mother be reassured that perineal shaving is unnecessary?

Basevi, V., & Lavender. T. 2009. Routine perineal shaving on admission to labor. *Cochrane Database of Systematic Reviews,* Issue 4. Art. No.: CD001236. doi:10.1002/14651858

Care Plan Activity: Presence of Extended Family

woman's labor, birth, and future childrearing choices. With the prevalence of domestic violence, it is imperative to ask the woman about family violence and sexual assault (Chambliss, 2008). Because many women find questions about psychosocial risk factors embarrassing, the nurse should always ask such questions when the woman is alone and should use a straightforward, nonjudgmental approach. For example, a question such as "How many times per week do you drink alcohol?" prompts the woman to be specific in her answer. If the woman reports that she does drink alcohol on a daily basis, the nurse then asks about the amount. Drug use can be assessed in a similar manner.

A social assessment should also include data about the woman's current living situation, availability of resources, preparedness for the infant, community resources, and the woman's social support network. This dialog provides an opportunity for the nurse to continue to build support, to provide information when requested, and to be direct yet supportive. Referrals to social services, the Special Supplemental Food Program for Women, Infants, and Children (WIC), and new parent support programs can be initiated. It is important to begin this dialog early in the admission process so that adequate resources can be obtained for the family.

Documentation of Admission

A nursing admission note is entered into the computer or the charting system. The admission note should include the reason for admission; the date, time, and method of the woman's arrival; notification of the CNM or physician; the condition of the woman and her baby; labor and membrane status; and pertinent social assessment information (Simpson & Creehan, 2008). Her comfort level and support system should also be addressed. For a woman who speaks a different language, an interpreter should be provided, and documentation should include that the interpreter was used and that the woman verbalized understanding.

Nursing Care During the First Stage of Labor

After completing the nursing assessment and diagnosis steps, the nurse creates a plan of care to achieve nursing goals (Simpson & Creehan, 2008). During the first stage of labor, the nurse is concerned about the physical safety of the laboring woman and her child, as well as the emotional well-being of the laboring couple and their support system. Therefore, the nurse continually assesses the effects of uterine contractions (UCs) on the course of labor and the well-being of the fetus, and monitors the woman's vital signs (VS), contraction pattern, cervical changes, and intake and output. Additionally, the nurse monitors the couple's and support system's responses to labor.

Developing a Birth Plan

Labor support is a primary role for nurses who are caring for couples during the first stage of labor. Couples look to their nurse for information about labor progress, pain management, procedures, and examinations, and for assistance with pain management techniques such as breathing and relaxation. Couples need reassurance that labor is progressing in normal trajectory and explanations when it is not within normal limits. They also need praise for their accomplishments and support during labor. For most couples, the nurse's presence in the room is highly valued as labor advances; however, the nurse should assess the woman's individual preferences, because some women may prefer privacy. Clinical research has established that laboring women have fewer complications and shorter labors when they perceive support from their nurse, doula, and/or friends and family members (Barnett, 2008; McGrath & Kennell, 2008).

Integration of Family Expectations

Laboring families have certain expectations of the experience, of themselves, of the nurse, and of the physician or certified nurse-midwife (CNM). Some of these expectations may not be realistic. Unrealistic expectations can increase the anxiety level of both the laboring woman and her partner. The labor nurse should assess the family's expectations to integrate them into the labor plan and/or assist the family in reestablishing expectations that are realistic. Some families may present to the facility with a birth plan (discussed in chapter 13 ∞). The plan should be reviewed and requests should be incorporated into the woman's nursing care plan whenever possible. Requests that cannot be met should be discussed and a clear rationale should be provided.

Laboring families' expectations of the nurse can range from wanting the nurse to be highly involved in the labor, to wanting the nurse to be minimally involved (Barnett, 2008). The couple who desires high involvement expects the labor nurse to be in the room continuously and to provide direct labor support. The couple may view the labor nurse as the woman's primary labor coach, providing guidance and emotional support. The couple who desires minimal involvement of the labor nurse prefers that the nurse is present only when assessments and interventions need to be done and when the couple requests the nurse's presence.

With the variety of expectations patients have of nurses, it becomes a challenge to provide individualized care. The nurse needs to assess and respond to the couple's needs and desires. To determine preferences, the nurse can look for cues. When the woman and her coach are admitted, do they seem to take control and know what is going to happen? Do they have a birth plan that they have already worked out, or do they seem hesitant and unsure of the process?

Although these two ends of the spectrum are obvious, they are a starting point. It would be fairly safe to assume that the "situation-is-in-control" couple would want a little less involvement, and the couple who is hesitant and asking questions will want more extensive involvement. The nurse can also gain more information by asking questions such as, "Other than the assessments that I will be making, what kind of involvement would you like from me? Would you like to call me when you need something or have me come in now and then, or would you be more comfortable if I stay in the room most of the time?" This gives the couple an opportunity to make their wishes known. This approach also provides the couple with the opportunity to ask questions and seek advice as needed. It is also important that the couple knows that the nurse understands that their wishes may change during labor and that the nurse will be available for them throughout the process.

During the labor process, the nurse also serves as an advocate for the woman and her partner. The partner may need support, guidance, or an opportunity for rest periods. The nurse models behavior to family members who may feel uncomfortable or uneasy in the labor and birth setting (Sauls, 2007).

Integration of Cultural Beliefs

Values, customs, and practices of different cultures are as important during labor as they are in the prenatal period. Research indicates that an individual's experiences in labor are highly dependent upon social and cultural norms (Reitmanova & Gustafson, 2008). Without this knowledge, a nurse is less likely to understand a family's behavior and may impose personal values and beliefs upon them. As cultural sensitivity increases, so does the likelihood of providing high-quality care (Spector, 2008).

The following sections briefly present a few possible cultural responses to labor. Additional information on culturally sensitive care is provided in chapter 2 ∞. It is difficult to present such a limited discussion without appearing to advance stereotypes. No statement of a specific behavior can accurately reflect the preference of all people in a group. Within every culture, each person develops his or her own beliefs and value system. Nurses must regard general information about any culture or belief system as background information to help them determine the person's own needs and desires.

CLINICAL TIP

It is best not to assume that women of any culture have the information they desire regarding birth, self-care, and newborn care, regardless of the number of children they have had. An important aspect of nursing is to teach, so always offer culturally sensitive information. Most nurses are not knowledgeable regarding all cultural practices. So be sensitive, and ask what is important to the mother. For example, is there special clothing she wants the newborn to wear, or does she have any preference about how she wants the umbilical stump cared for? Remain aware that the information you learned in class or a text reflects primarily the nursing culture and the Western, chiefly European, culture. To believe that the healthcare practices of these two cultures are relevant to all people is an example of ethnocentrism. Strive to increase your understanding of other cultures as your clinical practice base grows.

Modesty

Modesty is an important consideration for women, regardless of the culture to which they belong. However, some women may be more uncomfortable than others with the degree of exposure needed for some procedures during the labor and birth processes. Some women may be particularly uncomfortable when men are present and feel more comfortable with women; others may be uncomfortable with exposure of personal body parts regardless of the gender of the examiner or person who assists them. The nurse needs to be observant of the woman's responses to examinations and procedures and to provide appropriate draping and privacy (Spector, 2008). It is more prudent to assume that embarrassment will occur with exposure and take measures to provide privacy than to assume that it will not matter to the woman.

CLINICAL JUDGMENT

Case Study: Fatima Al Ahala

Fatima Al Ahala is a 22-year-old G1 who presents in labor. Fatima and her husband, Samir, are from Pakistan. The couple has stated that they can only accept care from female providers. The couple is being attended by a female nurse-midwife and the back-up physician is also a female. When her labor intensifies, Fatima requests an epidural. The only anesthesiologist available is a male physician.

Critical Thinking

What actions can you take to help this family meet their cultural preferences?

See www.nursing.pearsonhighered.com for possible responses.

For example, many Hispanic women may fear loss of privacy, so they labor at home as long as possible. Maintaining dignity for the couple is important (Spector, 2008). Some Asian women are not accustomed to male physicians and attendants, and some Muslims forbid any male (other than the husband) to see a woman who is uncovered. The nurse should be aware that in the Muslim culture, the man is the primary source of information. It may be necessary to speak to the man before interacting with the woman. This communicates respect and shows cultural sensitivity. The nurse should ensure coverage of the woman whenever possible, even during vaginal exams and the second stage (Spector, 2008).

Pain Expression

Women's reactions to the discomfort of labor vary greatly. Some turn inward and remain very quiet during the whole process, whereas others may be very vocal, with behaviors such as counting out loud, moaning quietly or loudly, crying, or cursing. They may also turn from side to side or change positions frequently. The nurse supports a woman's individual expression of pain, whatever it may be, to enhance the birthing experience for mother, baby, and family.

In the Korean culture it used to be important for the laboring woman to be silent so she would not bring shame on her family. However, today women are encouraged to be less passive. Vocalization is more common, although older in-laws or other family members may discourage shouting or outcries as aggressive behavior. Hmong women are frequently quiet during labor, although behavior varies from one individual to the next. European Americans demonstrate a wide variety of behaviors in response to pain. Especially in the transitional phase, some women want to squeeze their partner's (or the nurse's) hand, and some may be tempted to bite during the most intense part of the contraction. Vietnamese women tend to report more pain, use less pain medication, and regard labor as a negative experience (Fisher, Tran, & Tran, 2007).

Examples of Cultural Beliefs

Some differences between cultures are apparent with regard to specific practices related to position and food and drink

during labor. In most non-European societies uninfluenced by Westernization, women assume an upright position in childbirth. For example, during birth some Native American women use meditation, self-control, or indigenous plants, and the father may be expected to avoid certain rituals such as eating meat. Some Native Americans may ask to take the placenta home for a ritualistic ceremony that involves returning the placenta to the earth.

For Hmong women from Laos, the beginning of labor signifies the beginning of a transition and entails certain dietary restrictions. The woman usually prefers only "hot" foods, tea made with loose tea leaves, and warm water to drink. The woman usually maintains self-control, and may wish to move about freely during the first stage of labor. She may smile even throughout intense contractions. The husband is frequently present and actively involved in providing comfort. Traditionally, the woman prefers that the amniotic membranes not be ruptured until just before birth. It is thought that the escape of fluid at this time makes the birth easier. She may choose to kneel or squat for the birth of her baby. As soon as the baby is born, a soft-boiled egg must be given to the mother to restore her energy. During the postpartum period, the mother prefers "warm" foods, such as chicken prepared with warm water and warm rice (Hoang, Le, & Kilpatrick, 2009). The newborn is protected from praise to prevent jealousy from individuals outside of the family.

Latina women often want their partners to stay with them during labor and birth and to reassure them that everything will be all right. The women want their partners to show caring and love as they labor and to speak to them using affectionate words. Standing close to the woman and using touch are important roles for the partner (Spector, 2008).

Muslim women may have their husband, a female friend or relative, or a male relative with them during childbirth. Family support may be particularly important but does not preclude the importance of the nurse's presence. The woman may want to retain her head covering (*khimar*), and two long-sleeved gowns can be offered. Examinations should be done by a female nurse, physician, or CNM whenever possible. Some Muslim women are not comfortable in the presence of a male physician or nurse. If male physicians are involved with their care, they may wish for their husbands to remain in the room during all care by the physicians. Male providers should only enter the room after receiving permission from the husband. Modesty needs vary, and each individual will need to be assessed. After the birth, Muslim fathers traditionally call praise to Allah (*adhan*) in the newborn's right ear and clean the newborn. It is helpful if the birthing room personnel are aware of these practices so that the family's expectations and wishes can be incorporated into care. Many Middle-Eastern patients also believe that compliments addressed to the parents about their new baby will bring on the evil eye. The "evil eye" is the name given for the passage of sickness from one person to another, either intentionally or unintentionally, as a result of being jealous or envious (Spector, 2008). Thus, the nurse should avoid directly complimenting the couple, but instead direct compliments to God (*Allah*).

> "I am in an area with a very small Muslim population, and one of the nursing students with me had the opportunity to work with a Muslim couple during labor, birth, and then in the postpartum area the following day. During labor, the woman's sister remained at her side, and her husband sat on the other side of a drawn curtain inside the labor room and close to the door. He requested that a sign be placed on the door indicating that no males were to enter the room. We took care to ensure that we asked for a female lab tech for blood drawing, and a female physician attended the birth. The labor and birth went smoothly, and the woman did not utter any sound, even during pushing. After the birth, the father was shown the child before his wife held the newborn boy. The father was very pleased and talked quietly to his son, with his head down beside the newborn's ear. The next day, the student was once again assigned to this family. The sign remained on the door, and at all times that day, the sister and father remained in the room, the father always sitting away from the bed, close to the door. This was the woman's fifth child, so at first the student thought that she would not want much self-care, newborn, or breastfeeding information. But she began to talk to the woman, with her husband interpreting all questions and giving answers, and as each topic was brought up, the mother indicated that she wanted more information. Building on the trust that they had established the previous day in labor, the father told the student to "give the instruction," and he left the room. The mother and sister were full of questions about their health and their bodies—questions they had had for years! The student was proud that she did not make assumptions and was able to share so much information with them. It was an experience that the student and I will always remember with great joy."

Sometimes cultural norms are passed down from one generation to the next. African Americans, especially those whose ancestors are from Western Africa, may have beliefs rooted in traditional folk healing. Some African Americans have strong beliefs in healers and faith healers (Edgar, 2009). Some of these beliefs are centered on labor and childrearing. For example, it is widely believed that an infant born with a caul (a piece of the amniotic membrane covering the head at birth) will have the ability to communicate with spirits. This is viewed as a sign of good luck and is widely embraced within this culture.

In working with women from another culture, the nurse needs an awareness of their beliefs, values, and practices to understand their needs. The maternity nurse would do well to make it a priority to become acquainted with the beliefs and

practices of the various cultures in the community. In the birthing situation, the nurse supports the family's cultural practices as long as it is safe to do so.

Provision of Care in the First Stage

Throughout the first stage, the nurse needs to evaluate physical parameters of the woman and her fetus. Maternal temperature is monitored every 4 hours unless the temperature is over 37.5°C (99.6°F); in such cases, it must be taken every hour. Once the amniotic fluid has ruptured, temperature should be monitored every 2 hours.

The nurse monitors blood pressure, pulse, and respirations every hour. If the woman's blood pressure is over 140/90 mm Hg or her pulse is more than 100, the CNM or physician must be notified. The blood pressure and pulse are then reevaluated more frequently. The nurse palpates uterine contractions for frequency, intensity, and duration.

Intrapartal vaginal exams are done to assess cervical changes, status of membranes, fetal position, and station. However, frequent vaginal exams increase the risk of infection and should be performed only when needed. Some providers advocate performing vaginal examinations only when a change of management will occur, such as before an epidural or to provide scalp stimulation.

The fetal heart rate (FHR) is auscultated every 30 minutes as long as it remains between 110 and 160 beats per minute (beats/min) without the presence of decelerations (Association of Women's Health, Obstetric, and Neonatal Nurses [AWHONN], 2009b; Tucker, Miller, & Miller, 2008). The FHR should be auscultated throughout one contraction and for about 15 seconds after the contraction to ensure that there are no decelerations. If the FHR is not in the 110 to 160 range and/or decelerations are heard, continuous electronic monitoring is recommended. Table 24-3 summarizes nursing assessments in the first stage of labor. The nurse documents labor progress, status of fetus, and interventions in the woman's chart.

CLINICAL TIP

If the monitor is no longer recording the fetal heart tracing, check that there is adequate gel under the transducer and reposition it before you assume there is a problem with the baby.

Latent Phase

If the laboring woman has not had childbirth education classes, the latent phase is a time when the nurse can give anticipatory guidance. Most women are not too uncomfortable with contractions at this time and are responsive to teaching about breathing and other techniques for coping with labor contractions. In fact, many women in the latent phase seek information about what to expect. The unprepared woman may hesitate to ask questions and thus can benefit even more from anticipatory guidance by the nurse.

As long as there are no contraindications (such as vaginal bleeding or rupture of membranes [ROM] with the fetus unengaged), the woman may be encouraged to ambulate, because upright positions shorten labor (Hansen, 2009). A tour of the birthing facility can help decrease anxiety and distract her from her discomfort. Many women feel much more at ease and comfortable if they can move around and do not have to remain in bed. Ambulation also aids in fetal descent, increases the frequency and intensity of contractions, and provides the woman with a sense of control (Figure 24-1 ■).

The nurse should offer fluids in the form of clear liquids or ice chips at frequent intervals. Because gastric emptying time is prolonged during labor, solid foods are usually avoided. Fasting during labor is the subject of some controversy. Some providers believe that eating and drinking in labor should be an option for women. Research has shown that oral intake during labor does not result in adverse maternal or fetal outcomes (American College of Obstetricians and Gynecologists [ACOG], 2009). Although women are still advised to avoid solid foods for 6 to 8 hours before elective cesarean birth, modest amounts of clear liquids are recommended for women experiencing a normal labor (ACOG, 2009). Vomiting during labor occurs frequently because of the decreased gastric emptying time. It is not uncommon for women to vomit during the first stage, especially during the transition phase. The nurse should reassure the woman and provide oral care.

Active Phase

During the active phase, the contractions have a frequency of 2 to 3 minutes, a duration of 50 to 60 seconds, and moderate intensity. Contractions need to be palpated every 15 to 30 minutes. As the contractions become more frequent and

TABLE 24-3 Nursing Assessments in the First Stage

PHASE	MOTHER	FETUS
Latent	Blood pressure, respirations each hour if in normal range Temperature every 4 hours unless over 37.5°C (99.6°F) or membranes ruptured, then every hour Uterine contractions every 15–30 minutes	FHR every 30 minutes for low-risk women and every 15 minutes for high-risk women if normal characteristics present (presence of variability, baseline (BL) in the 110–160 beats/min range, without late decelerations). Note fetal activity. If electronic fetal monitor in place, assess for reactive nonstress test (NST).
Active	Blood pressure, pulse, respirations every hour if in normal range Uterine contractions palpated every 15–30 minutes	FHR every 30 minutes for low-risk women and every 15 minutes for high-risk women if normal characteristics are present (AWHONN, 2009a).
Transition	Blood pressure, pulse, respirations every 15–30 minutes Contractions palpated at least every 15–30 minutes	FHR every 15–30 minutes if normal characteristics are present.

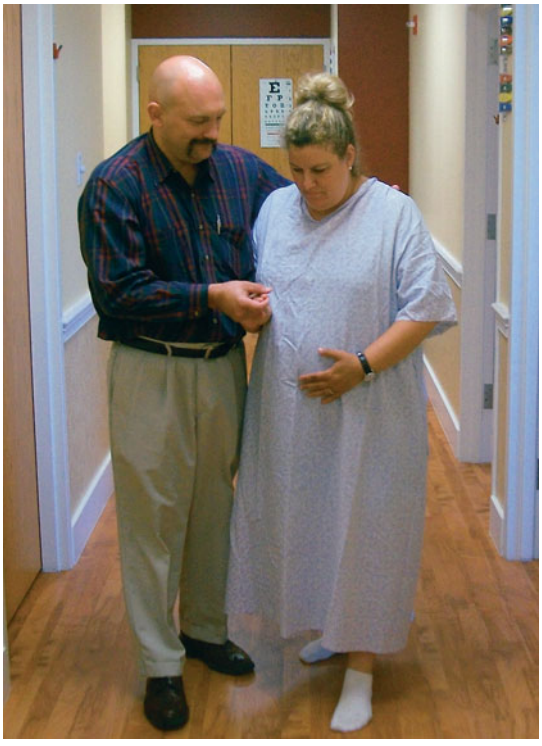

Figure 24-1 ■ Woman and her partner walking in the hospital during labor.

intense, intrapartal vaginal examination may be performed to assess cervical dilatation and effacement and fetal station and position. During the active phase, the cervix dilates from 4 to 7 cm, and vaginal discharge and bloody show increase. The woman should be encouraged to void because a full bladder can interfere with fetal descent. If the woman is unable to void, catheterization may be necessary. Maternal vital signs, including blood pressure, pulse, and respirations, should be assessed every hour for low-risk women (unless previously elevated), and every 30 minutes for high-risk women. The FHR is auscultated every 30 minutes for women without complications and more frequently (every 15 minutes) for women with complications (AWHONN, 2009a; Tucker, Miller, & Miller, 2008).

For the woman experiencing slow progress of labor or the inability to tolerate fluids, an intravenous (IV) electrolyte solution may be started to provide energy and prevent dehydration. If an IV is started, it becomes even more important to encourage voiding every 1 to 2 hours to prevent bladder distention.

CLINICAL TIP

Catheterizing a woman during a contraction is uncomfortable for her and difficult to do because of the increased downward pressure. To avoid these problems, pass the catheter between contractions. If the baby's head is low in the pelvis, you will have to change the direction of the catheter. Visualize passing it up and over the baby's head rather than straight into the urethra.

If the amniotic membranes have not ruptured previously, the CNM or physician may do so during this phase. When the membranes rupture, the nurse notes the color and odor of the amniotic fluid and the time of rupture and immediately auscultates the FHR. The fluid should be clear with no odor. Meconium-stained amniotic fluid may be a sign of a compromised fetus or may be present when the fetus is in a breech presentation. In the case of a breech fetus, meconium staining may not indicate a compromised fetus. In a cephalic presentation, however, meconium staining may indicate a compromised fetal state. When the fetus is compromised, the intestines and anal sphincter relax, leading to the release of meconium into the amniotic fluid. Meconium turns the fluid greenish brown (AWHONN, 2009b; Verklan & Walden, 2009). Whenever the nurse notes meconium-stained fluid, an electronic monitor is applied to continuously assess the FHR (AWHONN, 2009a; Tucker, Miller, & Miller, 2008). The time of rupture is noted because the incidence of amnionitis increases with rupture over 24 hours. An additional concern is prolapse of the umbilical cord, which occurs when membranes rupture and the fetus is not engaged. The concern is that the amniotic fluid coming through the cervix will propel the umbilical cord through the cervix (prolapsed cord). Prolapsed cord is assessed by monitoring for signs of nonreassuring fetal status and performing a vaginal examination with a sterile glove. The FHR is auscultated because a drop in the rate might indicate an undetected prolapsed cord. Immediate intervention is necessary to remove pressure on a prolapsed umbilical cord until a cesarean birth can be performed (see chapter 28 ∞). (See Table 24-4 for additional deviations from normal.)

See the section, Promotion of Comfort in the First Stage, later in the chapter for comfort management for the patient.

Transition Phase

During transition, the contraction frequency is every 2 to 3 minutes, duration is 60 to 90 seconds, and intensity is strong. Cervical dilatation increases from 8 to 10 cm, effacement is complete (100%), and a heavy amount of bloody show is usually present. Some multiparous women may not completely efface prior to the birth. Nulliparous women should completely efface prior to the birth of the infant. Contractions are palpated at least every 15 minutes. Sterile vaginal examination can be done during this stage of labor to assess rapid changes in status. Maternal blood pressure, pulse, and respirations are taken at least every 30 minutes, and FHR is auscultated every 30 minutes for low-risk women and every 15 minutes for high-risk women (AWHONN, 2009a; Tucker, Miller, & Miller, 2008).

Throughout labor the woman's center of focus gradually turns inward. She becomes less aware of what is going on around her and intensely aware of her uterine contractions. She experiences body boundary diffusion, which hampers her ability to know where her body ends and her external environment begins. Women during this time will reach out to others but may be uncomfortable with others touching them.

The woman's ability to speak in coherent sentences can be impaired during the transitional phase. This makes it difficult for the woman to communicate her needs to healthcare providers

TABLE 24-4 Deviations from Normal Labor Process Requiring Immediate Intervention

PROBLEM	IMMEDIATE ACTION
Women admitted with vaginal bleeding or history of painless vaginal bleeding	• Do not perform vaginal examination. • Assess FHR. • Evaluate amount of blood loss. • Evaluate labor pattern. • Notify physician/CNM immediately.
Presence of greenish or brownish amniotic fluid	• Continuously monitor FHR. • Evaluate dilatation of cervix and determine if umbilical cord is prolapsed. • Evaluate presentation (vertex or breech). • Maintain woman on complete bed rest on left side. • Notify physician/CNM immediately. • Have suction equipment and laryngoscope at the bedside to provide immediate suctioning upon delivery.
Decrease in FHR below 110 beats/min	• Perform vaginal examination to assess for prolapsed cord. • Turn woman to a side-lying or hands and knees position. • Administer oxygen by face mask. • Discontinue pitocin. • Call the CNM/physician. • Continue continuous external monitoring or place internal fetal monitor if hospital protocol allows and ROM has occurred. • Provide fetal scalp stimulation.
Absence of FHR and fetal movement	• Notify physician/CNM. • Provide truthful information and emotional support to laboring couple. • Remain with the couple.
Prolapse of umbilical cord	• Relieve pressure on cord manually. • Continuously monitor FHR; watch for changes in FHR pattern. • Notify physician/CNM. • Assist woman into knee-chest position or place in Trendelenburg position. • Administer oxygen.

Woman admitted in advanced labor; birth imminent	• Prepare for immediate birth.
	• Obtain critical information:
	  • Estimated date of birth (EDB)
	  • History of bleeding problems
	  • History of medical or obstetric problems
	  • Past and/or present use/abuse of prescription/OTC/illicit drugs
	  • Problems with this pregnancy
	  • FHR and maternal vital signs
	  • Whether membranes are ruptured and how long since rupture
	  • Blood type and Rh
	• Direct another person to contact physician/CNM.
	• Do not leave woman alone.
	• Provide support to couple.
	• Put on gloves.

and her support team. The support person(s) and nurse need to follow the woman's cues and change interventions as needed.

The nurse should encourage the woman to rest between contractions by instructing the woman at the end of her contraction to take a deep breath and to let it out slowly while she relaxes her muscles. Helping to maintain a quiet room between contractions can also enhance the woman's ability to rest. The woman during this phase is present focused; thus, providing instruction between contractions should be kept to a minimum.

Some women have difficulty coping with the intensity of labor during this time and need assistance in performing breathing techniques. Either the support person or the nurse can breathe along with the woman during each contraction to help her maintain her pattern. It is helpful to encourage her and assure her that she is doing a good job. The woman will begin to feel increased rectal pressure as the fetal presenting part moves down the birth canal and sometimes a burning sensation as the tissues begin to stretch. The nurse encourages the woman to refrain from pushing until the cervix is completely dilated. For the woman who is unmedicated, the urge to push may seem unbearable. Specific instructions, such as encouraging the woman to "blow in short breaths like you are blowing out a candle" or "pant like a puppy," can help prevent the woman from involuntarily pushing. This measure also helps prevent cervical edema or lacerations.

The end of transition and beginning of the second stage may be indicated by involuntary passage of flatus or stool and the movement of the fetus from the side of the maternal abdomen to the midline. Other indications include a change in the woman's voice or the sounds she is making. As the fetus moves down and she feels increased pressure and a bearing-down sensation, her voice tends to deepen. A moan during a contraction takes on a more guttural quality. Labor nurses recognize this sound as a sign that the woman may have entered the second stage.

Promotion of Comfort in the First Stage

The first step in planning care for the laboring woman is to talk with the woman and her partner or support person to identify their goals. Usually the couple is concerned with discomfort, so it is important to identify factors that may contribute to discomfort. These factors include uncomfortable positions, diaphoresis, continual leaking of amniotic fluid, a full bladder, dry mouth, anxiety, and fear. Nursing interventions can minimize the effects of these factors. These interventions are discussed later in this section.

There are many responses to pain. As the intensity of the contraction increases with the progression of labor, the woman becomes less aware of the environment and may have difficulty hearing and understanding verbal instructions. The pattern of coping with labor contractions varies from the use of highly structured breathing techniques to turning inward.

In labor, the more common pain reactions, such as increased pulse and respiratory rates, dilated pupils, increased blood pressure, and muscle tension, are transitory because the pain is intermittent. However, increased muscle tension may impede the progress of labor; therefore, the nurse encourages the woman to relax her skeletal muscles and avoid holding her breath.

Sounds are an important part of the labor and birthing process. Some women naturally make sounds such as moans and grunts and feel that it helps them cope and do the work of labor; they are responding to what their body tells them to do. Others begin to make loud sounds (screams) only as they lose their ability to cope and feel they do not have any other options.

Figure 24-2 ■ The woman's partner provides support and encouragement during labor.

Source: Photographer, Elena Dorfman.

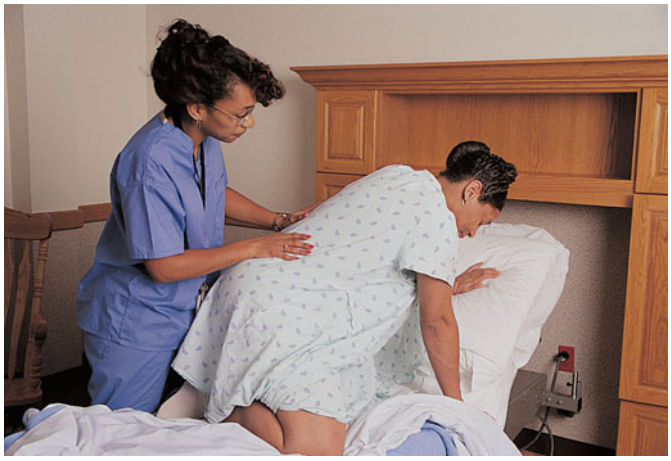

Figure 24-3 ■ The laboring woman is encouraged to choose a position of comfort. The nurse modifies assessments and interventions as necessary.

Source: Photographer, Elena Dorfman.

Some women may want physical contact during contractions. They may provide verbal and nonverbal signs, such as crying, moaning, and beseeching the coach or nurse to hold their hand or rub their back. They may look at the support person or reach out for help to indicate their anxiety. Touch may be used to convey support and enhance comfort for the woman (Figure 24-2 ■). She may be soothed by a neck or back rub or by holding the hand of her partner or the nurse. A woman generally wants touching and physical contact during the first part of labor, but when she moves into the transition phase, she may rebuff all efforts and pull away. Other women do not want to be touched at all, regardless of the phase of labor.

A decrease in the intensity of discomfort is one of the goals of nursing support during labor. Nursing measures to decrease pain include the following:

- Encouraging position changes
- Assisting with personal comfort measures
- Decreasing anxiety
- Providing information
- Using specific supportive relaxation techniques
- Encouraging paced breathing
- Administering pharmacologic agents as desired by the woman

Position Changes

Laboring Positions

Women in labor may wish to remain ambulatory to promote comfort and aid in labor progression (Roberts & Hanson, 2007). Some women who have been ambulatory up to this point may wish to sit in a chair or on a bed. The woman may also need to take periodic rest periods as contractions intensify.

The woman is encouraged to ambulate if the fetal head is engaged and the electronic fetal monitoring (EFM) has shown a reassuring FHR pattern. However, to avoid the risk of umbilical cord prolapse, the woman is generally instructed to remain in bed if membranes are ruptured and the presenting part is not engaged.

If she stays in bed, the woman is encouraged to assume any position that she finds comfortable (Figure 24-3 ■). A side-lying position is generally the most advantageous for the laboring woman. Care should be taken that all body parts are supported, with the joints slightly flexed. Pillows may be placed against her chest and under the uppermost arm. A pillow or folded bath blanket is placed between her knees to support the uppermost leg and relieve tension or muscle strain. A pillow (or warmed rolled blanket) placed at the woman's midback also helps provide support. If the woman is more comfortable on her back, the head of the bed should be elevated to relieve the pressure of the uterus on the vena cava, and the uterus should be tilted by placing a towel or blanket under the woman's back. Pillows may be placed under each arm and under the knees to provide support. Because a pregnant woman is at increased risk for thrombophlebitis, excessive pressure behind the knee and calf should be avoided, and frequent assessment of pressure points needs to be made.

CLINICAL TIP

When assisting with position changes, provide the woman with a sheet to provide continued coverage and assist with modesty and maintaining dignity throughout labor.

Frequent position changes (at least every hour) seem to achieve more efficient contractions, and contribute to comfort and relaxation. It is also helpful for the woman to sit up in a rocking chair or other comfortable chair, or in the shower.

Personal Comfort Measures

Because vaginal discharge increases, the nurse needs to change the underpads frequently. Washing the perineum with warm soap and water removes secretions and increases comfort. The nurse needs to use standard precautions to avoid exposure to vaginal secretions.

Diaphoresis and the constant leaking of amniotic fluid can dampen the woman's gown and bed linen. Fresh, smooth, dry bed linen promotes comfort. To avoid having to change the bottom sheet following ROM, the nurse may replace the underpads

at frequent intervals (standard precautions need to be followed). The perineal area should be kept as clean and dry as possible to promote comfort. The woman may also find comfort in applying a cool washcloth to her forehead or behind the back of her neck.

CLINICAL TIP

To promote maternal comfort, dampen a washcloth with cool water and wring it out thoroughly. Hold one corner of the washcloth and swing the cloth in a circular motion for a cooling fanlike effect.

A full bladder adds to the discomfort during a contraction and may prolong labor by interfering with the descent of the fetus. Even though the woman is voiding, urine may be retained because of the pressure of the fetal presenting part. A full bladder can be detected by palpation directly over the symphysis pubis. Some of the procedures for regional analgesia during labor contribute to the inability to void, and catheterization may be necessary. The woman should be encouraged to empty her bladder about every 1 to 2 hours. The nurse should offer the woman a bedpan before catheterization because some women are able to void despite anesthesia, and spontaneous voiding decreases the risk of infection that is associated with repeated catheterizations.

The woman may experience dryness of her mouth because her breathing is more rapid. The woman can be instructed to breathe in through her nose and out through her mouth. Clear fluids and ice chips are usually offered unless a complication exists that makes cesarean birth a possibility. The nurse can also apply A and D ointment or a lip emollient to the dry lips. Some prepared childbirth programs advise the woman to bring lollipops to suck on to help combat the dryness that occurs with some of the breathing patterns. If the woman vomits, the nurse should wipe her mouth and offer water to rinse her mouth.

Some women feel discomfort from cold feet. Wearing socks or slippers may increase their comfort. Some women may wish to wear their own nightgown, although they need to know that the gown will most likely be soiled and may be more difficult to move around in.

Birthing balls—large, heavy plastic balls that accommodate an adult's weight—are used by some laboring women to increase comfort (Figure 24-4 ■). The woman sits on the ball and can roll it back and forth gently. The slow rock is thought to widen the pelvis and enhance fetal descent, while leaning forward on the knees with the head, arms, and chest over the ball simulates a hands-and-knees position and may facilitate rotation of an occiput-posterior. When a birthing ball is used, the nurse should remain close by the woman to help provide balance. Many balls come with aluminum frames to prevent falls.

Some family members or support persons can assist the woman with comfort measures. They may help with position changes, provide ice chips, walk with the laboring woman, and give effleurage or back rubs. If the family is not already involved in providing comfort measures and seems to want to be, the nurse can act as a role model while providing comfort measures and then invite the support person(s) to join in if they like.

Figure 24-4 ■ A birthing ball is used to promote maternal comfort during labor. The birthing ball facilitates fetal descent and fetal rotation and helps increase the diameter of the pelvis.

Family members also need to be encouraged to maintain their own comfort. As their attention is directed toward the laboring woman, they may forget their own needs. The nurse may have to encourage them to take breaks, maintain food and fluid intake, and rest.

Reducing Anxiety

The anxiety experienced by women entering labor is related to a combination of factors inherent to the process. A moderate amount of anxiety enhances the ability to deal with the pain. But an excessive degree of anxiety decreases the woman's ability to cope with the pain.

To decrease anxiety that is not related to pain, the nurse can give information (which eases fear of the unknown), establish rapport with the couple (which helps them preserve their personal integrity), express confidence in the couple's ability to work with the labor process, and assist with breathing and relaxation techniques. In addition to being a good listener, the nurse needs to demonstrate genuine concern for the laboring woman. Remaining with the woman as much as possible conveys a caring attitude and dispels fear of abandonment. Praise for correct breathing, relaxation efforts, and pushing efforts not

only encourages repetition of the behavior but also decreases anxiety about the ability to cope with labor.

The woman's partner and other members of her support team may also experience increasing anxiety as the woman advances through labor. Their anxiety can stem from watching their loved one in pain, feeling helpless about their ability to assist her in reducing the pain, a lack of knowledge or information about the labor experience, and lack of support from the labor nurse. Their anxiety may be reduced or kept at a minimum by keeping them informed about the progress of labor, reassuring them that the sounds and behaviors of the woman in labor are normal, explaining procedures and the use of equipment, and praising them for their assistance in supporting the woman through labor.

Labor and childbirth may be a time of increased anxiety for the woman with a history of sexual abuse or rape. All women entering the healthcare arena need to be assessed for a history of sexual abuse or rape. It is not uncommon for women to deny sexual abuse or rape, because this information is difficult to share with a stranger. It is important to be alert for nonverbal cues, such as unexplained anxiety, unrelenting pain, or intense fear during vaginal examinations. The nurse should offer support, provide information, and introduce relaxation techniques to aid the woman in coping to offset her anxiety.

Providing Information

Providing information about the nature of the discomfort that will occur during labor is important and is best achieved in the early portion of labor. Stressing the intermittent nature and maximum duration of the contractions can be most helpful. The woman can cope with pain better when she knows how far she has progressed and that a period of relief will follow. Describing the type of discomfort and specific sensations that will occur as labor progresses helps the woman recognize these sensations as normal and expected when she does experience them.

A thorough explanation of surroundings, procedures, and equipment being used also decreases anxiety, thereby reducing pain. For some patients, attachment to an electronic monitor can produce fear because equipment of this type is associated with critically ill people. For others, hearing the infant's heartbeat is reassuring. The nurse should explain the purpose of the monitor and the monitor strip, and show the woman and her support persons how the monitor can help them use controlled breathing techniques to relieve pain. The monitor may indicate the beginning of a contraction just seconds before the woman feels it. The woman and coach can learn how to read the tracing to identify the beginning of the contraction.

Supportive Relaxation Techniques

Tense muscles increase resistance to the descent of the fetus and contribute to maternal fatigue and anxiety. This fatigue increases pain perception and decreases the woman's ability to cope with the pain. Comfort measures, massage, techniques for decreasing anxiety, and patient teaching can conserve energy. The laboring woman needs to be encouraged to use the periods between contractions to rest and relax her muscles.

Distraction is a method of increasing relaxation and coping with discomfort. During early labor, conversation or activities such as light reading, cards, or other games serve as distractions.

Touch is another type of distraction. Although some women regard touching as an invasion of privacy or threat to their independence, others want to touch and be touched during a painful experience. Nurses can make themselves available to the woman who desires touch. The nurse can place a hand on the side of the bed within the woman's reach. The person who needs touch will reach out for contact, and the nurse can pick up and follow through with this behavioral cue.

Mild to moderate abdominal discomfort during contractions may be relieved or lessened by effleurage. Back pain associated with labor may be relieved more effectively by firm pressure on the lower back or sacral area. To apply firm pressure, the nurse or a support person places a hand or a rolled, warmed towel or blanket in the small of the woman's back. Warm compresses can also provide relief.

Visualization techniques also enhance relaxation. For example, the nurse might encourage the woman to imagine herself floating in a warm pool of water, fully supported; to imagine the birth canal slowly opening up as the baby descends; or to visualize a rose opening its petals. Or the woman may simply wish to recall and concentrate on a pleasant experience she has had in the past. Table 24-5 describes a simple visualization method.

In addition to these measures, the nurse can enhance the woman's relaxation by providing encouragement and support for controlled breathing techniques.

Breathing Techniques

Breathing techniques may help the laboring woman. Breathing techniques increase the woman's pain threshold, encourage relaxation, provide distraction, enhance the ability to cope with uterine contractions, and allow the uterus to function more efficiently.

Many women learn breathing techniques during prenatal education classes. Patterned-paced breathing, which is commonly used in the Lamaze method, has three levels. The woman tends to begin with the first level and then proceed to the next when she feels the need. Regardless of the level of breathing used, a cleansing breath begins and ends each pattern. A cleansing

TABLE 24-5 Simple Visualization Method

- Direct a visualization by saying something like the following: "Think about a place you have been that has pleasant memories and feelings around it. A place that was relaxing, where all your stress disappeared. As you think about this place, take in a breath and remember the smells around it. If it was outside, feel the warmth of the sun or the way the breeze felt on your face. Sit in the place again in your mind. Let all your tension and tiredness leave your body as you feel the warmth and breezes."
- Give the woman a few moments to think about her special place: Ask if she would like to share information about the setting. If the woman chooses to do this, add the information to help her with the visualization (for example, "Think about the mountain cabin and the warmth of the sun on your face as you sit in the rocking chair on the front porch").
- After the woman has a visualization set up, suggest thinking about it during contractions as a means of increasing relaxation and focusing concentration. You could say, "As each contraction begins, think about this special place for a moment, and let your body relax. Keep a picture of your place in your mind as you breathe with the contraction. When the contraction is over, let your body stay relaxed. Feel the comfort of this room and support of those around you."

breath involves only the chest. It consists of inhaling through the nose and exhaling through pursed lips (as if blowing on a spoonful of hot food). See Table 24-6 for information regarding nursing support of patterned-paced breathing.

Other childbirth education models encourage different types of breathing exercises. Abdominal breathing, which is commonly used in the Bradley method, encourages the woman to move the abdominal wall upward as she inhales and downward as she exhales (see Table 24-6). This method tends to lift the abdominal wall off the contracting uterus and thus may provide some pain relief. The breathing is deep and rhythmic. If the woman has not been trained in a particular technique, teaching her the "quick method," which uses a pant-pant-blow breathing pattern, may help her from breathing too rapidly (see Table 24-6).

Hyperventilation may occur when a woman breathes very rapidly over a prolonged period of time. Hyperventilation is the result of an imbalance of oxygen and carbon dioxide (that is, too much carbon dioxide is exhaled, and too much oxygen remains in the body). The signs and symptoms of hyperventilation are tingling or numbness in the tip of nose, lips, fingers, or toes; dizziness; spots before the eyes; or spasms of the hands or feet (carpal-pedal spasms). If hyperventilation occurs, the woman should be encouraged to slow her breathing rate and to take shallow breaths. With instruction and encouragement, many women are able to change their breathing to correct the problem. Encouraging the woman to relax and counting out loud for her so she can pace her breathing during contractions are also helpful. If the signs and symptoms continue or become more severe (that is, if they progress from numbness to spasms), the woman can breathe into a paper surgical mask or into her hands until symptoms abate. Breathing into a mask or her hands causes rebreathing of carbon dioxide. The nurse should remain with the woman to reassure her.

As the woman uses her breathing technique, the nurse can assess and support the interaction between the woman and her coach or support person. In the absence of a coach, the nurse supports the laboring woman by helping to identify the beginning of each contraction and encouraging her as she breathes through it.

TABLE 24-6 Nursing Support of Patterned-Paced Breathing

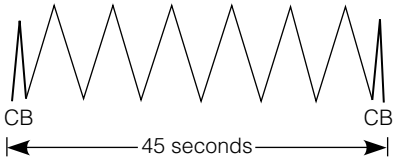
Determine which breathing method the woman (couple) has learned. Provide encouragement as needed in maintaining breathing pattern. Provide support to the labor coach and assist as needed.

Lamaze Breathing Pattern Levels

First Level (slow paced)

Pattern begins and ends with a cleansing breath (in through the nose and out through pursed lips as if cooling a spoonful of hot food). While inhaling through the nose and exhaling through pursed lips, slow breaths are taken, moving only the chest. The rate should be approximately 6–9 breaths/minute or 2 breaths/15 seconds. The coach or nurse may assist by reminding the woman to take a cleansing breath, and then the breaths could be counted out if needed to maintain pacing. The woman inhales as someone counts "one one thousand, two one thousand, three one thousand, four one thousand." Exhalation begins and continues through the same count.

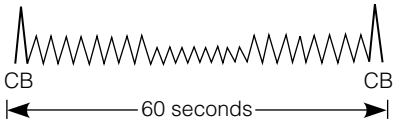
First level for use during uterine contractions (The level begins and ends with a cleansing breath [CB]).



Second Level (modified paced)

Pattern begins and ends with a cleansing breath. Breaths are then taken in and out silently through the mouth at approximately 4 breaths/5 seconds. The jaw and entire body need to be relaxed. The rate can be accelerated to 2—2 1/2 breaths/second. The rhythm for the breaths can be counted out as "one and two and one and two and . . ." with the woman exhaling on the numbers and inhaling on "and."

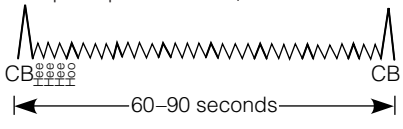
Second level



Third Level (pattern paced)

Pattern begins and ends with a cleansing breath. All breaths are rhythmical, in and out through the mouth. Exhalations are accompanied by a "hee" or "hoo" sound in a varying pattern, 2:1, which begins as 3:1 (hee hee hee hoo) and can change to 2:1 (hee hee hoo) or 1:1 (hee hoo) as the intensity of the contraction changes. The rate should not be more rapid than 2—2 1/2 breaths/second. The rhythm of the breaths would match a "one and two and . . ." count.

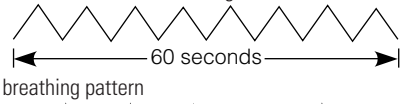
Third level (Darkened spike represents "hoo.")



Abdominal Breathing Pattern Cues

The abdomen moves outward during inhalation and downward during exhalation. The rate remains slow with approximately 6–9 breaths/minute.

Breathing sequence for abdominal breathing



Quick Method

When the woman has not learned a particular method and is in active phase of labor, the nurse may teach her a combination of two patterns. Abdominal breathing may be used until labor is more advanced. Then a more rapid pattern consisting of two short blows from the mouth followed by a longer blow can be used. (This pattern is called "pant-pant-blow" even though all exhalations are a blowing motion.)

Pant-pant-blow breathing pattern

Continued encouragement and support with each contraction through labor yield immeasurable benefits.

COMPLEMENTARY AND ALTERNATIVE THERAPIES

The use of hydrotherapy during labor promotes maternal relaxation and pain management and decreases the length of labor. Thus women can be encouraged to use a warm bath, shower, or whirlpool to increase comfort during labor. Centuries-old water immersion in hot springs, and more recently in hot tubs and whirlpools, is used all over the world to promote relaxation and relax muscles. Current evidence supports the use of hydrotherapy in labor as an effective method of pain management in the first stage of labor. Women who use hydrotherapy report less pain and use less analgesia during the first stage of labor. Use of hydrotherapy also facilitates upright positioning, which facilitates labor and coping (Stark, Rudell, & Haus, 2008). Water immersion has both physical and psychologic benefits, including counterpressure and support of stretching tissues.

Other Comfort Measures

In some instances, analgesic agents or regional anesthetic blocks may be used to enhance comfort and relaxation during labor. See chapter 25 ∞ for a discussion of analgesia and anesthesia.

Table 24-7 summarizes labor progress, possible responses of the laboring woman, and nursing care during the first and second stages of labor.

Nursing Care During the Second Stage of Labor

Nursing care in the second stage entails both physical and psychologic support, continual encouragement, and appropriate patient teaching to facilitate birth.

Provision of Care in the Second Stage

The second stage begins when the cervix is completely dilated (10 cm). The uterine contractions continue as in the transition

TABLE 24-7 Normal Progress, Psychologic Characteristics, and Nursing Support During First and Second Stages of Labor

PHASE	CERVICAL DILATATION	UTERINE CONTRACTIONS	WOMAN'S RESPONSE	SUPPORT MEASURES
Stage 1				
Latent phase	1–3 cm	Every 10–20 minutes, 15–20 seconds' duration Mild intensity *progressing to* Every 5–7 minutes, 30–40 seconds' duration Moderate intensity	Usually happy, talkative, and eager to be in labor Exhibits need for independence by taking care of own bodily needs and seeking information	Establish rapport on admission and continue to build during care. Assess information base and learning needs. Be available to consult regarding breathing technique if needed; teach breathing technique if needed and in early labor. Orient family to room, equipment, monitors, and procedures. Encourage woman and partner to participate in care as desired. Provide needed information. Assist woman into position of comfort; encourage frequent change of position; encourage ambulation during early labor. Offer fluids/ice chips. Keep couple informed of progress. Encourage woman to void every 1 to 2 hours. Assess need for an interest in using visualization to enhance relaxation and teach if appropriate.
Active phase	4–7 cm	Every 2–3 minutes, 50–60 seconds' duration Moderate to strong intensity	May experience feelings of helplessness Exhibits increased fatigue and may begin to feel restless and anxious as contractions become stronger Expresses fear of abandonment Becomes more dependent as she is less able to meet her needs	Encourage woman to maintain breathing patterns. Provide quiet environment to reduce external stimuli. Provide reassurance, encouragement, support; keep couple informed of progress. Promote comfort by giving back rubs, sacral pressure, cool cloth on forehead, assistance with position changes, support with pillows, effleurage. Provide ice chips, ointment for dry mouth and lips. Encourage to void every 1 to 2 hours. Offer shower/whirlpool/warm bath if available.
Transition phase	8–10 cm	Every 2–3 minutes, 60–90 seconds' duration Strong intensity	Tires and may exhibit increased restlessness and irritability May feel she cannot keep up with labor process and is out of control Physical discomforts Fear of being left alone May fear tearing open or splitting apart with contractions	Encourage woman to rest between contractions. If she sleeps between contractions, wake her at beginning of contraction so she can begin breathing pattern (increases feeling of control). Provide support, encouragement, and praise for efforts. Keep couple informed of progress; encourage continued participation of support persons. Promote comfort as listed above but recognize many women do not want to be touched when in transition. Provide privacy. Provide ice chips, ointment for lips. Encourage to void every 1 to 2 hours.
Stage 2	Complete	Every 1 1/2–2 minutes	May feel out of control, helpless, panicky, or may be happy that she can take a more active role in pushing	Assist woman in pushing efforts. Encourage woman to assume position of comfort. Provide encouragement and praise for efforts. Keep couple informed of progress. Provide ice chips. Maintain privacy as woman desires.

TABLE 24-8 Nursing Assessments in the Second Stage

MOTHER	FETUS
Blood pressure, pulse, respiration every 5–15 minutes.	FHR every 5 minutes.
Uterine contraction palpated continuously.	

phase. Sterile vaginal examinations are performed to assess fetal descent. Maternal pulse, blood pressure, and fetal heart rate (FHR) are assessed every 5 minutes; some protocols recommend assessment after each contraction (Cunningham et al., 2010). Table 24-8 summarizes nursing assessments in the second stage of labor.

As the woman pushes during the second stage, she may make a variety of sounds. At times, these sounds are disturbing for nurses and physicians, and they feel the need to help her or encourage her to be more quiet. Other nurses feel more comfortable with maternal sounds and use them as cues. For example, if the woman begins to feel she is losing control, her sound may change to a high-pitched cry or whimper, or she may even shriek in pain. The nurse stays sensitive to changes in the sounds for clues that the woman needs help coping with her pain. The nurse may encourage her to push harder and not let any breath out, or to put all her effort into the push and not into making noise. But the nurse needs to be aware that maternal sounds may be a coping mechanism for some women and may assist in their pain management.

Several nursing research studies have been conducted focusing on when a woman should push during the second stage of labor. A review article on research focusing on pushing during the second stage recommends that the woman be allowed to rest at the beginning of the second stage and to begin pushing when she feels the natural urge to bear down. There is a decrease in maternal fatigue levels and an increase in fetal oxygenation with fewer decelerations noted when women delay pushing until they feel the urge to push. Furthermore, women who delayed pushing pushed for a shorter period of time and experienced less postpartum fatigue (Lin, Lin, Li, et al., 2009).

When the woman reports feeling an uncontrollable urge to push (bear down), the nurse can help her greatly by letting her know that these new sensations are normal. This is because some women interpret the increased rectal pressure as a need to move her bowels. The instinctive response is to tighten muscles rather than bear down. The woman may also report that she fears she is "splitting apart" or that she feels a "ring of fire." The woman who expects these sensations and understands that bearing down contributes to progress at this stage is more likely to do so.

> "When I tried to push with the contractions, I felt as if I would tear apart. It hurt so badly that I was shaking. I knew it was time to push and my body was telling me, too, but it hurt so much. The nurse kept saying, "Just push and you will feel better." I wanted to scream at her. She had no idea what was happening to me."

Figure 24-5 ■ The nurse provides encouragement and support during pushing efforts.

Source: Margaret Miller/Photo Researchers, Inc.

When the contraction begins, the nurse tells the woman to take two short breaths, then to take a third breath and hold it while pulling back on her knees and pushing down with her abdominal muscles (Figure 24-5 ■). Some women prefer to exhale slightly (exhale breathing) while pushing to avoid the physiologic effects of the Valsalva maneuver. With this method the woman takes several deep breaths and then holds her breath for 5 to 6 seconds. Then, through slightly pursed lips, she exhales slowly every 5 to 6 seconds while continuing to hold her breath. The woman takes another breath and continues exhale breathing and pushing during the contraction.

> "I knew when I was completely dilated. I knew when to push and I did it without tearing. My body told me to listen. I knew what to do.
>
> When I began pushing, I felt in control because I could do something . . . I could push the baby out. I knew he was ready to be born."
>
> —Harriette Hartigan, Women in Birth

The woman is encouraged to rest between contractions. Although the laboring woman may appear exhausted at this time, most experience relief at being able to push with contractions. Perspiration increases with the pushing efforts, and a cold washcloth for the forehead and face is most soothing. The birthing woman may also appreciate sips of fluid or ice chips at this time.

The nurse and/or support person can assist the woman into a comfortable position for pushing. Maternal positions, such as standing, squatting while leaning back on a partner or leaning forward on a birthing bar (Figure 24-6 ■), lying in a lateral or Sims' position, or crouching on hands and knees, may increase comfort and effectiveness of pushing. Some women feel that sitting on a toilet seat is a comfortable position that assists their pushing efforts. This position may cause anxiety in the caregivers, however, for fear that the birth may occur quickly in this most inopportune place. Some women benefit from gripping

Figure 24-6 ■ Using a birthing bar.
Source: Photographer, Elena Dorfman.

the hands of the support person or nurse. This technique increases intra-abdominal pressure, which aids in the expulsion effort. Another variation of this technique, which can be quite effective, is to have the woman grip a towel while the support person or nurse pulls the towel in the opposite direction. Care should be taken that the nurse or support person does not suffer a back injury. Pushing efforts should be maximized by having the woman place her chin to her chest and avoid hyperextension of the neck by having her "curl around the baby" to facilitate descent into the pelvis.

If anticipated progress is not made or the laboring woman wants to try other positions for pushing, the nurse should support her. Some nurses have their own preferences and may be more comfortable directing the laboring woman to use these preferred positions; however, it is important to remember that the nurse is there to support the birth, and that frequent changes in position may assist in the descent of the baby.

If the maternal pushing effort diminishes because of frustration or fatigue, many women benefit from short rest periods. Rest periods are appropriate if maternal and fetal assessments are stable. In addition, the physician or certified nurse-midwife (CNM) should be informed of the actual time that has been spent pushing and not the time that has elapsed since the beginning of the second stage. If the maternal vital signs are stable and the FHR is reassuring, rest periods can be used to prevent maternal exhaustion (Cunningham et al., 2010).

Throughout the second stage, it remains important to provide information regarding progress and what is happening in the labor. It is also imperative to address the woman's questions honestly, to acknowledge her concerns, and to continue to provide support.

A nullipara is usually prepared for birth when the perineum begins to bulge. A multipara usually progresses much more quickly, so she may be prepared for the birth when the cervix is dilated 7 to 8 cm.

The woman's blood pressure and the FHR are monitored between contractions, and the contractions are palpated until the birth. The nurse continues to assist the woman in her pushing efforts. Both the woman and the coach are kept informed of procedures and of progress, and both are supported throughout the birth.

In addition to assisting the woman and her partner, the nurse assists the physician or CNM in preparing for the birth. The physician or CNM usually dons a sterile gown and gloves and may place sterile drapes over the woman's abdomen and legs. Some providers may perform a sterile preparation before birth; others may not do so as part of their normal routine. Although some physicians and CNMs may place the woman in stirrups for birth, others may opt to drop the foot of the bed lower than the upper portion and let the woman rest her feet on the bed to facilitate maternal comfort. An episiotomy may be done just before birth if there is a need for one or if the provider performs them on a routine basis. See the discussion of episiotomy in chapter 28 ∞.

Promotion of Comfort in the Second Stage

Most of the comfort measures that have been used during the first stage remain appropriate at this time. Cool cloths to the face and forehead may help provide cooling as the woman is involved in the intense physical exertion of pushing. If she has been diaphoretic, a dry gown may be comforting. The woman may feel hot and want to remove some of the covering. Care still needs to be taken to provide privacy even though covers are removed. Some women may want to remove all of their clothing. Healthcare providers should allow the woman to give birth in a way that will promote her comfort.

Additional comfort measures may be used during this stage. Warm perineal, abdominal, and back compresses may be used to increase muscle relaxation. Perineal massage and stretching with a lubricant (Lubafax) may relieve the tearing and burning sensation as the perineal tissue distends. Providing perineal massage before imminent crowning can result in considerable perineal edema. For this reason, some institutions may limit perineal massage to physicians and CNMs.

The woman can be encouraged to rest and "let all muscles go" during the period between contractions. The nurse and support person(s) can assist the woman into a pushing position with each contraction to further conserve energy. Sips of fluid or ice chips may be used to provide moisture and relieve dryness of the mouth. Constant reassurance is imperative.

Visualization techniques may be helpful. The woman can be encouraged to envision the infant descending the birth canal and the vagina opening up. Phrases such as "Open to your baby" and "Let the baby come; don't try to hold back" can be useful and calming. Many women benefit from visualizing the descent of the fetus in a mirror. The nurse should ask the woman if she would like to watch in the mirror.

Assisting the Couple and Physician or CNM During Birth

Shortly before the birth, the birthing room or delivery room is prepared with equipment and materials that may be needed. Family members do not need to change into other clothing if the birth occurs in a birthing room; they don a disposable scrub suit if the birth is to occur in a delivery room or surgery suite. Meticulous handwashing is required of the nurses and CNM or physi-

cian. Nurses who will be in direct contact with the mother at the time of birth need to wear protective clothing, such as an apron or gown with a splash apron, disposable gloves, and eye covering. The CNM or physician will also need to wear a gown with a splash apron or a plastic apron, eye covering, and sterile gloves.

Most facilities now use one room for labor, delivery, and recovery (LDR) rooms. Use of a separate birthing room is rare. If the laboring woman is to give birth in a separate birthing room, she will be moved shortly before birth on her bed or a cart. It is important to preserve her privacy during the transfer, and safety must be provided by raising the side rails into a locked position. In the birthing room, the labor bed or transfer cart must be carefully supported against the delivery table; this ensures the woman's safety during the transfer.

If the woman is to be moved from one bed to another, it should be done between contractions. During the contraction, the woman feels increased discomfort and may be involved in pushing efforts. Perineal bulging may be occurring, which adds to the discomfort and difficulty in moving. All of these factors make moving the woman very uncomfortable. If birth seems imminent (within the next minute), it is safer for the woman to give birth in her labor bed or on the cart. Transfer to the delivery table is then delayed until after the baby is born and the cord has been clamped and cut.

Even though there are differences in the birthing room setting, the family can still be together during the birth. It is important to provide encouragement for family members to participate because the delivery room environment may be unfamiliar and seem less relaxed. The family member may be hesitant to continue to provide support for fear of interfering or being in the way. The nurse can ensure that family members are included throughout the birthing process by giving them simple directions about how they can assist and be involved in the process.

Maternal Birthing Positions

The woman is usually positioned for birth on a bed, birthing chair, or delivery table. In some instances, she may give birth standing at the side of the bed or on her hands and knees on the floor. The position the woman assumes is determined not only by her individual wishes but also by the CNM or physician.

If stirrups are used, they should be padded to alleviate pressure, and both legs should be lifted simultaneously to avoid strain on abdominal, back, and perineal muscles. The stirrups should be adjusted to fit the woman's legs. The feet are supported in the stirrup holders. The height and angle of the stirrups are adjusted so there is no pressure on the back of the knees or the calf, which might cause discomfort and postpartal vascular problems. This is particularly true of women with epidural anesthesia. The birthing bed is elevated 30 to 60 degrees to help the woman bear down, and handles are provided so she may pull back on them.

The upright posture for birth was considered normal in most societies until modern times. Alternatively, women selected squatting, kneeling, standing, and sitting for birth. Only within the last 200 years has the recumbent position become the norm in the Western world. Its use in this century has been reinforced because of the convenience it offers in applying new technology, and it has thus become the conventional manner in which North American women give birth in hospitals. In searching for alternative positions, consumers and professionals alike continue to refocus on the comfort of the laboring woman and the advantages of alternative positions rather than on the convenience of the CNM or physician (Table 24-9).

RECUMBENT POSITION The recumbent (lithotomy) position for birth is used sometimes to enhance the maintenance of asepsis, assessment of FHR, and performance of episiotomy and repair. In contrast, when the comfort and well-being of the woman and fetus are considered, the following disadvantages have been noted (Blackburn, 2007):

- There is a decrease of as much as 30% in the blood pressure of 10% of women.
- Many women experience difficulty breathing because of pressure of the uterus on the diaphragm.
- The uterine axis is directed toward the symphysis pubis instead of the pelvic inlet, thus interfering with fetal alignment.
- Aspiration of vomit is more likely.
- The woman may feel resentment at being forced to assume an "embarrassing" position.
- Supine hypotension syndrome may occur.
- The labor may be prolonged and may lead to the use of medications to augment labor.
- The contractions may seem more uncomfortable, making coping more difficult.
- Tightening of the vagina and perineum as the thighs are flexed may increase the likelihood of an episiotomy or laceration.
- The position may interfere with the frequency and intensity of contractions.
- Stirrups cause excessive pressure on the legs.
- The woman works against gravity.

These disadvantages may be lessened slightly if the woman has her back elevated 30 to 40 degrees.

LEFT LATERAL SIMS' POSITION A common position favored by some women and birth attendants is the left lateral Sims' or side-lying position (Figure 24-7A ■). In assuming this position for birth, the woman lies on her left side with her left leg extended and her right knee drawn against her abdomen or flexed by her side or with both legs bent at the knees. Although the frequency of contractions may decrease in this position, the intensity increases, yielding greater uterine efficiency (Blackburn, 2007). Those who favor this position find that it increases overall comfort, does not compromise venous return from the lower extremities, puts less stress and pressure on the maternal neck, and diminishes the chances of aspiration should vomiting occur. Women also perceive the lateral Sims' as a more natural and comfortable position and less intrusive with no stirrups or overhead lights required. Birth attendants have found that the position has a positive effect on the management of fetal shoulder dystocias. Side-lying positions are also helpful in labors in which the fetus is in a posterior position, because this position allows the uterine weight and the fetus to tip away from the maternal back (Blackburn, 2007). Fewer episiotomies are required in this position because the perineum tends to be more relaxed.

TABLE 24-9 Comparison of Birthing Positions

POSITION	ADVANTAGES	DISADVANTAGES	NURSING ACTIONS
Recumbent	Enhances ability to maintain sterile field. May be easier to monitor FHR. Easier to perform episiotomy or laceration repair.	May decrease blood pressure. It is difficult for the woman to breathe due to pressure on the diaphragm. There is an increased risk of aspiration. May increase perineal pressure making laceration more likely. May interfere with uterine contractions.	Ensure that stirrups do not cause excess pressure on the legs. Assess legs for adequate circulation and support.
Left lateral Sims'	Does not compromise venous return from lower extremities. Increases perineal relaxation and decreases need for episiotomy. Appears to prevent rapid descent.	It is difficult for the woman to see the birth.	Adjust position so that the upper leg lies on the bed (scissor fashion) or is supported by the partner or on pillows.
Squatting	Size of pelvic outlet is increased. Gravity aids descent and expulsion of newborn. Second stage may be shortened (Cunningham et al., 2010).	It may be difficult to maintain balance while squatting.	Help woman maintain balance. Use a birthing bar if available.
Semi-Fowler's	Does not compromise venous return from lower extremities. Women can view birth process.	If legs are positioned wide apart, relaxation of perineal tissues is decreased.	Assess that upper torso is evenly supported. Increase support of body by changing position of bed or using pillows as props.
Sitting in birthing bed	Gravity aids descent and expulsion of the fetus. Does not compromise venous return from lower extremities. Woman can view the birth process. Leg position may be changed at will.		Ensure that legs and feet have adequate support.
Sitting on birthing stool	Gravity aids descent and expulsion of infant. Does not compromise venous return from lower extremities. Woman can view birth process.	It is difficult to provide support for the woman's back.	Encourage woman to sit in a position that increases her comfort.
Hands and knees	Increases perineal relaxation and decreases need for episiotomy. Increases placental and umbilical blood flow and decreases nonreassuring fetal status. Improves fetal rotation. Better able to assess perineum. Better access to fetal nose and mouth for suctioning at birth. Facilitates birth of infant with shoulder dystocia.	Woman cannot view birth. There is decreased contact with birth attendant. Caregivers cannot use instruments. There may be increased maternal fatigue.	Adjust birthing bed by dropping the foot down. Supply extra pillows for increased support.

The disadvantages cited relate to the difficulty of cutting and repairing large episiotomies and problems with difficult forceps births. These disadvantages, however, can be rectified by repositioning the woman if forceps are needed or if a repair is needed after the birth.

SQUATTING POSITION Squatting is favored by some women primarily for the positive use it makes of gravity, which allows the abdominal wall to relax (Blackburn, 2007). Squatting is thought to facilitate the entrance of the presenting part into the pelvic inlet, thus hastening engagement. This engagement facilitates pressure being applied to the cervix, which aids in stretching it. This in turn can stimulate the myometrium to produce more intense uterine contractions and shorten the length of labor. A squatting bar (birthing bar) may be used across a bed or on the floor to increase the woman's balance and provide some support (see Figure 24-6). During the second stage of labor, squatting increases the size of the pelvic outlet by 28% and helps in the woman's pushing efforts. The pressure from the thighs against the uterus can also aid in fetal descent and help facilitate a favorable fetal position (Blackburn, 2007). Some birth attendants object to this position because the perineum is relatively inaccessible, and it is difficult for them to control the birth process. Squatting also increases the difficulty of administering analgesia, using instruments, and monitoring fetal status. Perineal edema can also occur from prolonged squatting. Ice may be applied intermittently to lessen perineal edema. Women with epidural anesthesia may be unable to assume this position because of the heaviness in their lower extremities.

SEMI-FOWLER'S POSITION Some care providers advocate a semi-Fowler's position as an appropriate middle ground between the recumbent and upright positions. This position has also been associated with shorter first and second stages of labor than the traditional lithotomy position (Blackburn, 2007). This position enhances the effectiveness of the abdominal mus-

A

B

Figure 24-7 ■ Birthing positions. A. Side-lying (also known as left lateral Sims') position. B. Using a birthing stool.

Source: A. Photographer, Elena Dorfman. B. © Stella Johnson (www.stellajohnson.com).

cle efforts while the woman is pushing and thereby shortens the second stage of labor. Raising and supporting the torso helps the woman view the birth process. At the same time the birth attendant has access to the perineum. Supporting a woman in this position is not difficult with most birthing beds.

SITTING POSITION The sitting position is becoming an option for more women with the increased availability of birthing chairs. The use of birthing chairs or stools can be traced back to ancient Egypt, and they were widely used in ancient Greek, Roman, and Incan civilizations. In the wake of the 19th-century battle against puerperal fever, birthing chairs began to vanish on hygienic grounds. Birthing chairs are being used again during the second stage of labor and are perceived by some women as a positive way to participate in the birth process (see Figure 24-7B ■). A supported sitting position may also be achieved in a birthing bed.

The upright sitting position offers advantages similar to squatting. It has been associated with stronger, more effective uterine contractions. It has been postulated that the weight of a term fetus is sufficient force in itself to supply much of what is needed to bring the newborn into the world. Proponents of the birthing chair state that it makes possible spontaneous births that would have required operative assistance in the recumbent position. Women experiencing severe back pain have found that use of the chair can diminish or eliminate the pain. The woman can curl forward and grasp her knees and ankles during pushing efforts. She can usually see the birth without aid of mirrors, and following birth she can lift the baby up toward her face.

Duration of the second stage and fetal outcome are not significantly affected by use of the birthing chair. However, it may carry a potential for increased blood loss.

HANDS AND KNEES POSITION The hands and knees position is more comfortable for a woman experiencing back labor because there is less pressure on the maternal back from the fetus, and the fetus may be able to rotate more easily from the posterior position. The mother can be well supported by dropping the foot of the birthing bed and supplying extra pillows upon which she can rest her forearms. Because there is less pressure on the perineum, there is less need for an episiotomy, and the incidence of lacerations is less. The birth attendant is better able to assess the perineum for stretching and has good access to the fetal nose and mouth for suctioning at the time of birth. This position may also increase placental and umbilical blood flow during episodes of nonreassuring fetal status. This position also increases the intensity of the uterine contractions. Lastly, the hands and knees position may increase the pelvic diameter and facilitate birth of the infant with shoulder dystocia. Disadvantages of this position include decreased eye contact between the mother and birth attendant, the inability to use instruments, and the potential necessity of repositioning the mother for perineal repair. Women may also become easily fatigued in this position.

Cleansing the Perineum

If a perineal prep is to be performed, the woman is positioned for the birth, and her vulvar and perineal area is cleansed to increase her comfort and to remove the bloody discharge that is present before the actual birth. An aseptic technique such as the one that follows is recommended.

After thorough handwashing, the nurse opens the sterile prep tray, dons sterile gloves, and cleans the vulva and perineum with the cleansing solution. Beginning with the mons pubis, the area is cleansed up to the lower abdomen. A second sponge is used to clean the inner groin and thigh of one leg, and a third is used to clean the other leg, moving outward to avoid carrying material from surrounding areas to the vaginal outlet. The last three sponges are used to clean the labia and vestibule with one downward sweep each. The used sponges are discarded. Once the cleansing is completed, the woman returns to the desired birthing position. Not all birthing facilities use such formalized cleansing procedures. Some facilities use

a spray bottle with povidone-iodine (Betadine) or other cleansing agent and simply spray the perineal area. Because birth is not truly a "sterile procedure" some providers do not perform perineal cleansing techniques.

Supporting the Couple

The nurse assesses the woman's partner or other support person for comfort and knowledge and assists him or her in activities that will support the woman during the second stage. Some support persons will want to take an active role in coaching the woman through the birth process, whereas others will prefer simply to observe the birth process. The nurse assesses the roles the members of the support team desire and provides interventions that enhance these roles. It is important to keep the support team informed of the woman's progress, provide explanations of what is happening, and praise them for their supportive activities. A nurse who provides calm reassurance can help promote a positive experience.

Assisting with the Birth of the Infant

When the fetal head has distended the perineum, the clinician may perform a hand maneuver, such as supporting the perineum between the thumb and four fingers, which is believed to prevent undue trauma to the fetal head and maternal soft tissues. The woman may be asked to breathe rapidly, pant, or blow to avoid too rapid birth of the fetal head. The woman may also be instructed to push and take a breath intermittently to avoid rapid expulsion.

After the infant's head is born, the clinician palpates the neck for the presence of a cord, which can be slipped over the fetal head if it is loose. If the cord is tight, it is double-clamped and cut.

Restitution and external rotation occur after the head is born. The only assistance needed during this time is support of the maternal perineum. While awaiting completion of external rotation, the clinician suctions the newborn's nose and mouth to remove mucus. When the newborn's shoulder appears at the symphysis pubis, the clinician may use both hands to grasp the newborn's head gently and pull downward for release of the anterior shoulder. Gentle upward traction facilitates release of the posterior shoulder.

Birth of the newborn's body may be controlled by grasping the posterior shoulder with one hand, palm turned toward the perineum. The left hand may be used for this if the newborn is left occiput anterior (LOA). The right hand then follows along the infant's back, and the feet are grasped as they are expelled. The newborn's head is kept down and to the side as the feet, legs, and body are tucked under the clinician's left arm in a football hold. The clinician's right hand is then free for further care of the newborn, and the newborn is securely held. CNMs often place the newborn directly on the mother's abdomen. The nose and mouth are suctioned with a bulb syringe, and respiratory passages are cleared. Figure 24-8 ■ depicts an entire birthing experience.

Assisting with Clamping the Cord

There is controversy about when to clamp and cut the cord. If the newborn is held at or below the vagina as cord clamping is delayed, as much as 50 to 100 ml of blood may be shifted from the placenta to the newborn. If the newborn is held 50 to 60 cm above the vagina, blood may be transferred from the newborn to the placenta. The extra amount of blood added to the newborn's circulation by holding the newborn below the vagina may reduce the frequency of iron deficiency anemia, which can occur later in infancy. However, in some cases the circulatory overload may produce polycythemia and favor hyperbilirubinemia.

Some parents may specify a preference in their birth plan regarding exactly when the umbilical cord is to be cut. There is some evidence that suggests that delayed cord clamping in preterm infants results in fewer transfusions, lower rates of intraventricular hemorrhage, and a lower incidence of sepsis, although delayed clamping can interfere with immediate resuscitation efforts (Mercer, Vohr, Erickson-Owens, et al., 2009). Infants in one study of low birth weight males who had undergone delayed cord clamping had less motor disabilities at 7 months of age (Mercer et al., 2009). Delayed cord clamping may also benefit infants with a nuchal cord. One study that compared cutting the umbilical cord before the birth of the shoulders versus delayed cord cutting by reducing the cord around the fetal neck showed a reduction in hypovolemia, anemia, shock, hypoxic-ischemic encephalopathy, and cerebral palsy when the delayed approach was used (Mercer et al., 2009). The pros and cons of early and late cord clamping can be discussed before the birth.

The cord is usually clamped with two Kelly clamps and cut between them. The father, other support person, or the mother may wish to cut the cord after it has been clamped by the physician or CNM.

The physician or CNM may double-clamp the cord so that a section can be made available for the collection of cord blood gases. After the cord has been cut, cord blood is collected and sent to the lab as needed.

If the physician or CNM has not placed a cord clamp on the newborn's umbilical stump, it is the responsibility of the nurse to do so. Before applying the cord clamp, the nurse examines the cut end for the presence of two arteries and one vein. The umbilical vein is the largest vessel, and the arteries are smaller vessels. The presence of only one artery in the umbilical cord is associated with genitourinary abnormalities. The number of vessels is recorded on the birth and newborn records.

The cord is clamped approximately 1/2 to 1 inch from the abdomen to allow room between the abdomen and clamp as the cord dries (Figure 24-9 ■). Abdominal skin must not be clamped because this will cause necrosis of the tissue. The clamp is removed in the newborn nursery approximately 24 hours after birth if the cord has dried.

Cord Blood Collection for Banking

Growing numbers of parents are arranging for cord blood banking (see discussion in chapter 1 ∞). Immediately after the newborn's umbilical cord is clamped and cut and before the placenta is expelled, the physician or CNM withdraws blood from the umbilical cord. The blood is placed in a spe-

Figure 24-8 ■ A birthing sequence.

Source: © Stella Johnson (www.stellajohnson.com).

cial container that parents receive from the Cord Blood Registry and bring with them for the birth. The parents will have any special directions that are required for storage and care of the container. Although current recommendations for cord blood banking include a family history of an illness that can be treated with fetal cells and children whose parents are from a nontraditional lineage, such as mixed race backgrounds or other ethnic combinations that are uncommon, many families are choosing to bank their infants' cord blood. Stem cell transplants are now used to treat many different types of diseases (Table 24-10). The future of stem cell transplantation is promising, with rapid expansion of uses (Lanfranchi, Porta, & Chirico, 2009).

Table 24-7 on page 612 summarizes labor progress, possible responses of the laboring woman, and nursing care during the first and second stages of labor.

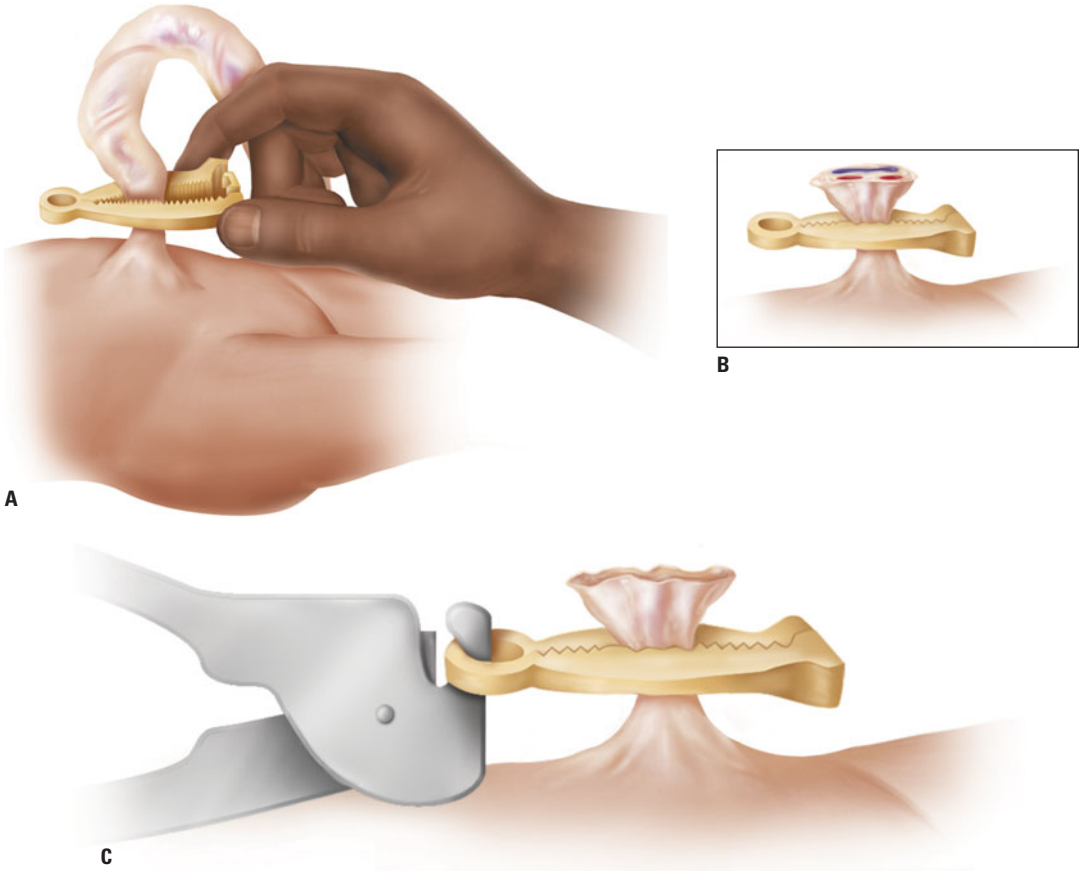


Figure 24-9 ■ Hollister cord clamp. A. Clamp is positioned 1/2 to 1 inch from the abdomen and then secured. B. Cut cord. The one vein and two arteries can be seen. C. Plastic device for removing clamp after cord has dried. After the cord is dried, the nurse grasps the Hollister clamp on either side of the cut area and gently separates it.

Third Stage of Labor

Nursing Care During the Third Stage of Labor

Nursing care in the third stage focuses on providing initial newborn care and assisting with birth of the placenta.

Provision of Initial Newborn Care

The physician or certified nurse-midwife (CNM) places the newborn on the mother's abdomen or in the radiant-heated unit to begin the initial care. If the newborn is not placed on the mother's abdomen, the radiant-heated unit is positioned so the parents can see the baby.

Because the first priority is to maintain respirations, the newborn is placed in a modified Trendelenburg position to aid drainage of mucus from the nasopharynx and trachea. The newborn is also suctioned with a bulb syringe or DeLee mucus trap as needed (see Procedure 24-1: Performing Nasal Pharyngeal Suctioning).

The second priority is to provide and maintain warmth, so the newborn is dried immediately with warmed, soft infant blankets. Wet blankets should be immediately removed to prevent heat loss. The nurse dries the newborn's head first to minimize heat loss. Warmth can be maintained by putting the newborn in skin-to-skin contact with the mother and placing warmed blankets over both of them. If the newborn is placed in a radiant-heated unit, he or she is dried, laid on a dry blanket, and left uncovered under the radiant heat. Because radiant heat warms the outer surface of objects, a newborn wrapped in blankets will receive no benefit. In many settings a stocking cap is placed on the newborn's head to conserve heat. See chapter 29 ∞ and chapter 31 ∞ for more information on infant heat loss and keeping infants warm.

Apgar Scoring System

The Apgar scoring system (Table 24-11) was designed in 1952 by Dr. Virginia Apgar, an anesthesiologist. The purpose of the **Apgar score** is to evaluate the physical condition of the newborn at birth. The newborn is rated 1 minute after birth and again at 5 minutes and receives a total score ranging from 0 to 10 based on the following criteria:

1. The heart rate is auscultated or palpated at the junction of the umbilical cord and skin. This is the most important assessment. A newborn heart rate of less than 100 beats/min indicates the need for immediate resuscitation.
2. The respiratory effort is the second most important Apgar assessment. Complete absence of respirations is termed *apnea.* A vigorous cry indicates good respirations.
3. The muscle tone is determined by evaluating the degree of flexion and resistance to straightening of the extremities.

TABLE 24-10 Diseases That May Be Treated with Stem Cell Transplants

Arthritis

Inherited Metabolic Disorders

TABLE 24-11 The Apgar Scoring System

	SCORE		
SIGN	**0**	**1**	**2**
Heart rate	Absent	Slow—below 100	Above 100
Respiratory effort	Absent	Slow—irregular	Good crying
Muscle tone	Flaccid	Some flexion of extremities	Active motion
Reflex irritability	None	Grimace	Vigorous cry
Color	Pale blue	Body pink, blue extremities	Completely pink

Source: Reprinted from Pediatric Clinics of North America, 13, *V. Apgar,* The Newborn (Apgar) Scoring System, Reflections and Advice, *p. 645. Copyright © 1966, with permission from Elsevier.*

A normal term newborn's elbows and hips are flexed, with the knees positioned up toward the abdomen.

4. The reflex irritability is evaluated as the newborn is dried or by lightly rubbing the soles of the feet. A cry is a score of 2. A grimace is 1 point, and no response is 0.
5. The skin color is inspected for cyanosis and pallor. Newborns generally have blue extremities, and the rest of the body is pink, which merits a score of 1. This condition, termed *acrocyanosis,* is present in 85% of normal newborns at 1 minute after birth. A completely pink newborn scores a 2, and a totally cyanotic, pale infant is scored 0. Newborns with darker skin pigmentation will not be pink. Their skin color is assessed for pallor and acrocyanosis, and a score is selected based on the assessment.

A score of 7 to 10 indicates a newborn in good condition and requires only nasopharyngeal suctioning. An Apgar score between 4 and 7 indicates the need for stimulation; a score under 4 indicates the need for resuscitation (ACOG, 2006). See further discussion in chapter 34 ∞.

Newborn Physical Assessment by the Nurse

An abbreviated systematic physical assessment is performed by the nurse in the birthing area to detect any abnormalities (Table 24-12). First, the nurse notes the size of the newborn and the contour and size of the head in relationship to the rest of the body. The newborn's posture and movements indicate tone and neurologic functioning. The appearance of the head is noted

PROCEDURE 24-1 Performing Nasal Pharyngeal Suctioning

NURSING ACTION

Preparation

- Suction equipment is always available in the birthing area to clear secretions from the newborn's nose or oropharnyx if respirations are depressed or if amniotic fluid was meconium stained.
- Tighten the lid on the DeLee mucus trap or other suction device collection bottle.

  Rationale: *This avoids spillage of secretions and prevents air from leaking out of the lid.*
- Connect one end of the DeLee tubing to low suction.

Equipment and Supplies

DeLee mucus trap or other suction device

Procedure: Clean Gloves

1. Don gloves.
2. Without applying suction, insert the free end of the DeLee tubing 3 to 5 inches into the newborn's nose or mouth (Figure 24-10 ■).

   Rationale: *Applying suction while passing the tube would interfere with smooth passage of the tube.*
3. Place your thumb over the suction control and begin to apply suction. Continue to suction as you slowly remove the tube, rotating it slightly.

   Rationale: *Suctioning during withdrawal removes fluid and avoids redepositing secretions in the newborn's nasopharnyx.*
4. Continue to reinsert the tube and provide suction for as long as fluid is aspirated.

Note: *Excessive suctioning can cause vagal stimulation, which decreases the heart rate.*

Figure 24-10 ■ A newborn infant being suctioned with a DeLee mucus trap to remove excess secretions from the mouth and nares.

Source: Photographer, Elena Dorfman.

5. If it is necessary to pass the tube into the newborn's stomach to remove meconium secretions that the newborn swallowed before birth, insert the tube through the newborn's mouth into the stomach. Apply suction and continue to suction as you withdraw the tube.

   Rationale: *Because the newborn's nares are small and delicate, it is easier and faster to pass the suction tube through the mouth.*
6. Document the completion of the procedure and the amount and type of secretions.

   Rationale: *This documentation provides a record of the intervention and the status of the infant at birth.*

along with palpation of the fontanelles. The face should be inspected along with the ears and neck.

The skin is inspected for discoloration, presence of vernix caseosa and lanugo, and evidence of trauma and desquamation (peeling of skin). *Vernix caseosa* is a white, cheesy substance normally found on newborns. It is absorbed within 24 hours after birth. Vernix is abundant on preterm infants and absent on postterm newborns. A large quantity of fine hair *(lanugo)* is often seen on preterm newborns, especially on their shoulders, foreheads, backs, and cheeks. Desquamation of the skin is seen in postterm newborns.

The nares are observed for flaring. As the newborn cries, the palate can be inspected for cleft palate. Mucus in the nose and mouth can be assessed and removed with the bulb syringe as needed. The chest is inspected for respiratory rate and the presence of retractions. If retractions are present, the newborn is assessed for grunting or stridor. A normal respiratory rate is 30 to 60 per minute. The lungs may be auscultated bilaterally for breath sounds. Absence of breath sounds on one side may indicate pneumothorax. Rales may be heard immediately after birth because a small amount of fluid may remain in the lungs; this fluid will be absorbed. Rhonchi indicate aspiration of oral secretions. The abdomen is inspected and palpated for masses. The heart is assessed for heart rate, rhythm, and the presence of any murmurs. The normal newborn heart rate is 110 to 160 beats/min. The umbilical cord is inspected, and the number of vessels is recorded.

The genital area, buttocks, and anus are inspected. The elimination of urine or meconium is noted and recorded on the newborn record. The extremities are inspected and compared for symmetry. Reflexes are assessed to determine central nervous system maturity. A complete newborn assessment can be found in chapter 30 ∞.

Newborn Identification

To ensure correct identification, the nurse gives the mother and the newborn identification bands with identical codes in the

TABLE 24-12 Initial Newborn Evaluation

ASSESS	NORMAL FINDINGS
Respirations	Rate 30–60 irregular No retractions, no grunting
Apical pulse	Rate 110–160 and somewhat irregular
Temperature	Skin temp above 36.5°C (97.8°F)
Skin color	Body pink with bluish extremities
Umbilical cord	Two arteries and one vein
Gestational age	Should be 38–42 weeks to remain with parents for extended time
Sole creases	Sole creases that involve the heel
In general, expect scant amount of vernix on upper back, axilla, groin, lanugo only on upper back; ears with incurving of upper 2/3 of pinnae and thin cartilage that springs back from folding; male genitals—testes palpated in upper or lower scrotum; female genitals—labia majora larger; clitoris nearly covered.	
In the following situations, newborns should generally be stabilized rather than remaining with parents in the birth area for an extended period of time.	
Apgar less than 8 at 1 minute and less than 9 at 5 minutes or baby requires resuscitation measures (other than whiffs of oxygen)	
Respirations below 30 or above 60, with retractions and/or grunting	
Apical pulse below 110 or above 160 with marked irregularities	
Skin temperature below 36.5°C (97.8°F)	
Skin color pale blue or circumoral pallor	
Baby less than 38 or more than 42 weeks' gestation	
Baby very small or very large for gestational age	
Congenital anomalies involving open areas in the skin (meningomyelocele)	

birthing or delivery room. One bracelet is placed on the mother's wrist and sometimes on the wrist of her partner or a support person whom she designates. Two bracelets are placed on the newborn—one on the wrist and one on the ankle. The newborn bands must be applied snugly to prevent their loss. Infants should not be removed from the room until these identification bands have been placed. The bands should remain in place until the mother and infant are discharged home.

Some facilities now use security devices that are placed on the umbilical cord clamp or the identification bracelet of the infant (Figure 24-11 ■). The alarm is left in place until discharge. The alarm sounds if the infant is removed from the hospital unit or if the alarm is cut or disengaged. Some systems activate a "lockdown" of the birthing unit, thus making abduction of an infant more difficult.

Additional security measures are now commonplace in many maternity settings. Staff must wear appropriate identification at all times. Parents are advised not to allow individuals without proper identification to remove their infant under any circumstances. The nurse also advises the parents to keep the infant on the side of the bed furthest from the door. The infant should be returned to the nursery if the mother plans to nap or shower if no other family member is present.

Although infants were once footprinted for security reasons, the practice is now performed to provide a souvenir for parents and is no longer considered a safety measure. To prepare the newborn for footprinting, the nurse wipes the soles of both the

Figure 24-11 ■ Umbilical alarm in place on a newborn infant.

newborn's feet to remove any vernix caseosa. The footprint can be placed on a card or in the parents' baby book.

Initiation of Attachment

The birth of the baby is usually an emotionally charged time for all members of the family. The sight of the new baby and the sounds of the first cry may fill the parents with utter amazement. As the baby is placed on the mother's abdomen or chest, she frequently reaches out to touch and stroke her baby. When the newborn is placed in this position, the father also has a very clear, close view and can also reach out to touch his baby.

When the parents feel comfortable in the environment, they may talk to the newborn, and some mothers talk to their babies in a high-pitched voice, which seems to soothe newborns. Some couples verbally express amazement and pride when they see they have produced a beautiful, healthy baby. Their verbalization enhances feelings of accomplishment and profound happiness.

If lights in the birthing area can be dimmed, the newborn will probably open his or her eyes wide and gaze at the surroundings. In this first hour after birth, the newborn is usually quiet and continues to gaze. This is a wonderful opportunity for eye contact with the parents, and many parents are content to gaze quietly at their newborn.

Even though the baby is on the mother's abdomen or chest, the nurse can complete any needed assessments or interventions such as footprinting and applying an identification bracelet to the child. As soon as possible the nurse can assist the mother to a more comfortable position for holding the newborn. Breastfeeding can be encouraged if the mother and baby desire. When the baby is held close to the breast, the baby will seek out the nipple. Even if the newborn does not actively nurse, she or he can lick, taste, and smell the mother's skin. This activity stimulates the maternal release of prolactin, which promotes the onset of lactation.

The initial parental-newborn attachment period can be enhanced if the care providers keep routine investigations to a minimum, delay instillation of ophthalmic antibiotic for the first hour, keep the room slightly darkened, avoid loud noises, talk in quiet tones, and provide privacy. Both parents need to be encouraged to do whatever they feel most comfortable doing. Parents may have differing wishes concerning contact with their newborn. Some want immediate and unlimited time; some prefer to wait until all birth-related activities are completed (the placenta is expelled and episiotomy repair is completed); others prefer limited contact immediately after birth and quiet time later. Although immediate contact may be important for attachment and initiation of breastfeeding, the parents' wishes need to be supported.

Parents can be encouraged to delay phone calls and visits from friends until after the first hour of birth because it is a time when the baby is the most alert. Most facilities have policies in place where the newborn is taken to the nursery for assessment and bathing after an initial visit with the parents. This is an excellent time for phone calls and visits with family and friends. It enables the new family to spend valuable time together and facilitates bonding.

> "I was hungry for the baby as he was born. I wanted to see, hold him. It was hours before I realized or even thought love in relation to him."
>
> —Harriette Hartigan, Women in Birth

Delivery of the Placenta

Placental Delivery

Delivery of Placenta

After the cord has been clamped and cut, the physician or CNM observes for the following signs of placental separation:

1. The uterus rises upward in the abdomen because the placenta settles downward into the lower uterine segment.
2. As the placenta proceeds downward, the umbilical cord lengthens.
3. A sudden trickle or spurt of blood appears.
4. The uterus changes from a discoid to a globular shape.

While waiting for these signs, the nurse gently palpates the uterus to check for ballooning caused by uterine relaxation and subsequent bleeding into the uterine cavity.

After the placenta has separated, it may be expelled by various techniques such as maternal bearing-down effort, controlled cord traction, and fundal pressure. Maternal effort allows the placenta to be expelled spontaneously and is best accomplished in an upright position. When the mother is in a dorsal recumbent or lithotomy position, she or the nurse can help the process by splinting or supporting her abdominal muscles. The mother or nurse can place her palms over the lower abdomen, or the mother can flex her thighs over her abdomen. The mother then bears down to expel the placenta.

DEVELOPING CULTURAL COMPETENCE

Midwife-Attended Births: Malaysia

In Malaysia, 75% of all births are attended by a *dukun* (midwife). In many parts of the country, especially in rural areas, a home setting is preferred over a hospital setting for birth. It is believed that the baby's first cry is symbolic of loyalty to the parents and should be heard at home. The birth itself is a social event in which many women sit with the laboring woman. It is customary for the woman in labor and her female company to chew red-staining betel nuts. At the time of birth, either the mother or a female relative is given the honor of cutting the umbilical cord.

To help the woman expel her placenta, the physician or CNM first ensures that separation has occurred and then places one hand above the symphysis pubis with the palm against the anterior surface of the uterus. The uterus is displaced upward and backward as the mother is asked to relax her abdominal muscles and breathe through an open mouth. The elevation of the uterus straightens out the birth canal and facilitates expulsion of the placenta, as well as protecting the uterus from inversion. Gentle traction is exerted on the umbilical cord. Excessive pulling may increase the risk of uterine inversion, snapping off of the cord, and subsequent hemorrhage. During this procedure, the nurse encourages the mother to continue breathing through an open mouth and to relax her abdominal muscles.

Fundal pressure is not a method of choice because it is very uncomfortable for the mother, may damage uterine supports, and may invert the uterus. If this method is needed, the mother is asked to relax her abdominal muscles, and then the hand of the physician or CNM is placed behind the uterus with the fingers directed downward toward the maternal spine. With a quick "scooping" motion, the contracted uterus is pressed downward in an arc. This motion is different from direct downward pressure, which folds the uterus over the lower segment and does not enhance movement of the placenta. During the procedure, the nurse provides continued encouragement to maintain abdominal relaxation. This is very difficult because of the discomfort of the procedure.

After expulsion of the placenta, the physician or CNM inspects the placental membranes to make sure they are intact and that all cotyledons are present. This inspection is especially important with placentas expelled via the Duncan mechanism (the chance of tearing off a portion of a cotyledon is greatest with this mechanism of placental separation). If there is a defect or a part missing from the placenta, a digital uterine examination is done. The time and mechanism (Schultze or Duncan) of expulsion of the placenta are noted on the birth record (see chapter 22 ∞ and Figures 11-11 ■ and 11-12 ■ on page 228). The vagina and

cervix are inspected for lacerations, and any necessary repairs are made. An episiotomy or laceration may be repaired now if it has not been done previously. (See further discussion of episiotomy in chapter 28 ∞.) The fundus of the uterus is palpated; normal position is at the midline and below the umbilicus. If the fundus is displaced, it may be because of a full bladder or a collection of blood in the uterus.

The medical-nursing culture tends to refer to the placenta as the "afterbirth" and considers that its value is fulfilled once it is expelled and examined. Disposal of the placenta is prescribed by the hospital or birth center, and no more thought is given to it. However, many cultures have other beliefs regarding the placenta. Some patients will have specific beliefs about disposal of the placenta and will ask to take it home with them. Labor nurses will need to review hospital policies for disposal of the placenta before giving the placenta to the woman or family members.

Use of Oxytocics

Some CNMs and physicians advocate the use of an oxytocic drug (Pitocin) to stimulate uterine contractions after birth and to reduce the incidence of third-stage hemorrhage.

The physician or CNM may request that 10 units of oxytocin be given intramuscularly to the woman when the anterior shoulder of the infant appears at the vaginal opening. Some practitioners believe that this procedure facilitates the expulsion of the placenta. Others question whether this method increases the incidence of neonatal hyperviscosity because an additional bolus of blood may be infused into the fetus when the uterus contracts in response to the oxytocin. At other times 10 units of oxytocin may be administered intramuscularly at the time of placental expulsion. Both techniques are thought to prevent uterine atony and excessive bleeding. Some prefer to add 10 to 20 units of oxytocin to IV fluids administered over a period of hours. Additional information and associated nursing implications are presented in the Drug Guide: Oxytocin (Pitocin) in chapter 28 ∞. Methylergonovine maleate (Methergine), 0.2 mg can be administered intramuscularly. Methergine should not be given if preeclampsia is present. Carboprost tromethamine (Hemabate) 250 mcg/ml can also be administered intramuscularly (See Drug Guide: Carboprost Tromethamine [Hemabate]). Although the use of misoprostol (Cytotec) in treating postpartum hemorrhage is an off-label use, it is used in some settings with favorable results; however, it does have undesirable side effects including shivering, pyrexia, and diarrhea (Anderson & Etches, 2007).

Nursing Care During the Fourth Stage of Labor

The period immediately following expulsion of the placenta is referred to as the fourth stage of labor and birth. Actually, the label is misleading because labor and birth are completed with delivery of the placenta, and the next few hours are actually the immediate recovery phase. The fourth stage is usually defined as lasting from 1 to 4 hours after the birth or until vital signs are stable. Nursing care in this phase involves the basics of postpartum nursing care.

Immediately after the placenta is expelled, the episiotomy or vaginal lacerations are repaired. The uterus is palpated at frequent intervals, usually every 15 minutes for an hour until bleeding is within normal limits, to ensure that it remains

DRUG GUIDE Carboprost Tromethamine (Hemabate)

PREGNANCY RISK CATEGORY: D

OVERVIEW OF ACTION

Carboprost tromethamine (Hemabate) is used to reduce blood loss secondary to uterine atony. It stimulates myometrial contractions to control postpartum hemorrhaging that is unresponsive to usual techniques. Carboprost tromethamine can also be used to induce labor in women desiring an elective termination of a pregnancy. The drug is also used to induce labor in cases of intrauterine fetal death and hydatidiform mole (Wilson, Shannon, & Stang, 2010).

ROUTE, DOSAGE, FREQUENCY

In cases of immediate postpartum hemorrhage, the usual intramuscular dose is 250 mcg (1 ml) which can be repeated every 1 1/2 to 3 1/2 hours if uterine atony persists. The dosage can be increased to 500 mcg (2 ml) if uterine contractility is inadequate after several doses of 250 mcg. The total dosage should not exceed 12 mg. The maximum duration of use is 48 hours (Wilson et al., 2010).

CONTRAINDICATIONS

The drug is contraindicated in women with active cardiac, pulmonary, or renal disease. It should not be administered during pregnancy or in women with acute pelvic inflammatory disease. It should be used with caution in women with asthma, adrenal disease, hypotension, hypertension, diabetes mellitus, epilepsy, fibroids, cervical stenosis, or previous uterine surgery (Wilson et al., 2010).

SIDE EFFECTS

The most common side effects are nausea and diarrhea. Fever, chills, and flushing can occur. Headache, muscle, joint, abdominal, or eye pain can also occur (Wilson et al., 2010).

NURSING CONSIDERATIONS

1. The injection should be given in a large muscle. Aspiration should be performed to avoid injection into a blood vessel which can result in bronchospasm, tetanic contractions, and shock.
2. After administration, monitor uterine status and bleeding carefully.
3. Report excess bleeding to the physician/CNM.
4. Check vital signs routinely, observing for an increase in temperature, elevated pulse, and decreased blood pressure.
5. Breastfeeding should be delayed for 24 hours after administration (Wilson et al., 2010).

firmly contracted. Although labor is completed, the uterus is sensitive to touch. Palpation of the uterine fundus will be uncomfortable for the woman. If the mother has not held her baby, immediate newborn care should be completed at her side and within her reach so that she can touch her baby during this time. As soon as immediate care is completed, the new mother is usually eager to cuddle and explore her baby. If she plans to breastfeed and the baby is interested, she should be encouraged and helped to do so right after birth while the baby is awake and alert. Care should be taken not to try to force an uninterested baby to breastfeed because it will just lead to frustration for both mother and baby.

Behavioral characteristics of the mother vary, according to such factors as the length of labor, level of fatigue, extent of interruption in normal sleep patterns, and cultural norms. After the initial excitement of becoming acquainted with their new baby and notifying others of the birth, many new mothers are very tired and want to rest. Others are wide awake, eager to talk about their labor, and satisfy basic body needs, such as hunger and thirst.

Provision of Care in the Fourth Stage

As soon as the certified nurse-midwife (CNM) or physician completes the repair of any perineal lacerations or an episiotomy, drapes (if used) are removed. If the mother is to remain in the birthing bed, the nurse places clean absorbent pads beneath her and applies maternity pads. A cold pack may be placed directly on the perineum if perineal edema is present or an episiotomy has been done. If a mother prefers to shower immediately after birth, the nurse can assist her as needed and change the bed linens while the mother is up.

If stirrups were used, her perineum is cleansed and maternity pads applied before her legs are removed from the stirrups. To avoid muscle strain, both legs are removed from the stirrups at the same time. The legs may be held together and gently pushed toward the woman's abdomen, back to a neutral position and then gently lowered toward her right side and then the left side to promote circulation return. If the woman has given birth on a delivery table, she is transferred to a recovery room bed. If the mother has not had a chance to hold her infant, she may do so before she is transferred from the birthing room. The nurse ensures that the mother and father or support person and newborn are given time to begin the attachment process.

In addition to encouraging family celebration of the birth, the immediate recovery period involves assessing both maternal bleeding and newborn stabilization. The most significant source of bleeding is from the site where the placenta was implanted and where uterine vessels previously provided pooling of maternal blood to nourish the fetus. It is therefore critical that the fundus stay well contracted to clamp off these uterine vessels and prevent hemorrhage. It is the nurse's responsibility to assess the mother's blood pressure, pulse, firmness and position of fundus, and amount and character of vaginal blood flow every 15 minutes for the first 1 or 2 hours. Deviations from the normal ranges require more frequent checking.

Blood pressure should return to the prelabor level, and pulse rate should be slightly lower than it was in labor. The maternal blood pressure should be monitored at 5- to 15-minute intervals. The return of the blood pressure is due to an increased volume of blood returning to the maternal circulation from the uteroplacental shunt. Baroreceptors cause a vagal response, which slows the pulse. The physiologic slowing may be offset by excitement, increased temperature, or dehydration. A rise in the blood pressure may be a response to oxytocic drugs or may be caused by preeclampsia. Blood loss may be reflected by a lowered blood pressure and a rising pulse rate. Table 24-13 summarizes maternal changes following birth.

TABLE 24-13 Maternal Adaptations Following Birth

CHARACTERISTIC	NORMAL FINDING
Blood pressure	Returns to prelabor level
Pulse	Slightly lower than in labor
Uterine fundus	In the midline at the umbilicus or 1–2 fingerbreadths below the umbilicus
Lochia	Red (rubra), small to moderate amount (from spotting on pads to 1/4–1/2 of pad covered in 15 minutes) Doesn't exceed saturation of one pad in first hour
Bladder	Nonpalpable
Perineum	Smooth, pink, without bruising or edema
Emotional state	Wide variation, including excited, exhilarated, smiling, crying, fatigued, verbal, quiet, pensive, and sleepy

The fundus should be firm at the umbilicus or lower and in the midline. The uterus should be palpated but not massaged unless boggy (atonic) (Procedure 24-2). When the uterus becomes boggy, pooling of blood occurs within it, resulting in the formation of clots. Anything left in the uterus prevents it from contracting effectively. Thus if it becomes boggy or appears to rise in the abdomen, the fundus should be massaged until firm. The uterus at this time is very tender, and palpation and massage cause discomfort. All palpation and massage should be done as gently as possible.

A boggy uterus feels very soft instead of firm and hard. The uterus may have relaxed so much that it cannot be found when the nurse attempts to palpate it. In this case the nurse places a hand in the midline of the abdomen at the level of the umbilicus and begins to make kneading motions. This motion stimulates the uterine fundus to contract, and the nurse will feel the fundus tighten to a firm, hard object.

CLINICAL TIP

Teach the woman to gently massage her own uterus by feeling for the uterus at the level of the umbilicus. Describe the uterus as a commonly known identifiable object, such as a grapefruit or a softball, to provide a visual cue for the woman. Once she identifies her uterus, she can gently massage it to increase uterine contractions.

The nurse inspects the bloody vaginal discharge, called *lochia,* for amount and charts it as minimal, moderate, or heavy (see chapter 35 ∞). It should be bright red. Because different brands of maternity pads absorb varying amounts of blood, it may be necessary to weigh the maternity pad to determine actual blood loss. A gram scale is used, and 1 g is equivalent to

PROCEDURE 24-2 Assessing the Uterine Fundus Following Vaginal Birth

NURSING ACTION

Preparation

- Explain the procedure, the information it provides, and what it might feel like.
- Ask the woman to void.

  Rationale: *A full bladder can cause uterine atony.*
- Have the woman lie flat in bed with her head on a pillow. If the procedure is uncomfortable, she may find that it helps to flex her legs.

  Rationale: *The supine position prevents falsely high assessment of fundal height. Flexing the legs relaxes the abdominal muscles.*

Equipment and Supplies

A clean perineal pad

Procedure

1. Gently place one hand on the lower segment of the uterus. Using the side of the other hand, palpate the abdomen until you locate the top of the fundus.

   Rationale: *One hand stabilizes the uterus while the other hand locates the top of the fundus.*

CLINICAL TIP

Gloves may be put on before assessing the abdomen and fundus or when you are ready to assess the perineum and lochia.

2. Determine whether the fundus is firm. If it is, it will feel like a hard round object in the abdomen. If it is not firm, massage the abdomen lightly until the fundus is firm.

   Rationale: *A firm fundus indicates that the uterine muscles are contracted and bleeding will not occur.*
3. Measure the top of the fundus in fingerbreadths above, below, or at the fundus. See Figure 24-12 ■.

   Rationale: *Fundal height gives information about the progress of involution.*
4. Determine the position of the fundus in relation to the midline of the body. If it is not in the midline, locate it and then evaluate the bladder for distention.

   Rationale: *The fundus may deviate from the midline when the bladder is full because the enlarged bladder pushes the uterus aside.*
5. If the bladder is distended, use nursing measures to help the woman void. If she is not able to void after a specified period of time, catheterization may be necessary.
6. Measure urine output for the next few hours until normal elimination is established.

   Rationale: *During the postpartum as diuresis occurs, the bladder may fill far more rapidly than normal, putting the woman at risk for uterine atony and hemorrhage.*
7. Assess the lochia.

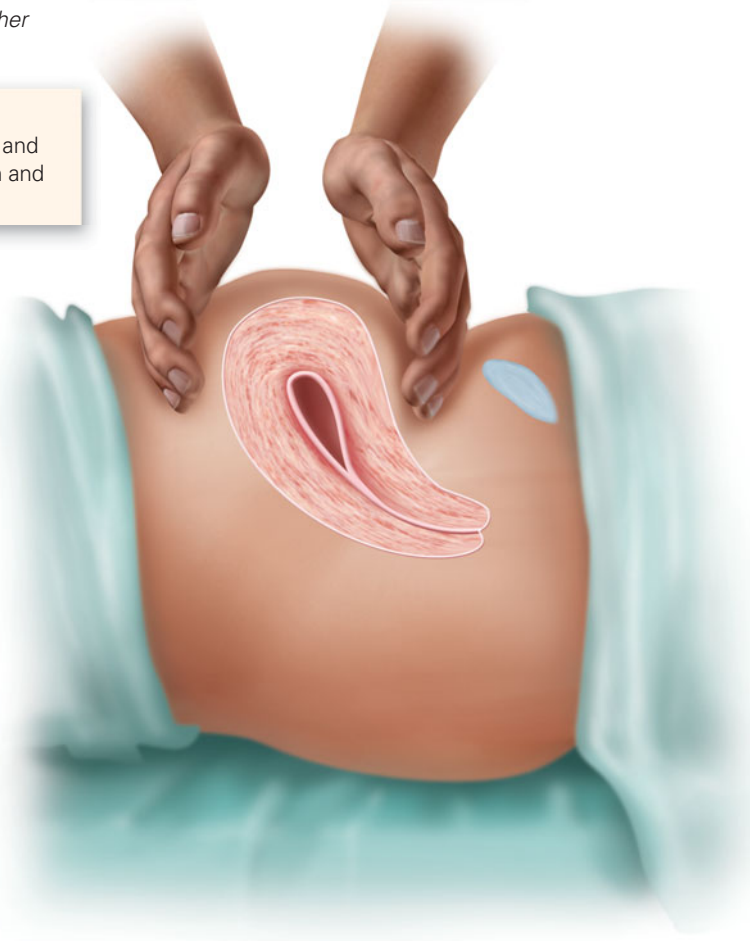

Figure 24-12 ■ Suggested method of palpating the fundus of the uterus during the fourth stage. The left hand is placed just above the symphysis pubis, and gentle downward pressure is exerted. The right hand is cupped around the uterine fundus.

Documentation

The nurse documents the position (midline, deviated to the left or right), fundal height in relation to the umbilicus (F @ U or F @ U ↑ 1 or F @ U ↓ 1), and consistency (firm, boggy). The bladder status should also be recorded (distended, appears empty), along with the time of the last void.

approximately 1 ml of blood. If the perineal pad becomes soaked in a 15-minute period or if blood pools under the buttocks, continuous observation is necessary. As long as the woman remains in bed during the first hour, bleeding should not exceed saturation of one pad. Laceration of the vagina, cervix, or an unligated vessel in the episiotomy may be indicated by a continuous trickle of blood even though the fundus remains firm. (See Procedure 35-2: Evaluating Lochia, on page 1011 ∞).

If the fundus rises and displaces to the right, the nurse palpates the bladder to determine whether it is distended. All measures should be taken to enable the mother to void. If she is unable to void, catheterization is necessary. Postpartal women have decreased sensations to void as a result of the decreased tone of the bladder caused by the trauma imposed on the bladder and urethra during childbirth. The bladder fills rapidly as the body attempts to rid itself of the extra fluid volume returned from the uteroplacental circulation and of IV fluid that may have been received during labor and birth. If the mother is unable to void, a warm towel placed across the lower abdomen, warm water poured over the perineum, or spirits of peppermint poured into a bedpan may help the urinary sphincter relax and thus facilitate voiding. A distended bladder can cause uterine atony, thus increasing postpartal bleeding.

The perineum is inspected for edema and hematoma formation. With an episiotomy or laceration, an ice pack often reduces swelling and alleviates discomfort. To fully visualize the episiotomy or laceration site, the nurse has the woman lie on her side and lifts her anterior buttock to visualize the suture line. The site should be well approximated and may appear swollen or bruised. No active bleeding at the site should be observed.

The following conditions should be reported to the CNM or physician: hypotension, tachycardia, uterine atony, excessive bleeding, or a temperature over 38°C (100°F). The nurse should be aware that the blood pressure may not fall rapidly in the presence of dangerous bleeding in postpartal mothers because of the extra systemic volume. However, an increasing pulse rate may be noted before a decrease in blood pressure is detected. A normal blood pressure with the mother in the Fowler's position is a good confirmation of a normotensive woman.

Promotion of Comfort in the Fourth Stage

Women frequently have tremors in the immediate postpartum period. It has been proposed that this shivering response is caused by exhaustion or a difference in internal and external body temperatures (higher temperature inside the body than on the outside). Another theory is that the woman is reacting to the fetal cells that have entered the maternal circulation at the placental site. Shivering is more common in women who have received epidural anesthesia (Blackburn, 2007). A heated bath blanket placed next to the woman and perhaps a warm drink tend to alleviate the problem.

The couple may be tired, hungry, and thirsty. Some hospitals serve the couple a meal. The tired mother may initially have a period of excitement but may then drift off into a welcome sleep because of exhaustion from the energy that was exerted during labor. The partner should also be encouraged to rest because his supporting role is physically and mentally tiring. The mother is usually transferred from the birthing unit to the postpartum unit after 2 hours or more, depending on agency policy and whether the following criteria are met: stable vital signs, stable lochia, nondistended bladder, firm fundus, and sensations fully recovered from any anesthetic agent received during childbirth.

Nursing Care of the Adolescent

Adolescent pregnancy rates have declined by 28% since 1990, although in 2006 the teenage pregnancy rates began slowly climbing after a 15-year decline (National Campaign to Prevent Teen and Unplanned Pregnancy [NCPTUP], 2010). The United States continues to have the highest adolescent pregnancy rate of any Western industrialized nation. Factors associated with teen pregnancy include early puberty, substance abuse, alcohol abuse, childhood sexual abuse, Latino ethnicity, teenage girls with live-in boyfriends, lack of community-based contraceptive clinics, and lack of an adult role model with whom a teen can discuss sexuality issues (Baker, Guthrie, Hutchinson, et al., 2007).

Adolescent patients need ongoing support throughout labor and the birth process. Each adolescent in labor is different. The nurse must assess what each patient brings to the experience by asking the following questions:

- Has the young woman received prenatal care?
- What are her attitudes and feelings about the pregnancy?
- How does her developmental stage influence her behavior, and how are her specific needs different?
- Who will support her during the birth, and what is the person's relationship to her?
- What preparation has she had for the experience?
- What are her expectations and fears regarding labor and birth?
- How has her culture influenced her?
- What are her usual coping mechanisms?
- Does she have adequate social support?
- Does she plan to keep the newborn? If so, does she need to learn parenting skills?
- Will the father of the baby be involved in the labor and birth experience?

Adolescents are at highest risk for pregnancy and labor complications and must be assessed carefully. Any adolescent who has not had prenatal care requires especially close observation during labor. The status of the fetus is monitored to ensure its well-being. The young woman's prenatal record is carefully reviewed for risks. The adolescent is more likely to have poor nutritional intake, preeclampsia, cephalopelvic disproportion (CPD), anemia, prematurity, drugs ingested during pregnancy, sexually transmitted infections, fetal death, and size-date discrepancies (gestation appears to be less than dates indicate because of minimal weight gain) (Baker et al., 2007; March of Dimes, 2009). Infants born to teenage mothers are more likely to have lower birth weights. They are also more likely to be exposed to alcohol, drugs, and tobacco in utero and in early childhood.

The nurse's support role depends on the young woman's support system during labor. When the patient is not accompa-

nied by someone who will stay with her during childbirth, it is even more important for the nurse to establish a trusting relationship with her. In this way, the nurse can help her cope with labor and understand what is happening to her. Establishing rapport without recrimination will provide emotional support and encouragement. The adolescent who is given positive reinforcement for "work well done" will leave the experience with increased self-esteem, despite the emotional stress and difficulty of giving birth at such a young age.

The adolescent who has taken childbirth education classes is generally better prepared than the adolescent who has had no preparation. The nurse must keep in mind, however, that the younger the adolescent, the less she may be able to participate actively in the process.

Age-Related Responses to Labor and Birth

The very young adolescent (under age 14) has fewer coping mechanisms and less experience to draw on than her older counterparts have. Because her cognitive development is incomplete, the younger adolescent may have fewer problem-solving capabilities. Her ego integrity may be more threatened by the experience, and she may be more vulnerable to stress and discomfort.

The very young woman needs someone to rely on at all times during labor. She may be more childlike and dependent than older teens. The nurse must be sure that instructions and explanations are simple and concrete. During the transition phase, the young teenager may become withdrawn and unable to express her need to be nurtured. Touch, soothing encouragement, and measures to promote her comfort help her maintain control and meet her needs for dependence. During the second stage of labor, the young adolescent may feel as if she is losing control and may reach out to those around her. By remaining calm and giving directions, the nurse helps her control feelings of helplessness.

> "One of the most memorable expectant mothers I cared for during my nursing course was Cara, a 13-year-old. I met her each week as she came into the OB clinic at our hospital and stayed with her as she waited for her appointment and was then seen by the medical student. I noticed that with each passing visit, she became more and more anxious. I did my best to determine the source of her anxiety, provide general teaching, and try to answer all of her questions. I consulted with my professor, and she sat in with me during some visits. But Cara became more and more anxious. Near term, she began asking if she could just have the baby cut out. Whatever was she afraid of? Finally, in the 38th week, after 2 1/2 months of building trust, she told me she was afraid because her baby had gotten too big, and it would never be able to come out through her belly button. I was speechless for a moment. For 2 1/2 months, I had answered questions and felt so proud of my support and teaching, and for all this time, she had not been able to ask the most important question of all—the question that paralyzed her with fear. I was finally able to provide specific information, made drawings on a paper towel, had the medical student talk with her, and best of all, was able to be on call and be with her in labor and during birth. The beautiful smile on her face as her baby daughter was born was unbelievable. Cara wasn't afraid! It's been 39 years since then, and I still remember her."

The middle adolescent (ages 14 to 16 years) often attempts to remain calm and unflinching during labor. If unable to break through the teenager's stoic barrier, the nurse needs to rise above frustration and realize that a caring attitude will still positively affect the young woman.

Many older adolescents (ages 16 to 19 years) feel that they "know it all," but they may be no more prepared for childbirth than their younger counterparts. The nurse's reinforcement and nonjudgmental manner will help them save face. If the adolescent has not taken classes, she may require preparation and explanations. The older teenager's response to the stresses of labor is similar to that of the adult woman.

The Adolescent Father

Consideration of the adolescent father is a very important aspect of labor and birthing care. Nurses need to be aware that this is a stressful time for the young father. There are some specific interventions that increase comfort, enhance education, and perhaps decrease stress. In the early part of labor, the nurse can talk with the father about his expectations for parenting the newborn and what resources are available in the community. Many adolescents are reluctant to ask questions, but an accepting attitude may help in establishing rapport and gaining trust.

The teen father may need encouragement to provide supportive care and to know what actions are acceptable in the birthing area. He may be encouraged to hold the mother's hand, to sit on the bed beside her, to give a back massage, or to stroke her forehead. He may need assistance in how to give a shoulder rub or back rub; he can watch the nurse first and then perform the action himself with the encouragement of the nurse. He may need more encouragement than the older father to share a Jacuzzi or shower or to support the mother in changing positions and ambulating. It is important for the nurse to speak in lay terms and to anticipate questions, to answer all vocalized questions honestly, and to provide opportunities for the parents to ask for further information.

Other Members of the Support Team

In addition to the adolescent's partner, the mother may want her parents or friends with her as members of her support team. Some teens may want their mothers as their primary support person, whereas others may strive to prove their independence and "do this on their own." Still other young women may look to friends for advice and support. The nurse includes parents and friends of the adolescent mother in the patient teaching and other aspects of the mother's care. It is important to respect the young woman's privacy and honor her wishes regarding whom

she wants in the room for the birth. The nurse may have to advocate for the young woman in certain circumstances.

Teaching the Adolescent Mother

During the latent phase of labor, the nurse can explain to the young woman what changes in body sensations and emotional reactions she might anticipate as labor and birth progress. The adolescent also needs teaching about what possible medical procedures (such as electronic fetal monitoring [EFM], etc.) might be used, as well as what nursing care measures are available. Some adolescents might not realize that they can request the nurse's presence, touch, or advice, unless the nurse specifically informs them that these options are available.

Adolescents are oriented to the present time and may not adequately predict future needs for themselves or their infant. The nurse should assess to make sure adequate resources are available, including infant and postpartum supplies, transportation to and from follow-up visits, and child care, if the adolescent mother is planning on returning to school or work.

Young mothers may need more information on infant care and feeding choices than older women. Some adolescents may be reluctant to breastfeed because of embarrassment or lack of information. The nurse can assist the young woman to explore her feelings related to breastfeeding and provide information (Figure 24-13 ■). The nurse should provide encouragement and support the young mother's decision. Sometimes, young women feel "pressured" to breastfeed their infants when they truly do not feel comfortable with this feeding choice. The nurse should give the young mother permission to make her own decision. Young women who choose to use formula should be given clear instructions on the importance of mixing the formula per the manufacturer's directions because overdiluting or underdiluting can cause adverse side effects for the baby.

Although rarer than in previous decades, some adolescents may choose to relinquish their newborns. In these situations, the nurse informs the adolescent that seeing the infant can facilitate the grieving process but lets her know that seeing the newborn is her choice. (See chapter 36 ∞ for further discussion of the relinquishing mother and the adolescent parent.)

Figure 24-13 ■ An adolescent mother receives breastfeeding assistance in the immediate postpartum period.

Nursing Care During Precipitous Birth

Occasionally, labor progresses so rapidly that the nurse is faced with the task of managing the birth of the baby. This is called a **precipitous birth**. The attending nurse has the primary responsibility for providing a physically and psychologically safe experience for the woman and her baby.

A woman whose physician or certified nurse-midwife (CNM) is not present may feel disappointed, frightened, cheated, and abandoned, especially if she is not prepared through childbirth education. The nurse can support the woman by keeping her informed about the labor progress and assuring her that the nurse will stay with her. If birth is imminent, the nurse must not leave the mother alone. Auxiliary personnel can be directed to contact the attending physician or CNM, or other physicians or CNMs who are in the facility. The auxiliary personnel should also retrieve the emergency pack ("precip pack"), which should be readily accessible to the birthing/labor rooms. A typical pack contains the following items: a small drape that can be placed under the woman's buttocks to provide a sterile field, a bulb syringe to clear mucus from the newborn's mouth, two sterile clamps (Kelly or Rochester) to clamp the umbilical cord before applying a cord clamp, sterile scissors to cut the umbilical cord, a sterile umbilical cord clamp, a baby blanket to wrap the newborn in after birth, and a package of sterile gloves.

As the materials are being gathered, the nurse must remain calm. The woman is reassured by the nurse's composure and feels that the nurse is competent. The primary goal of nursing care is the safe birth of the infant.

Birth of the Infant

The nurse manages precipitous birth in the hospital by encouraging the woman to assume a comfortable position. If time permits, the nurse scrubs both hands with soap and water and puts on sterile gloves. Sterile drapes are placed under the woman's buttocks.

At all times during the birth, the nurse gives clear instructions to the woman, supports her efforts, and provides reassurance. The nurse needs to remain calm and proceed in a slow, confident manner.

Most infants will be born in vertex presentation. When the infant's head crowns, the nurse instructs the woman to either blow or pant, which decreases her urge to push. The nurse checks whether the amniotic sac is intact. If it is, the nurse tears the sac with a clamp so that the newborn will not breathe in amniotic fluid with the first breath.

The nurse may place an index finger inside the lower portion of the vagina and the thumb on the outer portion of the perineum and gently massage the area to aid in stretching of perineal tissues and to help prevent perineal lacerations. This is called "ironing the perineum."

With one hand, the nurse applies gentle pressure against the fetal head to maintain flexion and prevent it from popping out rapidly. The nurse does not hold the head back forcibly. Rapid birth of the head may tear the woman's perineal tissues. The rapid change in pressure within the fetal head may cause subdural or

dural tears. The nurse supports the perineum with the other hand and allows the head to be delivered between contractions.

As the woman continues to blow or pant, the nurse inserts one or two fingers along the back of the fetal head to check for the umbilical cord. If the cord is around the neck, the nurse bends her fingers like a fish hook, grasps the cord, and pulls it over the baby's head, loosens it, or slips it down over the shoulders. It is important to check that the cord is not wrapped around more than one time. If the cord is tightly looped and cannot be slipped over the baby's head, the nurse places two clamps on the cord, cuts it between the clamps, and unwinds the cord. Because this ceases oxygenation to the baby, all efforts should be made to reduce (remove) the cord over the head whenever possible. The head typically rotates (restitutes) to the left or right. The nurse needs to let the head rotate (restitute) to the side before attempting delivery of the head.

Immediately after birth of the head, the nurse suctions first the mouth, throat, and then the nasal passages. The nurse places a hand on each side of the head and instructs the woman to push gently so that the rest of the body can be expelled quickly. The newborn must be supported as it emerges.

Breech vaginal births are quite rare. Because the incidence of breech presentations is only 3%, most breech presentations are scheduled for cesarean births, and women are advised to come to the hospital immediately if labor does begin spontaneously. Because the primary concern in a breech birth is to prevent the entrapment of the head in the cervix, intervention is avoided until the buttocks are born. The nurse then pulls down a loop of cord (to avoid stress on its point of insertion) and supports the breech in both hands. The infant's body is lifted slightly upward for birth of the posterior shoulder and arm. The newborn may then be lowered, and the anterior shoulder and arm will pass under the symphysis pubis. Suprapubic pressure should be applied to maintain the normal flexion of the baby's head and should be continued until the baby is born. The nape of the neck pivots under the symphysis, and the rest of the head is born over the perineum by a movement of flexion.

Regardless of the presentation at birth, the newborn is held at the level of the uterus to facilitate blood flow through the umbilical cord immediately after birth. The combination of amniotic fluid and vernix makes the newborn very slippery, so the nurse must be careful to avoid dropping the baby. Placing the woman in stirrups is not recommended for this reason; instead, the foot of the bed can be lowered. The nurse suctions the nose and mouth of the newborn again, using a bulb syringe. The nurse then dries the newborn quickly to prevent heat loss. Wet blankets should be removed and replaced with warmed, dry blankets.

As soon as the nurse determines that the newborn's respirations are adequate, the infant can be placed on the mother's abdomen. The newborn's head should be slightly lower than the body to aid drainage of fluid and mucus. The weight of the newborn on the mother's abdomen stimulates uterine contractions, which aid in placental separation. The umbilical cord should not be pulled. The Apgar score is assessed at 1 and 5 minutes.

The nurse is alert for signs of placental separation. When these signs are present, the nurse places one hand just above the symphysis pubis to guard the uterus and uses the other hand to maintain gentle downward traction on the cord while instructing the mother to push so that the placenta can be expelled. In some instances the mother can squat, and this usually helps expel the placenta. The nurse inspects the placenta to determine whether it is intact. Because the physician or CNM is usually en route, delivery of the placenta can be delayed until the practitioner arrives. Traction should not be applied because this can result in hemorrhage or detaching the umbilical cord from the placenta.

The nurse checks the firmness of the uterus. Palpation of the uterus should not be performed before separation of the placenta. The fundus may be gently massaged to stimulate contractions and decrease bleeding. Putting the newborn to breast also stimulates uterine contractions through release of oxytocin from the pituitary gland.

The umbilical cord may now be cut. Two sterile clamps are placed approximately 2 to 4 inches from the newborn's abdomen. The cord is cut between them with sterile scissors. A sterile cord clamp (Hollister or Hesseltine) can be placed adjacent to the clamp on the newborn's cord, between the clamp and the newborn's abdomen. The clamp must not be placed snugly against the abdomen because the cord will dry and shrink.

The area under the mother's buttocks is cleaned, and her perineum is inspected for lacerations. Bleeding from lacerations may be controlled by pressing a clean perineal pad against the perineum and instructing the woman to keep her thighs together. Further evaluation by the CNM or physician will be needed to determine if lacerations are present that need to be repaired.

If the arrival of the physician or CNM is delayed or if the newborn is having respiratory distress, the newborn should be transported immediately to the nursery. The newborn must be properly identified before he or she leaves the birthing area.

Record Keeping

The nurse notes and places on the record the following information:

1. Position of fetus at birth.
2. Presence of cord around neck or shoulder (nuchal cord).
3. Time of birth.
4. Apgar scores at 1 and 5 minutes after birth.
5. Gender of newborn.
6. Time of expulsion of placenta.
7. Method of placental expulsion.
8. Appearance and intactness of placenta.
9. Mother's condition.
10. Any medications that were given to mother or newborn (per agency protocol).

CLINICAL TIP

Since time is typically very limited and rushed in a precipitous birth, the nurse can write interventions and birth outcomes on the fetal heart rate (FHR) monitoring strip so that times and details are more precise and exact.

Postbirth Interventions

Postbirth interventions are the same as those discussed in the Nursing Care During the Third Stage of Labor section.

Evaluation

Evaluation provides an opportunity to determine the effectiveness of nursing care. As a result of comprehensive nursing care during the intrapartum period, the following outcomes may be anticipated:

- The mother's physical needs and the psychologic well-being of the family have been maintained and supported.
- The baby's physical and psychologic well-being has been protected and supported.
- The family has had input into the birth process, and members have participated as much as they desired.
- The birth was safe and promoted family cohesiveness.

FOCUS YOUR STUDY

- Admission to the birth setting involves assessment of many physiologic, psychologic, and social factors. The information gained helps the nurse establish priorities of care.
- Before initiating care, the nurse explains what will be done, the reasons, potential benefits and risks, and possible alternatives if appropriate. This helps the woman determine what happens to her body and is a critical element in the process of obtaining informed consent.
- Behavioral responses to labor vary with the phase of labor, the woman's preparation and previous experience, cultural beliefs, and developmental level.
- Each woman's cultural beliefs affect her need for privacy, her expression of discomfort, her expectations for the birth, and the role she wishes the father to play in the birth event.
- The laboring woman's comfort may be increased by general comfort measures, supportive relaxation techniques, methods of handling anxiety, controlled breathing, and support by a caring person.
- The laboring woman fears being alone during labor. Even though there is a support person available, the woman's anxiety may be decreased when the nurse remains with her.
- Maternal birthing positions include a wide variety of possibilities, such as recumbent, side-lying, sitting, squatting, and crouching on hands and knees.
- Immediate assessments of the newborn include evaluation of the Apgar score and an abbreviated physical assessment. These early assessments help determine whether there is a need for resuscitation and whether the newborn's adaptation to extrauterine life is progressing normally. The newborn who is not experiencing problems may remain with the parents for an extended period of time following birth.
- Immediate care of the newborn following birth also includes maintaining respirations, promoting warmth, preventing infection, and providing accurate identification.
- The new parents and their baby are given time together as soon as possible after birth.
- Nursing assessments continue after the birth and are important to ensure that normal physiologic adaptations are taking place.
- The adolescent has special needs in the birth setting. Her developmental needs require specialized nursing care.
- Nurse-assisted births are sometimes performed in the absence of the CNM or physician when birth is imminent.

CRITICAL THINKING IN ACTION

Anita Grey, a 22-year-old primigravida at 40 weeks' gestation, is admitted by you to the birthing center in labor. Anita was sent from her physician's office after being evaluated at her prenatal visit. While in the office, she was assessed to be 4 cm dilated, 100% effaced, vertex at 0 station with bulging membranes. She tells you that her husband is on his way to the birthing center and that she is anxious for him to arrive. A review of her prenatal record shows no complications affecting this pregnancy. Anita's vital signs are within normal limits. You assess the fetal heart rate and contraction pattern with the fetal monitor and observe a fetal heart rate of 140 to 150 beats/min with acceleration to 160s. Contractions are every 3 to 4 minutes × 30 seconds of moderate intensity by palpation. Anita seems to be tolerating the contractions well, but still seems anxious about her husband's arrival.

1. What steps can you take to reduce the stress and anxiety of the laboring woman and her family?
2. When you notify the physician/midwife, what pertinent information should the report contain?
3. What support measures can you give in the active phase of labor?
4. What measures can be used to decrease discomfort/pain as labor progresses?
5. What observations reflect the physiologic manifestations of pain?

CHAPTER 25

Pain Management During Labor

"We had attended childbirth classes and practiced through the last few weeks, and I had hoped to go through all of labor and birth without medication. But when the contractions really came on strong, I just wasn't ready for the amount and the kind of pain that I felt. I've always been able to tolerate pain well, but this was different. My husband and I talked about it and he reassured me that, if I felt I needed something, it was okay with him. My nurse was also very supportive. She helped me feel I was making a good decision and wasn't failing somehow."

LEARNING OUTCOMES

1. Discuss the nurse's role in supporting pharmaceutical pain relief measures in labor.
2. Describe the use of systemic analgesics to promote pain relief during labor.
3. Compare the major types of regional analgesia and anesthesia, including the area affected, advantages, disadvantages, techniques, and nursing implications.
4. Summarize possible complications of regional anesthesia.
5. Describe the three methods used to provide general anesthesia.
6. Delineate the major complications of general anesthesia.
7. Identify contraindications to specific types of analgesia and anesthesia for high-risk mothers.

KEY TERMS

Epidural block *645*
General anesthesia *656*
Local anesthesia *655*
Pudendal block *655*
Regional analgesia *641*
Regional anesthesia *641*
Spinal block *652*

When a childbearing woman experiences discomfort during labor and birth, the nurse can assist her to have a positive birth experience by providing effective comfort measures. Nursing interventions directed toward pain relief begin with the nonpharmacologic measures described in chapter 24 ∞, such as providing information, encouragement, back rubs, and clean linens. Many women need no further interventions.

For other women, the progression of labor brings increasing levels of pain that interfere with their ability to cope effectively. For these women, pharmacologic agents may be used to decrease discomfort, increase relaxation, and reestablish the ability to participate more actively in the labor and birth experience. In addition to systemic analgesics, regional nerve blocks (epidural, spinal, and combined epidural-spinal) and local anesthetic blocks (pudendal and perineal) are available. The methods are not mutually exclusive and may be used in combination with nonpharmacologic comfort measures.

Nurses need to recognize that the decision to have an unmedicated or a medicated birth involves many factors and reflects a great deal of thought and planning for most women and their families. Some of these factors include patient and caregiver preferences, availability of anesthesia and analgesia, fear of risks and complications, past life experiences, previous experiences with pain, and cultural influences. Other factors, such as the amount of sleep the woman has had or the length of labor, can also influence the need or desire for pharmacologic pain relief measures. The woman should be supported regardless of her decision even if it changes during the course of labor.

Each year in the United States, over 4 million infants are born. Of these births, 50% of all women will receive epidural anesthesia (Gibbs, Karlan, Haney, et al., 2008). Many couples who have had childbirth education approach their birth experience confident that the techniques they have learned will enable them to cope with the pain of labor. Nurses should respect these couples' choices and provide support to help them meet their goals. Analgesics and anesthetics do affect the fetus and can be accompanied by maternal side effects. Following an unmedicated birth, many women report a quicker postpartum recovery. Many are able to ambulate, urinate, shower, and eat within an hour of giving birth. Additionally, many women feel an enormous sense of empowerment after successfully having an unmedicated birth.

For the woman who has advised the nursing staff that she wants no pharmacologic remedies, the nurse should offer alternative comfort measures. All nurses in the intrapartum setting need to be familiar with various nonpharmacologic techniques available to help women cope with the pain they may experience. The nurse should avoid offering these women pain medications unless they specifically ask for them or for information about pharmacologic options.

On the other hand, many women are simply unprepared for the intense pain of active labor and may request medication. They may begin labor undecided about whether to use medication, then request pain relief as contractions intensify. Frequently, feelings of inadequacy and guilt accompany such decisions. The nurse plays a special role in assisting the woman and her partner to explore their options for pain relief realistically. The nurse can explain to the couple that, although pharmacologic agents do affect the fetus, so do the pain and stress experienced by the laboring mother. In response to stress, the woman's ventilation and oxygen consumption increase, thus decreasing the amount of oxygen available to the fetus. In addition, pain and stress can lead to metabolic acidosis and the release of catecholamines, causing the maternal blood vessels to constrict. This in turn decreases oxygen and nutrient supply to the fetus (Blackburn, 2007). Thus, if the woman's pain and anxiety are more than she can cope with, the adverse physiologic effects on the fetus may be as great as would occur with the administration of a small amount of an analgesic agent. The nurse should reassure the woman and her partner that accepting medication for pain is not a failure. The emphasis should be on the goal of a healthy, satisfying outcome for the family.

> "I felt really prepared for labor! We went through all of the classes and had envisioned the "perfect birth." After 16 hours of labor and no progress, I was exhausted and frustrated; sobbing, I totally broke down. I felt like a failure for getting an epidural. My nurse, Madison, was great! She comforted me and reinforced that I was not a failure. She reassured me that in the end the most important thing would be holding my daughter in my arms. She was right, my despair was forgotten when I was able to enjoy the rest of labor, rest, and get some much needed sleep before Katherine was born. As I gazed at my newborn daughter, I learned what was really important that day and in my life!"

Systemic Analgesia

The goal of systemic analgesia during labor is to provide maximal pain relief with minimal risk for the woman and fetus.

Multiple factors must be considered in the use of analgesic agents:

- Effects on the woman
- Effects on the fetus
- Effects on the labor contractions
- Medical status of the woman
- Progress of labor

The effects on the mother are of primary importance, because the well-being of the fetus depends on adequate functioning of the maternal cardiopulmonary system. Any alteration of function that disturbs the woman's homeostatic mechanism affects the fetal environment. Maintaining the maternal respiratory rate and blood pressure within normal range is thus of prime importance. The use of electronic fetal monitoring (EFM) provides a means of accurately assessing the effects of pharmacologic agents on uterine contractions.

All systemic analgesics can cross the placental barrier by simple diffusion, with some agents crossing more readily than others. Drug action in the body depends on the rate at which the

substance is metabolized by liver enzymes and excreted by the kidneys. The fetal liver enzymes and renal systems are inadequate to metabolize analgesic agents, so high doses remain active in fetal circulation for a prolonged period of time. The percentage of blood volume flowing to the fetal brain increases during intrauterine stress, so the hypoxic fetus receives an even larger amount of a depressant drug. The blood-brain barrier is more permeable at the time of birth, a factor that also increases the amount of drug carried to the central nervous system (Blackburn, 2007).

Administration of Analgesic Agents

The optimal time for administering analgesia is determined after a complete assessment of many factors. In the past, an analgesic agent was administered to nulliparas when the active phase of labor was well established (cervix had dilated to 5 or 6 cm) and to multiparas when the cervix had reached 3 or 4 cm dilatation. There is debate on the ideal timing of medication administration; however, both the American College of Obstetricians and Gynecologists (ACOG) and the American Society of Anesthesiologists (ASA) agree that a woman's request for pain medications is ample reason to administer them (Gibbs et al., 2008). In general, the woman should receive pain medication when she is uncomfortable and in a well-established labor pattern with contractions occurring regularly and of significant duration with moderate to strong intensity. Analgesia given too early may prolong labor and depress the fetus. Analgesia given too late is of no value to the woman and may cause neonatal respiratory depression. In many institutions, the nurse decides when to give the analgesic agent prescribed by the physician, certified nurse-midwife (CNM), or certified registered nurse anesthetist (CRNA). The nurse observes the woman for cues that indicate she would benefit from the administration of analgesics. The nurse performs needed assessments of both the mother and fetus and then notifies the CNM or physician. The decision to administer pain medication is based on a complete assessment of the woman and fetus and the progress of labor. The CNM or physician may evaluate the woman at the bedside or may rely on the nurse's assessment and instruct the nurse to administer the medications. In most institutions, the CRNA is available to monitor analgesia-related complications and provide ongoing monitoring for women who later receive an epidural. The American Society for Anesthesiologists practice guidelines mandate that all women undergo a history and physical examination prior to the initiation of anesthesia (ASA Task Force, 2007). Facilities may have anesthesiologists (physicians who specialize in administering anesthesia) or certified nurse anesthetists provide these services.

Maternal Assessment

The following maternal assessments are critical before administering systemic analgesics:

- The woman is willing to receive medication after being advised about it (Table 25-1).
- Vital signs are stable.
- Contraindications (such as drug allergies, respiratory compromise, or current drug dependence) are not present.
- Knowledge of other medications being administered, such as magnesium sulfate or tocolytics.

TABLE 25-1 What Women Need to Know About Pain Relief Medications

Before receiving medications, the woman should understand the following:

- Type of medication administered
- Route of administration
- Expected effects of medication
- Implications for fetus/newborn
- Safety measures needed (for example, remain in bed with side rails up)
- Side effects/complications

Fetal Assessment

The following assessments of the fetus are also required:

- Fetal heart rate (FHR) is between 110 and 160 beats per minute.
- Reactive nonstress test (NST) (accelerations of FHR are present with fetal movement).
- Variability is present.
- Periodic late decelerations or nonperiodic (variable) decelerations are absent.

Assessment of Labor

The following assessment parameters must also be evaluated:

- Contraction pattern
- Cervical dilatation
- Cervical effacement
- Fetal presenting part
- Station of the fetal presenting part

If normal parameters are absent or if nonreassuring maternal or fetal factors are present, the nurse may need to complete further assessments with the physician or CNM. In addition, no complications that would preclude administering an analgesic agent should be present, such as drug allergies or drug-specific contraindications.

Routes of Administration

Oral analgesics are not used because they are poorly absorbed and gastric emptying time is prolonged during labor. The intramuscular (IM), intravenous (IV), or subcutaneous (SC) routes are used instead. For IM administration, the needle must be of sufficient length to penetrate the muscle and the subcutaneous fat. The IV route is preferred because it results in prompt, smooth, and more predictable action with a smaller total dose required than the IM route. When an agent is given intravenously, it is suggested that the injection be given with the onset of a contraction, when the blood flow to the uterus and the fetus is normally decreased (Blackburn, 2007).

When an analgesic medication is administered by IM or SC route, it takes a few minutes for the effect to be felt. The nurse can continue with other supportive measures to enhance comfort until the effect of the medication is perceived. When the medication begins to take effect, the woman may be able to sleep between contractions. This short period of rest can restore her energy. When an IV route is prescribed, the woman feels the effect of the drug within a minute or two, so if any change of position is necessary or if the woman needs to void, the nurse may suggest that these activities be completed before the drug is administered

(Cunningham et al., 2010). As in all cases when there is a possibility of coming into contact with body fluids, Standard Precautions should be used. Consistent hand washing before and after procedures along with wearing disposable gloves can reduce the risk of blood or body fluid exposure. Sometimes analgesics are administered via IV and IM routes simultaneously. The benefit of this technique is that the woman receives a rapid onset from the IV route as well as the longer duration of pain control that is achieved with the IM route (Gibbs et al., 2008).

Before administering the medication, the nurse once again ascertains whether the woman has a history of any drug reactions or allergies and provides information regarding the medication (see Table 25-1). After giving the medication, the nurse records the drug name, dose, route, site, and the woman's blood pressure and pulse (before and after) on the EFM strip and on the woman's record. If the woman is alone, the nurse raises the side rails to provide safety and assesses the FHR for possible side effects of the medication.

CLINICAL TIP

The anesthesiologists should be notified of any complications or unexpected outcomes that occur as the result of medication administration.

Sedatives

In current labor and birth practice, sedatives are used primarily in the early latent phase of labor, when the cervix is long, closed, and thick, and rest is prescribed for the expectant woman. Sedatives promote relaxation and allow the woman to sleep for a few hours. Upon the woman's awakening, contractions have either ceased (i.e., the woman was in false labor) or contractions return and take on a regular pattern that promotes changes in cervical dilatation and effacement. Sedatives should not be given when a woman is in active labor because they can cause respiratory depression in the infant. Sedatives have minimal analgesic properties and can actually increase the reaction to painful stimuli. They should be administered only to decrease anxiety and promote sleep, because they cross the placenta and can cause depression in the newborn (Creasy, Resnik, Iams, et al., 2009).

Barbiturates

The most common barbiturates used in labor are secobarbital (Seconal) and zolpidem tartrate (Ambien). Seconal is fast acting, usually providing effects in 10 to 15 minutes with a duration of 3 to 4 hours. It is administered orally and is well tolerated. Its primary role is to treat false labor and produce a sedation effect. Both Seconal and Ambien can be used in latent labor to promote rest and relaxation and thereby prevent maternal exhaustion. Hypnotic effects also occur with many drugs in this category. Seconal has a long half-life and can remain in the maternal and fetal blood for up to 40 hours after administration, whereas Ambien has a half-life of 4.5 hours (Wilson, Shannon, & Shields, 2010). For this reason, Ambien may be more desirable for women in early labor. A barbiturate should not be administered to women in active labor because it can cause fetal depression and, in fact, is rarely used at anytime during true labor.

Benzodiazepines

Benzodiazepines, such as diazepam (Valium), are similar to barbiturates in their mechanism of action. They are primarily used to treat anxiety. They can also be used for their anticonvulsant action. They have a rapid onset of action and are absorbed quite easily when ingested orally. Although this class of drugs can be used to decrease anxiety, some have an amnesic effect, which may not be desirable for childbearing women. Fetal side effects have been reported but are usually mild. These include a decrease in variability of the FHR, hypotonicity, hypoactivity, impaired temperature regulation, and metabolic response to cold stress (Gibbs et al., 2008). Midazolam (Versed), which is commonly used during operative procedures, has been associated with low Apgar scores when administered 5 minutes or less before birth. Because of this side effect, it is not advisable to use midazolam for childbearing women (Gibbs et al., 2008). It is primarily used for maternal anxiety during cesarean births and is given after the fetus is born when the surgical procedure is being completed. Many practitioners are hesitant to use Versed because of its amnestic properties, which are unfavorable in the obstetrical setting (Gibbs et al., 2008). Flumazenil, the drug used to reverse benzodiazepine sedative effects, should be kept on hand in case of accidental overdose.

H_1-Receptor Antagonists

H_1-receptor antagonists block the action of histamines at the receptor sites. These drugs cross the blood-brain barrier and inhibit N-methyltransferase, which is a by-product of histamine. It is this mechanism that leads to the sedative effects of this class of drugs. In addition, these drugs also have anti-Parkinson and antiemetic effects. There are seven subtypes of H_1-receptor antagonists. These drugs cause drowsiness and are frequently used in early labor to promote sleep and decrease anxiety. The degree of drowsiness experienced depends on which drug is administered. Common H_1-receptor antagonists used in labor include promethazine (Phenergan), hydroxyzine (Vistaril), and diphenhydramine (Benadryl).

Promethazine (Phenergan), which is a phenothiazine, results in marked sedation and is often combined with opiates because it potentiates their effects. It also has strong antiemetic effects and can be combined with opiates to relieve nausea and vomiting, which can be a side effect of certain drugs, such as meperidine (Demerol). All phenothiazines cross the placental barrier and can result in decreased beat-to-beat variability. Promethazine has not, however, resulted in lower Apgar scores. Promethazine injections are typically painful and should be avoided if possible in laboring women (Gibbs et al., 2008). Phenothiazines can also bind to bilirubin binding sites in newborns whose mothers are exposed to the drug at term. This can result in an increased incidence of neonatal hyperbilirubinemia and jaundice (Wilson et al., 2010).

Hydroxyzine (Vistaril) is a piperazine subtype. It can be given in early or prodromal labor to decrease anxiety and nausea. It also results in sedation so the mother can rest. This drug is administered intramuscularly in a large muscle. Women in false labor are able to rest and frequently will awaken to find that their uterine contractions have dissipated. Commonly,

women who receive this drug in early or prodromal labor are able to rest and may enter active labor.

Diphenhydramine (Benadryl) is an ethanolamine subtype of the H_1 antagonists. Most commonly, this over-the-counter medication is used to treat allergic rhinitis and urticaria; however, it also possesses sedative and antiemetic properties that can be used to treat women in early labor. The drug has a relatively short half-life (1 to 4 hours) and can last up to 6 to 8 hours (Wilson et al., 2010). Nurses can advise women to use this drug at home if medically indicated, because it is readily available. It should be noted that this drug causes agitation in some women. If this side effect occurs, women should discontinue the medication (Wilson, et al., 2010).

NURSING CARE MANAGEMENT

The nurse should carefully assess the woman before administration of analgesic agents. Common indications for various medications are summarized in Table 25-2. Because they are not indicated for women in active labor, the nurse needs to determine the stage of labor. The nurse should evaluate the woman to determine the frequency, duration, and intensity of her contractions (Simpson & Creehan, 2008). A vaginal exam is performed to determine if cervical change has occurred. Fetal well-being is established by obtaining electronic fetal monitoring and ensuring a reactive fetal heart tracing. The nurse should explain the desired effects of the medication and possible side effects. If the woman is not in active labor, she can be given the medication and be advised to return home and rest. Since drowsiness can occur, however, the nurse needs to ensure the woman has a safe form of transportation home. Nurses need to review the symptoms of active labor and warning signs and advise the woman to call her healthcare provider should they occur.

Narcotic Analgesics

Narcotic analgesic agents that are injected into the circulation have their primary action at sites in the brain. Specifically, a narcotic that diffuses out of cerebral capillaries and reaches the periventricular/periaqueductal gray matter of the brain activates the neurons that descend to the spinal cord and inhibits the transmission of pain impulses in the substantia gelatinosa. Nausea and vomiting are produced by stimulation of the medullary chemoreceptor trigger zone.

A brief discussion of some selected narcotic analgesic agents follows. Both narcotic and non-narcotic analgesic drugs are summarized in Table 25-3.

Butorphanol Tartrate (Stadol)

Butorphanol tartrate (Stadol) is a mixed agonist-antagonist agent. The analgesic potency is 30 to 40 times that of meperidine and 7 times that of morphine (Wilson et al., 2010). Administration of butorphanol reverses the analgesic effect of other opioids or narcotics in the woman's body and precipitates withdrawal in drug-dependent individuals. For this reason, it is important to assess each woman's history of narcotic drug use during the admission assessment; if she has been using drugs, she should not receive butorphanol.

For the woman in labor, butorphanol is most frequently given by the IV route; however, it can also be given by IM injection. When administered intravenously, the recommended dose is 1 to 2 mg (the smaller dose is most frequently used). The onset of action is rapid, peak analgesia occurs in 30 to 60 minutes and duration is 3 to 4 hours (Wilson et al., 2010). If given by IM route, the recommended dose is 1 to 2 mg, although 2 mg is the most usual dose. Onset of action occurs in 10 to 15 minutes, peak analgesia occurs in 30 to 60 minutes, and duration is 3 to 4 hours (Wilson et al., 2010).

Respiratory depression of both the mother and fetus/newborn can occur. The effects of butorphanol (Stadol) can be reversed with naloxone (Narcan). Although not a common side effect, urinary retention can occur. The nurse should frequently assess the woman's bladder for distention. The nurse may need to perform an in-and-out catheterization using sterile technique to alleviate bladder distention. Major side effects include somnolence, dizziness, and feelings of dysphoria (Cunningham et al., 2010).

Fentanyl (Sublimaze)

Fentanyl (Sublimaze) is a short-acting synthetic opioid with moderate analgesia and mild sedation properties. The main advantage of fentanyl (Sublimaze) is that it has a rapid onset. In addition, the drug has limited placental transfer and thus has a lower incidence of reduced fetal heart rate variability. Women who receive fentanyl (Sublimaze) are less likely to require naloxone (Narcan) for neonatal respiratory depression. Be-

Benadryl (diphenhydramine hydrochloride)		X	X	X

TABLE 25-3 Analgesics Used in Labor

DRUG/CLASS	DOSAGE, ROUTE, FREQUENCY	COMMON SIDE EFFECTS	LIFE-THREATENING REACTIONS	CONTRAINDICATIONS
Stadol (butorphanol tartrate): central nervous system (CNS) agent, analgesic, narcotic agonist/antagonist	IM 1–4 mg every 3–4 hours IV 0.5–2 mg every 6–8 hours Intranasal: 1 mg (1 puff) may repeat in 90 seconds (max dose every 3–4 hours)	Sedation	Respiratory depression	Narcotic dependency, breastfeeding
Nubain (nalbuphine hydrochloride): CNS agent, analgesic, narcotic agonist, antagonist	10–20 mg every 3–6 hours prn SC/IM/IV	Sedation; sweaty, clammy skin; nausea and vomiting	Respiratory depression	Hypersensitivity to the drug
Demerol (meperidine hydrochloride): CNS agent, analgesic, narcotic agonist	50–100 mg IM or SC every 3–4 hours 25–50 mg IV every 3–4 hours	Nausea, vomiting, itching, urinary retention, sedation, respiratory depression, dizziness	Respiratory depression in mother and/or newborn, seizures, cardiovascular collapse, cardiac arrest, bronchoconstriction	Narcotic dependency, epilepsy, hypersensitivity to the drug
Morphine (morphine sulfate): CNS agent, analgesic, narcotic, agonist	IV 2.5–15 mg every 4 hours IM/SC 5–20 mg every 4 hours	Pruritus (itching), constipation, nausea	Anaphylactic reaction, respiratory depression; overdose; respiratory arrest, cardiac arrest	Hypersensitivity to opiates, increased intracranial pressure, convulsive disorders, acute alcoholism, acute asthma, chronic pulmonary diseases, decreased respirations, pulmonary edema, biliary tract surgery, anastomosis, pancreatitis, acute ulcerative colitis, liver/renal insufficiency, Addison's disease, hypothyroidism
Phenergan (promethazine hydrochloride): gastrointestinal (GI) agent, antiemetic, antivertigo agent, phenothiazine	25–50 mg every 3–4 hours po/pr/IM/IV	Sedation, drowsiness, dry mouth, blurred vision	Respiratory depression, agranulocytosis	Hypersensitivity to phenothiazines, glaucoma, peptic ulcer, pyloroduodenal obstruction, bladder neck obstruction, epilepsy, bone marrow depression, and breastfeeding
Vistaril (hydroxyzine pamoate): antihistamine, antianxiety, sedative, antipruritic, antiemetic	25–100 mg po/IM every 6 hours	Sedation, dizziness, dry mouth, nausea, headache	Seizures	Hypersensitivity to drug. Can be used with caution in glaucoma, urinary retention
Benadryl (diphenhydramine hydrochloride): antihistamine, antiemetic, antivertigo, antitussive, sedative-hypnotic	25–50 mg every 6 hours po/IM/IV	Drowsiness, sedation, dry mouth, hypotension, nausea and vomiting, GI symptoms	Anaphylaxis, seizures, coma, respiratory depression	Hypersensitivity to drug. Can be used during an acute asthma attack; use with caution in glaucoma, bladder obstruction, hypertension, hypothyroidism, renal disease

cause of its short half-life, repeated doses are required. The usual dosage is 50 to 100 μg every 1 hour (Gibbs et al., 2008).

NURSING CARE MANAGEMENT

Administering butorphanol or fentanyl with other central nervous system depressants, such as sedatives, phenothiazides, other tranquilizers, hypnotic agents, and general anesthetics, can exacerbate respiratory depression and cause other effects. For this reason, the nurse should evaluate the woman's respiratory and cardiac status by careful observation of vital signs and pulse oximetry. The woman's level of consciousness is also checked frequently. Continuous electronic monitoring of the FHR pattern is recommended. Respiratory depression in the mother or fetus/newborn can be reversed by naloxone (Narcan), which is a specific antagonist for this agent. The nurse ensures that naloxone is readily available should respiratory depression occur. A slightly depressed newborn is not likely to experience prolonged drowsiness or sluggishness, however, because the metabolites of butorphanol are inactive.

Nalbuphine Hydrochloride (Nubain)

Like butorphanol, nalbuphine hydrochloride (Nubain) is a synthetic agonist-antagonist narcotic analgesic and may precipitate drug withdrawal if the woman is physically dependent on narcotics (Cunningham et al., 2010). Nalbuphine crosses the placenta to the fetus and can cause nonreassuring fetal status and neonatal respiratory depression (Gibbs et al., 2008). Nalbuphine may be given by the IM, SC, or IV route. It is most frequently given by the IV route in the birth setting. The usual dose for adults is 10 mg/70 kg. If given intravenously, onset of action occurs in 2 to 3 minutes, peak of action occurs in 15 to 20 minutes, and duration is 3 to 6 hours. When given by the IM or SC route, the onset

DRUG GUIDE Nalbuphine Hydrochloride (Nubain)

OVERVIEW OF ACTION

Nubain is a synthetic narcotic analgesic with agonist and weak antagonist properties. Analgesic properties are equal to that produced by morphine. Nubain's potency is 3 to 4 times greater than pentazocine. The incidence of respiratory depression that occurs is equivalent to morphine.

DOSAGE ROUTE

Nubain is indicated for moderate to severe pain. Adults: 10–20 mg every 3–6 hours prn SC/IM/IV.

MATERNAL CONTRAINDICATIONS

Hypersensitivity or allergy to nalbuphine hydrochloride.

MATERNAL SIDE EFFECTS

Sedation; clammy, sweaty skin; dry mouth; bitter taste in mouth; nausea and vomiting; dizziness; vertigo; nervousness; restlessness; depression; crying; euphoria; dysphoria; confusion; hallucinations; unusual dreams; distortion of body image; numbness; tingling sensations; headache; miosis; hypertension; hypotension; bradycardia; tachycardia; flushing; abdominal cramps; dyspnea; asthma; speech difficulty; and urinary urgency.

NURSING CONSIDERATIONS

- Assess patient's sensitivity to narcotics on admission.
- Inform patient of potential side effects.
- Monitor and evaluate analgesic effect. Ask patient about comfort level and notify anesthesiologist of inadequate pain relief.
- Observe for symptoms of hypersensitivity: pruritus, urticaria, and/or burning sensation.
- May produce an allergic response in patients with sulfite sensitivity. If allergic reaction (urticaria, edema, or respiratory difficulties) occurs, administer naloxone or diphenhydramine per physician order.
- Assess respiratory rate before administration. Notify healthcare provider if respirations less than 12 per minute.
- Monitor urinary output and assess bladder for distention. Assist patient to void.
- Assist patient with ambulation after administration.
- Counsel patient that use with alcohol or other central nervous system depressants may increase medication effects.
- Counsel patient that prolonged use with abrupt discontinuation can result in symptoms consistent with narcotic withdrawal.

of action occurs in less than 15 minutes, peak of action occurs in 30 to 60 minutes, and duration is 3 to 6 hours. When given by the IV route, nalbuphine may be given directly into the tubing of a running IV infusion; 10 mg should be administered over 3 to 5 minutes (Wilson et al., 2010). Adverse maternal effects include respiratory depression, drowsiness, dizziness, crying, blurred vision, nausea, diaphoresis, and urinary urgency (Wilson et al., 2010). See Drug Guide: Nalbuphine Hydrochloride (Nubain).

NURSING CARE MANAGEMENT

The nurse assesses the woman's history to identify contraindications to use of nalbuphine, such as the possibility of current narcotic drug dependence, sensitivity to sulfites, and history of asthma (Wilson et al., 2010). If no contraindications exist, the IV route is frequently used during labor. The woman's respiratory rate, quality of respirations, and characteristics of the FHR must be carefully assessed. Anticipation of urinary urgency is important. Because the woman may experience dizziness and sedation, use of a bedpan may be necessary.

Meperidine Hydrochloride (Demerol)

Meperidine hydrochloride is also a synthetic agonist-antagonist narcotic analgesic. Like Nubain, it may also precipitate drug withdrawal if the woman is physically dependent on narcotics (Cunningham et al., 2010). Meperidine crosses the placenta within 90 seconds of maternal administration, with maternal and fetal concentrations achieving equilibrium at 6 minutes (Blackburn, 2007). Meperidine can be administered IM or IV in labor. The subcutaneous and oral routes are not routinely used for laboring women. The typical dose is 50 to 100 milligrams IM or 25 to 50 milligrams IV (Wilson et al., 2010). Whereas IM administration can take up to 40 to 50 minutes to be effective, IV administration can provide pain relief within 5 to 10 minutes after administration (Wilson et al., 2010). Adverse maternal effects include nausea, vomiting, itching, urinary retention, sedation, respiratory depression, and dizziness (Wilson et al., 2010). Since meperidine can cause convulsions, it should not be given to women with known convulsive disorders, such as epilepsy (Wilson et al., 2010).

Meperidine has multiple fetal side effects, including alteration in fetal electroencephalogram, decreased or absent respiratory movements, a decrease in fetal movements, and decreased variability with the FHR (Blackburn, 2007). In addition, newborns who have received meperidine take longer to sustain respirations after birth, have lower Apgar scores, lower oxygen saturation, a higher incidence of respiratory acidosis, and a higher incidence of abnormal neurologic examinations at birth (Blackburn, 2007). Meperidine has also been associated with delays in initiation of successful breastfeeding. Newborns whose mothers had received meperidine during labor had more sucking problems, including lack of sucking and incorrect sucking technique (Blackburn, 2007).

NURSING CARE MANAGEMENT

The nurse assesses the woman's history to identify if contraindications exist, such as the possibility of current narcotic drug dependence or convulsive disorders (Wilson et al., 2010). If no

contraindications exist, the IV or IM route is frequently used during labor. Because respiratory depression can occur, the woman's respiratory rate and quality of respirations are routinely assessed. Characteristics of the FHR must be carefully assessed. Although meperidine can cause a decrease in variability, the FHR should be continuously assessed for signs of late decelerations. Anticipation of urinary retention is important. The woman is offered a bedpan, and bladder distention is routinely assessed. If her bladder becomes distended and she is unable to void, catheterization may be necessary. Because the woman may experience dizziness and sedation, the woman typically remains on bed rest and does not ambulate after the medication is administered. The nurse assesses the woman for side effects and reports undesired side effects to the physician or CNM.

Opiate Antagonist: Naloxone (Narcan)

Because naloxone (Narcan) is an antagonist with little or no agonistic effect, it exhibits little pharmacologic activity in the absence of narcotic agents. Naloxone can be used to reverse the mild respiratory depression, sedation, and hypotension following small doses of opiates (Creasy et al., 2009). Naloxone exerts its effect by competing for opiate receptors and taking the place of the opiate on the receptor. In this manner, naloxone blocks or reverses the action of the narcotic analgesic (Cunningham et al., 2010). The drug is useful for respiratory depression caused by butorphanol (Stadol), nalbuphine (Nubain), and meperidine hydrochloride (Demerol) (Cunningham et al., 2010). *Naloxone is the drug of choice when the depressant is unknown because it will cause no further depression.* Naloxone's duration of action is less than that of most narcotic analgesics; however, respiratory depression may return as the antagonistic effect of naloxone wears off. Withdrawal symptoms may occur when Narcan is given to a woman or a newborn who is physically dependent on narcotics. A careful assessment that includes opiate drug use is imperative.

CLINICAL TIP

Each patient birthing room should be stocked with Naloxone (Narcan) at the bedside. Upon admission of a new patient, check the room to ensure the medication is supplied.

NURSING CARE MANAGEMENT

When naloxone is administered to the laboring mother or to the newborn just after birth, resuscitative measures and trained personnel should be readily available in the event that additional respiratory support is needed. When administered to the laboring mother, naloxone may be injected undiluted at a rate of 0.4 mg over 15 seconds into the tubing of a running IV infusion. Naloxone may also be diluted in an IV infusion of 5% dextrose or normal saline for a titrated dose. Titrated doses of naloxone are more likely to be used in a postoperative setting, when epidural analgesia has been given with a cesarean birth. After the direct IV administration, maternal vital signs should be obtained at 5-minute intervals until the respiratory rate has been stabilized and then every 30 minutes (Balestrieri-Martinez, 2009). Neonatal administration can be administered via IV, IM, or endotracheal (ET) routes. The standard neonatal dosage is 0.01 mg/kg (Wilson et al., 2010).

The duration of naloxone is shorter (minutes to hours) than the analgesic drug it is acting as an antagonist for, so the nurse must be alert to the return of respiratory depression and the need for repeated doses. Naloxone should be given with caution in women with known or suspected opiate dependence, because it may precipitate severe withdrawal symptoms in the mother and the newborn.

Regional Analgesia and Anesthesia

Regional anesthesia is the temporary and reversible loss of sensation produced by injecting an anesthetic agent (called a local anesthetic) into an area that will bring the agent into direct contact with nervous tissue. Loss of sensation occurs because the local agents stabilize the cell membrane, which prevents initiation and transmission of nerve impulses. The regional anesthetic blocks most commonly used in childbearing include epidural, spinal, or combined epidural-spinal. Epidural blocks may be used for analgesia during labor and vaginal birth and for anesthesia during cesarean birth. A combined epidural-spinal block may also be used. With this approach, the epidural is used to provide analgesia for labor, and the spinal provides anesthesia for birth or analgesia following birth.

An epidural relieves pain associated with the first stage of labor by blocking the sensory nerves supplying the uterus. Pain associated with the second stage of labor and with birth can be alleviated with epidural, combined epidural-spinal, and pudendal blocks (Figure 25-1 ■ and Table 25-4).

Regional anesthesia carries considerably less risk than general anesthesia. Risk of maternal death with general anesthesia during a cesarean birth is primarily related to intubation difficulties and hypovolemia. Other risk factors include obesity, African American race, and faulty monitoring during general anesthesia (Mhyre, Riesner, Polley, & Naughton, 2007).

PROFESSIONALISM IN PRACTICE

Timing Epidural Anesthesia

If the laboring woman has voiced a desire to have epidural anesthesia, advise her to tell you ahead of time when she might want it so the anesthesiologist has ample time to arrive before the woman's pain level becomes too intense.

Until fairly recently, the same anesthetic agents used for regional epidural anesthesia were also used to produce **regional analgesia** (pain relief) during labor. This approach was somewhat problematic because anesthetic agents alter the transmission of impulses to the bladder, making voiding difficult. The agents also interfere with the woman's ability to maintain her blood pressure and move her lower extremities. In addition, the descent of

Through the Eyes of a Nurse
Epidural for Pain Management

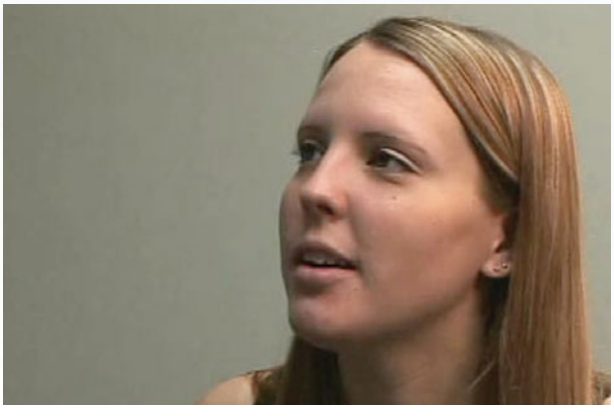
Family's Experience

"I know I really want to have the option of having something for pain, but I learned in our (childbirth) class that some of the medications can affect the baby's heart rate. I don't want anything that will hurt the baby! What is the safest choice for me and the baby?"

Nurse's Response

"Typically, the intravenous medications, such as Demerol or Nubain, can cause some changes in the baby's heartbeat and can cause respiratory problems at birth. For this reason, those medications are not given when birth will occur within a few hours.

"The epidural is another option and gives better pain relief. It can be given throughout labor. It can affect the heartbeat when it is first given if the mother's blood pressure drops immediately after it is administered. This is prevented by giving intravenous fluids to the mother before administering the epidural."



Nurse's Actions and Rationale

There are many types of analgesic and anesthesia options to the laboring woman. Analgesics commonly used in labor are summarized in Table 25-3. The nurse reviews the pros and cons of each option. Epidural anesthesia can also have risks and benefits. The medications should be reviewed with the woman before administration. Although complications are rare, the nurse explains possible complications that can occur. The nurse gives clear objective information based on evidence-based practice. All questions should be answered before the onset of labor so the woman can make informed choices when labor occurs.

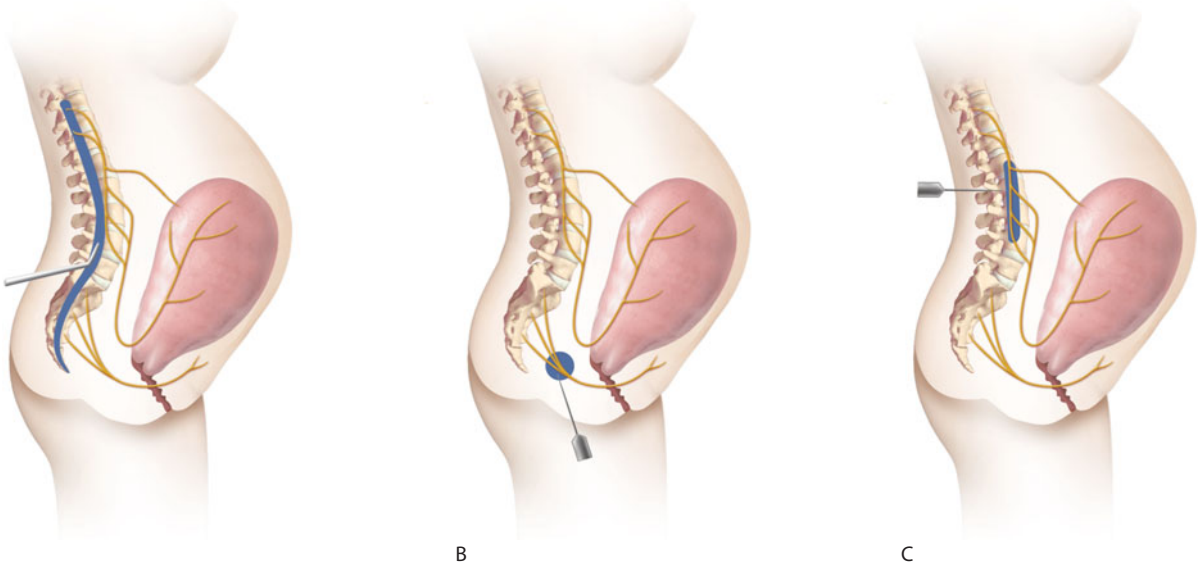


Figure 25-1 ■ Schematic diagram showing pain pathways and sites of interruption. A. Lumbar sympathetic (spinal) block: relief of uterine pain only. B. Pudendal block: relief of perineal pain. C. Lumbar epidural block: Dark area demonstrates peridural (epidural) space and nerves affected, and the gray tube represents a continuous plastic catheter.

the fetus may be slowed, because the agents also decrease the woman's ability to push effectively during the second stage of labor (Cunningham et al., 2010). To address these problems, regional analgesia is now obtained by injecting a narcotic agent such as fentanyl along with only a small amount of a local anesthetic agent. This approach yields effective pain relief without the troubling side effects of epidural anesthesia. The woman's pain is relieved, her blood pressure remains stable, and, because there is no motor blockage, she may be able to move about freely and ambulate. Urinary retention can still occur, but it can be treated with the placement of an indwelling Foley catheter or an in-and-out catheter (Cunningham et al., 2010). Urinary retention is usually a short-term complication that resolves on its own after the anesthesia has completely worn off.

The intrathecal injection of narcotics results in another type of regional analgesia. In this case, the narcotic is injected into the subarachnoid (spinal) space. Fentanyl citrate and preservative-free morphine are the most frequently used narcotic agents. The woman's pain is usually relieved; however, she may experience urinary retention. Delayed respiratory depression may also occur and seems to be more frequent with the use of morphine (Wilson et al., 2010).

It is important for the laboring woman to have information about the regional analgesia or anesthesia that is to be administered. As with other procedures, the woman needs to know how the block is given, the expected effect on her and the fetus, advantages and disadvantages, and possible risks. Many women discuss possible analgesic and anesthetic blocks with their physician or certified

TABLE 25-4 Summary of Commonly Used Regional Blocks

TYPE OF BLOCK	AREAS AFFECTED	USE DURING LABOR AND BIRTH	NURSING ACTIONS
Lumbar epidural	Uterus, cervix, vagina, and perineum	Given in first stage and second stage of labor.	Assess woman's knowledge regarding the block. Act as advocate to help her obtain further information if needed. Monitor maternal blood pressure to detect the major side effect, which is hypotension. Provide support and comfort. See Nursing Care Plan: For Epidural Anesthesia on page 651 for further nursing actions.
Combined spinal-epidural	Uterus, cervix, vagina, and perineum	Spinal analgesia may be given in latent phase for pain relief. Epidural is given when active labor begins.	Assess woman's knowledge regarding the block. Monitor maternal vital signs and fetal heart rate (FHR) status. Provide comfort measures.
Pudendal	Perineum and lower vagina	Given in the second stage just before birth to provide anesthesia for episiotomy or for low forceps birth.	Assess woman's knowledge regarding the block. Act as advocate to help her obtain further information if needed.
Local infiltration	Perineum	Administered just before birth to provide anesthesia for episiotomy or after birth for repair of a laceration.	Assess woman's knowledge regarding the block. Provide information as needed. Provide comfort and support. Observe perineum for bruising or other discoloration in the recovery period.
Spinal	Uterus, cervix, vagina, and perineum	Given during first stage for pain relief. Provides immediate onset of anesthesia.	Assess woman's knowledge regarding the block. Monitor maternal vital signs and FHR status.

nurse-midwife (CNM) during the pregnancy. If they have not, they should have an opportunity to ask questions and obtain information before receiving any regional analgesia or anesthesia while in labor. The nurse should answer questions and address concerns in early labor before the onset of acute pain. This ensures that the woman fully understands the information and can make an informed choice. Informed consent is obtained in writing before the administration of the medication.

Action and Absorption of Anesthetic Agents

Local anesthetic agents block nerve conduction by impairing propagation of the action potential in axons along with impairing the transmission of nerve impulses by stabilizing the cell membrane. The agents interact directly with specific receptors on the sodium channel, inhibiting sodium ion influx (Chestnut, Polley, Tsen, et al., 2009). The types of nerve fibers are differentially sensitive to the various anesthetic agents. In general, the smaller the fiber, the more sensitive it is to local agents. For example, it is possible to block the small C and A delta fibers, which transmit pain, touch, and temperature, without blocking the larger A alpha, A beta, and A gamma fibers, which continue to maintain a sense of pressure, muscle tone, position sense, and motor function (Chestnut et al., 2009).

Absorption of local anesthetic agents depends primarily on the vascularity of the area of injection. The agents also increase blood flow by causing vasodilatation (Chestnut et al., 2009). Higher concentrations cause greater vasodilatation. Good maternal physical condition or a high metabolic rate aids absorption. Malnutrition, dehydration, electrolyte imbalance, and cardiovascular and pulmonary problems increase the potential for toxic effects. The pH of tissues affects the rate of absorption, which has implications for fetal complications, such as acidosis (Blackburn, 2007). The addition of vasoconstrictors, such as epinephrine, delays absorption and prolongs the anesthetic effect. Epinephrine decreases uteroplacental blood flow, making it an undesirable additive in many situations. The breakdown of local anesthetics in the body is accomplished by the liver and plasma esterase, and the resulting substance is eliminated by the kidneys. It is important to use the weakest concentration and the smallest amount necessary to produce the desired results (Bucklin, Gambling, & Wlody, 2008).

Types of Local Anesthetic Agents

Three types of local anesthetic agents are currently available—esters, amides, and opiates. The ester type includes procaine hydrochloride (Novocain), chloroprocaine hydrochloride (Nesacaine), and tetracaine hydrochloride (Pontocaine). Esters are rapidly metabolized; therefore, toxic maternal levels are not as likely to be reached, and placental transfer to the fetus is prevented.

Amide types include bupivacaine hydrochloride (Marcaine), mepivacaine hydrochloride (Carbocaine), and lidocaine hydrochloride (Xylocaine). Amide types are more powerful and longer-acting agents than ester types. They readily cross the placenta, can be measured in the fetal circulation, and affect the fetus for a prolonged period. Newer amide types of local anesthetic agents, such as ropivacaine and levobupivacaine, are becoming more commonly used because they have a long action but fewer toxic effects (Bucklin et al., 2008).

Opioids are used with epidural blocks to produce analgesia for labor. Some of the agents used include morphine, fentanyl, butorphanol, and meperidine. When only opioids are used epidurally, the amount of pain relief is not as great. A combination of opioids and a low dose of a local anesthetic agent achieve better pain control with reduced motor impairment (Yentis, May, & Mahotra, 2007). There does appear to be a higher incidence of pruritus when this combination method is used, however. While the addition of opiates has been associated with undesirable side effects, such as nausea, vomiting, hypotension, respiratory depression, and sedation, the incidence appears to be low. These agents are commonly used, especially in women undergoing a cesarean birth, because of their high effectiveness rates in controlling postpartal pain (Yentis et al., 2007). Women who receive fentanyl can experience interference with early breastfeeding, with higher dosages having more negative impact than lower dosages (Gambling, Douglas, & McKay, 2008). Other evidence supports the use of fentanyl and butorphanol for administration in labor. There are no differences in cesarean and operative birth rates between women who received epidural opiates and those who received systemic analgesia. In fact, women who receive epidural opiates sometimes have a shorter first stage than those who receive systemic analgesic agents (Yentis et al., 2007).

A variety of anesthetic agents and a wide range of doses have been used for epidural anesthesia with varying results. The most commonly used agents are lidocaine 2% with epinephrine 1:200,000, bupivacaine 0.25%, and 2-chloroprocaine 3%. Each agent provides adequate anesthesia with 15 to 20 ml of the solution, but each has been associated with side effects. The pharmacology of each drug must be understood before it is used (Balestrieri-Martinez, 2009).

Adverse Maternal Reactions to Anesthetic Agents

Reactions to local anesthetic agents range from mild symptoms to cardiovascular collapse. Mild reactions include palpitations, vertigo, tinnitus, apprehension, confusion, headache, and a metallic taste in the mouth. Common side effects include pruritus, vertigo, dizziness, and urinary retention (Macksey, 2009). Moderate reactions include more severe degrees of the mild symptoms plus nausea and vomiting, hypotension, and muscle twitching, which may progress to convulsions and loss of consciousness. Severe reactions are sudden loss of consciousness, coma, severe hypotension, bradycardia, respiratory depression, and cardiac arrest (Macksey, 2009). High concentrations of the agents may also cause local toxic effects on tissues. It is important to remember that when the mother experiences an adverse reaction, the fetus is also affected.

Systemic toxic reactions most commonly occur with an excessive dose because of too great a concentration or too large a volume. Pregnant women in labor generally require less medication because of hormonal factors, uterine compression, an increase in cardiac output, and an increased sensitivity of the neural axons (Barash, Cullen, Stoelting et al., 2009). Accidental intravenous (IV) injection that suddenly increases the amount of the drug in maternal circulation results in depression of vasomotor, respira-

tory, and other medullary centers of the brain (Blackburn, 2007). It also depresses the heart and peripheral vascular bed. A massive intravascular dose can result in sudden circulatory collapse within 1 minute. Reactions to subcutaneous and extradural injection occur in 5 to 40 minutes. The short-acting agent procaine can produce toxic reactions in 10 to 15 minutes, and the long-acting agent mepivacaine in 20 to 40 minutes (Chestnut et al., 2009). It is imperative that the woman is under close supervision by knowledgeable personnel throughout the time that an agent is being used and that an IV line is in place.

If epinephrine has been added to the anesthetic agent to prolong the anesthesia, it is necessary to differentiate between reaction to the anesthetic agent and to the epinephrine. Reaction to epinephrine is characterized by pallor, perspiration, dyspnea, and a greater increase in blood pressure and pulse than occurs with reactions to anesthetic agents.

Psychogenic reactions such as severe anxiety, hallucinations, inability to move or speak, or catatonic appearance can also occur, with symptoms similar to those occurring with systemic toxic reactions (Chestnut et al., 2009). This phenomenon may occur as the procedure is begun and before the injection of the anesthetic agent. Regardless of the cause, the symptoms must be treated.

Allergic reactions to anesthetic agents may also occur. The manifestations of the antigen-antibody reaction include urticaria, laryngeal edema, joint pain, swelling of the tongue, and bronchospasm.

Treatment of Systemic Toxicity

Preferred treatment of mild toxicity involves the administration of oxygen by mask and IV injection of a short-acting barbiturate to decrease anxiety (Gambling et al., 2008). The clinician should anticipate the possibility of convulsions or cardiovascular collapse and make appropriate preparations to treat them.

Treatment of Convulsions

The best treatment for convulsions is to establish the airway and administer 100% oxygen. Thiopental or diazepam may be administered to stop convulsions (Chestnut et al., 2009). Small doses are adequate and help avoid cardiorespiratory depression.

Treatment of Sudden Cardiovascular Collapse

In sudden cardiovascular collapse, an airway must be established as cardiopulmonary resuscitation begins. IV fluids are increased, and emergency cesarean birth may be started immediately (Chestnut et al., 2009).

Lumbar Epidural Block

A lumbar **epidural block** involves injection of a local anesthetic agent into the epidural space. The epidural space is a potential space between the dura mater and the ligamentum flavum, extending from the base of the skull to the end of the sacral canal (Figure 25-2 ■). It contains areolar tissue, fat, lymphatics, and the internal vertebral venous plexus (Blackburn, 2007). This space is accessed through the lumbar area. The technique is most often used as a continuous block to provide analgesia and anesthesia from active labor through the birth and episiotomy repair. Complete pain relief is achieved for 85% of women; 12% experience partial relief; and only 3% of women report no relief at all (Cunningham et al., 2010).

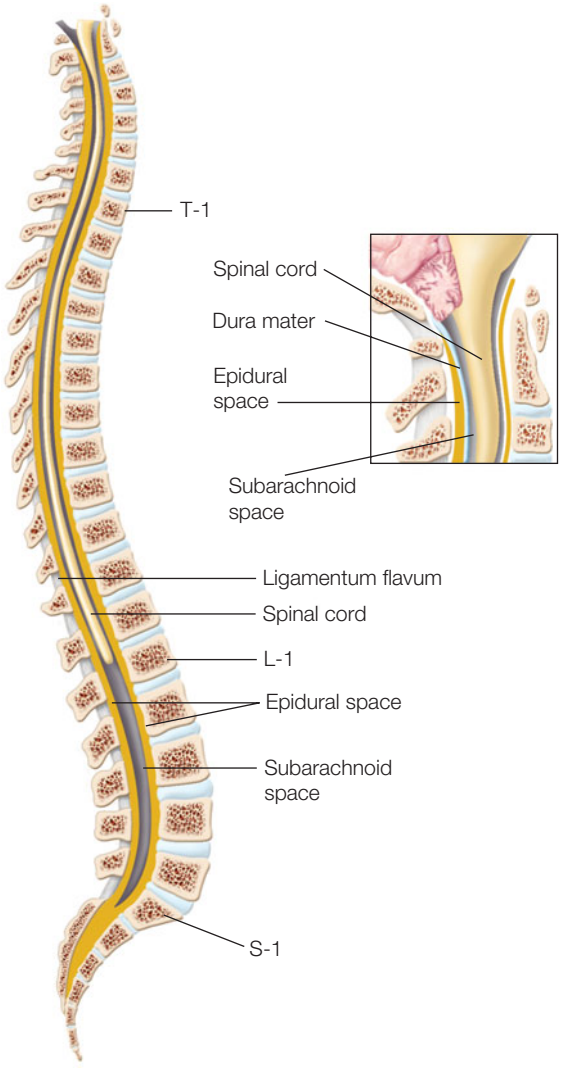

Figure 25-2 ■ The epidural space lies between the dura mater and the ligamentum flavum, extending from the base of the skull to the end of the sacral canal.

Lumbar epidural block has become fairly common during labor and birth. In the United States, epidural blocks are used by more than 60% of all women giving birth (Wolf, 2009). Moreover, recent studies have shown that the use of epidural anesthesia is the preferred method of pain relief for laboring women.

In the United States, epidural rates have continued to rise because of an increase in 24-hour availability of anesthesia services, the rise in cesarean birth rates, and a decline in the number of women who attempt a vaginal birth after a previous cesarean section (VBAC) (Wolf, 2009). In the past, it was thought that epidural availability might be linked to socioeconomic status. Recent research has shown that women in lower socioeconomic groups and those of African American race are less likely to accept epidural anesthesia than those in higher socioeconomic groups (Ochroch, Troxel, & Farrer, 2007). Women who were employed, had a college degree, and had previous experiences with epidural anesthesia were more likely to desire an epidural placement (Ochroch et al., 2007). Another study examining racial differences in epidural preference found that even when controlling for insurance coverage, clinical

characteristics, and practitioner preferences, African American and Hispanic women were less likely to desire epidural anesthesia (Glance et al., 2007).

Epidural blocks can be administered in a number of ways. To provide analgesia and anesthesia during labor, the block can be administered as a single dose with an epidural needle, as a single dose through an epidural catheter with additional doses (called "top-ups" or "top-offs") given as needed, or as a continuous epidural. The most commonly used epidural technique for laboring women is the continuous epidural infusion via a pump that allows the woman to get a predetermined amount of medication on a continual basis. If the woman becomes uncomfortable, a bolus of additional medication can be given to achieve comfort.

Many women equate the quality of their labor experience directly with their satisfaction with the anesthesia they receive while in labor. Although many women desire the pain relief from regional anesthesia, many do not like its side effects, such as inability to void, decreased motor sensation in the lower extremities, and the need to maintain bed rest. Although some procedures require that the woman remain in bed, others—called "walking," "ambulatory," or "mobile" epidurals—are given with analgesic agents or anesthetic agents, or both, that leave the woman with sufficient motor control to be out of bed (Macksey, 2009).

Current guidelines by the American Society of Anesthesiologists (ASA) states that epidural placement should be performed when the woman experiences pain and asks for an epidural. Early epidural use is not associated with an increase in operative or cesarean births and improves analgesia effectiveness (ASA Task Force, 2007).

Epidurals: Risks and Benefits

Advantages

The lumbar epidural block produces good analgesia that alters maternal physiologic responses to pain. The woman is fully awake during labor and birth. The continuous technique allows different blocking for each stage of labor so that internal rotation of the fetus can be accomplished. In many cases, the dose of anesthetic agent can be adjusted to preserve the woman's reflex urge to bear down.

Disadvantages

The most common complication of an epidural block is maternal hypotension. Hypotension commonly occurs as a result of peripheral vasodilatation (Braveman, 2006). This is increased by the blockade of the sympathetic nerve supply to the adrenal glands, which prevents the release of catecholamines (Blackburn, 2007). This is generally prevented by preloading with a rapid infusion of IV fluids, then providing IV fluids continuously. Although hypotension can occur, the incidence of hypotension requiring ephedrine is relatively low, less than 2% (Cunningham et al., 2010). Other serious complications, although rare, have been reported, including postdural puncture seizures, meningitis, cardiorespiratory arrest, and vertigo (vestibulocochlear dysfunction) (Barash et al., 2009).

There are multiple regional anesthesia approaches for women undergoing cesarean birth. When an epidural block is used for cesarean birth, an epidural catheter is inserted and a single dose can be given. This approach allows for a more gradual onset and requires less medication to be administered. This reduces the risk of hypotension (Gambling et al., 2008). The catheter provides access to the epidural space, so that additional anesthetic agents and opioids may be administered if needed and so that opioids may be given to provide pain relief for the 24 hours following birth.

Another disadvantage of an epidural block is that the onset of analgesia may not occur for up to 30 minutes. In addition, an epidural block requires skilled personnel for administration and close observation of the woman and her fetus. The anesthesia provider must be careful while administering the block to avoid perforating the dura mater, which would place the needle in the subarachnoid space; if the error is not recognized, the anesthetic agent would be injected into the spinal canal. Skilled nurses are also required to maintain close observation of the laboring woman and her fetus. Variability of the fetal heart rate (FHR) may decrease, and late decelerations can occur if maternal hypotension develops. Finally, epidural anesthesia is more costly than systemic agents. This may be a crucial factor for women and families without insurance who are paying out of pocket for their birthing costs.

Some women with epidurals may have decreased sensation and movement, or they may have essentially no control over movement in the anesthetized region. Some studies have demonstrated that epidural use prolonged the first stage of labor and contributed to the need to augment labors with oxytocin (Chestnut et al., 2009). On the other hand, other clinical studies, along with healthcare providers, assert that epidural analgesia may shorten the active and transition phases because of the pain relief (Wolf, 2009). A meta-analysis showed that women who had received continuous infusion epidural anesthesia had a longer second stage (24 minutes) compared to women who received parenteral opioids (ASA Task Force, 2007). Women with epidurals experienced greater pain relief than those who received opioids by intramuscular or intravenous routes (ASA Task Force, 2007).

Contraindications

Absolute contraindications for epidural block are (New York School of Regional Anesthesia, 2009):

- Maternal refusal
- Local or systemic infection
- Uncorrected hypovolemia
- Coagulation disorders
- Actual or anticipated maternal hemorrhage
- Increased intracranial pressure
- Allergy to a specific class of local anesthetic agents

Relative contraindications include (New York School of Regional Anesthesia, 2009):

- Platelet count less than 100,000/mm^3
- Severe anatomic abnormalities of the spine
- Uncooperative patient
- Sepsis
- Hypertension

Patients with previous back surgery, suspicion of neurologic disease, long-term use of aspirin or anti-inflammatory agents, abruptio placentae, acute infection at the epidural site, and the lack of trained staff at the facility are also causes for concern that need to be evaluated on an individual basis (New York School of Regional Anesthesia, 2009).

Epidurals can be used in women with heart failure or aortic stenosis although invasive monitoring may be needed to evaluate blood pressure variations (Ioscovich, Goldszmidt, Fadeev, et al., 2009). Often a cesarean birth is indicated to prevent the stress associated with the second stage and maternal pushing efforts (Ioscovich et al., 2009).

Technique for Continuous Lumbar Epidural Block

In administering a continuous lumbar epidural block, the following actions are taken (Barash et al., 2009; Chestnut et al., 2009):

1. Maternal and fetal status and labor progress are assessed. Because maternal blood pressure and pulse will be taken frequently, an automatic blood pressure device may be useful. FHR is continuously monitored by electronic fetal monitoring (EFM) by the nurse.
2. Oxygen and resuscitative equipment is readied. The nurse ensures all equipment is in the room and properly functioning.
3. An IV infusion is begun, and a preload of 500 to 2000 ml of IV fluid (e.g., 0.45% normal saline or lactated Ringer's) is given over approximately 15 to 30 minutes by the nurse.
4. The woman is positioned on her left or right side, at the edge of the bed (the mattress is firmer and provides more support) with the assistance of the nurse, with her legs slightly flexed, or she is asked to sit on the edge of the bed. She is advised to drop her shoulders, round out the small of her back, and place her chin on her chest. It may be helpful to advise the woman to "arch her back like a cat" to achieve the proper position. This position is especially effective for positioning obese women. The spinal column is not kept convex, as it is for a spinal block, because the convex position reduces the peridural space to a greater degree and stretches the dura mater, making it more susceptible to puncture. The epidural space is decreased during pregnancy because of venous engorgement. It is also smaller in obese and short individuals (Cunningham et al., 2010). A small pillow may be placed under the woman's head and in front of her chest to provide support for her arms. The nurse typically stands beside the woman, offering support and assisting her in maintaining this position. The nurse assists the woman with breathing techniques and alerts the anesthesia provider when a contraction occurs. See Figure 25-3 ■ for incorrect and correct positions for lumbar epidural block.

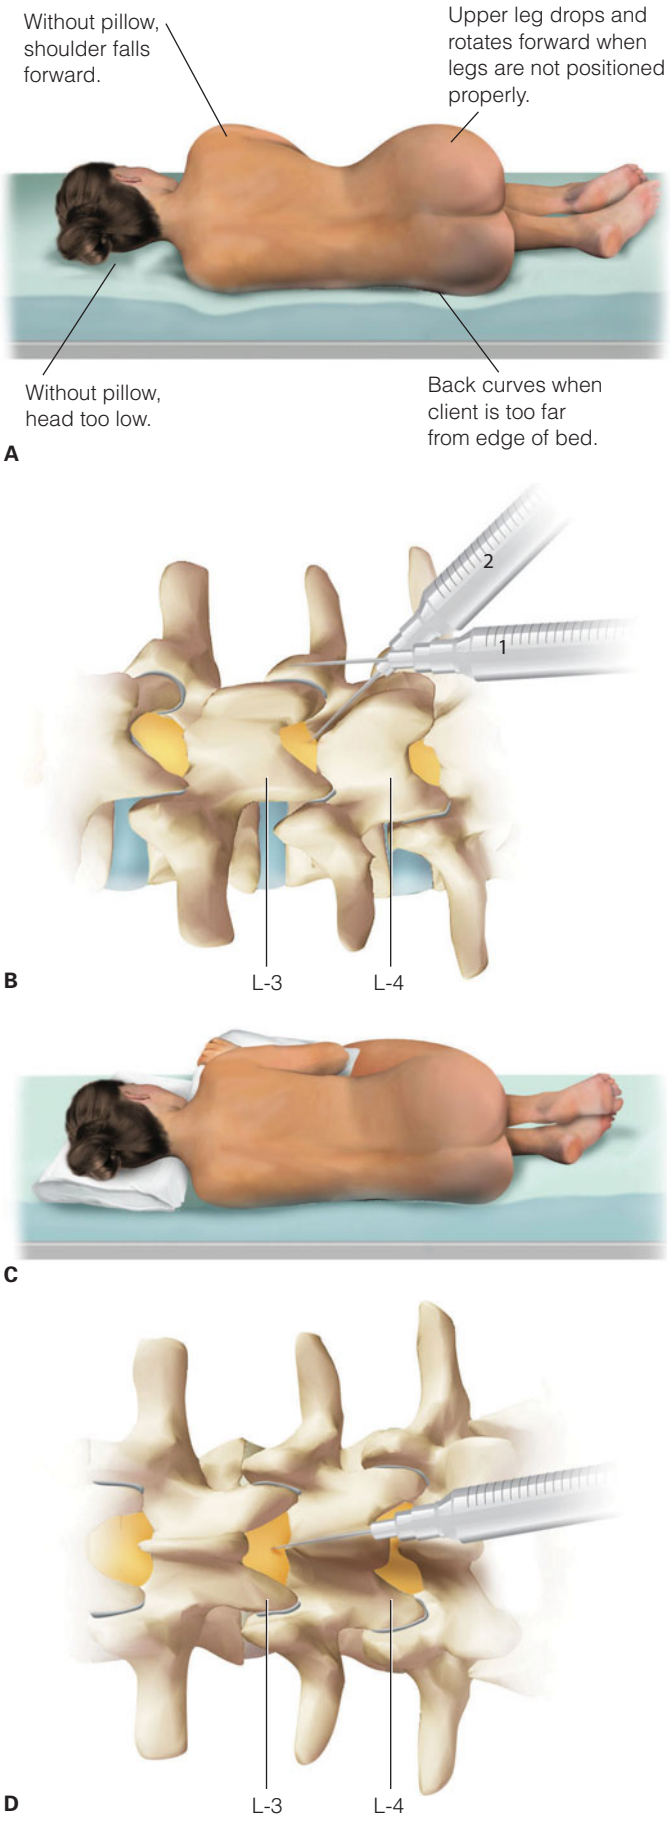

Figure 25-3 ■ Positioning woman for epidural anesthesia block. A. Incorrect maternal positioning for placing subarachnoid or epidural block. The upper shoulder has fallen forward, upper leg has rotated forward, and the patient is positioned on the center of the bed so that there is no support from the edge and the back can curve. B. Vertebral position with patient in incorrect position. The vertebrae rotate forward and, if the needle is inserted in the usual way (needle 1), the apophyseal joints are encountered. Needle 2 shows the proper insertion of the needle entering the epidural space. C. Correct maternal positioning. The back is straight and vertical, the shoulders are square, and the upper leg is prevented from rolling forward. D. Vertebral position with the woman correctly positioned.

Epidural Placement

5. The skin is prepared with an antiseptic agent by the anesthesia provider.
6. A skin wheal of a small amount of local anesthesia is given intradermally by the anesthesia provider to anesthetize the supraspinous and interspinous ligaments (Chestnut et al., 2009).
7. The anesthesia provider then inserts a short, beveled 16- to 18-gauge needle with stylet that is passed to the ligamentum flavum in the widest interspace below the second lumbar vertebra (usually in the third or fourth lumbar interspace) (Figure 25-4 ■). The ligamentum flavum is identified by its resistance to injection of saline or air (called loss of resistance technique). Resistance disappears as the peridural space is entered.
8. The anesthesia provider then injects 5 ml of preservative-free saline in order to pass the catheter into the epidural space more easily.
9. The catheter is inserted approximately 1 to 2 cm into the epidural space by the anesthesia provider. The needle is removed. Aspiration for blood (indicating that a vessel has been inadvertently entered) or cerebrospinal fluid (indicating the dura mater has been punctured) is attempted.
10. If aspiration tests are negative, a test dose of local anesthetic agent containing 1.5% lidocaine with epinephrine 1:200,000 concentration or 3 ml of 0.25% bupivacaine with 1:200,000 concentration of epinephrine is injected. The anesthesiologist usually injects the medication after aspiration and after a uterine contraction to minimize the risk of tachycardia that can occur if the drug is directly injected into a vessel (Cunningham et al., 2010). If the subarachnoid space has been entered, sensory and motor changes occur in the woman's extremities. If there are no untoward effects, additional anesthetic agent is injected. The catheter is securely taped so that its placement will not be disturbed. Pain relief should occur within 15 to 20 minutes after administration (Cunningham et al., 2010).
11. The nurse then assists the woman into a semireclining position with a lateral tilt of her uterus for 10 minutes to allow for distribution of the block. This also prevents aortocaval compression (see chapter 14 ∞). She is then maintained in a side-lying position to maximize uteroplacental perfusion. If she needs to be turned to a supine position for fetal blood sampling or other procedures, the nurse turns the woman as quickly as possible and repositions her on her side.

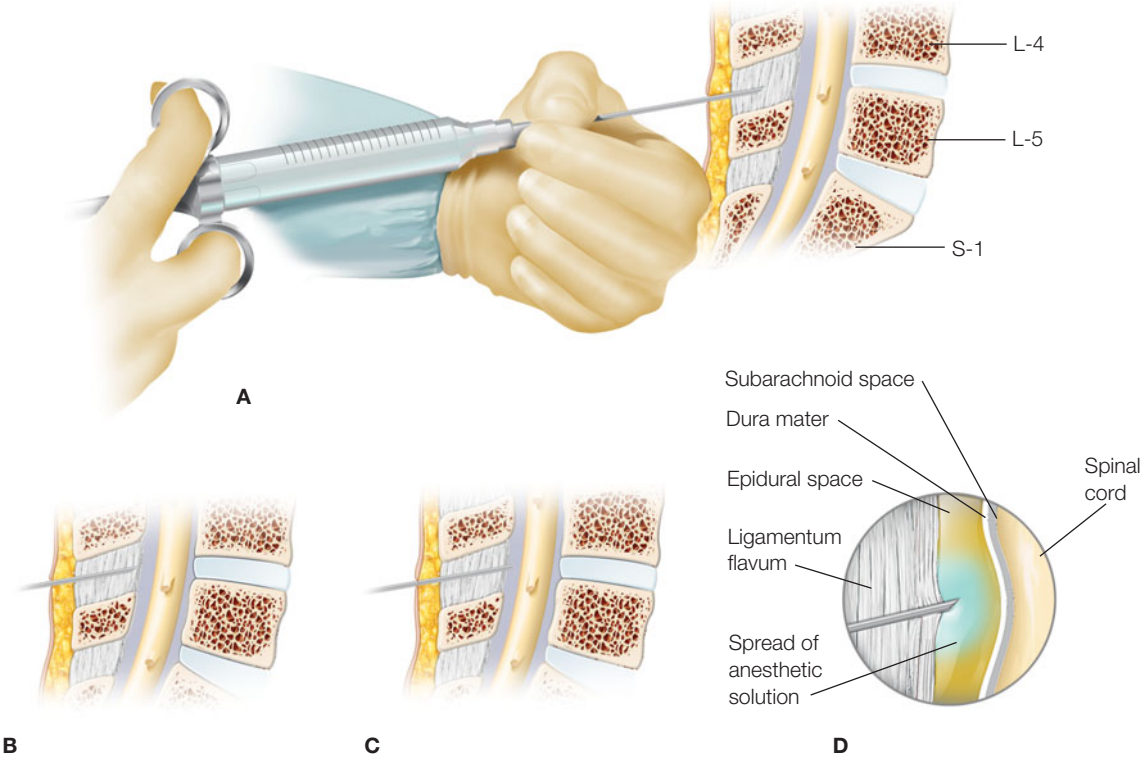

Figure 25-4 ■ Technique for lumbar epidural block. A. Proper position of insertion. B. Needle in the ligamentum flavum. C. Tip of needle in epidural space. D. Force of injection pushing dura away from tip of needle.

12. The anesthesia provider or the nurse then monitors the maternal blood pressure every 1 to 2 minutes for the first 10 minutes past the injection and then every 5 to 15 minutes until the block wears off. Maternal vital signs are evaluated by either the nurse or the anesthesia provider against baseline readings obtained just before the beginning of the procedure. The nurse is responsible for documentation of assessment data that are obtained throughout the procedure.
13. The woman must be attended by a nurse, nurse anesthetist, or an anesthesiologist for the first 20 minutes following the initial dose and after administration of any additional dose.
14. If hypotension (a 20% to 30% fall in systolic pressure or a drop to below 100 mm Hg) occurs, the nurse ensures that left lateral displacement of the uterus is maintained, and the IV fluids are infused more rapidly. Oxygen is delivered by a face mask to ensure proper oxygenation of the fetus. A 10- to 20-degree Trendelenburg position may be used. If the blood pressure is not restored within 1 to 2 minutes, a vasopressor such as ephedrine, 5 to 15 mg, may be administered IV.
15. The maternal blood pressure and pulse and the FHR continue to be monitored by the nurse.
16. If the epidural is not being administered by continuous pump, the anesthesiologist aspirates the catheter before administering subsequent doses.

Technique for Single-Dose Lumbar Epidural Block

The procedure for a single-dose lumbar epidural block is the same as for the lumbar block just described, except that instead of injecting 5 ml of saline, the anesthesiologist injects a test dose of 2 to 3 ml of anesthetic agent to make sure the dura mater has not been penetrated. After checking again to confirm that the dura mater has not been perforated, the clinician injects a single dose of 10 to 12 ml to provide anesthesia for birth. Subsequent care continues as for the procedure just described, from step 11 (Chestnut et al., 2009).

Problems and Adverse Effects

The major adverse effect of epidural anesthesia is maternal hypotension caused by a spinal blockade, which lowers peripheral resistance, decreases venous return to the heart, and subsequently lessens cardiac output and lowers blood pressure. Maternal hypotension results in uteroplacental insufficiency in the fetus, which is manifested as late decelerations on the fetal monitoring strip. The risk of hypotension can be minimized by hydrating the vascular system with 500 to 1000 ml of IV solution (Balestrieri-Martinez, 2009) before the procedure and changing the woman's position and/or increasing the IV rate afterward.

A potentially distressing maternal problem is an inadequate block, unilateral block, or block failure. Epidural anesthesia has a higher failure rate than spinal anesthesia because the catheter must be properly placed to produce adequate anesthesia (Macksey, 2009). A one-sided block is fairly common and can be overcome by having the woman lie on the unanesthetized side and injecting more of the local anesthetic agent. If the woman has a continuous epidural block, she should turn from side to side every hour to avoid a one-sided block. A block may be effective except for a "spot" ("hot spot") or "window" of pain in the inguinal or suprapubic area. Breakthrough pain may occur at any time during the epidural infusion. It usually occurs when the continuous

Case Study: Patient Requesting an Epidural

Care Plan Activity: Managing Side Effects of an Epidural

infusion rate of the anesthetic agent is below the recommended rate for a therapeutic dose. Breakthrough pain can also occur when the woman has a full bladder or when the cervix is completely dilated. The nurse assesses the woman carefully before calling the anesthesia provider for additional medication administration. It may also occur when the infusion pump rate is altered or the integrity of the epidural line is broken.

Pruritus may occur at any time during the epidural infusion. It usually appears first on the face, neck, or torso and is generally the result of the agent used in the epidural infusion (Yentis et al., 2007). Frequently Benadryl, an antihistamine, can be administered to manage pruritus (Cunningham et al., 2010).

Maternal temperature may be elevated to 37.8°C or higher with the use of epidural anesthesia. Sympathetic blockade may decrease sweat production and, in turn, diminish heat loss. It has also been suggested that heat loss may result from a failure of the central nervous system to regulate temperature. Headaches, migraine headaches, neck aches, and tingling of the hands and fingers have also been reported (Cunningham et al., 2010).

Short-term localized tenderness at the needle puncture site occurs in about 40% of women during the first week after birth. Backache is fairly common and is thought to result from inadvertently maintaining stressed positions during periods of muscle relaxation and pain relief from the epidural block. Long-term back pain is uncommon. Other problems or adverse effects include urinary retention, shivering, nausea, and vomiting.

Complications

One of the most serious complications of regional anesthesia, systemic toxic reaction, has been discussed in "Adverse Maternal Reactions to Anesthetic Agents" on p. 644. Toxic reactions following a lumbar epidural block may be caused by unintentional placement of the drug in the arachnoid or subarachnoid space, excessive amount of the drug in the epidural space (massive epidural), or accidental intravascular injection (Chestnut et al., 2009). Because large quantities of anesthetic agent are used for epidural block, the likelihood of toxic reactions is higher than with some of the other regional procedures. The incidence of drug reactions is relatively low, but the possibility is always present.

Pain during cesarean birth with epidural anesthesia has been reported by a growing number of women. In light of this, some anesthesiologists use both temperature and pinprick tests to assess sensory loss. Dermatomes from T_4 to S_3 should be tested for sensory loss before beginning a cesarean (Chestnut et al., 2009). The method of assessment and the results should be documented in the anesthesia record.

Spinal headaches can also be a complication that occurs with epidural anesthesia. Spinal headaches occur when the dura is accidently punctured during epidural placement (Bucklin et al., 2008).

NURSING CARE MANAGEMENT

The nurse assesses the maternal vital signs and the FHR for baseline information and to ensure that both maternal and fetal vital signs are within normal limits. (*Note*: All information regarding assessments, procedures, and other activities is recorded on the fetal electronic monitor strip as well as in the nursing notes. Some facilities may use checklist or computerized charting systems.)

Labor progress is also assessed. The procedure and expected results are explained, and the woman's questions are answered. The nurse acts as an advocate and arranges for consultation with the anesthesiologist if questions arise. The family, significant other, or support person should be included to promote a family-centered approach. Informed consent for the epidural should be obtained.

The nurse starts an IV infusion, if one is not already in place. The nurse preloads at a rapid infusion rate to increase both blood volume and cardiac output per physician's order or agency protocol. It is recommended that dextrose-free solutions be used, because dextrose can cause fetal hyperglycemia with rebound hypoglycemia the first few hours after birth (Bucklin et al., 2008). It is helpful to provide an opportunity for the woman to void just before administering the block, because her urge to urinate will be decreased afterward (Gambling et al., 2008). The nurse assists the woman with positioning on either side or in a sitting position on the side of the bed or stretcher. The nurse provides physical and emotional support throughout the procedure.

After the epidural block is given, the woman may be positioned in a semireclining position (head at 25 degrees) with lateral uterine tilt to provide equal distribution of the block; then she is turned to a side-lying position (Yentis et al., 2007). If she is supine for procedures such as sterile vaginal examinations or fetal scalp blood sampling, the nurse places a wedge under her hip to help eliminate aortocaval compression. The nurse takes maternal blood pressure and pulse every 5 minutes for at least 30 minutes and then at least every 30 minutes thereafter while the block is present (Macksey, 2009). The FHR is monitored and assessed by continuous EFM.

If hypotension (systolic blood pressure below 100 mm Hg) occurs, the nurse assists with corrective measures such as positioning the woman in a left side-lying position, increasing the flow rate of the IV infusion, and placing the bed in a 10- to 20-degree Trendelenburg position (Balestrieri-Martinez, 2009). If maternal blood pressure does not increase within 1 to 2 minutes, 5 to 15 mg of ephedrine may be administered IV per physician or protocol order. These measures are usually sufficient; however, if hypotension persists, oxygen by mask at 7 to 10 L/min and additional vasopressors may be needed (Cunningham et al., 2010). During episodes of maternal hypotension, the nurse observes the FHR for signs of late decelerations related to uteroplacental insufficiency. Nausea and vomiting may be associated with hypotension. An antiemetic may be ordered to increase the woman's comfort. With severe or prolonged hypotension, added treatment includes elevating the woman's legs for 2 or 3 minutes to increase blood return from the extremities (Macksey, 2009). See Nursing Care Plan For Epidural Anesthesia for more information about maternal hypotension associated with epidural anesthesia.

If additional local anesthetic agents are injected, the regimen of assessing maternal blood pressure and initial surveillance should be repeated each time the epidural catheter is reinjected. If the woman's legs have been in stirrups during a

NURSING CARE PLAN For Epidural Anesthesia

INTERVENTION	RATIONALE
1. Nursing Diagnosis: Risk for Injury related to maternal hypotension associated with epidural anesthesia secondary to vasodilation and venous pooling	
Goal: Maternal and fetal effects associated with hypotension will be minimized.	
■ Obtain baseline maternal vital signs and fetal heart rate.	■ Normal ranges include temperature 98 to 99.6°F/36.6 to 37.5°C, pulse 60 to 90, respirations 14 to 22/min, blood pressure 90–140/60–90, fetal heart rate 110 to 160 beats/min.
■ Insert IV with large gauge catheter.	■ Allows for IV fluid to be administered quickly if hypotension occurs.
■ Provide hydration with 500 to 1000 ml of intravenous solution (e.g., lactated Ringer's) 15 to 30 min before procedure. Dextrose-free solution is recommended.	■ Increases intravascular volume and maintains cardiac output by preloading the patient before epidural anesthesia. Rapid infusion of dextrose solution can cause fetal hyperglycemia and rebound neonatal hypoglycemia.
■ Educate the patient about treatment measures to expect if unwanted side effects from the epidural occur.	■ Advance preparation will decrease anxiety and the patient will be more compliant. Treatment measures include oxygen administration, increase of IV fluids, possible administration of a vasopressor such as ephedrine, and repositioning the patient.
■ Assist the patient into position for the procedure.	■ Place patient in a supine position for 5 to 10 min following administration of block to allow medication to diffuse bilaterally. After 5 to 10 min, position patient on side.
■ Monitor blood pressure every 1 to 2 min for the first 10 min then every 5 to 15 min until the block wears off.	■ Hypotension is the most common side effect of epidural anesthesia. Close monitoring will allow for quick assessment and treatment of any changes from baseline blood pressure before the procedure.
EXPECTED OUTCOMES: Decrease in blood pressure is identified and treated successfully.	
■ Observe, record, and report symptoms of hypotension, including systolic pressure <100 mm Hg or a 20% to 30% fall in systolic pressure, apprehension, restlessness, dizziness, tinnitus, and headache.	■ These signs are related to hypotension and must be treated immediately to avoid health risk to mother and fetus.
EXPECTED OUTCOMES: Hypotension is identified and treatment measures started.	
■ Initiate treatment measures to reverse hypotension.	■ Treatment measures include placing patient in left lateral position as directed, increase IV rate, administer oxygen by face mask at 7 to 10 L/min as needed, administer vasopressors as ordered (usually ephedrine 5 to 10 mg IV), manually displace uterus laterally to left using a wedge or pillow. Notify analgesia provider or certified nurse anesthetist immediately.
EXPECTED OUTCOMES: Hypotension is treated successfully, and blood pressure returns to normal limits.	
■ Observe, record, and report fetal bradycardia (FHR less than 110 beats/min) and loss of beat-to-beat variability.	■ Maternal hypotension results in decreased blood flow to the fetus. Normal fetal heart rate ranges between 110 and 160 beats/min. Fetal bradycardia occurs when the fetal heart rate falls below 110 beats/min during a 10-min period of continuous monitoring. When fetal bradycardia is accompanied by decreased beat-to-beat variability, it is considered ominous and could be a sign of advanced fetal compromise.
EXPECTED OUTCOMES: Treatment of maternal hypotension increases blood flow to the fetus, reversing fetal bradycardia. Fetal heart rate stays within normal limits with good beat-to-beat variability.	

vaginal birth, her blood pressure should be assessed as soon as her legs are taken out of the stirrups. While the legs were elevated, circulating blood volume in the trunk increased. Restoring circulation to the legs decreases the overall blood volume and may precipitate hypotension.

Additional nursing care following the block includes frequent assessment of the bladder to avoid bladder distention. Catheterization may be necessary, because most women are unable to void; however, the nurse should first offer the woman a bedpan, because catheterization increases the risk of urinary tract infections (Berman, Synder, Kozier, & Erb, 2008).

Shivering may be caused by heat loss from increased peripheral blood flow or alteration of thermal input to the central nervous system when warm but not cold sensations have been

suppressed. New studies suggest the maternal temperature in the lower extremities is lower than in the upper extremities and thus stimulates a shivering reaction (Doufas, Morioka, Maghoub, et al., 2008). Although warming intravenous fluids enhances maternal comfort, it does not reduce shivering (Woolnough, Allam, Hemingway, et al., 2009). Applying warmed blankets and reassuring the woman may make her feel more comfortable.

The nurse assesses the woman's level of pain relief. The nurse can promote equal distribution of the anesthetic agent by assessing the temperature of the woman's feet. If one foot warms more quickly than the other, the woman should be positioned with the cooler side dependent (Doufas et al., 2008). It is important for the woman to turn from side to side every hour to promote equal distribution of the anesthetic agent. Again, the woman should be assessed for advanced cervical dilatation and bladder distention. If positioning changes and emptying the bladder do not help and the woman has inadequate pain relief, the anesthesia provider needs to be notified. During a continuous epidural block, the anesthesiologist should titrate the infusion to maintain a sensory level of T_{10}, and the presence of motor block and height of sensory block should be documented at least hourly (Chestnut et al., 2009).

Respiratory rate and quality of the respirations should be assessed at least every 15 to 30 minutes. The nurse should notify the anesthetist of any significant decreases in respiratory rate or respiratory pattern changes. If the respiratory rate falls below 14 respirations per minute, naloxone (Narcan) may be given to remove the effect of the anesthetic agent; respirations will then return to a normal rate (Bucklin et al., 2008).

The nurse asks the woman if she is experiencing pruritus and is alert for signs of scratching, especially on the face, neck, and torso. If present, pruritus is usually treated with diphenhydramine (Benadryl), 25 mg administered IV or 50 mg IM per physician's or CNM's order (Cunningham et al., 2010).

During the second stage of labor, the woman may require assistance with pushing, because she may not feel her contractions or experience the urge to push. If the woman does not feel the urge to push, the nurse may collaborate with the anesthesia provider so that the block can be turned down or temporarily turned off until the urge to push returns. She may also need assistance holding or controlling her legs in order to push. After birth, return of complete sensation and the ability to control the legs are essential before ambulation is attempted. This may take several hours, depending on the agent and the total dose. The woman must also be able to maintain blood pressure in a sitting and then standing position.

Epidural Analgesia After Birth

To provide analgesia for approximately 24 hours after the birth, the anesthesiologist may inject an opioid, such as morphine (Duramorph) 5 mg or 7.5 mg, into the epidural space immediately following the birth. These agents are typically reserved for women who have had a cesarean birth. The analgesic effect of Duramorph begins approximately 30 to 60 minutes after the injection. The side effects include pruritus, nausea and vomiting, and urinary retention (Wilson et al., 2010). See Drug Guide: Postbirth Epidural Morphine in chapter 36 ∞.

Other agents are being examined that offer equal or better pain control with fewer side effects. Meperidine (Demerol) may be injected during an epidural block for birth, and then continued through use of patient-controlled epidural analgesia (PCEA). Epidural meperidine is associated with fewer side effects than epidural morphine and does not cause hemodynamic changes (Chestnut et al., 2009). Epidural fentanyl and lidocaine have also been used. The addition of lidocaine has been associated with a more rapid onset of sensory block without the increased side effects (Chestnut et al., 2009).

Spinal Block

In a **spinal block**, a local anesthetic agent is injected directly into the spinal fluid in the subarachnoid space to provide anesthesia for cesarean birth. The subarachnoid space is the fluid-filled area between the dura mater and the spinal cord. During pregnancy, the space decreases because of the distention of the epidural veins. Thus a specific dose of anesthetic produces a much higher level of anesthesia in the pregnant woman than in the nonpregnant woman. When a spinal block is properly administered, failure rate is low. Unlike epidural anesthesia, spinal blocks allow the anesthesia to mix directly with the cerebrospinal fluid, which eliminates "windows" where anesthesia coverage is not obtained (Chestnut et al., 2009). Cesarean birth requires anesthetic blockade to the T_4 dermatome (Figure 25-5 ■).

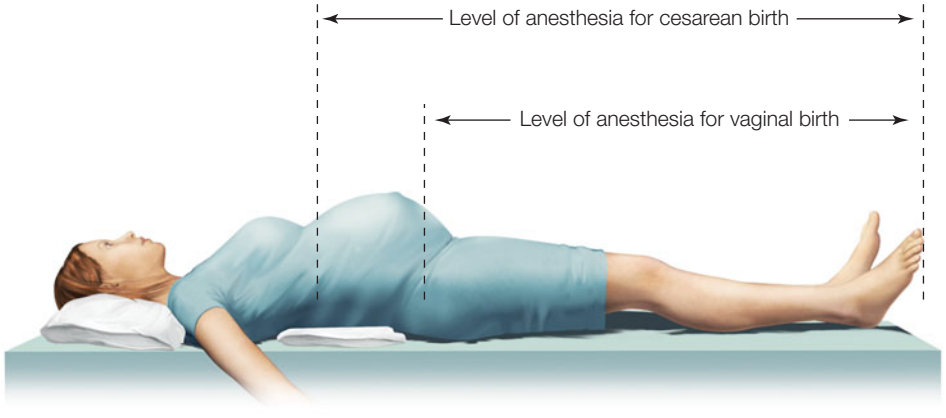

Figure 25-5 ■ Levels of anesthesia for vaginal and cesarean births.

Source: Reprinted with permission of Ross Laboratories, Columbus, OH. From Clinical Education Aid No. 17.

Advantages

The advantages of spinal block are immediate onset of anesthesia, relative ease of administration, a smaller drug volume, and maternal compartmentalization of the drug. Spinal anesthesia is frequently the regional block of choice in acute obstetrical emergencies because it is the safest and fastest anesthesia technique (Chestnut et al., 2009).

Disadvantages

The primary disadvantage of spinal block is intense blockade of sympathetic fibers, resulting in a high incidence of hypotension. This leads to a greater potential for fetal hypoxia. In addition, uterine tone is maintained, which makes intrauterine manipulation difficult. Spinal anesthesia is traditionally short acting, and it is difficult to maintain adequate anesthesia coverage for prolonged procedures (Chestnut et al., 2009).

Contraindications

Spinal anesthesia is contraindicated for women with severe hypovolemia, regardless of cause; central nervous system disease; infection over the site of puncture; maternal coagulation problems; and allergy to local anesthetic agents (Chestnut et al., 2009). Sepsis and active genital herpes may be considered relative rather than absolute contraindications. Spinal block is also contraindicated for women who do not wish to have spinal procedures or are unable to appropriately consent (Cunningham et al., 2010).

Technique

The following steps are followed in administering a subarachnoid block (Chestnut et al., 2009):

1. The nurse assists the woman into a sitting or left lateral position.
2. Intravenous infusion is checked for patency.
3. The woman places her arms between her knees, bows her head, and arches her back to widen the intervertebral space.
4. The anesthesiologist or nurse anesthetist prepares the skin carefully, maintaining sterility before initiating the procedure.
5. A skin wheal is made over L_3 or L_4.
6. An 18- or 19-gauge needle is introduced through the skin and into the interspinous ligament. Then, a 24- to 27-gauge pencil-point needle is introduced inside the larger needle and inserted into the ligamentum flavum, the epidural space through the dura mater, and into the subarachnoid space (Figure 25-6 ■).
7. The appropriate amount of anesthetic agent is injected slowly, and both needles are removed.
8. Upon removal, a drop of cerebrospinal fluid can be seen in the hub of the needle if the subarachnoid space has been entered.
9. With hyperbaric solutions, the woman remains sitting up for 45 seconds.
10. The nurse assists the woman onto her back with a pillow under her head. Position changes can alter the dermatome level if done within 3 to 5 minutes. After 10 minutes, a position change will not affect the level of anesthesia.

(This item omitted from WebBook edition)

Figure 25-6 ■ Double-needle technique for spinal injection. A. Large needle in epidural space. B. 25-gauge needle in larger needle entering the subarachnoid space.

11. The nurse monitors blood pressure, pulse, and respirations every 1 to 2 minutes for the first 10 minutes, then every 5 to 10 minutes.

The nurse provides encouragement and support during the procedure. The nurse informs the physician when a contraction is beginning so the anesthetic agent will not be injected at that time.

In the absence of maternal hypotension or toxic reaction, a spinal block exerts no direct effect on the fetus. The amount of anesthetic used is too small to reach fetal circulation in a quantity that might cause fetal depression. Spinal anesthesia has been shown to be well tolerated by a healthy fetus when a maternal IV fluid preload in excess of 500 to 1000 ml precedes the administration of the spinal.

Complications

The complications of spinal anesthesia include hypotension, drug reaction, total spinal neurologic sequelae, and spinal headache. The side effects include nausea, shivering, and urinary retention.

Hypotension can be minimized by prehydrating with 500 to 2000 ml of non–dextrose-containing fluids and displacing the uterus to a lateral position. The practice of placing an already hypotensive woman in a sitting position following injection to prevent upward spread of hyperbaric solution is dangerous because it will cause venous pooling in the lower extremities, further decreasing the maternal blood pressure (Blackburn, 2007). The normal curve of the thoracic spine prevents cranial spread

of an intrathecal agent. A pillow is placed under the woman's head to exaggerate the curve (Simpson & Creehan, 2008).

Treatment of hypotension is the same as with an epidural block: positioning the woman in a lateral and head-down position and rapidly infusing IV fluids. Preventing cardiovascular collapse requires early detection, supplemental oxygen, assisted ventilation, and measures to maintain the blood pressure. The extent to which the fetus is affected relates to the degree of maternal hypotension. When maternal hypotension has been reversed, it is best to delay the birth for 4 to 5 minutes to allow the fetus to recover. If hypotension does not resolve in a short period of time, ephedrine can be administered IV. Resuscitative equipment and trained personnel must be available to treat the mother and baby.

Complications that involve anesthesia occurring in the phrenic nerve (C_3–C_5) or higher can occur (Chestnut et al., 2009). In a "high-level" block, respiratory function becomes impaired, requiring mechanical ventilation to maintain adequate respiratory functioning until the block recedes. Another extremely rare complication is the "complete spinal" in which respiratory assistance is needed and loss of consciousness also occurs. A "total spinal" block occurs when there is paralysis of the respiratory muscles. It is a relatively rare but critical event. The symptoms include apnea, dilation of pupils, loss of consciousness, and absence of blood pressure. The onset of symptoms usually occurs within minutes of the injection but can occur in a span of time ranging from 30 seconds to 45 minutes. Resuscitative treatment, airway control, and support of blood pressure must begin immediately. If this complication occurs, it is important to remember that the woman is not asleep; although she may be paralyzed, she may be aware of everything going on around her. She requires assurance that her respiratory status will be maintained until she can breathe on her own again (Chestnut et al., 2009).

On the other hand, a spinal block can render inadequate anesthesia coverage (in which the anesthesia does not reach the T_4 level) and discomfort can occur. During intraoperative procedures, this may warrant the need for a repeat insertion or the need for general anesthesia (Chestnut et al., 2009).

Neurologic complications may occur coincidentally with spinal anesthesia, for example, with preexisting disease or faulty positioning of the woman. Hypotension and apnea can occur, requiring prompt treatment to prevent cardiac arrest. The woman should be positioned with a left tilt, and fluids should be administered to treat hypotension (Cunningham et al., 2010). Genuine neurologic sequelae, such as paralysis, are extremely rare.

Although much less serious than other complications, headache may be an unpleasant aftermath of spinal anesthesia. It is the most frequent complication with an incidence of about 1% to 3% (Cunningham et al., 2010). Leakage of spinal fluid at the site of dural puncture is thought to be the cause. Several techniques have been suggested to decrease the possibility of headache. The use of a narrow-gauge pencil-point anesthesia needle (24- to 27-gauge) reduces the incidence of spinal headache (ASA Task Force, 2007). Conservative treatments, such as hyperhydration and keeping the woman flat in bed after birth, have been used with minimal success. An abdominal binder may provide some relief. Postdural headaches can last up to 7 days and not only are painful but can also interfere with maternal-infant interactions and breastfeeding success. In severe cases, a blood patch can be performed. A few milliliters of the woman's blood is drawn and, before coagulation occurs, injected into the epidural space at the site of the puncture, which generally results in immediate pain relief.

NURSING CARE MANAGEMENT

The nurse should assist in positioning the woman, provide oxygen via nasal cannula or mask, assess and record baseline vital signs of the mother and fetus, and start an IV infusion before the block. A bolus of fluid should be given before initiation of the block whenever possible (Bucklin et al., 2008). After the block is instilled, the nurse should continue to monitor maternal blood pressure, pulse, and respiration until the anesthesiologist takes over. The nurse monitors the FHR at least every 5 minutes until it is no longer accessible because the abdominal surgical prep is begun. The anesthesiologist is responsible for assessing and recording the level of the spinal block.

The nurse positions the woman as described earlier and supports her in this position. The nurse palpates the woman's uterus to detect the beginning of a contraction. Intrathecal agents are not administered during a contraction because the increased pressure could cause a higher level of anesthesia than desired. After the agent has been administered, the woman is supported upright for the length of time determined by the anesthesiologist and is then assisted to the supine position with a wedge under her right hip to displace the uterus; a pillow is placed under her head. In the surgical setting, a safety belt is placed across the woman's thighs to prevent injury. The nurse regularly monitors blood pressure, pulse, and respirations every 5 minutes until the birth. Oxygen may be given as a prophylactic measure. The woman should be kept informed of everything that is going on in the birthing area, particularly if she is receiving mask oxygen. Raising her legs facilitates venous return from the extremities. If using stirrups, both legs should be raised at the same time to avoid undue tension and possible injury to back muscles.

If hypotension should occur, the IV fluids should be increased and the uterus displaced manually to the left (Barash et al., 2009). If the woman reports that she is having difficulty breathing, she needs to be assessed very carefully. Total spinal block rarely occurs, but the possibility must always be kept in mind. The woman should be observed for apnea, unconsciousness, pupil dilation, and unobtainable blood pressure. Prompt treatment, which may include the use of a vasopressor (such as ephedrine), may avert maternal or fetal death. It is essential to establish an airway and give oxygen with positive pressure until the woman can be intubated and other emergency measures instituted.

Following the birth, the woman may be kept flat. Although the effectiveness of the supine position to avoid headache following a spinal is controversial, the physician's orders may include lying flat for 6 to 12 hours.

Combined Spinal-Epidural Block

Spinal anesthesia may be combined with an epidural block. The combined spinal-epidural (CSE) can be used for labor analgesia and for cesarean birth. The anesthetic and analgesic agents used differ according to the purpose of the CSE. A CSE is accomplished by inserting an epidural needle into the epidural space. A narrow-gauge pencil-point anesthesia needle (24- to 27-gauge) is inserted through the epidural needle, through the dura, and into the cerebrospinal fluid. A small amount of local anesthetic agent, opioid, or both, is injected, and the needle is withdrawn. An epidural catheter is then threaded through the epidural needle into the epidural space. The epidural needle is removed and the epidural catheter is securely placed against the woman with tape.

An advantage of CSE is that the spinal agent will have a faster onset than medications that are injected into the epidural space. A CSE is versatile in that medication can be added to increase the effectiveness. Maternal satisfaction is high when a CSE is used because there is a quick onset of pain relief. Additional medication can also be added if an instrument-assisted birth or cesarean is needed (Okutomi, Saito, Mochizuki, et al., 2009). Studies show that the optimal timing of an epidural with the CSE is within 30 minutes of the spinal placement (Okutomi et al., 2009). CSE also preserves motor functioning. Most drugs are used in low dose, so spinal analgesia may be given in early labor to assist with labor pain. The nurse assesses the woman's strength and motor functioning before ambulation occurs. If ambulation is desired, a continuous assessment of the FHR and the maternal blood pressure is needed. Close supervision is needed to prevent falls or other injuries. When CSE is used, there does appear to be a higher incidence of nausea and pruritus. There are no reports of increased risks of fetal or neonatal complications.

Pudendal Block

The **pudendal block** technique provides perineal anesthesia for the second stage of labor, birth, and episiotomy repair. An anesthetic agent is injected below the pudendal plexus, as shown in Figure 25-1. The pudendal plexus arises from the anterior division of the second and third sacral nerves and the entire fourth sacral nerve. Below the plexus, the branches converge into the pudendal nerve, which crosses the sacrosciatic notch and passes the tip of the ischial spine, where it divides into the perineal, dorsal, and inferior hemorrhoidal nerves of the pudendal plexus. The perineal nerve, which is the largest branch of the pudendal plexus, supplies the skin of the vulvar area, the perineal muscles, and the urethral sphincter. The dorsal nerve supplies the clitoris, and the inferior hemorrhoidal nerve supplies the skin and muscles of the perineal region as well as the internal anal sphincter. Pudendal block provides relief of pain from perineal distention but does not relieve pain of uterine contractions (Figure 25-7 ■).

Advantages and Disadvantages

The advantages of pudendal block are ease of administration and absence of maternal hypotension. It also allows the use of low forceps or vacuum extraction for birth.

A moderate dose of anesthetic agent (10 ml per side) has minimal ill effects on the woman and the course of labor. The urge to bear down during the second stage of labor may be decreased, but the woman is able to do so with appropriate coaching. There is usually little effect on the uncompromised fetus unless overly rapid or intravascular injection occurs. The block may be done by a transvaginal or transperineal approach. The woman may experience a burning sensation when the block is administered. Transvaginal injection is simpler, safer, and more direct, making it the procedure of choice.

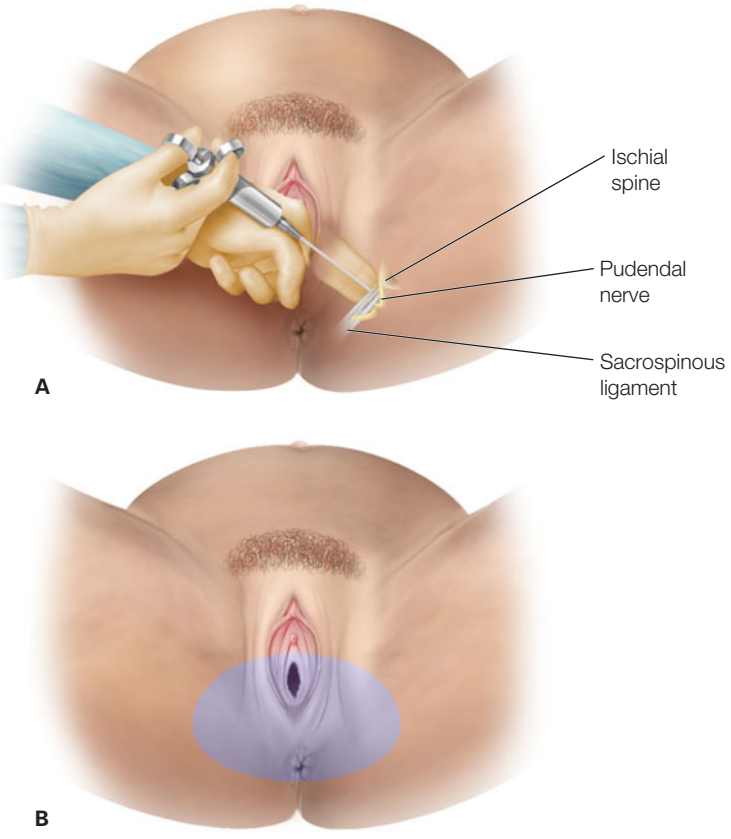

Figure 25-7 ■ A. Pudendal block by the transvaginal approach. B. Area of perineum affected by pudendal block.

Complications

A systemic toxic reaction can occur from accidental vascular injection. Other possible maternal complications specific to pudendal block include broad ligament hematoma, perforation of the rectum, and trauma to the sciatic nerve.

NURSING CARE MANAGEMENT

The nurse explains the procedure and the expected effect and answers any questions. Pudendal block does not alter maternal vital signs or FHR, so assessments in addition to the expected ones are not necessary.

Local Infiltration Anesthesia

Local anesthesia is accomplished by injecting an anesthetic agent into the intracutaneous, subcutaneous, and intramuscular

areas of the perineum (Figure 25-8 ■). It is generally used at the time of birth for episiotomy and repair or after birth if a laceration has occurred; it is especially useful for women giving birth without previous pharmacologic interventions. The procedure is essentially free from complications. The woman may experience a burning sensation at the time of administration.

Advantages

The major advantage of the local block is that it involves the use of the least amount of anesthetic agent. It can be done if an episiotomy is needed just before the birth. It can also be used when a laceration has occurred and a repair is needed.

Disadvantages

The major disadvantage is that large amounts of solution must be used. Although any local anesthetic may be used, chloroprocaine (Nesacaine), lidocaine (Xylocaine), and mepivacaine (Carbocaine) are the agents of choice in local infiltration because of their capacity for diffusion. A burning sensation at the time of injection is common.

(This item omitted from WebBook edition)

Figure 25-8 ■ Local infiltration anesthesia. A. Technique of local infiltration for episiotomy and repair. B. Technique of local infiltration showing fan pattern for the fascial planes.

NURSING CARE MANAGEMENT

The nurse explains the procedure and the expected effect and answers any questions. Local anesthetic agents have no effect on maternal vital signs or FHR, so additional assessments are unnecessary.

General Anesthesia

General anesthesia (induced unconsciousness) may be needed for cesarean birth and surgical intervention with some obstetric complications. The method used to achieve general anesthesia may be intravenous (IV) injection, inhalation of anesthetic agents, or a combination of both methods. The use of general anesthesia in the obstetrical setting continues to decline because of adverse fetal effects and the increase in maternal risks. The most common indications for general anesthesia include perceived lack of time for regional anesthesia, contraindications to regional anesthesia, failure to successfully insert regional anesthesia, and patient refusal (Chestnut et al., 2009).

Intravenous Anesthetics

Sodium thiopental (Pentothal) is an ultra-short-acting barbiturate, which means that it exerts its effect rapidly and has a brief duration of action. Sodium thiopental produces narcosis within 30 seconds after IV administration. Introduction and emergence from its effects are smooth and pleasant, with little incidence of nausea and vomiting. Sodium thiopental is most frequently used for initiating unconsciousness and as an adjunct to other more potent anesthetics. Ketamine is an intermediate-acting barbiturate that is used for anesthesia induction. The effects typically last 20 to 60 minutes. Hypersalivation can occur but can be treated with an anticholinergic drug to decrease this side effect. The drug is contraindicated in women with preeclampsia or chronic hypertension.

Inhaled Anesthesia Agents

The most commonly used inhaled anesthesia agent is nitrous oxide. Nitrous oxide does not produce significant uterine relaxation. Although it crosses the placenta immediately after administration, fetal tissue uptake occurs 20 minutes after administration, which results in a lower fetal arterial concentration and less neonatal depression. In recent years, the recommended dosage has been decreased to 50% (down from 70%) and the time from administration until birth has been shortened as much as possible. In order to decrease the length of fetal exposure and tetrogenic effects, it is recommended that the woman be fully prepped and the obstetrician be fully prepared to make the initial incision when nitrous oxide is introduced (Yentis et al., 2007).

The use of other low-dose halogenated agents, such as isoflurane, halothane, sevoflurane, desflurane, and enflurane, are also used, often in combination with nitrous oxide. These agents have been used commonly and have been found to increase maternal in-

spired oxygen levels and may increase uterine blood flow (Yentis et al., 2007). The use of sevoflurane has been associated with uterine relaxation when administered in high dosages, suggesting that the lowest dose possible should be used (Yentis et al., 2007).

Inhaled anesthetic agents have also been used in combination with spinal or epidural techniques when the epidural anesthesia was ineffective or severe maternal anxiety was present. Inhaled agents may also be used for women with aortic stenosis instead of regional anesthesia if advised by the cardiologist. Inhaled anesthetic agents have been associated with cardiovascular stability throughout surgery without adverse fetal outcomes (Gambling et al., 2008).

Complications of General Anesthesia

A primary danger of general anesthesia is fetal depression. Most general anesthetic agents reach the fetus in about 2 minutes. The depression of the fetus is directly proportional to the depth and duration of the anesthesia. The long-term significance of fetal depression in a normal birth has not been determined. The poor fetal metabolism of general anesthetic agents is similar to that of analgesic agents administered during labor. General anesthesia is not advocated when the fetus is considered to be at high risk, particularly in preterm birth.

Most general anesthetic agents cause some degree of uterine relaxation although the inhalation agents effect uterine relaxation to a lesser degree than the IV agents. They may also cause vomiting and aspiration.

Pregnancy results in decreased gastric motility, and the onset of labor halts the process almost entirely. Food eaten hours earlier may remain undigested in the stomach. Even when food and fluids have been withheld, the gastric juice produced during fasting is highly acidic and can produce chemical pneumonitis if aspirated. This pneumonitis is known as Mendelson syndrome. The signs and symptoms are chest pain, respiratory distress, cyanosis, fever, and tachycardia. Women undergoing emergency cesarean births appear to be at considerable risk for adverse events. The leading cause of maternal deaths in women who have had general anesthesia is the failure to establish a patent airway (Bucklin et al., 2008).

Care During General Anesthesia

Prophylactic antacid therapy is given to reduce the acidic content of the stomach before general anesthesia. Administration of a nonparticulate antacid (such as Bicitra) may be used. Cimetidine (Tagamet) may also be used (Cunningham et al., 2010).

Before the induction to anesthesia, the woman should have a wedge placed under her hip to displace the uterus and avoid vena caval compression in the supine position. She should also be preoxygenated with 3 to 5 minutes of 100% oxygen. IV fluids should be started so that access to the intravascular space is immediately available.

During the process of rapid induction of anesthesia, the nurse applies cricoid pressure. This is accomplished by depressing the cricoid cartilage 2 to 3 cm posteriorly so that the esophagus is occluded. Cricoid pressure is continued until the anesthesiologist has placed the cuffed endotracheal tube and indicates that the pressure can be released. Figure 25-9 ■ shows the appropriate technique. The woman's neck should be supported by the nurse's other hand.

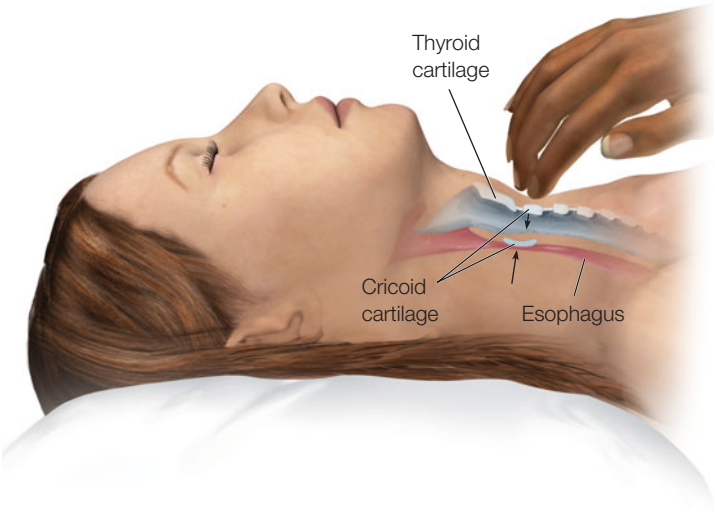

Figure 25-9 ■ Proper position for fingers in applying cricoid pressure until a cuffed endotracheal tube is placed by the anesthesiologist or certified nurse anesthetist. The cricoid cartilage is depressed 2 to 3 cm so that the esophagus is occluded.

Neonatal Neurobehavioral Effects of Anesthesia and Analgesia

Studies have focused on the neurobehavioral effects on the newborn of pharmacologic agents used during labor and birth. Although analgesic and anesthetic agents may alter the behavioral and adaptive function of the newborn, physiologic factors such as hunger, degree of hydration, time within the sleep-wake cycle, gestational age, and birth weight may also exert an influence (Nabhan, El-Din, Rabie, & Fahmy, 2009).

Women who receive general anesthesia are also slower to initiate breastfeeding in the immediate postpartum period, which could have long-term effects on breastfeeding success. Women who receive general anesthesia and undergo a cesarean birth need more assistance with breastfeeding than women who deliver vaginally (Cakmak & Kuguoglu, 2007).

Analgesic and Anesthetic Considerations for the High-Risk Mother and Fetus

Up to this point the discussion of obstetric analgesia and anesthesia has dealt with the healthy woman and healthy fetus. Pain relief for high-risk women during labor and birth requires skill in decision making, close observation, and awareness of potential threats to the woman and fetus. Safety for all involved requires the close cooperation of the obstetrician, anesthesiologist, pediatrician, and labor nurse. The pathophysiologic changes that accompany maternal disorders have a direct influence on the choice of agent or technique. It is difficult to separate maternal and fetal complications because whatever alters the woman's response will also affect the fetus. The effects on the woman cannot be considered without the potential effects on the fetus.

RESEARCH EVIDENCE IN PRACTICE

Transcutaneous Electrical Nerve Stimulation for Pain Relief in Labor

CLINICAL QUESTION

Is transcutaneous nerve stimulation (TENS) an effective means of reducing the pain of labor?

RESEARCH EVIDENCE

Transcutaneous nerve stimulation (TENS) has been proposed as a means of reducing pain in labor. A TENS unit emits low-voltage electrical impulses that vary in frequency and intensity, and have been shown to be effective for a variety of painful conditions. The mechanism of action is not well understood. It is thought that the electrical pulses stimulate nerve pathways in the spinal cord that block the transmission of pain. In labor, electrodes from the TENS machine are attached to the lower back, and the mother controls the electrical current using a handheld device.

A Cochrane review of 19 studies with a total of 1671 women was conducted to determine the effectiveness of TENS in the control of labor pain. In addition, a group of nurse midwife-researchers conducted a national survey of the use of TENS in labor in Great Britain, where the National Health Service has issued recommendations against the use of TENS machines, based on a reported lack of documented effectiveness.

The Cochrane review did in fact identify that there was little difference in pain control between women using TENS and control groups. There was some evidence that women using TENS were less likely to rate their pain as severe, but the results were not consistent nor widespread among the studies. TENS did not seem to have an effect on length of labor or the well-being of mothers or babies. However, the British survey did find that women who used TENS believed it helped their pain and reported they would use it again given the chance.

Given the perceptual nature of pain, it may be that TENS exerts a placebo effect that is helpful to some women. The device may offer a useful distraction, and the fact that the woman operates the device may enhance her sense of control. However, it cannot be demonstrated that TENS has a predictable or consistent effect in reducing the pain of labor.

WHAT QUESTIONS REMAIN UNANSWERED?

The treatments were inconsistently described in these trials. Could the consistent application of a standard TENS device help reduce the severity of pain?

WHAT IS BEST PRACTICE?

While TENS may offer a distraction from the pain of labor and may help women feel more in control of their labor, there is no conclusive evidence that TENS offers better pain relief than placebo.

CRITICAL THINKING

Are there other ways to help mothers achieve the sense of control that may be the source of the placebo effect in these trials? Are there other distractions that could help mothers manage the pain of labor better?

Preterm Labor

The preterm fetus has special risks and requirements. An immature fetus is more susceptible to depressant drugs because he or she has less protein available for binding; has a poorly developed blood-brain barrier, which increases the likelihood that pharmacologic agents will attain a higher concentration in the central nervous system; and has a decreased ability to metabolize and excrete drugs after birth (Blackburn, 2007). Analgesia during labor should be avoided whenever possible. If it becomes necessary, the smallest dose that will provide relief should be administered. General anesthesia should be avoided in premature gestations (Creasy et al., 2009). Emotional support will be very valuable to the woman in this situation.

Preeclampsia

Pregnancies complicated by preeclampsia are high-risk situations, as indicated in chapter 20 ∞. The potential for chronic placental insufficiency or preterm birth is also present. The woman with mild preeclampsia usually may have the analgesia or anesthesia of choice, although the incidence of hypotension with epidural anesthesia is increased (Creasy et al., 2009). If hypotension occurs with the epidural block, it provides further stress on an already compromised cardiovascular system. Hypotension can usually be managed with judicious fluid increase and positioning.

The woman with severe preeclampsia poses a real challenge. Regional anesthesia seems to be the preferred method as long as hypotension can be avoided. Raising the central venous pressure by 3 to 4 cm H_2O with IV fluids helps avoid hypotension, but it must be remembered that this woman is already threatened with heart failure (Creasy et al., 2009). The effect of fluid intake can be monitored with a pulmonary artery occlusion pressure monitoring catheter. Pulmonary artery catheterization is used to correct volume deficits and appears more accurate than central pressure catheters in monitoring left- and right-side cardiac filling pressures, cardiac output, and systemic vascular resistance (Creasy et al., 2009). Although invasive monitoring is indicated, it is not associated with better maternal or neonatal outcomes (ASA Task Force, 2007). It is important to monitor and record the fluid intake and output. Some physicians use vasopressors; others avoid them because of the possible decrease in uterine blood flow to an already compromised fetus and the threat of a maternal cerebral vascular accident (Creasy et al., 2009). Spinal anesthesia is rarely used because of the greater potential for hypotension.

The use of general anesthesia poses a risk of aggravating maternal hypertension. In general, the safest method for general anesthesia is intubation, but because it may cause a hypertensive episode, it is avoided if possible. Another important consideration is that women with preeclampsia are more prone to have mucosal edema in the oral cavity and glottis, making intubation more difficult (Creasy et al., 2009).

Diabetes Mellitus

The fetus of a mother with diabetes mellitus may have a reduction in placental blood flow. Hypotension, which can result during regional anesthesia, can deplete this blood flow even further. If the fetus is tolerating labor well without an indication of nonreassuring fetal status, the continuous epidural technique may be undertaken. If nonreassuring fetal status occurs, cesarean birth may be necessary.

Anesthesia for cesarean birth requires special consideration in this case. The diabetic woman is more likely to experience cardiovascular depression during a regional block because of higher sympathetic blockade (Chestnut et al., 2009). If a regional block is selected, it is recommended that acute hydration (preload) be provided by administering dextrose-free solution. In addition, left uterine displacement is initiated before the administration of the block and maintained throughout the surgery. Hypotension is treated promptly.

Cardiac Disease

Pregnancy imposes significant risks for the woman with cardiac disease. With mild mitral stenosis, the preferred anesthetic is continual epidural anesthesia with low forceps birth. This method avoids the cardiovascular changes associated with contractions and the Valsalva maneuver during bearing down in the second stage of labor. Hypotension can be avoided with carefully controlled IV fluids and by measuring central venous pressure to avoid overload. Epidural block or general anesthesia may be used in cesarean birth. Ketamine should be avoided because it produces tachycardia (Creasy et al., 2009). Women at risk for congestive heart failure require invasive pulmonary artery occlusion pressure monitoring (Creasy et al., 2009).

Bleeding Complications

The current trend in treating bleeding complications during labor is to schedule cesarean birth when possible. When the maternal cardiovascular system is stable and there is no evidence of nonreassuring fetal status, an epidural may be given for birth. However, when either of these conditions results in active bleeding, the threat of hypovolemia must be treated immediately. Maternal hypovolemia and shock produce fetal hypoxia, acidosis, and possible fetal death (Creasy et al., 2009).

Regional blocks are contraindicated during active bleeding because the sympathetic block causes vasodilatation and further reduction of the vascular volume. Women with thrombocytopenia should also avoid regional blocks. Platelet status is an important consideration when choosing the best approach for anesthesia and, when at all possible, hematologic conditions should be corrected before initiating birth (Creasy et al., 2009). General anesthesia is recommended for these cases. Sodium thiopental may be used, but it is a cardiac depressant and vasodilator, and ketamine may be a more appropriate choice for induction. Following birth of the infant and placenta, oxytocin should not be given as an intravenous (IV) bolus to contract the uterus because it causes vasodilatation, which in turn causes a decrease in blood pressure and in total peripheral resistance. Oxytocin should be given as a dilute infusion to gain an oxytocic effect to treat uterine atony (relaxation) and to control postpartum bleeding. Resources that should be on hand to handle hemorrhagic emergencies include large-bore IV catheters, a fluid warmer, a forced-air body warmer, the woman's specific blood type or O negative blood, trained personnel, and equipment to infuse blood products rapidly (Chestnut et al., 2009).

FOCUS YOUR STUDY

- Pain relief during labor may be enhanced by nonpharmacologic methods and administration of analgesic agents and regional anesthesia blocks. The nurse can offer alternative comfort measures, avoid offering pain medication to women who do not desire pain medication, provide the woman who does desire pain medication with the opportunity to explore available options, and provide education and reassurance to the expectant woman and her support person.
- The goal of pharmacologic analgesia during labor is to provide maximal pain relief with minimal risk for the woman and fetus.
- The optimal time for administering analgesia is determined after a complete assessment of vital factors, including maternal, fetal, and labor assessments and the woman's perception of her pain level and her need and desire for pain medication.

- Two common analgesic agents are butorphanol (Stadol) and nalbuphine (Nubain).
- Opiate antagonists, such as naloxone (Narcan), counteract the respiratory depressant effect of the opiate narcotics by acting at specific receptor sites in the central nervous system.
- Sedatives, including barbiturates, benzodiazepines, and H_1-receptor antagonists, are primarily used in latent or early labor to promote rest and allow the woman to sleep.
- Regional anesthesia is achieved by injecting local anesthetic agents into an area that will bring the agent into direct contact with nerve tissue. Methods most commonly used in childbearing include lumbar epidural, spinal block, combined spinal-epidural block, pudendal block, and local infiltration.
- Three types of local anesthetic agents used in regional blocks are amides, esters, and opiates. The amides are absorbed quickly and can be found in maternal blood within minutes after administration. The esters are metabolized more rapidly and have only limited placental transfer. Opiates act on specific opiate receptors in the spinal cord and have a greater analgesic effect when combined with a low dose of local anesthetic.
- Possible maternal complications of regional anesthesia, although rare, include systemic toxicity, convulsions, and sudden cardiovascular collapse.
- Agents in use for epidural and spinal routes include the opioids morphine and fentanyl. Adverse reactions of the woman to local anesthetic agents range from mild symptoms, such as palpitations, to cardiovascular collapse. The newer amides, including ropivacaine and levobupivacaine, are longer acting and have fewer side effects.
- Pudendal blocks provide perineal anesthesia during the second stage of labor, birth, episiotomies, or laceration repair.
- General anesthesia can be achieved by intravenous injection, inhalation of anesthetic agents, or a combination of both methods.
- The goal of general anesthesia is to provide maximal pain relief with minimal side effects to the woman and her fetus.
- Complications of general anesthesia include fetal depression, uterine relaxation, vomiting, and aspiration.
- The choice of analgesia and anesthesia for the high-risk woman and fetus requires careful evaluation.

CRITICAL THINKING IN ACTION

Source: George Dodson/Pearson Education.

Sandra, a 26-year-old G1 P0000, is in active labor when she presents to you at the birthing center. She has been in labor for 5 hours and is clearly tired and seems to be having difficulty coping with the pain. Her contractions are occurring every 2 to 4 minutes lasting 50 to 60 seconds, and are moderate to strong in intensity. You assess the fetal heart rate of 120 to 130 with early decelerations; moderate long-term variability is present. Sandra's vital signs are stable and her laboratory results are within normal limits. She is requesting an epidural analgesia for pain control. A vaginal exam demonstrates the cervix is 100% effaced, 6 cm dilated with the vertex at 0 station in the LOT position. You notify the physician of Sandra's wish for pain relief and labor progress. You review the client's record for written consent for regional analgesia and assist the anesthesiologist with the procedure.

1. Discuss the advantages of regional analgesia.
2. Describe the nursing responsibility during the administration of regional analgesia.
3. Discuss the side effects of regional analgesia.
4. What are the absolute contraindications for an epidural block?
5. How do you assist Sandra with the second stage of labor when she cannot feel her contractions?

See www.nursing.pearsonhighered.com for possible responses.

CHAPTER 26

Childbirth at Risk: Prelabor Complications

As a fourth time mother, I was unprepared to deal with the hardship of 6 months of bed rest after having three uncomplicated pregnancies. Each day brought me closer to a safe delivery, but the stress and strain of three active young children and the worry of the condition of my unborn baby made each day a struggle.

LEARNING OUTCOMES

1. Identify the causes and risk factors of cervical insufficiency.
2. Describe the clinical therapies and appropriate nursing interventions for the mother with cervical insufficiency and her unborn fetus.
3. Identify the causes and risk factors for premature rupture of membranes.
4. Describe the clinical therapy for premature rupture of membranes and preterm labor in determining hospital-based and community-based nursing care management of the woman and her fetus-newborn.
5. Analyze the implications and maternal and fetal risks of preterm labor.
6. Compare placenta previa and abruptio placentae, including implications for the mother and fetus, and their nursing care.
7. Analyze the maternal and fetal-newborn implications and clinical therapy in determining community-based and hospital-based nursing care of the woman with a multiple gestation.
8. Describe the identification of the woman with hydramnios and the maternal and fetal-neonatal implications.
9. Describe the identification of the woman with oligohydramnios and the maternal and fetal-neonatal implications.
10. Compare the clinical therapy and nursing care management of the woman with hydramnios and the woman with oligohydramnios.

KEY TERMS

Abruptio placentae *675*
Cerclage *663*
Cervical insufficiency *663*
Hydramnios *688*
Incompetent cervix *663*
Oligohydramnios *688*
Placenta previa *680*
Premature rupture of membranes (PROM) *664*
Preterm labor (PTL) *668*
Tocolysis *671*
Vasa previa *681*

After the first trimester, the majority of pregnancies progress smoothly to term. In some cases, however, complications can occur before the onset of labor that significantly impact the outcome of pregnancy. This chapter presents information related to the most common of these conditions. It also serves as a prelude to the labor-related complications discussed in chapter 27 ∞.

Care of the Woman with Cervical Insufficiency

Many questions remain unanswered about cervical insufficiency (formerly termed **incompetent cervix**). The classic definition presents **cervical insufficiency** or *cervical incompetence* as painless dilatation of the cervix without contractions because of a structural or functional defect of the cervix. The woman is usually unaware of contractions and presents with advanced effacement and dilatation and, possibly, bulging membranes. It is difficult to determine the incidence because of the inconsistency in definition and lack of clear diagnostic criteria (American College of Obstetricians and Gynecologists [ACOG], 2008).

The origin of cervical insufficiency is multifactorial; the etiology may be either congenital or acquired (Johnson & Iams, 2009). Factors that may contribute to the tendency for the cervix to dilate prematurely can be divided into three categories: congenital factors, acquired factors, and biochemical (hormonal) factors. Congenitally incompetent cervix may be found in women exposed to diethylstilbestrol (DES) or those with a bicornuate uterus. Acquired cervical incompetence may be related to inflammation, infection, subclinical uterine activity, cervical trauma, cone biopsy, late second trimester elective abortions, or increased uterine volume (as with a multiple gestation). Loop electrosurgical excision procedure (LEEP) of the cervix has been found to significantly increase the risk of preterm births in both singleton and twin gestations (Noehr, Jensen, Frederiksen, et al., 2009). The hormone relaxin may be an endocrine cause of cervical incompetence.

A woman's obstetric history may give her healthcare provider an indication of increased risk for incompetent cervix. Factors include multiple gestations, repetitive second trimester losses, previous preterm birth, progressively earlier births with each subsequent pregnancy, short labors, previous elective abortion or cervical manipulation, DES exposure, or other uterine anomaly. These women will benefit from close surveillance of cervical length with transvaginal ultrasound beginning between 16 and 24 weeks' gestation. Cervical effacement occurs from the internal os out and can be seen on ultrasound as "funneling." Alteration is apparent in transvaginal scan when fundal pressure is applied or the woman assumes a standing position. In addition, women at risk for incompetent cervix need to be informed early in pregnancy of warning signs of impending birth, such as lower back pain, pelvic pressure, and changes in vaginal discharge.

A number of contemporary studies have concluded that endovaginal ultrasound measurements of cervical length between 15 and 28 weeks' gestation identify groups at risk for preterm birth. However, the placement of a cervical cerclage (see the following discussion) does not substantially reduce the risk of prematurity (Johnson & Iams, 2009). This has led to a reconsideration of both medical and surgical treatment options for women with a history of midtrimester losses. Medical therapies used are serial cervical ultrasound assessments, bed rest, progesterone supplementation, antibiotics, and anti-inflammatory drugs (Berghella, Roman, Daskalakis, et al., 2007; Mancuso & Owen, 2009).

Cerclage Procedures

A **cerclage** is a surgical procedure in which a stitch is placed in the cervix to prevent a spontaneous abortion or premature birth (Encyclopedia of Surgery, 2010). See Figure 26-1 ■. Surgical options include the various types of cerclage procedures. An elective cervical cerclage may be placed late in the first trimester or early in the second trimester with an 80% to 90% success rate in preventing fetal loss and premature labor and birth (Encyclopedia of Surgery, 2010). A cerclage placed for emergent reasons, when dilatation and effacement have already occurred, is successful in 40% to 60% of cases (Encyclopedia of Surgery, 2010). A cervical cerclage involves using a heavy suture to reinforce the cervix at the level of the internal os. The McDonald cerclage utilizes a purse-string technique high up on the cervix to tie it closed. The Shirodkar method uses a submucosal band placed at the level of the internal os.

An abdominal cerclage approach may be required for women with a congenitally short or amputated cervix, cervical defects, a cervix previously scarred, or unhealed lacerations or subacute cervicitis (ACOG, 2008). Figure 26-2 ■ compares a cervix of normal length with one indicative of cervical shortening. A cerclage is in place.

In cases in which cervical dilatation is discovered unexpectedly, an attempt may be made to "rescue" the pregnancy by

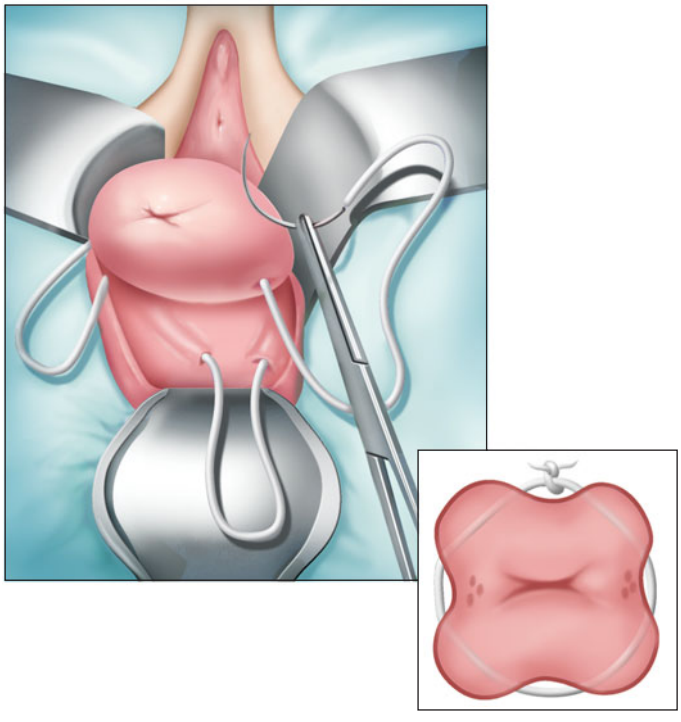

Figure 26-1 ■ A cerclage or purse-string suture is inserted in the cervix to prevent preterm cervical dilatation and pregnancy loss. After placement, the string is tightened and secured anteriorly.

placing a cerclage after cervical dilatation is advanced. In some instances, decompression of a bulging amniotic sac must be accomplished immediately before the cerclage placement. In this situation, a preoperative evaluation for infection, ruptured membranes, and uterine activity may be prudent. Tocolytics (drugs that stop labor), broad-spectrum antibiotics, and anti-inflammatory agents are given perioperatively and for ongoing treatment. Exposure of the amniotic membranes increases the chance of cerclage failure when compared with an elective placement of a cerclage.

An uncomplicated elective cerclage may be done on an outpatient basis or the woman may be hospitalized and discharged after 24 to 48 hours. An emergency cerclage, however, requires hospitalization for 5 to 7 days or longer. After 37 completed weeks' gestation, the suture may be cut and vaginal birth permitted, or the suture may be left in place and a cesarean birth performed to avoid repeating the procedure in subsequent pregnancies.

Care of the Woman with Premature Rupture of Membranes

Spontaneous rupture of the membranes before the onset of labor is known as **premature rupture of membranes (PROM)**. Some authorities define PROM as the rupture of the bag of waters any time after 37 completed weeks but before the onset of labor (Jazayeri, 2008); some have further defined PROM as a specific period elapse without labor, generally between 1 and 12 hours. Preterm PROM (PPROM) has been described as rupture before 37 weeks' gestation. Prolonged rupture of the membranes is rupture more than 24 hours before birth. In the United States, PPROM complicates more than 3% (or 150,000) of pregnancies each year and is associated with more than 30% to 40% of the preterm births (Jazayeri, 2008).

Whereas preterm labor tends to be the cause of preterm birth in more educated and affluent women, PPROM is seen more frequently in less educated women of lower economic status. Although the cause of PPROM is unknown, it is thought that PPROM occurs because of multiple, interrelated factors. The most significant risk factors for PPROM are previous preterm birth and previous PPROM; hence, incompetent cervix may be the cause of second trimester PPROM. Cervicitis, urinary tract infection (UTI), asymptomatic bacteriuria, amniocentesis, placenta previa, abruptio placentae, hydramnios, history of laser conization or loop electrosurgical excision procedure (LEEP) of the cervix, multiple pregnancy, and maternal genital tract anomalies may also result in PPROM. It has been suggested that nulliparous women who work outside the home are at increased risk as well. Other risk factors include smoking, substance abuse, connective tissue disorders, fetal anomalies, and lower socioeconomic status; however, in most cases the cause is undefined (Gibbs, Karlan, Haney, et al., 2010). Once membranes have ruptured, labor may occur within a relatively short time. The latency period, the period of time between rupture of membranes and the onset of labor, decreases with increasing gestational age. Shorter latency periods are associated with oligohydramnios, cervical dilatation more than 1 centimeter, fetal growth restriction, and nulliparity (Melamed, Hadar, Ben-Haroush, et al., 2009). With appropriate and conservative therapy, 50% of those women who rupture membranes between 28 and 34 weeks will give birth within 7 days (Jazayeri, 2008).

Maternal Risks

Maternal risk is related to infection, specifically *chorioamnionitis* (intra-amniotic infection resulting from bacterial invasion and inflammation of the membranes before birth) and *endometritis* (infection of the endometrium postpartally that may be related to chorioamnionitis or may occur independently).

Chorioamnionitis occurs in about 3% to 15% of all cases of PROM but in 13% to 60% of cases of preterm PROM (Jazayeri, 2008). Collection of amniotic fluid by amniocentesis permits analysis of the fluid for subclinical chorioamnionitis. Gram stain, white cell count, glucose concentration, and culture of the fluid are useful in determining treatment; however, the results of the amniotic fluid culture could take as long as 48 hours. Interleukin-6 concentrations appear to be the best biomarker for infection but most hospitals do not yet have the ability to measure them (Gibbs et al., 2010). In addition, fluid gathered either by amniocentesis or from fluid that has pooled in the vagina can be analyzed for fetal lung maturity. The lecithin/surfactant ratio is the biochemical marker associated with fetal lung maturity. A ratio greater than 2.0 is associated with fetal lung maturity. When the fetal lungs are mature, the risk of serious pulmonary complication in newborns is minimal and labor is allowed to progress naturally.

Abruptio placentae occur more frequently in women with PPROM. It is not clear whether infection causes inflammation of the decidua, which facilitates premature separation, or whether the bleeding episode contributes to a weakening of the membranes, which eventually leads to rupture. Childbirth may be complicated by malpresentation and reduced amniotic fluid volume (Jazayeri, 2008).

Fetal-Neonatal Risks

The most significant cause of neonatal morbidity and mortality is prematurity and its associated complications such as respiratory distress syndrome, necrotizing enterocolitis, and intraventricular hemorrhage (see chapter 33 ∞). Neonatal infection (sepsis) occurs in 2% to 4% of newborns, but the preterm infant is much more likely to develop sepsis and die than a baby born at term. Fetal hypoxia may occur from cord prolapse or cord compression. In cases of early, prolonged PPROM, the oligohydramnios that occurs may result in fetal pulmonary hypoplasia, facial anomalies, limb position defects, and fetal growth restriction (Hutzal et al., 2008).

Clinical Therapy

Any time a woman complains of watery vaginal discharge or a sudden gush of fluid, rupture of the membranes must be considered. The woman should be questioned about the time of initial loss of fluid; if continuous leaking is occurring; the color, consistency, and amount of the fluid; and any odor noted. These questions not only help to determine whether there is blood, meconium, or vernix present but also may help to differentiate PROM/PPROM from increased vaginal secretions associated with infection or preterm labor, urinary incontinence, normal leukorrhea of pregnancy, or the passage of the mucous plug.

During the initial physical inspection, any fluid leaking from the vaginal introitus can be checked with nitrazine paper or nitrazine swabs. This test relies on the fact that amniotic fluid is more alkaline (pH 7 to 7.5) than normal vaginal secretions (pH 4.5 to 5.5). A color change in the paper to blue-green or blue is highly suggestive of ruptured membranes. Factors that can yield a false-positive result are contamination of the fluid with semen, urine, 50% or more blood in the specimen, or antiseptic cleansers and soap. The elevated pH associated with bacterial vaginosis can also lead to misleading results. If there is copious fluid leaking from the vaginal introitus, the diagnosis of PROM/PPROM is considered confirmed.

If further evaluation is required, a sterile speculum exam is done. Unless the woman is in active labor, direct digital exam of the cervix or vagina is avoided until PPROM is ruled out or a management plan has been determined. Speculum exam relies on gross pooling of amniotic fluid in the vaginal vault. The woman can be asked to "bear down," performing a Valsalva maneuver, if fluid is not visualized in the vagina. The woman may also remain in a supine position for several hours to allow collection of fluid to occur; the exam is then repeated. In addition to performing a nitrazine test on the fluid, a fern test can be performed by applying a thin sample of secretions onto a clean slide and looking for microscopic evidence of a fernlike pattern (see chapter 12 ∞). When combined with patient history, positive nitrazine testing and positive ferning have been shown to have an accuracy rate of 93.1% (Cunningham et al., 2010). Vaginal cultures for group B streptococcus, chlamydia, and gonorrhea may be obtained at this time. Ultrasound can be used in conjunction with other tests to look for reduced amniotic fluid.

In situations in which the diagnosis of PPROM cannot be made with any certainty, an amniocentesis may be performed to instill either indigo carmine or Evan's blue dye. A tampon is inserted in the vagina for several hours and then is inspected for blue tinged fluid. The woman should be warned that as the dye is absorbed, it will temporarily change her urine to a green color.

Concurrently, fetal well-being should be assessed through a fetal heart rate tracing or biophysical profile. In addition, the gestational age of the fetus must be calculated to decide on a management plan (Table 26-1). At greater than 36 weeks' gestation, labor will begin in 50% of women within 12 hours. Labor induction may be delayed for 12 to 24 hours unless a situation exists that would preclude expectant management.

Management of PPROM in the absence of infection and gestation of less than 37 weeks is usually conservative. Amniocentesis may be done to evaluate for intra-amniotic infection. Fetal lung maturity studies will also be done if the fetus is nearing 34 weeks' gestation. The woman is hospitalized on bed rest. An admission, complete blood count (CBC), and urinalysis are obtained. Nonstress tests (NSTs) or biophysical profiles are used to monitor fetal well-being. Typically, NSTs are performed every shift (8–12 orders per policy) or the frequency is determined by physician/certified nurse-midwife (CNM) order. Biophysical profiles should be performed every 24 hours (Gjoni, 2010). Maternal blood pressure, pulse, and temperature are assessed every 4 hours. Regular laboratory evaluations should be performed to detect maternal infection. After initial treatment and observation, if the fetus has not reached viability or if leaking of fluid ceases, some women may be followed at home; however, careful screening is warranted (Ellestad et al., 2008). The woman is advised to continue bed rest (with bathroom privileges); monitor her temperature

TABLE 26-1 Currently Used Plans for Women with Premature Rupture of Membranes

Preterm

- Expectant management (observation); birth when labor or clinical infection develops
- Fetal pulmonary status determined by amniotic fluid testing; birth if fetus is mature
- Risk of infection determined by amniotic fluid Gram stain; white cell count, glucose and culture; maternal white cell count and assessment for maternal fever or uterine tenderness; assessment for fetal well-being through electronic fetal monitoring or ultrasound for biophysical profile scoring; birth if infection develops
- Penicillin G or ampicillin for treatment of group B streptococcus (GBS), or antibiotic prophylaxis if GBS status unknown
- Adjunctive antibiotic therapy with erythromycin or azithromycin for 7 days to increase latency period from PPROM to birth
- Administration of corticosteroids, with or without birth in 48 hours after first dose; tocolytics as needed to delay birth for 48 hours to promote fetal lung maturity
- Birth after an arbitrary latent period (e.g., 16–72 hours)
- Assess for group B streptococci, chlamydia, or *Neisseria gonorrhoeae;* treatment indicated if positive
- Combinations of the above

Term

- Induction if spontaneous labor does not begin in approximately 12 hours, or if cervix is ripe, or if there are other complications (e.g., preeclampsia)
- Expectant management for women with uncomplicated pregnancies and cervix unfavorable for induction

RESEARCH EVIDENCE IN PRACTICE

Antibiotics for Premature Rupture of Membranes

CLINICAL QUESTION

Do antibiotics reduce the risk of complications following the premature rupture of membranes?

RESEARCH EVIDENCE

Premature rupture of the membranes (PROM) is an important problem, placing both mother and child at risk of infection, preterm delivery, and the complications of prematurity. There are multiple causes of PROM. Infection appears to play a central role, both as a cause and as a result of PROM. Some organisms weaken the amnion and chorion and lead to PROM; other infections may occur secondary to membrane rupture. Infections may also be linked to preterm labor, because it is thought that some bacteria may stimulate the biosynthesis of prostaglandins that subsequently stimulate labor. Antibiotic therapy has been advanced as a treatment to reduce maternal and fetal infections and to delay the progression to preterm birth.

A large number of trials have focused on the effectiveness of antibiotic therapy and its sequelae for mother and baby. Twenty-two randomized trials involving more than 6000 women were summarized in a Cochrane review, one of the most rigorous sources of evidence. Additional studies have focused on the length of time needed for optimal antibiotic therapy and the most effective type of antibiotic to use. A meta-analysis was also conducted, which focused on whether antibiotics were effective in preventing preterm labor following PROM.

All of the reviews and trials showed that routine antibiotic administration to women with PROM reduced maternal and neonatal morbidity. The evidence supported the effectiveness of antibiotic therapy in postponing preterm labor in women with PROM. Chorioamnionitis and neonatal infections were also reduced by antibiotic use. Other complications—including babies requiring oxygen therapy, time in neonatal intensive care, abnormal cerebral ultrasound, intraventricular hemorrhage, and low birthweight—were also lower when antibiotic therapy was used following PROM.

Relative to the length of antibiotic therapy, both 3- and 7-day regimens were tested, and there was no advantage detected for the longer length of therapy. While any penicillin and macrolide antibiotics (clindamycin or erythromycin) were effective and unrelated to complications, the use of co-amoxiclav antibiotics, while effective, were associated with higher rates of necrotizing enterocolitis.

WHAT QUESTIONS REMAIN UNANSWERED?

What is the long-term consequence of the abnormal cerebral ultrasounds in the neonates whose mothers were not treated with antibiotics? Are there overall effects on perinatal mortality?

WHAT IS BEST PRACTICE?

A 3-day course of either a penicillin or a macrolide antibiotic should be routinely administered to mothers with premature rupture of membranes. Neither antibiotic causes untoward complications for mother or baby, and effective use will prevent many complications associated with PROM.

CRITICAL THINKING

How can the nurse incorporate this information into the teaching and treatment plan of the mother with premature rupture of the membranes? Premature rupture of the membranes is often a traumatic experience, but mothers are often resistant to using medications during pregnancy. How can she be reassured that antibiotic use will prevent subsequent complications and will have no untoward effects?

Kenyon, S., Boulvain, M., & Neilson, J. (2009). Antibiotics for preterm rupture of membranes. *Cochrane Database of Systematic Reviews* (2), Art. No.: CD001058. doi: 10.1002/14651858

Marowitz, A., & Jordan, R. (2007). Midwifery management of prelabor rupture of membranes at term. *Journal of Midwifery & Women's Health, 52*(3), 199–206.

4 times a day; keep a fetal movement record; and avoid intercourse, douches, and tampons ("pelvic rest"). The woman is advised to contact her physician and return to the hospital if she has fever, uterine tenderness or contractions, increased leakage of fluid, decreased fetal movement, or a foul vaginal discharge. During this time, twice weekly NSTs and CBCs and weekly ultrasound and cervical visualization may be completed. Research indicates no significant difference in latency periods, gestational age at birth, infection, or perinatal outcomes between home care and hospitalization when this regimen is followed (Gjoni, 2010).

Authorities disagree regarding the ideal management of PPROM. Prophylactic antibiotics are administered to any woman with an unknown group B streptococcal (GBS) status or a history of a positive culture during the present pregnancy (Hutzal et al., 2008). The goal of antibiotic use for preterm PROM is to treat or prevent ascending infection to prolong the interval from rupture of membranes to childbirth. Antibiotic use also may allow sufficient time for corticosteroids used to enhance fetal lung maturity to take effect. In addition, the neonatal mortality rate is significantly lower in newborns whose mothers received antibiotics (Hutzal et al., 2008). If vaginal cultures are positive, antibiotics will be continued for at least 7 days. If amniotic fluid studies indicate a low glucose level, high white blood cell (WBC) count, a positive Gram stain, or organisms in the fluid, immediate birth is indicated. Results of studies about the potential benefits versus the risks of cervical cerclage retention after PPROM are conflicting. Current practice includes early cerclage removal after PPROM; a multicentered randomized trial to answer this question is needed.

Betamethasone, a corticosteroid, decreases the likelihood of neonatal respiratory distress syndrome, necrotizing enterocolitis, intraventricular hemorrhage, and perinatal death in infants who are born prematurely. Administration of single-course betamethasone (12 mg intramuscularly [IM] with a second dose in 24 hours or dexamethasone 6 mg im every 12 hours for 2 doses) is the current recommendation (Abbasi, Oxford, Gerdes, et al., 2009; Simpson & Creehan, 2008). Corticosteroids have been associated with increased maternal and neonatal infection, decreased neonatal birth weight, reduction of brain size, maternal and fetal adrenal suppression, and psychomotor delay and behavioral problems. Data on these effects are not conclusive, but until there are additional data from clinical trials, the recommendation is that repeat courses of corticosteroids should not be used routinely (Mazumder, Sarkar, & Khatun, 2009). See Drug Guide: Betamethasone.

Use of tocolytics is generally not indicated in the woman who has ruptured membranes. Short-term use of tocolytics may be considered, however, to allow a course of steroids to be given.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Determining the time, amount, color, odor, and duration of the rupture of membranes is a significant component of the antepartal assessment. The nurse asks the woman when her membranes ruptured and when contractions began because the risk of infection may be directly related to the time involved. The color and odor are important variables that can indicate possible infection or meconium passage. Gestational age is determined to prepare for the possibility of a preterm birth. The nurse observes the mother for signs and symptoms of infection, especially by reviewing her WBC count, temperature, and pulse rate, and the character of her amniotic fluid. If the mother has a fever, the nurse checks hydration status. Fetal heart rate tracings should be watched for tachycardia, loss of variability, or decelerations. When a preterm or cesarean birth is anticipated, the nurse evaluates the childbirth preparation and coping abilities of the woman and her partner.

Nursing diagnoses that may be used for the woman with PPROM include the following:

- ***Risk for Infection*** related to premature preterm rupture of membranes
- ***Risk for Impaired Gas Exchange (Fetus)*** related to compression of the umbilical cord secondary to prolapse of the cord
- ***Ineffective Coping*** related to unknown outcome of the pregnancy

Nursing Plan and Implementation

Nursing actions should focus on the woman, her partner, and the fetus. Uterine activity and fetal response to the labor are evaluated, but vaginal exams are not done unless absolutely necessary. The woman is encouraged to rest on her right or left side to promote optimal uteroplacental perfusion. Comfort measures may help promote rest and relaxation. The nurse must also ensure that hydration is maintained, particularly if the woman's temperature is elevated.

Health Promotion Education

Education is another important aspect of nursing care. The couple needs to understand the implications of PROM and all treatment methods. It is important to address side effects and alternative treatments. The couple needs to know that although the membranes are ruptured, amniotic fluid continues to be produced. Accurate information about neonatal outcomes for the given gestational age will help the woman and those she looks to for support have a more realistic view of the situation. This is often done by a care provider experienced in the care of high-risk newborns such as a neonatologist or a neonatal nurse practitioner. Providing psychologic support for the couple is critical. The nurse may reduce anxiety by listening empathetically, relaying accurate information, and providing explanations of procedures. It may be necessary to prepare the couple for a cesarean birth, a preterm newborn, and the possibility of fetal or neonatal demise.

Evaluation

Expected outcomes of nursing care include the following:

- The woman's risk of infection and cord prolapse are decreased.
- The couple is able to discuss the implications of PPROM and all treatment options.
- The pregnancy is maintained without trauma to the mother or fetus.

DRUG GUIDE Betamethasone (Celestone Soluspan)

OVERVIEW OF MATERNAL-FETAL ACTION

Studies have provided ample evidence that glucocorticoids such as betamethasone are capable of inducing pulmonary maturation and decreasing the incidence of respiratory distress syndrome in preterm infants. The mechanism by which corticosteroids accelerate fetal lung maturity is unclear, but it is related to the stimulation of enzyme activity by the drug. The enzyme is required for biosynthesis of surfactant by the type II pneumocytes. Surfactant is of major importance to the proper functioning of the lung in that it decreases the surface tension of the alveoli. Glucocorticoids also increase the rate of glycogen depletion, which leads to thinning of the interalveolar septa and increases the size of the alveoli. The thinning of the epithelium brings the capillaries into closer proximity with the air spaces and improves oxygen exchange.

ROUTE, DOSAGE, FREQUENCY

Prenatal maternal intramuscular injections of 12 mg of betamethasone are given once a day for 2 days. Dexamethasone may also be given in doses of 6 mg every 12 hours for 2 doses (Simpson & Creehan, 2008). To obtain maximum results, birth should be delayed for at least 24 hours after completing the first round of treatment. The effect of corticosteroids may be transient. Currently, it is suggested that repeat courses of corticosteroids should not be used routinely.

CONTRAINDICATIONS

- Inability to delay birth
- Adequate lecithin/sphingomyelin L/S ratio
- Presence of a condition that necessitates immediate birth (e.g., maternal bleeding)
- Presence of maternal infection, diabetes mellitus (relative contraindication)
- Gestational age greater than 34 completed weeks
- Cushing's syndrome

MATERNAL SIDE EFFECTS

Increased risk for infection has not been supported in large studies. There may, however, be some increase in the incidence of infection in women with premature rupture of the membranes. Maternal hyperglycemia may occur during corticosteroid administration. Women with insulin-dependent diabetes may require insulin infusions for several days to prevent ketoacidosis. Corticosteroids possibly may increase the risk of pulmonary edema, especially when used concurrently with tocolytics, which may cause sodium and fluid retention, nausea, and impaired wound healing (Wilson, Shannon, & Shields, 2010).

EFFECTS ON FETUS/NEWBORN

- Lowered cortisol levels at birth, but rebound occurs by 2 hours of age
- Hypoglycemia
- Increased risk of neonatal sepsis

Animal studies have shown serious fetal side effects such as reduced head circumference, reduced weight of the fetal adrenal and thymus glands, and decreased placental weight. Human studies have not shown these effects, however (Wilson et al., 2010).

NURSING CONSIDERATIONS

1. Assess for presence of contraindications.
2. Provide education regarding possible side effects.
3. Administer betamethasone deep into the gluteal muscle, avoiding injection into the deltoid (high incidence of local atrophy). (Dexamethasone may be administered IM or IV.)
4. Periodically evaluate blood pressure (BP), pulse, weight, and edema.
5. Assess laboratory data for electrolytes and blood glucose.

Although concomitant use of betamethasone and tocolytic agents has been implicated in increased risk of pulmonary edema, the betamethasone has little mineral corticoid activity; therefore, it probably does not add significantly to the salt and water retention effects of beta-adrenergic agonists. Other causes of noncardiogenic pulmonary edema should also be investigated if pulmonary edema develops during administration of betamethasone to a woman in preterm labor.

Early Preterm Labor

Care of the Woman at Risk Due to Preterm Labor

Labor that occurs between 20 and 37 completed weeks of pregnancy is referred to as **preterm labor (PTL)**. Prematurity continues to be the number one cause of neonatal mortality in the United States today—preterm births are preceded by preterm labor 50% of the time (Ross & Eden, 2009). Preterm birth has risen by more than 20% since 1990 (March of Dimes, 2007).

In the United States, preterm birth occurs in 12.8% of births and is the leading cause of neonatal mortality in the United States (Hamilton, Martin, & Ventura, 2007). Preterm birth accounts for 70% of neonatal morbidity. Most healthcare dollars spent on preterm births are due to the 2% of premature births that occur prior to 32 gestational weeks (Ross & Eden, 2009). In the United States, African American women experience preterm birth and have low-birth-weight infants at twice the rate of white women (Ross & Eden, 2009). Regardless of gestational age or birth weight, black infants are less likely than white infants to survive. Despite new diagnostic and therapeutic technologies, efforts to prevent preterm birth have been largely ineffective. Table 26-2 presents a list of risk factors for spontaneous preterm birth.

Maternal Risks

The initial cause of preterm labor—for example, antepartum hemorrhage, trauma, or maternal infection—may pose a risk to the pregnant woman. In addition, the treatment itself is another area of significant risk. Certain medications are needed to manage preterm labor and prevent premature birth. Beta-sympathomimetic drugs cause a myriad of maternal side effects, including pulmonary edema, especially in women with multiple gestations, overdistention of the uterus, or chorioamnionitis. Diabetes, cardiac disease,

TABLE 26-2 Risk Factors for Spontaneous Preterm Labor

Abdominal surgery during the second or third trimester	Insulin-dependent diabetes
Abdominal trauma	Known cervical incompetence
Age (less than 18 or more than 35)	Low maternal weight
Alcohol consumption	Low socioeconomic status
Anemia	More than two first trimester abortions
Asymptomatic bacteriuria	Multiple gestation
Bacterial vaginosis, *E. coli* (ascending intrauterine infection)	Non-white race
Bleeding after 12 weeks	Periodontal disease
Cervical cerclage in situ	Polyhydramnios
Cervical incompetence	Poor weight gain
Cervix dilated more than 1 cm at 32 weeks	Previous preterm birth
Cigarettes—more than 10/day	Previous preterm labor with term birth
Diethylstilbestrol (DES) exposure	Second trimester abortion
Domestic violence	Sexually transmitted infection (STI) (trichomoniasis, chlamydia)
Drug abuse	Smoking
Febrile illness	Stress
Fetal abnormality	Substance abuse
Foreign body (intrauterine device [IUD])	Uterine anomaly
History of cone biopsy	Uterine fibroids
History of pyelonephritis or other maternal infection	Uterine irritability
In vitro fertilization (singleton or multiple gestation)	Uteroplacental ischemia
Inadequate prenatal care	

and thyrotoxicosis may contribute to maternal risk with the administration of this class of drugs. Magnesium sulfate is a drug used to displace intracellular calcium, which inhibits uterine contractions. Prostaglandin synthesis inhibitors inhibit contractions by interfering with prostaglandin synthesis. Calcium channel blockers antagonize the action of calcium within the myometrial cells, which reduces contractions. These agents may have adverse maternal consequences and require close monitoring during administration (El-Mowafi, 2010).

Bed rest is frequently prescribed for women having preterm contractions, although there is no evidence to support or refute its use to prevent PTL (Denney, Culhane, & Goldenberg, 2008). Bed rest in general is associated with adverse physiologic effects, including maternal thromboembolism and decreased muscle mass. It is also linked with psychologic effects that extend to the entire family. Financial loss, child care issues, disruption of routines, depression, anxiety, and family/marital stress are among the problems that the woman and her family face. Hospitalization of those women with threatened preterm birth for enforced bed rest has an even greater impact on these issues. The social and financial blow to families who face a long-term hospitalization far from home, either because they had traveled away from their usual site of residence on holiday or have been transported to a hospital that provides a higher level of care, adds to the stress of a high-risk pregnancy and the ability of the patient and her partner to cope.

Fetal-Neonatal Risks

Mortality increases for newborns born before 37 weeks' gestation. In fact, preterm birth accounts for 75% of neonatal morbidity and mortality in infants who are born without congenital anomalies (Ross & Eden, 2009). Although the preterm infant is faced with many maturational deficiencies (fat storage, heat regulation, immaturity of organ systems), the most critical factor is the lack of development of the respiratory system—to the extent that life cannot be supported. Infants born at 24 gestational weeks have a 70% chance of acquiring respiratory distress syndrome (RDS) and a 40% survival rate, whereas a 32-week infant has a 95% survival rate with only a 28% chance of developing RDS. The greater the gestational age, the lower the incidence of RDS and the higher the survival rate (Ross & Eden, 2009). In some instances, such as severe maternal diabetes or serious isoimmunization, continuation of the pregnancy may be more life threatening to the fetus than the hazards of prematurity. See chapter 33 ∞ for in-depth consideration of the preterm newborn.

Clinical Therapy

The prevention and treatment of PTL has been widely studied. In the 1970s, the focus on prevention of preterm birth was on the use of tocolytic drug therapy. It has been found that these agents have limited effectiveness. The primary goal of tocolytic therapy should be to delay birth by 48 hours so the maximum benefit of glucocorticoids can occur and decrease the incidence of RDS (Whitworth & Quenby, 2008). Preterm birth prevention programs, which were implemented in the 1980s and early 1990s, focused on identifying women who were at high risk for PTL. Once identified, those women were educated about signs and symptoms of PTL and had weekly contact with a nurse or other healthcare provider. However, these educational programs did not significantly prevent preterm birth. One contributing factor is that risk assessment screenings have poor ability to predict those women who will eventually develop PTL and give birth early. Up to 60% of preterm births

occur in women who would initially be scored at low risk. Nevertheless, the screening tests currently used, such as fetal fibronectin (fFN), cervical length, screening for bacterial vaginosis, and Bishop's score, a prelabor status evaluation scoring system (see chapter 28 ∞ and Table 28-3 on page 732), have not been recommended for use in asymptomatic, low-risk women. Screening might be helpful in women with a history of preterm birth and those with symptoms of PTL. Screening can also be done at well woman gynecology exam visits since 30% of those women will become pregnant in the next 2 years (Ross & Eden, 2009).

Nonpharmacologic treatments that historically have been used to prevent preterm births, specifically bed rest, pelvic rest, and hydration, do not appear to aid in PTL prevention and should not be routinely recommended (Ross & Eden, 2009).

Prompt diagnosis of PTL is difficult because many of its symptoms are also common in normal pregnancy. These include the following:

- Abdominal pain
- Back pain
- Pelvic pain
- Menstrual-like cramps
- Vaginal bleeding
- Increased vaginal discharge (may be pinkish stained or mucus-like in consistency)
- Pelvic pressure
- Urinary frequency
- Diarrhea

Some women have frequent contractions without changes in the cervix. In these women, a clinical assay for fFN obtained between 22 weeks' and 34 weeks' gestation may aid in diagnosis. fFN is an extracellular matrix protein that is an adhesive "glue" produced by the fetal membranes and binds the membranes and placenta to the decidua.

The presence of fFN in the cervicovaginal fluid is normal in the first half of pregnancy as the gestational sac attaches to the inside of the uterus. After 20 weeks' gestation, its presence is abnormal and can signal inflammatory or mechanical disruption of the fused membranes. fFN is also found in the amniotic fluid, and a positive test can indicate ruptured membranes. Near term, it is normal for fFN to once again appear in vaginal secretions (Pelaez, Fox, & Chasen, 2008). The negative predictive value of the fFN test is 99.2%. This means that a negative fFN in a woman with preterm contractions is associated with a very low risk (less than 1 in 100 chances) of birth within 14 days (Berghella, Hayes, Vistintine, et al., 2008). A positive test is associated with recent sexual intercourse, vaginal examination, bacterial vaginosis, and vaginal bleeding. With a positive predictive value of 15% to 25%, fFN does not give a good indication of those women who will give birth in the next 14 days. Although conducting fFN testing is associated with a lower preterm birth rate, a Cochrane review of 474 women did not recommend routine screening for all women in preterm labor but did encourage more extensive study (Berghella et al., 2008).

Contraction frequency alone is not enough to establish a diagnosis of preterm labor. A woman suspected of being in PTL should have a digital cervical examination once rupture of the membranes has been ruled out. If she is a candidate for fFN testing, this should be performed before a digital or endovaginal ultrasound exam. Electronic fetal monitoring should take place for a minimum of 1 to 2 hours to detect uterine contractions.

Although assessing cervical length by endovaginal ultrasonography is another diagnostic tool that has been used, a Cochrane review found that there was no statistical difference in women who had undergone a transvaginal ultrasound of the cervix and those who had not (Berghella, Baxter, & Hendrix, 2009). Studies have shown that in symptomatic women, a cervical length of at least 30 mm (3 cm) is good evidence that the woman is not in PTL (Berghella et al., 2009). However, only 30% to 40% of women with a shortened cervix will give birth prematurely (Chao, Chao, & Hsieh, 2008). Care should be taken when performing an endovaginal ultrasound for cervical length, as excessive pressure on the vaginal probe or a full maternal bladder are associated with falsely long measurements. A cervical length of less than 25 mm in the presence of regular contractions, or a digital exam that identifies the cervix to be 3 cm or more dilated or 80% or more effaced in the presence of regular contractions, establishes the diagnosis of PTL (Chao et al., 2008). fFN testing is useful when the digital or ultrasound information is equivocal (Duhig, Chandiramani, Seed, et al., 2009).

Intervention to reduce preterm birth can be divided into primary prevention and secondary prevention. Primary prevention includes diagnosis and treatment of infections, cervical cerclage, and progesterone administration. Secondary prevention strategies are antibiotic treatment and tocolysis.

Maternal bacterial infection has been implicated as a causative factor of PTL with microbial invasion of the amniotic cavity being present in approximately 10% of women with PTL (Jones, Harris, Azizia, et al., 2009). The microbial colonization may even precede conception and ascend from the cervix and vagina into the uterus. A woman who is diagnosed with an STI has a 25% risk of becoming reinfected within the next 12 months (Ross & Eden, 2009). Lower genital tract infections that are associated with preterm birth include bacterial vaginosis (BV), *Trichomonas vaginalis, Chlamydia trachomatis,* urinary group B streptococcus (GBS), mycoplasmas, gonorrhea, high concentration of anaerobes, or aerobic gram-negative rods. It is hypothesized that there may be an association with the ability of a species of bacteria to stimulate prostaglandin production. Hydrogen peroxide–producing lactobacilli, which help to maintain an acidic vaginal environment, are associated with a significant decrease in preterm birth (Yeganegi et al., 2009).

BV is the most common lower genital tract infection among women of reproductive age and has consistently been associated with increased risks of PTL, preterm premature rupture of membranes (PPROM), miscarriage, chorioamnionitis, endometritis, and cesarean section wound infections. In spite of this, it remains unclear whether screening and treatment of BV will reduce the frequency of these complications (Denney & Culhane, 2009). Treatment of BV in low-risk populations has not been shown to improve obstetric outcomes, but some studies have shown that women with a history of preterm birth who received oral treatment

with metronidazole or clindamycin had a reduction in preterm birth or premature rupture of membranes (PROM).

An estimated 20% to 30% of all women are GBS carriers. Neonatal infection from GBS is a potentially severe consequence of maternal GBS infection; nevertheless, there is no association of preterm birth and vaginal GBS colonization (Ohlsson & Shah, 2009). GBS is discussed more fully in chapter 20 ∞.

PTL is also associated with urinary tract infections (UTIs), so it is prudent to obtain a clean-catch or catheterized urine specimen to identify and treat the infection. If untreated, asymptomatic bacteriuria is associated with a 30% incidence of pyelonephritis later in pregnancy and an up to 50% increase in preterm birth (Mazor-Dray, Levy, Schlaeffer, et al., 2009). Even asymptomatic bacteriuria alone increases the risk of preterm birth; therefore, screening and treatment of all pregnant women at the first prenatal visit are important components of care. Women with a positive culture should be retested following therapy to ensure that the infection is resolved. Because asymptomatic bacteriuria is common during pregnancy, women with frequent UTIs can be given low-dose suppression therapy with daily antibiotics.

A link has been identified between preterm, low-birthweight infants, and gum disease, and it suggests that periodontal treatment during pregnancy reduces preterm birth (Marakoglu, Gursoy, Marakoglu, et al., 2008).

As early as the 1950s, progesterone had been investigated for its ability to improve pregnancy outcome. Progesterone's importance related to pregnancy lies in its ability to promote uterine relaxation, suppressing contractions, and to prevent gestational immune tolerance or immune tolerance in pregnancy (Blackburn, 2007). It is produced by the corpus luteum and the placenta and is essential for the maintenance of early pregnancy.

When given to women at high risk for preterm births, studies have shown a significant improvement in preterm birth rates (Anderson, Martin, Higgins, et al., 2009). Trials examining the use of progesterone for the treatment of PTL have not demonstrated effectiveness in halting labor or as an adjunct to the use of other tocolytic drugs to halt labor (Anderson et al., 2009).

If the efficacy of progesterone is a result of immune suppression, this may explain why progestogins can be effective if given prophylactically but not once labor has started. Currently the evidence points to treatment for prevention of preterm birth in women with singleton pregnancies at high risk for labor with 17-alpha-hydroxyprogesterone caproate (17P) 250 mg/week. This is administered intramuscularly beginning at 16 weeks and continuing to 36 weeks (Anderson et al., 2009). At this time, 17P has not been approved by the Food and Drug Administration (FDA) for use in the prevention of preterm birth. Moreover, the drug is not readily available and must be obtained from a compounding pharmacy. Table 26-3 summarizes common criteria for diagnosing PTL.

No attempt is made to stop labor if any of the following conditions exists (Ross & Eden, 2009):

- Fetal demise
- Lethal fetal anomaly
- Severe preeclampsia/eclampsia
- Hemorrhage/abruptio placentae
- Chorioamnionitis
- Severe fetal growth restriction
- Fetal maturity
- Acute nonreassuring fetal status

Tocolysis is the use of medications in an attempt to stop labor. These medications may delay birth for 24 to 48 hours (Simpson & Creehan, 2008). Although the delay of childbirth in itself may not improve neonatal outcome, it may permit the administration of betamethasone for fetal surfactant induction or allow for the transport of the mother to a tertiary care facility. Such a facility can generally provide better equipment and services and more experienced, highly trained staff. If labor cannot be arrested, the priority becomes successful preterm birth and management of its psychologic effect on the woman and her partner.

Ritodrine hydrochloride (Yutopar) remains the only drug approved by the FDA for use as a tocolytic (Simpson & Creehan, 2008). However, drugs currently used for tocolysis include beta-adrenergic agonists (also called β-mimetics or β-agonists), magnesium sulfate, calcium channel blockers (nifedipine), and prostaglandin synthetase inhibitors (celecoxib, sulindac, indomethacin, ketorolac). There is no clear choice for a tocolytic; instead a pharmacologic agent is chosen on an individual basis based on the presentation of labor and maternal history. The use of β-mimetics does pose a significant risk to the mother in PTL. β-mimetics, which may be administered intravenously, intramuscularly, subcutaneously, or orally, can significantly affect maternal cardiovascular and metabolic physiology. The most serious effects include hypotension, cardiac arrhythmia, tachycardia, palpitations, myocardial ischemia, pulmonary edema, and maternal hyperglycemia.

Magnesium sulfate, long used in the treatment of preeclampsia, is the most commonly prescribed pharmacologic agent in the United States because it is effective and has fewer side effects than beta-adrenergic agonists. The usual recommended loading dose is 4 to 6 g intravenously in 100 ml of intravenous (IV) fluid over 20 minutes. The maintenance dose is then 1 to 4 g/hr titrated to deep tendon reflexes and serum magnesium levels. The therapy is maintained for 12 hours at the lowest rate to significantly diminish contractions (Simpson & Creehan, 2008). The maternal

TABLE 26-3 Criteria for Diagnosis of Preterm Labor in Gestations 20–37 weeks

Uterine contractions very 5 minutes for 20 minutes
or
8 contractions in a 60 minute period
and
Documented cervical change or cervical effacement of 80% or more
or
Cervical dilation greater than 1 centimeter

serum level that is usually necessary for tocolysis seems to be 5.5 to 7.5 mg/dl.

Side effects with the loading dose may include flushing, a feeling of warmth, headache, nystagmus, nausea, dry mouth, and dizziness. Other side effects include lethargy and sluggishness and a risk of pulmonary edema if the woman has predisposing conditions such as multiple gestation or infection; has had excessive IV fluid administration; or has concurrent β-sympathomimetic therapy (Simpson & Creehan, 2008). Fetal side effects may include hypotonia and lethargy that persist for 1 or 2 days following birth, hypoglycemia, and hypocalcemia. See Drug Guide: Magnesium Sulfate in chapter 20 ∞ for other side effects.

Of the calcium channel blockers approved for use in the United States, nifedipine is frequently used as a tocolytic. Nifedipine acts by reducing the flow of extracellular calcium ions into the intracellular space of the myometrial smooth muscle cells, thereby inhibiting contractile activity. Nifedipine is well absorbed either orally or sublingually, has fewer side effects than comparative agents, and is at least as effective (Simpson & Creehan, 2008). The most common side effects are related to arterial vasodilation, that is, hypotension, tachycardia, facial flushing, and headache. Because the mechanism of action of nifedipine is different from the beta-adrenergic drugs, coadministration of nifedipine and terbutaline or ritodrine may prove beneficial in the treatment of PTL. Because both magnesium sulfate and nifedipine block calcium, however, coadministration of them has been implicated in serious maternal side effects related to low calcium levels and has resulted in maternal cardiovascular collapse (Simpson & Creehan, 2008). Nifedipine is contraindicated in women with heart disease, cardiovascular compromise, intrauterine infection, multiple pregnancy, and maternal hypertension (Simpson & Creehan, 2008).

Prostaglandins enhance the formation of myometrial gap junctions and stimulate the influx of intracellular calcium ions needed for muscle contraction. Prostaglandin synthetase inhibitors, therefore, are a logical choice for tocolysis. Indomethacin, sulindac, or celecoxib are the prostaglandin synthetase inhibitors most often used to suppress labor. Maternal side effects are few. Dyspepsia, nausea, vomiting, depression, and dizzy spells may occur. On rare occasions, psychosis or renal failure may result. These drugs are best administered with an antacid or taken with meals to reduce the chance of gastrointestinal (GI) upset. Prostaglandin synthetase inhibitors are generally not used in women with drug-induced asthma, coagulation disorders, hepatic or renal insufficiency, or peptic ulcer disease.

Indomethacin crosses the placenta readily, and oligohydramnios and premature closure of the fetal ductus arteriosus may occur with long-term use. Consequently the drug, which is no longer widely used, is not recommended after 34 weeks' gestation or for a course of therapy longer than 48 hours (Simpson & Creehan, 2008). Indomethacin has been associated with necrotizing enterocolitis and grades III and IV intravascular hemorrhage (IVH) in the newborn. The risk for IVH increases with decreasing gestational age at birth. Chorioamnionitis is associated with an increased risk of intraventricular hemorrhage in the newborn and may be the cause of IVH rather than the therapy itself.

The National Institute of Child Health and Human Development (NICHD) recommends that corticosteroids (typically betamethasone or dexamethasone) be administered antenatally to women at risk of preterm birth because of their beneficial effect on fetal lung maturation (Simpson & Creehan, 2008). Any women who are candidates for tocolysis are candidates for antenatal corticosteroids, regardless of fetal gender, race, or availability of surfactant therapy for the newborn, especially between 24 and 34 weeks' gestation.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

During the antepartal period, the nurse identifies the woman at risk for PTL by noting the presence of predisposing factors. The primary areas for ongoing assessment are change in risk status for PTL, educational needs of the woman and her loved ones, and the woman's responses to medical and nursing interventions.

Nursing diagnoses that may apply to the woman with PTL include the following:

- ***Readiness for Enhanced Knowledge*** related to an expressed desire to understand the causes, identification, and treatment of PTL and its implications
- ***Fear*** related to early labor and birth
- ***Ineffective Coping*** related to need for constant attention to pregnancy
- ***Anxiety*** related to the possibility of a preterm birth (PTB)

Nursing Plan and Implementation

Community-Based Nursing Care

Once uterine activity stops, the woman is sometimes placed on continued pharmacologic therapy. She may then be discharged and followed by home care nurses or as part of a specialized prematurity prevention program.

Home Care

Once thought to be a potentially effective tool for home management of PTL, more recent studies have cast doubt on the value of home uterine activity monitoring (Simpson & Creehan, 2008). The only exception is the woman who is paralyzed and cannot feel any uterine contractions (Ross & Eden, 2009). Outpatient management of a woman at risk for preterm birth includes frequent office visits to assess symptoms and cervical length and in-depth patient education about the signs and symptoms of PTL.

Consideration of the woman's ability to care for herself, the impact of the changes in relationships that will occur, and care of any young children in the home are among the issues that affect the woman's ability to cope effectively with this situation. Care providers need to be alert to any signs that the woman is failing to achieve the emotional and developmental tasks of pregnancy, such as lack of maternal attachment. An individualized nursing management plan helps focus on each woman's specific needs. Although current evidence does not show that increased social support or home uterine activity monitoring are effective in preventing preterm birth (Ross & Eden, 2009), these therapies continue to be used.

Health Promotion Education

Once the woman at risk for PTL has been identified, she needs to be taught about the importance of recognizing the onset of labor. Increasing the woman's awareness of the subtle symptoms of PTL is one of the most important teaching objectives of the nurse (see Patient Teaching: Preterm Labor).

Signs and symptoms of preterm labor include the following:

- Uterine contractions that occur every 10 minutes or less with or without pain.
- Mild menstrual-like cramps felt low in the abdomen.
- Constant or intermittent feelings of pelvic pressure that may feel like the baby pressing down.
- Rupture of membranes.
- Low, dull backache, which may be constant or intermittent.
- A change in the vaginal discharge (an increase in amount, a change to more clear and watery, or a pinkish tinge).
- Abdominal cramping with or without diarrhea.

The woman is also taught to evaluate contraction activity once or twice a day. She does so by lying down tilted to one side with a pillow behind her back for support. The woman places her fingertips on the fundus of the uterus (which is above the umbilicus after 20 weeks' gestation). She checks for contractions (hardening or tightening in the uterus) for about 1 hour. It is important for the pregnant woman to know that uterine contractions occur occasionally throughout the pregnancy. If they occur every 10 minutes for 1 hour, however, the cervix could begin to dilate, and labor could continue.

The nurse ensures that the woman knows when to report signs and symptoms. If contractions occur every 10 minutes (or less) for 1 hour, if any of the other signs and symptoms is present for 1 hour, or if clear fluid begins leaking from the vagina, she should telephone her physician or nurse-midwife, clinic, or hospital birthing unit and make arrangements to be checked for ongoing labor. If the woman experiences any PTL symptoms for more than 15 minutes while physically active, she should be instructed to do the following:

- Empty her bladder.
- Lie down tilted toward her side.
- Drink 3 to 4 (8 oz) cups of fluid.
- Palpate for uterine contractions, and if contractions occur 10 minutes apart or less for 1 hour, notify the healthcare provider.
- Soak in a warm tub bath with the uterus completely submerged.
- Rest for 30 minutes after the symptoms have subsided, and gradually resume activity.
- Call her healthcare provider if symptoms persist, even if uterine contractions are not palpable.

Caregivers need to be aware that the woman is knowledgeable and attuned to changes in her body and to take her call seriously. When a woman is at risk for PTL, she may have many episodes of contractions and other signs or symptoms. If she is treated positively, she will feel freer to report problems as they arise. Other preventive measures the woman might follow are presented in Table 26-4.

Hospital-Based Nursing Care

Providing supportive nursing care to the woman in PTL is important during hospitalization. This care consists of promoting bed rest, monitoring vital signs, measuring intake and output, and continuously monitoring fetal heart rate (FHR) and uterine contractions. Placing the woman on her left side facilitates maternal-fetal circulation. Vaginal examinations are kept to a minimum. If tocolytic agents are being administered, the mother and fetus are monitored closely for any adverse effects.

Whether PTL is arrested or proceeds, the woman and her partner, if one is involved, experience intense psychologic stress. Decreasing the anxiety associated with the unknown and the risk of a preterm newborn is a primary aim of the nurse. The nurse also recognizes the stress of prolonged bed rest and of lack of sexual contact and helps the couple find satisfactory ways of dealing with these stresses. With empathetic communication, the nurse can facilitate the couple's expression of their feelings, which commonly include guilt and anxiety, thereby helping the couple identify and implement coping mechanisms. The nurse also keeps the couple informed about the labor progress, the treatment regimen, and the status of the fetus so that their full cooperation can be elicited. In the event of imminent vaginal or cesarean birth, the couple should be offered brief but ongoing explanations to prepare them for the actual birth process and the events following the birth. The nurse may also offer to arrange consultations for the woman and her support person with the neonatologist, social worker, or hospital chaplain if requested.

TABLE 26-4 Self-Care Measures to Prevent Preterm Labor

- Rest 2 or 3 times a day, lying on your left side.
- Drink 2 to 3 quarts of water or fruit juice each day. Avoid caffeine drinks. Filling a quart container and drinking from it will eliminate the need to keep track of numerous glasses of fluid.
- Empty your bladder at least every 2 hours during waking hours.
- Avoid lifting heavy objects. If small children are in the home, work out alternatives for picking them up, such as sitting on a chair and having them climb on your lap.
- Pace necessary activities to avoid overexertion.
- Sexual activity may need to be curtailed or eliminated.
- Find pleasurable ways to help compensate for limitations of activities and boost the spirits.
- Try to focus on 1 day or 1 week at a time rather than on longer periods of time.
- If on bed rest, get dressed each day and rest on a couch rather than becoming isolated in the bedroom.

Preterm Labor

Family's Experience

"I am getting some contractions throughout the day. I am not sure if I should be concerned or not. I wouldn't say they are painful, but I can definitely feel them. I don't want to be overly concerned, but I don't want to ignore them and end up having the baby early. I read the signs on the sheet the other nurse gave me at my last appointment, but I am still unsure if this is normal or something to be worried about."

Her husband is also concerned about her. "She seems to feel them more at the end of the day. When I get home and see her having contractions, I don't know whether to panic or assume it is normal."

Nurse's Response

"Many women experience Braxton-Hicks contractions during the third trimester. This type of contraction is normal. It feels like tightening but is not really painful. Typically, they are irregular, not in a regular pattern. They also occur infrequently compared with preterm labor contractions. It is not uncommon to get them at the end of the day when you have been on your feet all day. When you feel them, get off your feet, rest, and drink several glasses of water. If they continue, you need to time them and call us if they are occurring regularly or if there are more than eight contractions in 1 hour.

"Preterm labor is diagnosed when there are at least eight contractions in 1 hour and cervical change occurs. In order to diagnose preterm labor, you need to call us if you are having frequent contractions and come to the hospital for an examination to see if your cervix has changed."

Nurse's Actions and Rationale

The nurse reviews preterm labor symptoms with the couple. The woman should be assessed for possible risk factors. Risk factors are included in Table 26-2. Since Braxton-Hicks contractions are quite common, the differences between preterm labor and these types of contractions should be thoroughly explained. The nurse provides written instructions and provides the couple with a telephone number to call should preterm labor occur.

PATIENT TEACHING **Preterm Labor**

PATIENT GOALS At the completion of teaching the woman will be able to:

1. Discuss the risks of preterm labor.
2. Describe the purpose of home monitoring.
3. Demonstrate the correct procedures for doing home monitoring.
4. Explain self-care measures that help decrease the risk of preterm labor.

TEACHING PLAN

Content	Teaching Method
■ Describe the dangers of preterm labor, especially the risk of prematurity in the infant, and all the potential problems.	Discuss the risks specifically. Many people understand in a general way that prematurity can be dangerous, but they fail to understand how the baby is affected.
■ Emphasize that many of the early symptoms of labor, such as backache and increased bloody show, may be subtle initially.	Use handouts during the discussion. Help the woman clearly understand the value of the program because, to be successful, it requires a real commitment on her part.
■ Be prepared to reinforce the information provided and answer questions that may arise.	Teach the woman how to palpate for uterine contractions. Do a demonstration and ask for a return demonstration.
■ Summarize self-care measures, such as maintaining generous fluid intake (2 to 3 quarts daily), voiding every 2 hours, avoiding lifting and overexertion, avoiding nipple stimulation or orgasm, limiting sexual activity, and cooperating with activity restrictions and bed rest requirements. (See Table 26-4.)	Use a handout during the discussion. Provide opportunities for discussion. If the woman has concerns about certain recommendations, try to modify the approach to best meet her needs.

Evaluation

At the end of the teaching session the woman will be able to discuss the risks of preterm labor, demonstrate home monitoring techniques and explain their rationale, and implement self-care activities to decrease the risks of preterm labor.

Documentation

Document the information given to the woman, including specifics on risk factors, early symptoms, and self-care measures. Specify if written instructions were provided in addition to verbal ones and describe the type of teaching method used. Document the woman's verbalization of understanding and your clarification of any information.

Evaluation

Expected outcomes of nursing care include the following:

- The woman can discuss the cause, diagnosis, and treatment of PTL.
- The woman affirms that her fears about early labor are decreased.
- The woman states that she feels comfortable in her ability to cope with her situation and has resources to call on if needed.
- The woman can identify signs and symptoms of PTL that need to be reported to her caregiver.
- The woman can describe appropriate self-care measures to initiate in the event that she experiences any symptoms of PTL.
- The woman successfully gives birth to a healthy infant.

Care of the Woman and Fetus at Risk Because of Placental Problems

Maintaining placental function is paramount to ensuring fetal well-being and continuation of the pregnancy. Because the placenta is highly vascular, problems that develop are usually associated with maternal and possibly fetal hemorrhage. Causes and sources of hemorrhage are reviewed in Table 26-5. Other placental problems are discussed in chapter 27 ∞.

Abruptio Placentae

Abruptio placentae is the premature separation of a normally implanted placenta from the uterine wall. The incidence of abruptio placentae requiring delivery is 1% of all pregnancies, but it accounts for 15% of perinatal mortality (Beckmann et al., 2010). It is more frequent in pregnancies complicated by smoking, premature rupture of membranes, multiple gestation, advanced maternal age, cocaine use, chorioamnionitis, and hypertension (Beckmann et al., 2010). The risk of recurrence is 10 times higher if a previous abruption has occurred (Beckmann et al., 2010).

The cause of abruptio placentae is largely unknown. Theories have been proposed relating its occurrence to decreased blood flow to the placenta through the sinuses during the last trimester. It is estimated that maternal hypertension is the most common cause (44%) with maternal trauma accounting for 2% to 10% of the cases. Domestic violence, abdominal trauma, presence of fibroids, uterine overdistention, fetal growth restriction, alcohol consumption, a short umbilical cord, and high parity also contribute (Beckmann et al., 2010). Abruptions also appear to be more common in certain ethnic groups. Caucasian and African American women have higher incidences of abruptions than Asian and Latin American women (Cunningham et al., 2010). Classification of abruption is based on the extent of separation (Table 26-6).

TABLE 26-5 Causes and Sources of Hemorrhage

CAUSES AND SOURCES	SIGNS AND SYMPTOMS
Antepartum Period	
Abortion	Vaginal bleeding Intermittent uterine contractions Rupture of membranes
Placenta previa	Painless vaginal bleeding after seventh month
Abruptio placentae	
Partial	Vaginal bleeding: no increase in uterine pain
Severe	Vaginal bleeding may or may not be present Extreme tenderness of abdominal area Rigid, boardlike abdomen Increase in size of abdomen
Intrapartum Period	
Placenta previa	Bright red vaginal bleeding
Abruptio placentae	Same signs and symptoms listed above
Uterine atony in Stage III	Bright red vaginal bleeding Ineffectual contractility
Postpartum Period	
Uterine atony	Boggy uterus Dark vaginal bleeding Presence of clots
Retained placental fragments	Boggy uterus Dark vaginal bleeding Presence of clots
Lacerations of cervix or vagina	Firm uterus Bright red blood

TABLE 26-6 Classification of Abruption

Class 0	Asymptomatic; diagnosed after birth
Class I	Mild; most common, occurring in 48% of cases
Class II	Moderate; both mother and fetus show signs of distress; 27% of cases
Class III	Severe; maternal shock and fetal death likely; 24% of cases

Pathophysiology

Premature separation of the placenta may be divided into three types (Figure 26-3 ■):

1. ***Marginal:*** The blood passes between the fetal membranes and the uterine wall and escapes vaginally. Separation begins at the periphery of the placenta; this marginal sinus rupture may or may not become more severe.
2. ***Central:*** The placenta separates centrally, and the blood is trapped between the placenta and the uterine wall. Entrapment of the blood results in concealed bleeding.
3. ***Complete:*** Massive vaginal bleeding is seen in the presence of almost total separation.

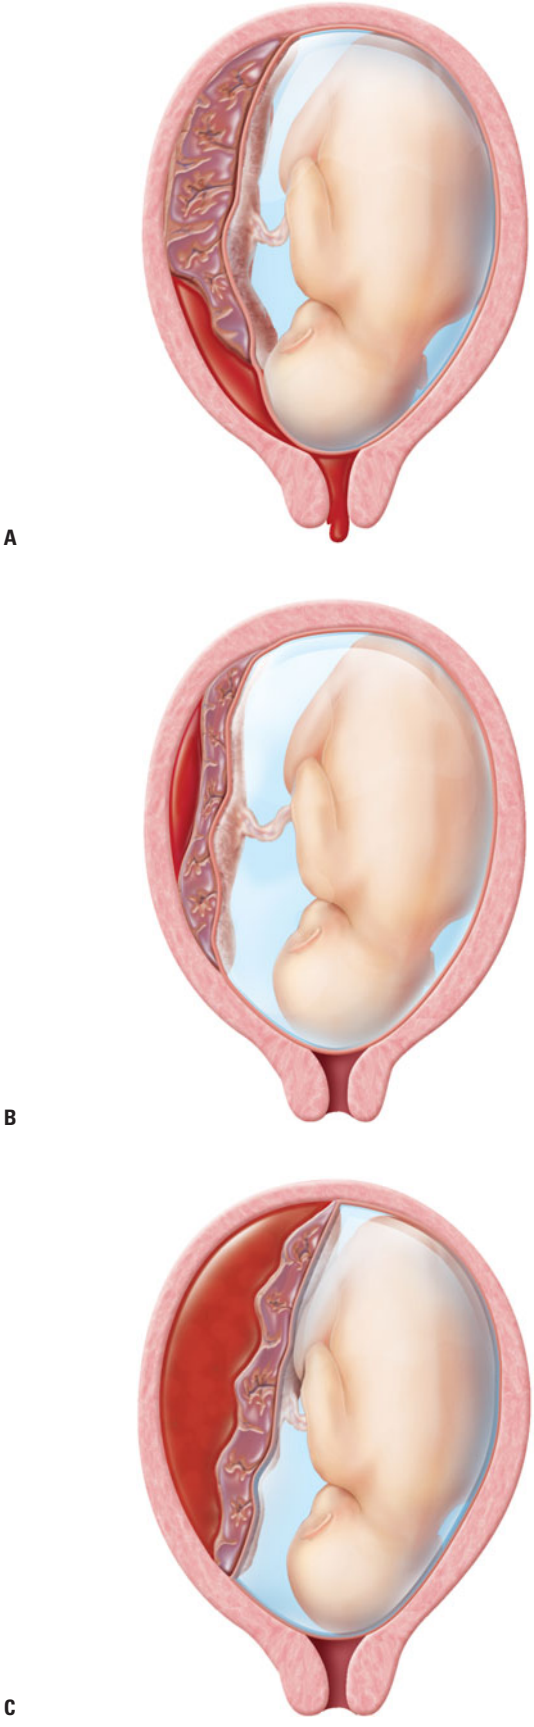

Figure 26-3 ■ Abruptio placentae. A. Marginal abruption with external hemorrhage. B. Central abruption with concealed hemorrhage. C. Complete separation.

In severe cases of central abruptio placentae, a blood clot forms behind the placenta. With no place to escape, the blood invades the myometrial tissues between the muscle fibers. This occurrence accounts for the uterine irritability that is a significant sign of premature separation of the placenta. If hemorrhage continues, eventually the uterus turns entirely blue in color. After the baby is born, the uterus contracts only with difficulty. This syndrome is known as a *Couvelaire uterus* and frequently necessitates hysterectomy.

As a result of the damage to the uterine wall and the retroplacental clotting with covert abruption, large amounts of thromboplastin are released into the maternal blood supply, which in turn triggers the development of disseminated intravascular coagulation (DIC) and the resultant hypofibrinogenemia. Fibrinogen levels, which are ordinarily elevated in pregnancy, may drop to incoagulable amounts within a matter of minutes as a result of rapidly developing premature separation of the placenta. Additional information on DIC may be found in a medical–surgical nursing textbook.

Maternal Risks

Maternal mortality is now uncommon, although maternal morbidity is still common (Beckmann et al., 2010). Problems following the birth depend in large part on the severity of the intrapartal bleeding, coagulation defects (DIC), hypofibrinogenemia, and length of time between separation and the birth. Moderate to severe hemorrhage results in hemorrhagic shock, which ultimately may prove fatal to the mother if not reversed. In the postpartal period, women who have suffered this disorder are at risk for hemorrhage and renal failure due to shock, vascular spasm, intravascular clotting, or a combination of the three. Another cause of renal failure is incompatible emergency blood transfusion. Failure is directly proportional to the number of units transfused. In some cases, hysterectomy is performed if bleeding cannot be controlled.

Fetal-Neonatal Risks

Perinatal mortality associated with abruptio placentae is approximately 25% (Cunningham et al., 2010). In severe cases in which separation occurs to approximately 50% of the placenta, infant mortality is 100%. In less severe separation, fetal outcome depends on the level of maturity. The most serious complications in the newborn arise from preterm labor, anemia, and hypoxia. If fetal hypoxia progresses unchecked, irreversible brain damage or fetal demise may result. Neurologic defects within the first year of life occur in approximately 14% of infants who survive (Cunningham et al., 2010). With thorough assessment and prompt action on the part of the healthcare team, fetal and maternal outcome can be optimized.

Clinical Therapy

Because of the risk of DIC, evaluating the results of coagulation tests is imperative. DIC occurs as a complication secondary to a major medical complication. In DIC, fibrinogen levels and platelet counts are usually decreased; prothrombin times (PT) and partial thromboplastin times (PTT) are normal to prolonged (Creasy, Resnik, Iams, et al., 2009). If the values are not markedly abnormal, serial testing may be helpful in establishing an abnormal trend that is indicative of coagulopathy. Another very sensitive test determines fibrin degradation products; these levels rise with DIC.

After the diagnosis is established, emphasis is placed on maintaining the cardiovascular status of the mother and developing a plan for effecting the birth of the fetus. Intravenous access with a large-gauge cannula is warranted along with continuous electronic fetal monitoring (EFM). Which birth method is selected depends on the condition of the woman and fetus; in many circumstances cesarean birth may be the safest option (Creasy et al., 2009).

If the separation is mild and gestation is near term, labor may be induced, and the fetus may be born vaginally with as little trauma as possible. If rupture of membranes and oxytocin infusion by pump do not initiate labor within a short time, a cesarean birth is usually done. A longer delay would increase the risk of hemorrhage, with resulting hypofibrinogenemia. Supportive treatment to decrease risk of DIC includes typing and cross-matching for blood transfusions (at least three units), clotting mechanism evaluation, and intravenous fluids (Creasy et al., 2009).

In cases of moderate to severe placental separation, a cesarean birth is done after hypofibrinogenemia has been treated by intravenous infusion of cryoprecipitate or fresh frozen plasma (FFP). Vaginal birth is impossible in the event of a Couvelaire uterus because it could not contract properly in labor. Cesarean birth is necessary in the face of severe hemorrhage to allow an immediate hysterectomy to save both woman and fetus.

The hypovolemia that accompanies severe abruptio placentae is life threatening and must be combated with whole blood. If the fetus is alive but experiencing stress, emergency cesarean birth is the method of choice. With a stillborn fetus, vaginal birth is preferable unless shock from hemorrhage is uncontrollable. Intravenous fluids of a balanced salt solution such as lactated Ringer's solution are given through a 16- or 18-gauge cannula (Cunningham et al., 2010). Central venous pressure (CVP) monitoring may be needed to evaluate intravenous fluid replacement. Hemodynamic monitoring is an essential aspect of nursing care for the woman with abruption. If there is any evidence of hypovolemia, two venous lines should be started. Urine output should be monitored with an indwelling catheter. If the output drops below 30 ml per hour with adequate fluid replacement, CVP should be used to assess for hypovolemia. CVP will be the guide to fluid replacement. An absolute level is not as significant as the response to fluid replacement. Pulmonary artery catheter measurement, such as with a Swan-Ganz catheter, may be necessary to manage the hemodynamic changes. However, a significant abruption may preclude placing a catheter in the jugular or subclavian vein because the DIC is causing bleeding from multiple sites. The CVP is evaluated hourly, and results are communicated to the physician. Elevations of CVP may indicate fluid overload and pulmonary edema. The hematocrit is maintained at 30% through the administration of packed red cells or whole blood, or both (Cunningham et al., 2010).

Laboratory testing is ordered to provide ongoing data regarding hemoglobin, hematocrit, and coagulation status. A clot observation test may be done at the bedside to evaluate coagulation

status. A red top glass tube containing 5 ml of maternal blood is inverted 4 to 5 times. If a clot fails to form in 6 minutes, a fibrinogen level of less than 150 mg/dl is suspected. If a clot is not formed in 30 minutes, the fibrinogen level may well be less than 100 mg/dl. A clot observation test may be completed by a physician or a nurse.

Measures are taken to stimulate labor to effect vaginal birth as indicated by the condition of the mother and fetus. The birth may be hastened by performing an amniotomy and by oxytocin stimulation. Previously, birth within 6 hours of the diagnosis of severe placental abruption was recommended to reduce maternal mortality and morbidity. Currently, changing medical practice directed to ensuring adequate fluid replacement, especially blood, appears to accomplish the same outcome (Cunningham et al., 2010). These interventions should be started immediately as birth is to be facilitated without delay.

A Kleihauer-Betke is also needed to determine the amount of fetal maternal hemorrhage in Rh negative women. The appropriate amount of Rh D immunoglobulin is calculated based on the test results and number of units of blood that is given (Beckmann et al., 2010).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Electronic monitoring of the uterine contractions and resting tone between contractions provides information regarding the labor pattern and effectiveness of the oxytocin induction. Because uterine resting tone is frequently increased with abruptio placentae, it must be evaluated frequently for further increase. Abdominal girth measurements may be ordered hourly and are obtained by placing a tape measure around the maternal abdomen at the level of the umbilicus. Another method of evaluating uterine size, which increases as more bleeding occurs at the site of abruption, is to place a mark at the top of the uterine fundus. The distance from the symphysis pubis to the mark may be evaluated hourly.

Nursing diagnoses that may apply to the woman with abruptio placentae include the following:

- ***Risk for Deficient Fluid Volume*** related to hypovolemia secondary to excessive blood loss
- ***Ineffective Peripheral Tissue Perfusion*** related to blood loss secondary to uterine atony following birth
- ***Anxiety*** related to concern for personal status and the baby's safety
- ***Impaired Gas Exchange (Fetus)*** related to decreased blood volume and hypotension

Nursing Plan and Implementation

The psychologic aspects of nursing care are very important. Maternal apprehension increases as the clinical picture changes. Factual reassurance and an explanation of the procedures and what is happening are essential for the emotional well-being of the expectant couple. The nurse can reinforce positive aspects of the woman's condition, such as normal fetal heart rate (FHR), normal vital signs, and decreased evidence of bleeding.

Other nursing care measures are addressed in the Nursing Care Plan: Hemorrhage in the Third Trimester on pages 678–680.

Evaluation

Expected outcomes of nursing care include the following:

- The woman and her baby have a safe labor and birth without further complications for the mother or child.
- The woman and family verbalize understanding of reasons for medical therapy and risks.

NURSING CARE PLAN Hemorrhage in the Third Trimester

INTERVENTION	RATIONALE
1. Nursing Diagnosis: Risk for Deficient Fluid Volume related to excessive vascular loss during pregnancy **Goal:** Woman will not experience significant fluid volume deficit during the third trimester of pregnancy.	
■ Monitor vital signs (i.e., temperature—normal range is 96.8°–100.4°F, pulse—normal is 60–90, respirations—normal is 12–22, blood pressure—normal range is 110/70 to 135/85, central venous pressure—normal range is 5–10 mm H_2O). Compare present blood pressure with woman's baseline blood pressure. Note pulse pressure.	■ Any deviations in a woman's baseline vital signs could indicate intravascular fluctuations.
■ Weigh pads and chux. If the woman has bathroom privileges, instruct her on initiating pad counts. Teach the woman how to weigh pads and chux, with each gram equal to approximately 1 ml of blood loss.	■ The combination of weighing and counting pads and chux assists medical personnel in determining the woman's blood loss.
■ Report amount of blood loss within a specific period (e.g., 50 ml of bright-red blood on pad in 20 minutes).	
■ Monitor urinary output hourly and measure urine specific gravity (normal: 1.010–1.025).	■ A decrease in urinary output (less than 30 ml/hr) and an increase in specific gravity suggest dehydration and a need for an increase in fluid intake.

NURSING CARE PLAN Hemorrhage in the Third Trimester continued

INTERVENTION	RATIONALE
■ Palpate bilateral peripheral pulses (normal: equal and strong) and note capillary refill (normal: less than 3 seconds). Also, assess skin color and temperature (normal: pink, warm, dry, and intact).	■ Helps determine signs of circulatory loss or hypovolemic shock that include weak pulses, capillary refill greater than 3 seconds, skin color that is cyanotic or pallor, and skin temperature that is cool and clammy.
■ Assess mental status at frequent intervals.	■ Excessive blood loss can lead to changes in mentation.
■ Assess the woman for signs and symptoms of disseminated intravascular coagulation.	■ Provides vital information on maternal status.
■ Instruct the woman on the importance of strict bed rest and avoidance of any sexual activity that involves nipple stimulation or that might lead to orgasm.	■ Bleeding may cease with limited activity. Pressure on the abdomen and orgasms can stimulate uterine activity, thereby causing bleeding. Nipple stimulation may result in uterine contractions, as can orgasm.
■ Monitor fetal status and uterine activity by continuous fetal monitoring.	■ May determine the origin of bleeding and fetal well-being.
Collaborative:	
■ Collect and review blood work: complete blood count (CBC), type and cross-match, Rh titer, fibrinogen levels, platelet count, activated partial thromboplastin time (APTT), prothrombin time (PT), and human chorionic gonadotropin (hCG) levels.	■ Determines blood loss and need for intervention if blood work is abnormal.
■ Administer appropriate isotonic IV solutions and blood products (e.g., plasma expanders, whole blood, serum albumin, or packed red blood cells) as ordered by the physician.	■ Reverses shock symptoms by increasing blood volume.
■ Insert Foley catheter.	■ Close monitoring of urinary output will aid in determining adequate renal perfusion.

EXPECTED OUTCOME: The woman will show signs of adequate fluid volume during pregnancy as evidenced by vital signs within normal limits, capillary refill in less than 3 seconds, adequate sensorium, and urine output greater than 30 ml/hr.

2. Nursing Diagnosis: Ineffective Peripheral Tissue Perfusion (Uteroplacental) related to hypovolemia secondary to excessive maternal blood loss
Goal: The fetus will have no evidence of hypoxia during pregnancy.

■ Assess maternal vital signs.	■ Closely monitoring maternal physiologic status and circulatory status will assist in determining if an episode of bleeding has occurred and allow for interventions to protect maternal and fetal well-being.
■ Monitor fetal heart tones continuously, assessing for variability, accelerations, and decelerations, and record.	■ Continuous electronic fetal monitoring will aid in detecting signs of fetal hypoxia and allow time for appropriate intervention.
■ Assess fundal height.	■ Determines an approximate gestational age.
■ Assess labor progression by determining cervical dilatation and effacement if contractions are present.	■ This provides information on maternal labor status.
Collaborative:	
■ Perform scalp stimulation to assess fetal accelerations.	■ FHR acceleration is considered 15 beats above the baseline lasting for 15 seconds and is indicative of fetal well-being.
■ Assess amniotic fluid for meconium.	■ Impaired gas exchange relaxes fetal intestinal motility, causing expulsion of meconium into amniotic fluid.
■ Assist the physician during ultrasonography and amniocentesis for lecithin/sphingomyelin (L/S) ratio sample.	■ Determines viability and alerts appropriate medical personnel of fetal age if birth is imminent.

EXPECTED OUTCOME: Fetus will demonstrate adequate tissue perfusion as evidenced by fetal heart tones that remain within 110–160 beats/min, long-term variability and short-term variability present, positive periodic changes (no variable or late decelerations), and fetal scalp blood pH greater than 7.25.

(continued)

NURSING CARE PLAN **Hemorrhage in the Third Trimester** continued

INTERVENTION	RATIONALE
3. Nursing Diagnosis: Fear/Anxiety related to personal and fetal well-being secondary to third-trimester hemorrhage **Goal:** The woman will verbalize a decrease in fear and anxiety.	
■ Maintain frequent contact with the woman and family members.	■ Establishes trust with the woman and her family members, so the patient will not feel alone or abandoned.
■ Provide the woman with accurate, reliable information concerning diagnosis and prognosis.	■ Fear and anxiety will lessen when the woman is informed of health status and is allowed to make decisions based on present situation.
EXPECTED OUTCOME: The woman will actively seek information about diagnosis and prognosis.	
■ Allow the woman and family members to verbalize the origin of fears.	■ Recognizing the origin of fear gives the woman and her family the appropriate tool to begin the process of developing coping strategies for dealing with the fears.
■ Explain all procedures in an easy-to-understand, nonthreatening manner, and allow the woman and family members to ask questions.	■ Accurate information prepares the woman and family members for the impending procedures, thereby reducing fear of the unknown.
EXPECTED OUTCOME: The woman and her family members develop appropriate coping strategies that decrease fear and anxiety.	

Placenta Previa

Application: Placenta Previa

In **placenta previa**, the placenta is improperly implanted in the lower uterine segment. This implantation may be on a portion of the lower segment or over the internal os (Figure 26-4 ■). As the lower uterine segment contracts and dilates in the later weeks of pregnancy, the placental villi are torn from the uterine wall, thus exposing the uterine sinuses at the placental site. Bleeding begins, but because the amount depends on the number of sinuses exposed, it may initially be either scanty or profuse.

The cause of placenta previa is unknown. Statistically, it occurs in about 1 in 200 pregnancies (Beckmann et al., 2010). Factors associated with placenta previa are previous placenta previa, multiparity, increasing age, placenta accreta (discussed in a following section), defective development of blood vessels in the decidua, prior cesarean birth or other uterine surgery, cocaine use, smoking, a recent spontaneous or induced abortion, and a large placenta (Beckmann et al., 2010).

Placenta previa is classified in four degrees:

1. ***Total placenta previa:*** Internal os is covered completely by the placenta.
2. ***Partial placenta previa:*** Internal os is partially covered by the placenta.
3. ***Marginal placenta previa:*** Edge of the placenta is at the margin of the internal os.
4. ***Low-lying placenta:*** Placenta is implanted in the lower segment but does not reach the os although it is in close proximity of it.

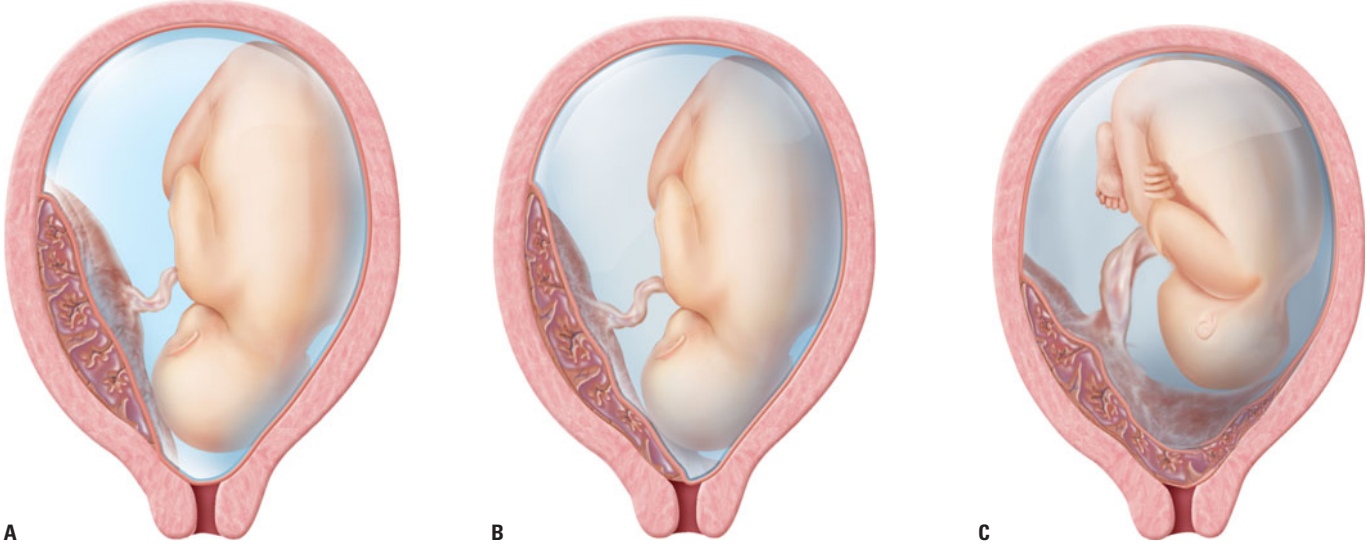

Figure 26-4 ■ Placenta previa. A. Low placental implantation. B. Partial placenta previa. C. Total placenta previa.

Another condition, **vasa previa**, occurs when the fetal vessels course through the amniotic membranes and are present at the cervical os. Vasa previa occurs in 1 in 2500 pregnancies. Although this is a rare cause of antepartum bleeding, it is associated with a high rate of fetal death (Beckmann et al., 2010).

Clinical Therapy

Women who present with vaginal bleeding should be questioned regarding any history of abnormal placenta placement that was diagnosed during the pregnancy. When possible, prenatal records should be reviewed. Women who have not had a routine ultrasound examination and have no history of bleeding during the pregnancy may have an undiagnosed placenta previa. The goal of medical care is to identify the cause of bleeding and to provide treatment that will ensure birth of a mature newborn. It must be determined whether the cause of the bleeding is placenta previa or advanced labor with copious bloody show (which is normal). Indirect diagnosis is made by localizing the placenta via tests that require no vaginal examination. The most commonly employed diagnostic test is the transabdominal ultrasound scan. Abdominal or transvaginal sonography is used to identify the presence of placenta previa. If placenta previa is ruled out, a vaginal examination can be performed with a speculum to determine the cause of bleeding (such as cervical lesions or polyps).

Direct diagnosis of placenta previa can be made only by feeling the placenta inside the cervical os. However, such an examination may cause profuse bleeding because of tearing of tissue in the cotyledons of the placenta. Because of the danger of bleeding, a vaginal examination is generally contraindicated and is performed only if ultrasound is not available, the pregnancy is near term, and there is already profuse vaginal bleeding. The examination is done by a physician using a double setup procedure; that is, the delivery room is set up for the vaginal examination and normal vaginal birth and for a cesarean birth should placenta previa be present and the examination precipitate brisk bleeding. Adequate personnel must be present to respond to treatment decisions.

CLINICAL TIP

When assessing a woman for vaginal bleeding, make sure to have the woman lift her bottom completely off the bed so you can observe for blood loss beneath the buttocks.

The differential diagnosis of placental or cervical bleeding takes careful consideration. Table 26-7 provides a comparison of the signs and symptoms of placenta previa and abruptio placentae. Partial separation of the placenta may also present with painless bleeding, and a true placenta previa may not demonstrate overt bleeding until labor begins, thus confusing the diagnosis. In fact, the causes of slight to moderate antepartal bleeding episodes in 20% to 25% of women are never accurately diagnosed.

Care of the woman with painless late gestational bleeding depends on (1) the week of gestation during which the first bleeding episode occurs and (2) the amount of bleeding (Figure 26-5 ■). If the pregnancy is less than 37 weeks' gestation, expectant management is employed to delay birth until about 37 weeks' gestation to allow the fetus to mature. Expectant management involves stringent compliance with the following:

1. Bed rest with bathroom privileges only as long as the woman is not bleeding.
2. No vaginal examinations.
3. Monitoring of blood loss, pain, and uterine contractility.
4. Evaluation of FHR with external monitor.
5. Monitoring of maternal vital signs.
6. Complete laboratory evaluation: hemoglobin, hematocrit, Rh factor, and urinalysis.
7. Administration of intravenous fluid (lactated Ringer's solution) with drip rate monitored.
8. Availability of two units of cross-matched blood for possible transfusion.
9. Administration of betamethasone to facilitate fetal lung maturity.

TABLE 26-7 Differential Signs and Symptoms of Placenta Previa and Abruptio Placentae

	PLACENTA PREVIA	ABRUPTIO PLACENTAE
Onset	Quiet and sneaky	Sudden and stormy
Bleeding	External	External or concealed
Color of blood	Bright red	Dark venous
Anemia	= Blood loss	Greater than apparent blood loss
Shock	= Blood loss	Greater than apparent blood loss
Toxemia	Absent	May be present
Pain	Only labor	Severe and steady
Uterine tenderness	Absent	Present
Uterine tone	Soft and relaxed	Firm to stony hard
Uterine contour	Normal	May enlarge and change shape
Fetal heart tones	Usually present	Present or absent
Engagement	Absent	May be present
Presentation	May be abnormal	No relationship

10. Administration of Rh D immunoglobulin in Rh D negative women.

If frequent, recurrent, or profuse bleeding persists or if fetal well-being appears threatened, a cesarean birth needs to be performed.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Assessment of the woman with placenta previa must be ongoing to prevent or treat complications that are potentially lethal to the mother and fetus. Painless, bright red vaginal bleeding is the best diagnostic sign of placenta previa. If this sign should develop during the last 3 months of a pregnancy, placenta previa should always be considered until ruled out by ultrasound examination. The first bleeding episode is generally scanty. If no vaginal examinations are performed, it often subsides spontaneously. However, each subsequent hemorrhage is more profuse.

The uterus remains soft, and if labor begins, it relaxes fully between contractions. The FHR usually remains stable unless profuse hemorrhage and maternal shock occur. As a result of the placement of the placenta, the fetal presenting part is often unengaged, and transverse lie is common.

The nurse appraises blood loss, pain, and uterine contractility from both subjective and objective perspectives. Maternal vital signs and the results of blood and urine tests provide the nurse with additional data about the woman's condition. FHR is evaluated with an external fetal monitor. Another nursing responsibility is observing and verifying the family's ability to cope with the anxiety associated with an unknown outcome.

Nursing diagnoses that may apply to the woman experiencing placenta previa are as follows:

- ***Deficient Fluid Volume*** related to hypovolemia secondary to excessive blood loss
- ***Ineffective Peripheral Tissue Perfusion*** related to blood loss secondary to uterine atony following birth
- ***Anxiety*** related to concern for own personal status and the baby's safety
- ***Impaired Gas Exchange*** related to decreased blood volume and hypotension
- ***Fear*** related to concern for safety of the baby

Nursing Plan and Implementation

The nurse continues to monitor the woman and her fetus to determine the status of the bleeding and to determine the mother's and baby's responses. Vital signs, intake and output, and other pertinent assessments must be made frequently. The nurse evaluates the electronic monitor tracing to evaluate the fetal status.

Emotional support for the family is an important nursing care goal. When active bleeding is occurring, the assessments and management must be directed toward physical support. However, emotional aspects need to be addressed simultaneously. The nurse can explain the assessments being completed and the treatment measures that need to be done. Time can be provided for questions, and the nurse can act as an advocate in obtaining information for the family. The nurse can also offer emotional support by staying with the family and by the use of touch.

Case Study: Patient with Placental Problems

The newborn's hemoglobin, cell volume, and erythrocyte count should be checked immediately after birth and then monitored closely. The newborn may require oxygen and administration of blood and admission into a neonatal intensive care unit.

Additional information regarding nursing care is addressed in the Nursing Care Plan: Hemorrhage in the Third Trimester.

Evaluation

Expected outcomes of nursing care include the following:

- The cause of hemorrhage is recognized promptly, and corrective measures are taken.
- The woman's vital signs remain in the normal range.
- The woman and her baby have a safe labor and birth.
- The family understands what has happened and the implications and associated problems of placenta previa.

CLINICAL TIP

When faced with an emergent situation, tell the woman she needs to follow your instructions quickly and that you will explain what is happening as soon as possible once you take the necessary measures to ensure that she and the baby are safely cared for.

Care of the Woman with a Multiple Gestation

The incidence of twins in the United States accounts for 3% of all pregnancies; however, with advances in reproductive technologies, the incidence is increasing (Gibbs et al., 2010). It is estimated that triplets and higher order multiples account for 1.8% of all births. The incidence of these higher order births is declining because of recent recommendations from the American College of Obstetricians and Gynecologists (ACOG) to reduce the number of fetuses transferred during in vitro fertilization procedures. Because twin birth is by far the most common multiple birth, the discussion focuses on this type. The chapter also identifies specific variations for triplets and higher order multiple gestations as appropriate.

Embryology of Multiple Gestation

Terminology related to various types of twins is presented in Table 26-8. Twins can develop from either the fertilization of two separate ova or from the division of one fertilized ovum. Twins that occur from two separate ova are called *dizygotic* (two zygotes, also referred to as fraternal twins). In this type, the fetuses may be the same sex or different sexes and there are two complete amnions and two chorions. The fetuses are no more closely related genetically than any other siblings. The majority of twins conceived through in-vitro fertilization are fraternal since multiple fertilized ova are inserted into the uterus (Gibbs et al., 2010).

In contrast, 33% of twins are *monozygotic* (also referred to as identical twins); that is, they develop from one fertilized ovum (Blackburn, 2007). These twins are genetically identical, and thus always of the same sex (see Table 26-8). If the zygote divides within the first 72 hours past fertilization, the twins will be diamniotic and dichorionic. If the division occurs from the fourth to the eighth day past fertilization, the embryos will develop with two separate amnions and one chorion. If the division happens after the eighth day, the two fetuses will share both a common amniotic sac and chorion. The terminology is important because the perinatal morbidity and mortality rates differ greatly among different types of twins (Blackburn, 2007). For example, monozygotic twins have a high incidence of cord entrapment, twin-to-twin transfusion, and fetal demise (Blackburn, 2007).

Pregnancy Loss in Multiple Gestation

The development of sensitive human chorionic gonadotropin (hCG) assays and increasingly sensitive ultrasound techniques

TABLE 26-8 Characteristics of Twin Pregnancy

TYPE	TIME OF DIVISION	CHARACTERISTICS	FREQUENCY
Dizygotic			
(Two separate ova) Fraternal twins Dichorionic-diamniotic twins	Develop from two ova released at the same time.	Each twin has own placenta, chorion, amnion. Dizygotic twins are called fraternal twins. They may be the same or different sex. Increases with maternal age up to 35 years, then falls abruptly. Increases with parity.	67% of all twins
Monozygotic			
(Single ovum identical twins)			33% of all twins
Dichorionic-diamniotic twins	Division occurs within 72 hours past fertilization. Inner cell mass not yet developed.	Each twin has own chorion, amnion, placenta.	30% of monozygotic twins
Monochorionic-diamniotic twins	Division occurs at blastocyst stage, 4 to 8 days after fertilization. Inner cell mass divides in two.	Placenta has one chorion and two amnions. Each twin lies in own sac.	70% of monozygotic twins
Monochorionic-monoamniotic twins	Division occurs in primitive germ disk, 9 to 13 days past fertilization.	Twins lie in the same amniotic sac. Increased risk of umbilical cords becoming tangled or knotted.	2% of monozygotic twins

Source: Adapted from Creasy, R. K., Resnik, R., Iams, J. D., Lockwood, C. J., & Moore, T. R. (2009). Creasy & Resnik's maternal-fetal medicine: Principles and practices *(6th ed.). Philadelphia, PA: Saunders.*

has made it possible to determine more accurately the early pregnancy loss rate of twins, including both complete pregnancy loss and spontaneous resorption of one twin (called the "vanishing twin" phenomenon). Of all twin pregnancies, approximately 25% are lost before the end of the first trimester (Blackburn, 2007). Causative factors in the loss of both twins in the first trimester include environmental factors, infectious organisms, trophoblast dysfunction, poor embryo quality, or a lower concentration of placentally produced substances. Although loss of one twin can occur at any time during the pregnancy, it more commonly occurs in the first trimester. Marginal and velamentous cord insertions (discussed in chapter 27 ∞) are more likely to be present when there is a vanishing twin, and the presence of a monochorionic placenta is more likely to result in either a singleton gestation (because of a vanishing twin) or complete pregnancy loss (Blackburn, 2007).

Pregnancy loss of twins in the second trimester is associated with congenital anomalies, growth restriction, chromosomal abnormalities, and cervical incompetence. Congenital anomalies are twice as likely to occur in twin gestations (Gibbs et al., 2010). In a monochorionic placenta, there may be a vascular anastomosis that leads to twin-to-twin transfusion syndrome. When this syndrome is present, blood is chronically drained from one fetus to the other. The donor fetus becomes growth restricted, and oligohydramnios develops. The recipient fetus becomes polycythemic and hydropic, and hydramnios develops. If the fetuses become severely affected during the second trimester, untreated mortality may be 100% (Cunningham et al., 2010).

The incidence of preterm birth is also higher in multiple gestations. Preterm birth occurs in 50% of twins, 76% of triplets, and 90% of quadruplets (Simpson & Creehan, 2008). In singletons, the perinatal mortality is at the lowest point at 40 weeks' gestation; for twins, the perinatal mortality rate decreases until 37 weeks and then increases steadily from 38 to 42 weeks. The optimal delivery time for triplet pregnancies is 35 weeks (Gibbs et al., 2010). A woman pregnant with twins who has not spontaneously begun labor by 38 gestational weeks is typically induced.

Implications

Women with a multiple gestation are more likely to develop complications, which include the following (Simpson & Creehan, 2008):

- Spontaneous abortions are more common, as previously discussed.
- Gestational diabetes occurs more often in multiple gestations. Three percent to six percent of twin pregnancies and 22% to 39% of triplet pregnancies are complicated by gestational diabetes.
- Hypertension is the major maternal complication. The risk of developing severe hypertension or preeclampsia is 2.6 times higher in twins and significantly higher in triplets.
- Multiple gestations are more likely to acquire HELLP (hemolytic anemia, elevated liver enzymes, and low platelet count) syndrome, a complication resulting from eclampsia or preeclampsia (discussed in chapter 20 ∞).
- Women with multiple gestations are more likely to develop acute fatty liver, which is manifested by severe coagulopathy, hypoglycemia, and hyperammonemia, which can lead to maternal and fetal death.
- Pulmonary embolism is 6 times more likely to develop during pregnancy with multiple gestations.
- Maternal anemia occurs because of demands of the multiple gestation. The hemoglobin averages 10 g/dl from the 20th week on. Anemia is indicated by hemoglobin levels below 11 g/dl in the first or third trimester or below 10.5 g/dl in the second trimester. When decreased hemoglobin is accompanied by serum ferritin concentration of less than 12 mg/dl, iron deficiency anemia is diagnosed.
- Hydramnios may be due to increased renal perfusion from cross-vessel anastomosis of monozygotic twins.
- Premature rupture of membranes, incompetent cervix, and intrauterine growth restriction occur more commonly.
- Rare complications associated with twins include twin-to-twin transfusion (previously discussed), conjoined (Siamese) twins, and *acardia* (twin reversed arterial perfusion sequence).
- Complications during labor include preterm labor, uterine dysfunction due to an overstretched myometrium, abnormal fetal presentations, instrumental or cesarean birth, and postpartum hemorrhage.
- Due to cardiovascular changes, pulmonary edema is more common in multiple gestations.
- Dermatologic complications, such as pruritic urticarial papules and plagues of pregnancy (PUPP), occur in 2.9% of twin and 14% of triplet pregnancies.
- Multiple births account for 21% of low-birth-weight infants, 19% to 24% of very low-birth-weight infants, 20% of neonatal intensive care unit (NICU) admissions, and 26% of neonatal deaths.

The woman with a multiple gestation may experience more physical discomfort during her pregnancy, such as shortness of breath, dyspnea on exertion, backaches, round ligament pain, heartburn, pelvic or suprapubic pressure, and pedal edema because of the oversized uterus.

Clinical Therapy

The goals of medical care are to promote normal fetal development, to prevent maternal complications, to prevent preterm birth, and to diminish fetal trauma during labor.

Ultrasound examinations play a crucial role in the care and treatment of multiple gestations. Ultrasound assists with identifying the presence of more than one fetus early in the pregnancy, providing accurate dating of the pregnancy, and detecting fetal anomalies. Because the incidence of perinatal mortality and morbidity is increased in twins, use of ultrasound in the first and second trimesters can be particularly helpful. Evidence supports the use of ultrasound for accurately determining chorionicity and amnionicity in multiple pregnancies (Beckmann et al., 2010).

Knowledge of chorionicity is essential in differentiating twin-to-twin transfusion from fetal growth restriction secondary to

abnormal placental blood flow. Knowledge of chorionicity is also important in determining the management of a multiple pregnancy in which one twin is sonographically abnormal. If the twins are dichorionic/diamniotic (DC/DA), then selective termination could be considered.

Determination of amnionicity is based on ultrasound visualization or the lack of visualization of an intertwin membrane. Visualization of this membrane becomes more difficult as the gestation advances because of progressive thinning of the intertwin membrane, fetal crowding, and an increasing incidence of oligohydramnios. Knowledge regarding the presence of one amnion is crucial, because management of monochorionic/monoamniotic (MC/MA) twins requires more intensive surveillance and earlier birth, usually by cesarean (Beckmann et al., 2010; Gibbs et al., 2010). Women with (MC/MA) twins are frequently cared for by perinatologists in a facility that has high-risk services available.

Preventing preterm labor is a major goal. Prenatal care should begin early, and more frequent visits are usually scheduled. Many practitioners perform vaginal examinations at each visit after 28 weeks to identify cervical changes, such as cervical shortening, effacement, or dilatation, or the beginning of bulging membranes. Assessing cervical length via ultrasound has been predictive in identifying women at risk for preterm birth (PTB). A cervical length of less than 25 mm between 14 and 20 weeks is associated with PTB prior to 32 weeks. Cervical length less than 25 mm for triplets between 15 and 20 weeks is associated with a 100% delivery rate by 28 weeks (Simpson & Creehan, 2008). Digital examinations are often helpful as well but to be accurate they should be performed by the same examiner at each prenatal visit (Simpson & Creehan, 2008). Fetal fibronectin (fFN) as a predictor of preterm labor has been well established in singleton pregnancies. A study of 147 twin gestations revealed that a negative fFN test is associated with a less than 3% risk of PTB in the following 2-week period. This test can be beneficial since women with multiple gestations are often symptomatic (Gibbs et al., 2010). Further research is needed to determine if this test results in fewer PTBs.

There is insufficient evidence to support policies for routine cervical cerclage, reduced activity and work, and prophylactic bed rest (Gibbs et al., 2010). A systematic review of studies of hospitalization and bed rest for multiple gestation showed insufficient evidence to support routine bed rest (Gibbs et al., 2010). Although home monitoring was commonly used in the 1990s, the effectiveness of this intervention has been disputed by large randomized studies and is no longer endorsed for preterm labor monitoring (Gibbs et al., 2010).

Some areas offer twin clinics, which provide many advantages for the woman with a multiple gestation. These advantages include consistent evaluation, intensive prenatal education, counseling, and support from the same healthcare providers.

Intrapartal management and assessment require careful attention to maternal and fetal status. The mother should have an intravenous infusion in place with a large-bore needle. Anesthesia and cross-matched blood should be readily available. The twins are monitored by dual electronic fetal monitoring (EFM). The labor may progress very slowly or very quickly.

The decision about method of birth may not be made until labor occurs, and the method depends on a variety of factors. The presence of maternal complications such as placenta previa, abruptio placentae, or severe preeclampsia usually indicates the need for cesarean birth. Fetal factors such as severe intrauterine growth restriction (IUGR), preterm birth, fetal anomalies, nonreassuring fetal status, or unfavorable fetal position or presentation also require cesarean birth. Typically, a cesarean birth is performed if the presenting twin is in a presenting position other than vertex and cannot be turned to a vertex presentation.

Birth of three or more fetuses is best accomplished by cesarean because of the risk of fetal insult due to decreased placental perfusion and hemorrhage from the separating placenta during the intrapartal period (Cunningham et al., 2010). Complicated obstetric maneuvers such as breech extraction and podalic version, the risk of prolapse of the cord, and an increase in fetal collision provide additional reasons for cesarean birth.

Any combination of presentations and positions can occur with twins (Figure 26-6 ■). Approximately 40% of twins present in a vertex/vertex presentation. More than 80% of twins in vertex/vertex presentation are born vaginally. Another 40% of twins present in vertex/nonvertex presentation. Although research shows no differences in infant mortality or morbidity when the second twin is born via breech delivery, many practitioners choose to deliver any nonvertex presentation via cesarean birth (Gibbs et al., 2010). In 20% of cases, twin A is nonvertex and requires a cesarean birth (Gibbs et al., 2010).

The placentas are examined after the birth. If the twins are of the same sex, the placentas are sent to the pathology laboratory for examination to determine whether they are monozygotic or dizygotic twins.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

When obtaining a maternal history at the beginning of antenatal care, the nurse should identify any family history of twinning. Equally important is a history of medication taken to enhance fertility or artificial reproductive technology that may have been used to conceive. These facts should be noted on the antepartal record.

At each antepartal clinic visit, the nurse should measure the fundal height. During the prenatal period, a fundal height greater than expected for the weeks of gestation and auscultation of two heartbeats that differ by at least 10 beats per minute are the most likely clues of twin pregnancy. Some women experience severe nausea and vomiting and develop severe anemia despite the intake of multiple-vitamin therapy.

Any growth, fetal movement, or heart tone auscultation out of proportion to gestational age by dates is indicative of twins. During palpation, the nurse may feel many small parts on all

Figure 26-6 ■ Twins may be in any of these presentations in utero.

sides of the abdomen (Figure 26-7 ■). If twins are suspected, the nurse should attempt to auscultate two separate heartbeats in different quadrants of the maternal abdomen. Use of the Doppler device may be helpful. Conclusive evidence of twins is found on sonography.

During the prenatal visits the nurse should determine the family's level of preparation for integrating more than one new member. Although the thought of having twins can be very exciting, the reality of attaching to two infants and adapting to the parental role may be trying.

During labor it is important to monitor each fetus. In the case of twins, an external electronic monitor can be applied to both, or if conditions permit, the internal monitor can be applied to twin A and the external monitor to twin B. The heart rates may be auscultated on different quadrants of the maternal abdomen, but continuous monitoring is more beneficial. Signs of nonreassuring heart rate patterns should be reported to the certified nurse-midwife (CNM) or obstetrician.

After a multiple birth, the mother is closely monitored for postpartal hemorrhage. Nursing diagnoses that may apply to a woman with a multiple gestation include the following:

- ***Fear*** related to unknown outcome of the birth process
- ***Ineffective Coping*** related to uncertainty about the labor and birth plan
- ***Deficient Knowledge*** related to lack of information about the problems associated with multiple gestation
- ***Impaired Gas Exchange (Fetuses)*** related to decreased oxygenation secondary to cord compression

Nursing Plan and Implementation

Community-Based Nursing Care

Antepartally, the woman may need counseling about diet and daily activities. The nurse can help her plan meals to meet her increased needs. A daily intake of 4000 kcal (minimum) and 135 g of protein are recommended for optimal weight gain and fetal

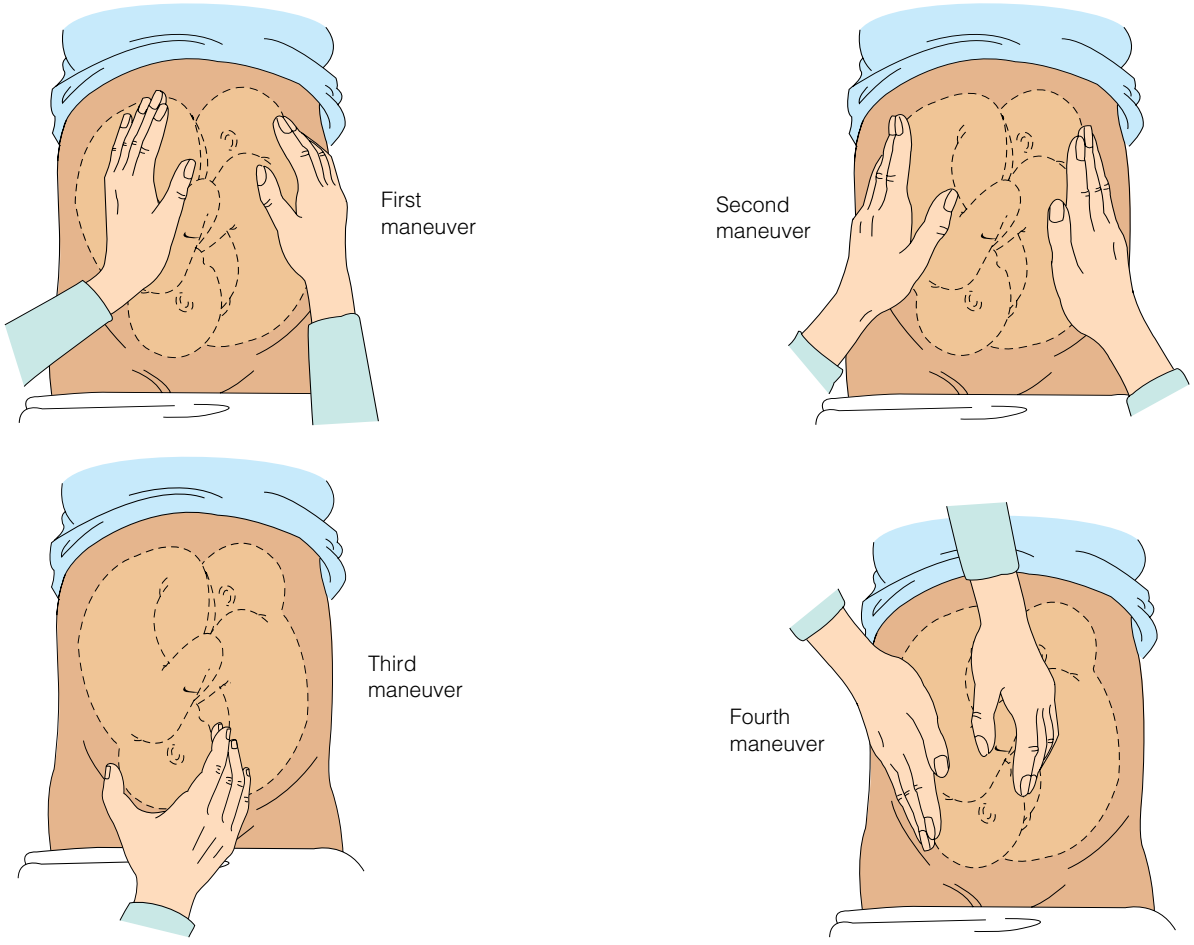

Figure 26-7 ■ Leopold's maneuvers in twin pregnancy for determining the fetuses' head positions, presentations, and lie. The fetus on the mother's right side is in cephalic presentation, and the fetus on the left is in breech presentation. Leopold's maneuvers may be done in a different sequence.

growth. A prenatal vitamin and 1 mg of folic acid and iron should also be taken daily. A weight gain of 35 to 45 lb is recommended.

Maternal hypertension is treated with bed rest in the lateral position to increase uterine and kidney perfusion. Back discomfort can be alleviated by pelvic rocking, good posture, and good body mechanics. The nurse can help the woman schedule frequent periods of rest during the day. Family members or friends may be willing to care for the woman's other children periodically to allow her time to get rest. Community support systems, such as neighbors or church members, may be available to assist the family with meals, grocery shopping, and household chores. Many communities now have support groups specifically designed for mothers of multiples. Members provide invaluable peer support throughout pregnancy and the postpartum period. Teaching regarding prevention and recognition of preterm labor is very important.

Hospital-Based Nursing Care

The nurse needs to prepare to receive multiple newborns. This means a multiplication of resuscitation equipment and newborn identification papers and bracelets. The newborns may be placed in individual radiant warmers or in the same one once identification bands have been applied. Additional staff members should be available for newborn resuscitation, monitoring, and newborn care. Special precautions should be observed to ensure correct identification of the newborns. The first born is usually tagged Baby A; the second, Baby B; and so on.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to discuss the implications and problems associated with a multiple gestation.
- The woman feels she is able to cope with the pregnancy and birth.
- The woman understands the treatment plan and how to gain further information.
- The mother, father, and babies have a safe prenatal course, labor, and birth and a safe postpartal and newborn course.

Care of the Woman and Fetus at Risk Because of Amniotic Fluid-Related Complications

Complications related to amniotic fluid include hydramnios and oligohydramnios.

Hydramnios

Hydramnios (also called *polyhydramnios*) occurs when there is over 2000 ml of amniotic fluid. It typically occurs in 1% of all pregnancies (Beckmann et al., 2010). The exact cause of hydramnios is unknown; however, it often occurs in cases of major congenital anomalies. It is postulated that a major source of amniotic fluid is found in special amnion cells that lie over the placenta (Beckmann et al., 2010). In cases of hydramnios, no pathology has been found in this amniotic epithelium. However, during the second half of the pregnancy, the fetus normally begins to swallow and inspire amniotic fluid and to urinate, which contributes to the amount present. Fetal malformations that affect this swallowing mechanism—as well as neurologic disorders in which the fetal meninges are exposed in the amniotic cavity—can result in hydramnios (Beckmann et al., 2010).

This condition is also found in cases of anencephaly in which the fetus is thought to urinate excessively because of overstimulation of the cerebrospinal centers. When a monozygotic twin manifests hydramnios, it is possible that the twin with the increased blood volume urinates excessively. The weight of the placenta has been found to be increased in some cases of hydramnios, indicating that increased functioning of the placental tissue may contribute to the problem.

There are two types of hydramnios: chronic and acute. The chronic type, in which the fluid volume gradually increases, is a problem of the third trimester. Most cases are of this variety. In acute cases, the volume increases rapidly over a period of a few days. The acute type is usually diagnosed between 20 and 24 weeks' gestation.

When the amount of amniotic fluid is over 3000 ml, the woman experiences shortness of breath and edema in the lower extremities from compression of the vena cava. If hydramnios is severe enough, she can experience intense pain. The acute form of hydramnios tends to be more severe. Milder forms of hydramnios occur more frequently and are associated with minimal symptoms. Hydramnios is associated with such maternal disorders as diabetes and Rh sensitization. It can also occur as a result of infections such as syphilis, toxoplasmosis, cytomegalovirus, herpes, and rubella (Beckmann et al., 2010).

Fetal malformations and preterm birth are common with hydramnios; thus there is a fairly high rate of perinatal mortality. Prolapsed umbilical cord can occur when the membranes rupture, which adds a further complication for the fetus. The incidence of malpresentations is also increased (Beckmann et al., 2010).

Clinical Therapy

Hydramnios is managed with supportive treatment unless the intensity of the woman's distress and symptoms dictate otherwise.

If the accumulation of amniotic fluid is severe enough to cause maternal dyspnea and pain, hospitalization and removal of the excessive fluid are required. This can be done vaginally by artificial rupture of membranes (AROM) or by amniocentesis. The dangers of performing AROM vaginally are prolapsed cord and the inability to remove the fluid slowly. A *needle amniotomy* may be preferred because this releases the fluid at a slower rate and allows the presenting part to descend gradually. A needle amniotomy is performed by the certified nurse-midwife (CNM) or physician. A needle or a fetal scalp electrode is used to make a small puncture in the amniotic sac. There is a risk that the force of the fluid could make a larger hole in the amniotic sac, thus increasing the risk of a prolapsed cord. If amniocentesis is performed, it should be done with the aid of sonography to prevent inadvertent damage to the fetus and placenta.

A prostaglandin synthesis inhibitor (indomethacin) is often used to treat hydramnios. Indomethacin has been shown to decrease amniotic fluid volume by decreasing fetal urine output (Cunningham et al., 2010).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Hydramnios should be suspected when the fundal height increases out of proportion to the gestational age.

With increased fluid, the nurse may have difficulty palpating the fetus and auscultating the fetal heart rate (FHR). In more severe cases the maternal abdomen appears extremely tense and tight on inspection. On sonography large spaces can be identified between the fetus and the uterine wall.

Nursing diagnoses that may apply for a woman with hydramnios include the following:

- ***Impaired Gas Exchange*** related to pressure on the diaphragm secondary to hydramnios
- ***Fear*** related to unknown outcome of the pregnancy
- ***Acute Pain*** related to abdominal pressure secondary to hydramnios

Nursing Plan and Implementation

When amniocentesis is performed, sterile technique is used to prevent infection. The nurse can offer support to the couple by explaining the procedure to them.

If the fetus has been diagnosed with a congenital defect in utero or is born with the defect, psychologic support is needed to assist the family. Often the nurse collaborates with social services to offer the family this additional help. The nurse can also offer to contact chaplain services at the family's request.

Evaluation

Expected outcomes of nursing care include the following:

- The woman and her partner can discuss the procedure, implications, risks, and characteristics that need to be reported to the caregiver.

Oligohydramnios

Oligohydramnios is defined as a less than normal amount of amniotic fluid (approximately 500 ml is considered normal). Although no exact amount of fluid has been definitively identified as diagnostic of this condition, oligohydramnios is diagnosed when the largest vertical pocket of amniotic fluid visible on ultrasound examination is 5 cm or less (Beckmann et al., 2010). The exact cause of oligohydramnios is unknown. It is found in cases of postmaturity, with intrauterine growth restriction

(IUGR) secondary to placental insufficiency, and in fetal conditions associated with major renal malformations, including renal aplasia with dysplastic kidneys and obstructive lesions of the lower urinary tract. If oligohydramnios occurs in the first part of pregnancy, there is a danger of fetal adhesions (one part of the fetus may adhere to another part).

During the gestational period, fetal skin and skeletal abnormalities may occur because fetal movement is impaired as a result of inadequate amniotic fluid volume. Because there is less fluid available for the fetus to use during fetal breathing movements, pulmonary hypoplasia may develop. During the labor and birth, the lessened amounts of fluid reduce the cushioning effect for the umbilical cord, and cord compression is more likely to occur.

Clinical Therapy

During the antepartum period, oligohydramnios may be suspected when the uterus does not increase in size in accordance with established gestational dating, the fetus is easily palpated and outlined by the examiner, and the fetus is not ballottable. The fetus can be assessed by biophysical profile (BPP), nonstress tests (NSTs), and serial ultrasounds. During labor the fetus will be monitored by continuous electronic fetal monitoring (EFM) to detect cord compression, which will be indicated by nonperiodic decelerations. Amnioinfusion can replace some fluid volume and remove pressure on the umbilical cord (see chapter 28 ∞).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Oligohydramnios should be suspected when the fundal height is less than the gestational age and the fetal parts are easily palpated through the fundal wall. Continuous EFM is an important part of assessment during the labor and birth. The nurse evaluates the EFM tracing for the presence of nonperiodic decelerations or other nonreassuring signs (such as increasing or decreasing baseline, decreased variability, or presence of periodic decelerations). If nonperiodic decelerations are noted, the nurse can change the woman's position (to relieve pressure on the umbilical cord) and must then notify the physician or CNM. If position changes are insufficient to relieve the pattern, an amnioinfusion may be performed. After the birth, the newborn is evaluated for signs of congenital anomalies, pulmonary hypoplasia, or postmaturity.

On sonography there is a lack of amniotic fluid. An amniotic fluid index is typically performed to determine the amount of amniotic fluid. Less than 5 cm of amniotic fluid is considered low and the diagnosis of oligohydramnios is made (Simpson & Creehan, 2008).

Nursing diagnoses that may apply for a woman with hydramnios include the following:

- ***Impaired Gas Exchange*** related to cord compression secondary to oligohydramnios
- ***Fear*** related to unknown outcome of the pregnancy

Nursing Plan and Implementation

The fetus is continually monitored during labor and birth. An amnioinfusion (discussed in chapter 28 ∞) is often performed to increase the amount of fluid surrounding the fetus and to decrease the incidence of variable decelerations. In the event that the fetal heart rate tracing is nonreassuring, late decelerations occur, and birth is not imminent, a cesarean birth may be performed.

Evaluation

Expected outcomes of nursing care include the following:

- The woman and her partner can discuss the diagnosis, implications, and risks to the caregiver.
- The fetus remains uncompromised during labor and birth.

FOCUS YOUR STUDY

- Cervical insufficiency (incompetent cervix), the premature dilatation of the cervix, is the most common cause of second-trimester abortion. It is treated surgically with a cerclage, which involves placing a suture in the cervix to keep it from opening.
- Both premature rupture of membranes and preterm labor place the fetus at risk. Women with preterm premature rupture of membranes (PPROM) and no signs of infection are managed conservatively with bed rest and careful monitoring of fetal well-being.
- Preterm labor is often treated with tocolytics, which can be effective in stopping labor; however, they do have side effects.
- Abruptio placentae is the separation of the placenta from the uterine wall before the birth of the infant that often results in painful vaginal bleeding. Abruptio placentae may be central, marginal, or complete.

- Placenta previa occurs when the placenta implants low in the uterus or over the cervix. A low-lying or marginal placenta is one that lies near the cervix. In a partial placenta previa, part of the placenta lies over the cervix. In a complete placenta previa, the entire placenta covers the cervix. Bleeding associated with placenta previa is typically painless.
- Placental problems can be either developmental or degenerative.
- Multiple gestation is associated with both maternal and fetal/neonatal complications.
- Hydramnios, also known as polyhydramnios, occurs when there is more than 2000 ml of amniotic fluid contained within the amniotic membranes.
- Oligohydramnios occurs when there is a severely reduced volume of amniotic fluid. Oligohydramnios is associated with intrauterine growth restriction (IUGR), postmaturity, and fetal renal and urinary malformations. The fetus is more likely to experience variable decelerations because the amniotic fluid is insufficient to keep pressure off the umbilical cord.

CRITICAL THINKING IN ACTION

Source: George Dodson/Pearson Education.

Monique Waleski, a 34-year-old G1 P0000, at 32 weeks' gestation, contacts her physician's office because she has been experiencing labor contractions that have gradually increased in frequency. She reports that she has been having about 8 contractions an hour for the past 2 hours. She is instructed to meet her doctor at the birthing unit for further evaluation.

At the birthing unit a vaginal examination reveals that Monique's cervix is dilated 3 cm and 80% effaced. Contractions continue to occur every 7 to 8 minutes. Her fFN test is positive. She is diagnosed with preterm labor.

You position her on her left side and start an IV infusion.

Her physician tells Monique that she wants to begin tocolysis using magnesium sulfate and then prescribes 2 doses of betamethasone. You explain to Monique and her partner that you will be giving her the magnesium sulfate by infusion pump and the betamethasone by IM injection once a day today and tomorrow. She asks you about the two medications, including their specific purposes.

1. Explain the concept of tocolysis and the purpose of magnesium sulfate.
2. Describe the concept of a loading dose and maintenance dose.
3. How will you know if Monique is developing toxic levels of magnesium?
4. Describe the role of corticosteroids used during preterm labor.

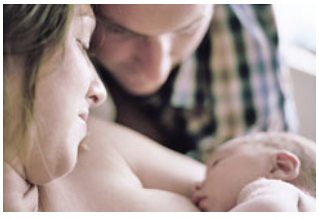
CHAPTER 27

Childbirth at Risk: Labor-Related Complications



I couldn't wait to begin labor. I wasn't afraid. We had wonderful plans for our labor and birth. My nurse helped me with my breathing as I entered transition. Everything was going so well. Suddenly, the baby began having decelerations. The nurse assisted me onto my side and called for assistance. Time seemed to stand still as the once rapidly beating heart suddenly sounded so slow. It seemed like it took forever to return to its previous rapid pace. For an instant, I was terrified, but after that one episode, there were no further problems.

LEARNING OUTCOMES

1. Describe psychologic disorders that may contribute to difficulty in coping during labor and birth.
2. Discuss dysfunctional labor patterns.
3. Identify the potential maternal risks of precipitous labor and birth.
4. Describe the impact of postterm pregnancy on the childbearing family.
5. Summarize various types of fetal malposition and malpresentation and possible associated problems.
6. Discuss the implications of macrosomia and hydrocephalus on the woman and the fetus.
7. Analyze the implications of abnormal placenta and umbilical cord variations.
8. Discuss the interventions needed in caring for a woman with a prolapsed umbilical cord.
9. Discuss the identification, management, and nursing care of women with amniotic fluid embolus.
10. Identify the signs and symptoms associated with a uterine rupture.
11. Delineate the effects of pelvic contractures on labor and birth.
12. Identify complications related to uterine rupture.
13. Discuss complications of the third and fourth stages of labor.

KEY TERMS

Active management of labor (AMOL) *698*
Amniotic fluid embolism *718*
Anaphylactoid syndrome of pregnancy *718*
Brachial plexus injury *712*
Cephalopelvic disproportion (CPD) *719*
Dystocia *696*
Macrosomia *711*
Persistent occiput posterior (OP) position *702*
Placenta accreta *721*
Placenta increta *721*
Placenta percreta *721*
Postterm pregnancy *700*
Precipitous labor and birth *699*
Prolapsed umbilical cord *717*
Psychologic disorders *693*
Retained placenta *721*
Uterine rupture *719*

The successful completion of the 40-week gestational period requires the harmonious functioning of the five critical factors we discussed in chapter 22 ∞: the birth passage, the fetus, the relationship between the passage and fetus, forces of labor, and psychosocial considerations. Disruptions in any of these components may result in dystocia (at-risk or difficult labor). Some of the most common at-risk conditions during labor are discussed in this chapter.

Care of the Woman at Risk Because of Psychologic Disorders

Anxiety and fear are common emotions in many women in labor. Joy, happiness, excitement, fear of the unknown, and anxiety related to pain sensations may all occur. Even women who are well prepared can experience anxious feelings. Although these reactions are expected in the woman with normal coping mechanisms and adequate social support, women with psychologic disorders may face additional emotional challenges and need additional nursing care and support in the intrapartum period.

The prevalence of psychologic disorders of adults in the United States is 26.2% or roughly 1 in 4 adults (Table 27-1). **Psychologic disorders** are characterized by alterations in thinking, mood, or behavior. Each year, more than half a million women with psychiatric illnesses become pregnant (American College of Obstetricians and Gynecologists (ACOG), 2008). It is further estimated that one third of all pregnant women are exposed to psychotrophic medications at some time during their pregnancies (ACOG, 2008). Although there are many different types of psychologic disorders, only the most common are presented here. Because an in-depth description is beyond the scope of this text, we focus on the impact of these disorders on labor and birth (Table 27-2). Postpartum psychologic disorders are discussed in chapter 39 ∞.

Maternal Implications

Depression affects millions of Americans annually. More women are affected than men (National Institute of Mental Health [NIMH], 2009). Depression is believed to be caused by a central nervous system (CNS) imbalance in serotonin and other neurotransmitters. The hormonal changes associated with pregnancy can directly impact a woman with a previous history of depression. Individuals with depression may have persistent sad mood, anxiety, physical slowing, agitation, energy loss, feelings of worthlessness, difficulty thinking or concentrating, and sleep disturbances (NIMH, 2009).

Depression can affect the labor process in a variety of ways. The woman may be unable to concentrate or process information being provided by healthcare team members. Because depression often causes difficulty sleeping, she may begin labor fatigued or sleep deprived. The labor process may overwhelm her physically and emotionally, because she has no energy "reserves" on which to draw. She may feel unworthy of motherhood or experience hopelessness about the outcome of her labor. However, she may not be able to articulate any of these feelings and may instead appear irritable or withdrawn.

Women with depression are more likely to deliver a low birth weight infant, have decreased fetal growth, and are more likely to have postnatal complications when compared to nondepressed women (ACOG, 2008). It is estimated that 1 in 10 women will experience depression during the pregnancy or postpartum period. Treatment of pregnant women with selective serotonin reuptake inhibitors (SSRIs) should be individualized on a case-by-case basis. Women who take SSRIs are not at greater risk for birth defects and therefore should be managed with pharmacologic agents as needed (ACOG, 2007). Infants commonly have higher cortisol and catecholamine levels, cry more often, and are more frequently admitted to the neonatal intensive care nursery (ACOG, 2008). This is also true of infants of women with bipolar disorder.

TABLE 27-1 Prevalence of Psychologic Disorders

DISORDER	U.S. PREVALENCE	PREVALENCE IN WOMEN/MEN	MATERNAL IMPLICATION
Generalized anxiety disorder (GAD)	6.8 million (3.1%)	Two times higher in women	Anxiety related to the birth process or medical interventions
Bipolar disorder	5.7 million (2.6%)	Women and men equally affected	Depressive or manic symptoms during labor
Depression	18.1 million (8.2%)	Two times higher in women	Withdrawn behavior, physical fatigue due to insomnia, crying spells, sadness, hopelessness, feelings of guilt, lack of interest in baby, thoughts of suicide, headaches during pregnancy
Obsessive-compulsive disorder (OCD)	2.2 million (1.0%)	Equal in men and women	Ritualistic behaviors or thoughts, difficulty focusing on directions
Panic disorder	6 million (2.7%)	Two times higher in women	Intense fear or sense of panic related to birth process
Phobias	19.2 million (8.7%)	Higher in women	May have specific fear related to an individual(s) or a procedure or place
Post-traumatic stress disorder (PTSD)	7.7 million (3.5%)	Higher in women	Repressed memories may be triggered during labor, causing intense anxiety, fear, and emotional distress
Schizophrenia	2.4 million (1.1%)	Affects men and women equally	Typically starts in the late 20s and early 30s. May have hallucinations or delusions, lack of sense of present events, high risk for suicide

TABLE 27-2 Psychologic Disorders That Can Affect Labor and Birth

ANXIETY DISORDERS	PERSONALITY DISORDERS
Generalized anxiety disorder (GAD)	Antisocial personality
	Avoidant personality
Social anxiety disorder	Borderline personality
Obsessive-compulsive disorder (OCD)	Dependent personality
	Narcissistic personality
Post-traumatic stress disorder (PTSD)	Obsessive-compulsive personality
	Schizoid personality
Panic disorder	Schizotypal personality
Specific phobias	Paranoid personality
Depression	**Dissociative Identity Disorder**
Major depression	**Schizophrenia**
Dysthymia	**Schizoaffective Disorder**
Bipolar depression	

Individuals with *bipolar disorder* can have depressive symptoms that alternate with episodes of mania. Although a complete discussion of bipolar disorder is beyond the scope of this text, students should refer to a psychiatric nursing text for a more complete discussion. Individuals with bipolar disorder experience the same symptoms as depression (previously discussed) during the depressive phase. Mania is characterized by expansiveness, elation, agitation, hyperactivity, and increased speed of thought and ideas (NIMH, 2009). During manic phases, individuals commonly exhibit poor judgment and hyperexcitability. A pregnant woman experiencing a manic episode may engage in behaviors that are dangerous for herself or her fetus, including alcohol or drug use, fast driving, driving without a seat belt, or engaging in unprotected intercourse with individuals at high risk for sexually transmitted infections (see chapter 6 ∞). There is also a higher risk of suicide in individuals with mood disorders. Women with a previous diagnosis of bipolar depression are at greater risk for developing a mood disorder in the postpartum period (ACOG, 2008). Although postpartum psychosis is a rare disorder (see chapter 39 ∞), it is more common in women with bipolar disorder.

Anxiety disorders include a cluster of diagnoses, such as panic disorder, obsessive-compulsive disorder (OCD), post-traumatic stress disorder (PTSD), generalized anxiety disorder (GAD), social phobia, and other specific phobias. These disorders can cause a wide range of symptoms in laboring women. Following childbirth, 16% of women may have an anxiety disorder (Ford & Ayers, 2009). Specifically, women with panic attacks can experience intense feelings of terror without warning that result in physical symptoms (chest pain, shortness of breath, weakness, faintness, or dizziness) and/or psychologic symptoms (fear, terror, or anxiety) (ACOG, 2008). Other serious medical conditions need to be excluded (e.g., amniotic fluid embolism, cardiac complications, asthma attack). Women with OCD may need to repeat specific rituals as a means of coping in labor. Ritualistic activities that are safe for the mother and the fetus can be used to reduce anxiety. Women who have a history of rape or sexual abuse may suffer from PTSD (ACOG, 2008). Following birth, 2% of women experience PTSD (Ford & Ayers, 2009). The events of labor may trigger flashbacks, avoidance behaviors, or anxiety symptoms. Generalized anxiety disorder, although not acutely disabling, may make the woman very uncomfortable as she enters labor. A woman with social phobia may feel overwhelmed or embarrassed, especially if excessive numbers of staff are needed to care for her or her newborn. These women may also exhibit symptoms that mimic more serious medical conditions (ACOG, 2008). Women with specific phobias may exhibit fears that seem irrational to healthcare providers, such as fear of needles or of their own contractions. Such phobias may be difficult to manage intrapartally and may require pharmacologic intervention.

Schizophrenia is the most disabling psychologic disorder. It is often difficult to treat schizophrenia in pregnant women because many of the medications are contraindicated because they are teratogenic. Women with uncontrolled schizophrenia may have difficulty managing emotions, interacting with the healthcare team, or thinking clearly. The woman's behavior may be dramatically inappropriate or she may simply be withdrawn. Women with schizophrenia are at risk for medication-related congenital malformations. Specifically, antipsychotics can cause cardiovascular defects. These women have an increased incidence of preterm birth, low birth weight, small for gestational age, placental abnormalities, and antenatal hemorrhage (ACOG, 2008). Infants born to schizophrenic mothers have higher postnatal death rates (ACOG, 2008).

> "As a nurse-midwife, all of the women I care for are special, but Karen was one person I will never forget. Karen was diagnosed with bipolar disorder with psychotic episodes that became uncontrolled in pregnancy as a result of discontinuing her medication. In labor, she arrived in a manic state. Her speech was excessively fast-paced, and she rocked in her bed violently throughout the labor. We ensured her physical safety throughout the labor, monitored her contractions and the baby as infrequently as possible, and provided continuous encouragement. At one point, Karen was adamant everyone must "get low" and sit on the floor to facilitate fetal descent. Although it did not seem rational to us, we did sit on the floor. Remarkably, her anxiety dramatically decreased and the sense of control she felt enabled her to focus and 15 minutes later, she pushed her baby out. At her 6-week postpartum visit, Karen was back on medication and enjoying her new role as a mother."

In general, women with psychologic disorders tend to exhibit somewhat exaggerated behaviors during labor. They may need absolute control of everything that happens and refuse to participate until they feel secure (Ford & Ayers, 2009). Although responses vary with different disorders, the woman may not be able to articulate her fears or needs, may not respond to supportive nursing measures, may be unaware of what will happen in la-

bor and birth, may be unable to understand what is happening, or may be suddenly overwhelmed by terrifying memories.

> One young woman I'll call Cheryl Ann was in preterm labor. I was evaluating her, and she was cooperative but anxious. Then the on-call physician began the vaginal exam. Suddenly, Cheryl Ann's face changed, and she began screaming over and over: "Don't hurt me, I'll do anything you want. No, keep the fire away, please, please, please." She was not with us in the room, she was in another event in her life, and she was terrified! I didn't know what to do. I stayed right beside her and kept talking softly. "It's all right, Cheryl Ann, you are here in the birth center. I'm your nurse. I will stay with you, and I won't let anyone hurt you. There is no fire here. Can you look at me? Hold my hand. You are safe here." She held my hand and in a few moments was able to look at me. She became less anxious and finally was able to be present in her experience.

Clinical Therapy

The goal of clinical therapy is to provide support that will help decrease the woman's anxiety, keep her oriented to reality, and promote optimal functioning while in labor. The physician or certified nurse-midwife (CNM) may prescribe a sedative, as needed, to help with symptoms and may seek the assistance of the on-call psychiatrist to assess and talk with the woman. The physician or CNM may also provide written orders for analgesic medications because relieving the pain may decrease the psychologic symptoms.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Unless birth is imminent or severe complications exist, the nurse begins the assessment by reviewing the woman's background. Factors such as age, parity, family support, culture, past and present experiences, and knowledge of the labor process affect the woman's psychologic response to labor. Past or current history of psychologic disorders should be evaluated. Current and past treatment can also yield helpful information. A careful history should include documentation of all psychotrophic medications used during pregnancy, because some medications can have adverse effects on pregnancy (ACOG, 2008).

As labor progresses, the nurse remains alert for the woman's verbal and nonverbal behavioral responses to the pain and anxiety of labor. The woman who is agitated and seems uncooperative or too quiet and compliant may require further appraisal for psychologic symptoms. Questions such as, "Is everything okay?" or "What's going on?" usually indicate some degree of anxiety and concern. Some women may be irritable, require frequent explanations, or repeat the same questions. The nurse further observes for nonverbal cues, including a tense posture, clenched hands, or pain out of context to the stage of labor. Recognizing the impact of fatigue on pain and anxiety is another important nursing responsibility. Women with sudden physical complaints need extensive evaluation to determine if the etiology is physical or psychologic. The nurse should assess what coping mechanisms have been effective for the woman in the past.

Nursing diagnoses that may apply to the woman with a psychologic disorder include the following:

- ***Ineffective Coping*** related to increased anxiety and stress
- ***Compromised Family Coping*** related to anxiety associated with labor and birth
- ***Fear*** related to invasive medical procedures and unknown outcome of birth process
- ***Anxiety*** related to unfamiliar surroundings and care by unknown medical personnel
- ***Disturbed Visual Sensory Perception*** related to reactivation of traumatic memories

Nursing Plan and Implementation

Primary nursing interventions center on supporting the laboring woman and her family and support persons. If the woman begins to lose her ability to cope or her orientation to reality, the nurse may be able to help her regain control and orientation by:

- Ensuring that the woman's external environment is free from excessive stimuli.
- Maintaining consistency in care providers to the extent possible.
- Encouraging her to identify and to use coping mechanisms that work well for her.
- Identifying and reducing the source of distress if possible.
- Acknowledging the woman's fears, pain, and other symptoms.
- Repeatedly orienting the woman to person, place, and time by statements such as "Janine, I am Tony Martinez and I am your nurse. It is Tuesday and you are in the birthing center because you are in labor now."
- Offering methods to promote relaxation and comfort.
- Providing clear but succinct information about the labor process, medical procedures, the environment, simple breathing exercises, and relaxation techniques.
- Employing a calm, caring, confident, and nonjudgmental approach.
- Providing frequent attention and therapeutic interaction.

Although providing emotional support and comfort measures is imperative, some women with severe uncontrolled psychologic disorders may continue to have excessive symptoms throughout labor and birth. Care for these women should focus on maintaining a safe environment and ensuring maternal and fetal well-being. Pharmacologic interventions may be needed to control excessive symptoms. In addition, some women may warrant referral for focused psychiatric support.

Evaluation

Expected outcomes of nursing care include the following:

- The woman experiences a decrease in physiologic and psychologic stress and an increase in physiologic and psychologic comfort.

- The woman remains oriented to person, place, and time.
- The woman uses effective coping mechanisms to manage her stress and anxiety in labor.
- The woman's and the family's fear is decreased.
- The woman verbalizes feelings about her labor.

Dystocia

Care of the Woman Experiencing Dystocia Related to Dysfunctional Uterine Contractions

Dystocia is an abnormal labor pattern in which abnormalities occur with the power (uterine contractions or maternal expulsion forces), the passenger (fetal size, position, or presentation), or the passage (soft tissues or pelvis). Dystocia encompasses many problems in labor, the most common of which is dysfunctional (or uncoordinated) uterine contractions that result in a prolongation of labor. This form of dystocia is the most common indication for cesarean birth in nulliparous women, accounting for 60% of cesarean births in this group (Gabbe, Niebyl, & Simpson, 2007).

Although there is considerable controversy regarding the definition of a normal labor, there is agreement that women enter the active phase of labor when the cervix is dilated 3 to 4 cm. During this time, contractions occur in a regular pattern and the cervix changes rapidly as plotted against time. As the cervix dilates, the fetal part progressively descends. Alternatively, cervical dilatation may be slower than normal (protraction disorders) or cease altogether (arrest disorders). Figure 27-1 ■ depicts normal and hypotonic uterine contraction patterns.

Tachysystole Labor Patterns

In tachysystole latent labor patterns, ineffectual uterine contractions of poor quality occur in the latent phase of labor, and the resting tone of the myometrium increases. Tachysystole labor patterns are most common in nulliparous women (Gabbe et al., 2007). Contractions usually become more frequent and are more than 5 contractions in a 10 minute period that have occurred over at least 30 minutes (Macones, Hankins, Spong, et al., 2008). Although the contractions are painful, they are ineffective in dilating and effacing the cervix, and a prolonged latent phase may result.

Maternal risks of tachysystole labor include the following:

- Increased discomfort due to uterine muscle cell anoxia.
- Fatigue as the pattern continues and no labor progress results.
- Stress on coping abilities.
- Dehydration and increased incidence of infection if labor is prolonged.

Fetal-neonatal risks include the following:

- Nonreassuring fetal status because contractions and increased resting tone interfere with the uteroplacental exchange.
- Prolonged pressure on the fetal head, which may result in cephalhematoma, caput succedaneum, or excessive molding.

Clinical Therapy

Management of tachysystole labor may include bed rest and sedation to promote relaxation and reduce pain. Typically, the woman will enter active labor, and cervical effacement and dilatation will begin to occur. If the tachysystole pattern continues and develops into a prolonged latent phase, oxytocin infusion or amniotomy may be considered (Strasser, Kwee, & Visser, 2009) (see chapter 28 ∞). These methods are instituted only after cephalopelvic disproportion (CPD) and fetal malrepresentation have been ruled out. CPD is a disparity between the size of the maternal pelvis and the size of the presenting fetal head due to position, presentation, or increased fetal weight that precludes a vaginal birth. When an oxytocin infusion is used to stimulate uterine contractions, the physician or certified nurse-midwife (CNM) needs to assess whether vagi-

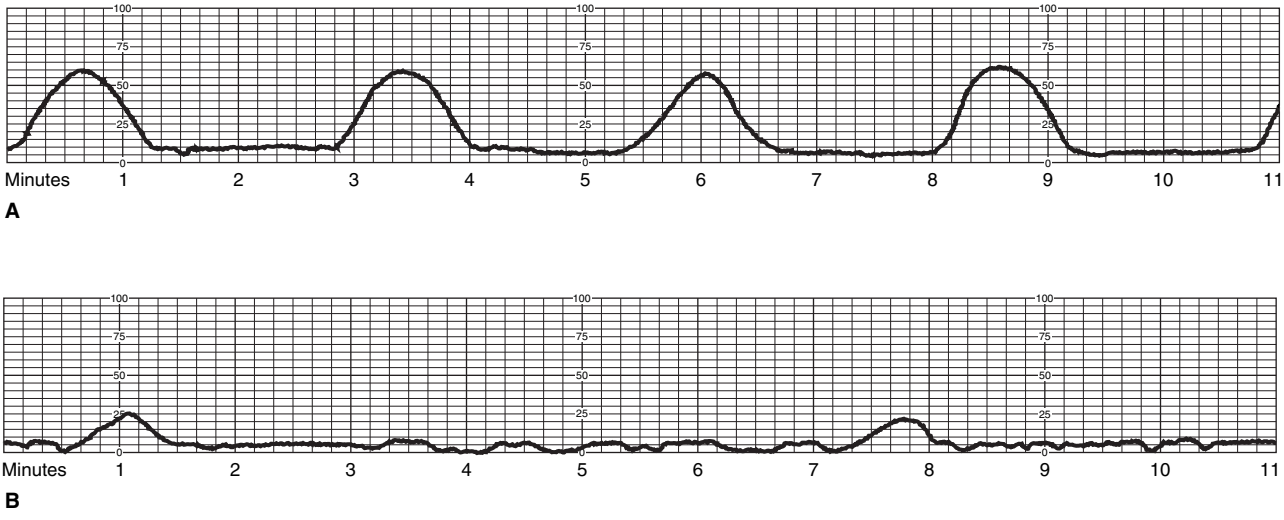

Figure 27-1 ■ Comparison of labor patterns. A. Normal uterine contraction pattern. Note that the contraction frequency is every 3 minutes; duration is 60 seconds. The baseline resting tone is below 10 mm Hg. B. Hypotonic uterine contraction pattern. Note in this example that the contraction frequency is every 7 minutes with some uterine activity between contractions, duration is 50 seconds, and intensity increases approximately 25 mm Hg during contractions.

nal birth is possible (i.e., whether the maternal pelvis is large enough for the fetus to pass through) (Strasser et al., 2009). If the maternal pelvis diameters are less than average, or if the fetus is particularly large or is in a malpresentation or malposition, CPD is said to be present. In the presence of true CPD, labor is not stimulated because vaginal birth is not possible.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

As part of the labor assessment, the nurse should evaluate the relationship between the intensity of the pain being experienced and the degree to which the cervix is dilating and effacing. The nurse should also note whether anxiety is negatively affecting labor progress. Evidence of increasing frustration and discouragement on the part of the mother and her partner may indicate that the nurse needs to provide some additional information or assurance.

Nursing diagnoses that may apply to the woman in tachysystole labor include the following:

- ***Acute Pain*** related to the woman's inability to relax secondary to tachysystole uterine contractions
- ***Ineffective Coping*** related to ineffectiveness of breathing techniques to relieve discomfort
- ***Anxiety*** related to slow labor progress

Nursing Plan and Implementation

A key nursing responsibility is to provide comfort and support to the laboring woman and her partner. The woman experiencing a tachysystole labor pattern will probably be very uncomfortable because of the increased force of contractions. Her anxiety level and that of her partner may be high. The nurse attempts to reduce the woman's discomfort and promote a more effective labor pattern.

The nurse may suggest supportive measures such as a change of position: left lateral side-lying, high Fowler's, rocking in a rocking chair, sitting up, or walking. Soothing measures include a warm shower, whirlpool, quiet environment, backrub, Therapeutic Touch, and visualization. Mouth care, change of linens, effleurage, and relaxation exercises may provide comfort. If sedation is ordered, the nurse ensures that the environment is conducive to relaxation. The labor partner may also need assistance in helping the woman cope. A calm understanding approach by the nurse offers the woman and her partner further support. Providing information about the cause of the tachysystole labor pattern and assuring the woman that she is not overreacting to the situation are important nursing actions.

Patient education is key for the woman experiencing tachysystole labor. She needs information about the dysfunctional labor pattern and the possible implications for herself and her baby. Information will help relieve anxiety and thereby increase relaxation and comfort. The nurse needs to explain treatment options and offer opportunities to ask questions.

Evaluation

Anticipated outcomes of nursing care include the following:

- The woman has increased comfort and decreased anxiety.
- The woman and her partner are able to cope with the labor.
- The woman experiences a more effective labor pattern.

Hypotonic Labor Patterns

The specific cause of hypotonic contractions is unknown; however, genetic factors may control the normal physiologic processes of labor. Cesarean birth and operative vaginal birth (use of forceps or vacuum extractor), for example, tend to run in families. Some research suggests there is a relationship between uterine dysfunction and advancing maternal age (Beckmann et al., 2008). The familial tendencies for difficult labor give rise to the theory that genetic processes control normal labor. It is hypothesized that there may be an inheritable tendency toward poor uterine contractions and/or soft-tissue relaxation (Beckmann et al., 2008).

CLINICAL TIP

Normal cervical dilatation in a first-time mother—commonly known as a "primip"—is just over 1 cm per hour, and dilatation in a "multip" is about 1.5 cm per hour. If your assessments reveal that this expected pattern is not occurring, consider that a problem may be developing. The most likely causes of the problem are related to either the contractions or to fetal position or size.

Clinical Therapy

When uterine contractions are irregular and of low amplitude and there is commonly less than 1 cm cervical dilatation per hour (called protracted labor) or there has been no change of cervical dilatation for 2 hours (arrest of progress), the physician or CNM evaluates the woman for the presence of any factor that would preclude the use of oxytocin (Pitocin) augmentation. The physician or CNM evaluates the size of the maternal pelvis, the position and presentation of the fetus, and fetal weight. The physician or CNM carefully considers the possibility of CPD. Station is a key component when evaluating for CPD. If the presenting part is not engaged ("out of the pelvis"), especially in a nulliparous woman, it is possible that CPD is present. The physician or CNM may attempt to push the presenting part into the pelvis with fundal pressure to assess if CPD exists. If CPD exists, oxytocin (Pitocin) augmentation should not be used and a cesarean birth is indicated.

When CPD is ruled out, an amniotomy (artificial rupture of membranes [AROM]) can be performed if membranes are intact. Amniotomy is associated with a reduction of labor duration and a decrease in use of oxytocin (Pitocin) (Beckmann et al., 2008). According to a Cochrane Review, amniotomy can reduce duration of labor and cesarean section birth rates (Wei et al., 2009). Amniotomy should not be performed if the presenting part is not well applied to the cervix because this increases the risk of cord prolapse (discussed later in the chapter). However, it is an accepted procedure with the diagnosis of dystocia secondary to

uterine hypocontractility. Oxytocin (Pitocin) augmentation can be implemented if adequate contractions do not occur. Oxytocin should be used with caution since it is a drug that appears on the high-alert list due to its ability to cause tachysystole. (See Drug Guide: Oxytocin [Pitocin] in chapter 28 ∞.)

ACOG has outlined two regimens of oxytocin administration: a low-dose regimen and a high-dose regimen (see complete discussion in chapter 28 ∞). Although low-dose regimens are associated with less uterine tachysystole, fetal outcomes have not differed between the two groups. High-dose regimens are said to shorten the mean length of labor, decrease the length of second stage, decrease the incidence of chorioamnionitis and neonatal sepsis, and reduce the incidence of cesarean births related to dystocia (Gabbe et al., 2007). High-dose regimens are mainly used for augmentation of labor and not labor induction (Gabbe et al., 2007). The current data do not support the notion that low-dose regimens are safer or superior to high-dose regimens (Beckmann et al., 2008). Continuous electronic fetal monitoring (EFM) is used to provide ongoing information regarding fetal response to the augmentation. With augmentation of labor, the contraction pattern and progressive cervical dilatation pattern should improve, and fetal descent (measured by station) should occur. If there is no improvement in these areas, cesarean birth may be necessary.

Some practitioners support the use of **active management of labor (AMOL)**. This method of labor management of nulliparous women has four components: (1) standardized criteria for diagnosis of labor, (2) standardized method of labor management, (3) one-to-one nursing care throughout the course of labor, and (4) prenatal education to teach women about the protocol (Chaillet & Dumont, 2007). In this process labor is managed from the beginning with amniotomy, timed cervical examinations, and augmentation of labor with intravenous oxytocin if adequate progress is not made. AMOL begins with careful assessment of the laboring woman, AROM (if the membranes are still intact) within 1 hour of diagnosis of the presence of actual labor, and hourly cervical examinations for the first 3 hours. Thereafter cervical examinations are performed every 2 hours, and at least an additional 1 cm of dilatation is expected at each examination. If cervical dilatation is less than expected, augmentation with an intravenous oxytocin infusion is begun. AMOL also incorporates a strong one-to-one nursing care program, in which the nurse remains with the woman. This permits ongoing assessment and provides the beneficial aspect of constant nursing support. Recent large-scale studies have shown that AMOL does not increase maternal and infant mortality or morbidity. Proponents have voiced support because it does shorten labor in nulliparous women. Interestingly, the rates of caesarean births are not decreased with AMOL (Cunningham et al., 2010).

Those who oppose AMOL contend that labor needs to be considered a normal process and allowed to progress without automatic intervention. Frequent examinations can increase the risk of maternal fever, intrauterine infection, and fetal compromise. Although some women may not strictly adhere to the expected normal time limits of labor, many will go on to give birth without complications if given an opportunity to progress through labor at their own pace. Just as all women do not have the same emotional reactions to labor, all women do not go through labor at the same pace and speed. Frequent examinations and interventions can also lead to maternal anxiety. Only if problems occur should the labor be augmented.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Assessing maternal vital signs, contractions, cervical dilatation, fetal descent, and fetal heart rate (FHR) characteristics provides the nurse with data to evaluate maternal-fetal status. The nurse also assesses for signs and symptoms of infection and dehydration. During the vaginal examination, the fetal presenting part (usually vertex) is assessed for the development of a caput. If the fetal vertex presses down on the cervix during contractions without further descent, a *caput succedaneum* may occur. As hypotonic labor continues, the caput increases in size; it seems that the head is descending, but it is not (Figure 27-2 ■).

Because labor progress is slow, the nurse assesses the woman's stress and coping, noting whether anxiety is having a deleterious effect on labor progress. Evidence of increasing frustration and discouragement on the part of the mother and her partner may become apparent as labor continues.

The laboring woman should maintain adequate fluid and nourishment throughout labor. Oral fluid intake or intravenous fluids can be provided. Women can eat light snacks in early labor as well. The nurse should ensure adequate urinary output is occurring.

Nursing diagnoses that may apply to the woman experiencing dysfunctional labor include the following:

- ***Acute Pain*** related to rapid increase in frequency and intensity of uterine contractions
- ***Ineffective Coping*** related to ineffectiveness of breathing techniques to relieve discomfort
- ***Anxiety*** related to slow labor progress

Nursing Plan and Implementation

Nursing measures are aimed at promoting maternal and fetal well-being. The nurse frequently monitors maternal vital signs; notes the frequency, duration, and strength of contractions; and assesses the fetal heart rate (FHR). Once the amniotic membranes are ruptured, the nurse assesses the amount of fluid and the presence of blood or meconium (dark green or black stool present in the large intestine of the fetus). Because meconium can be associated with a compromised fetus, ongoing observation of the amniotic fluid is critical. Maternal hydration status can be monitored by recording intake and output. The nurse assesses the bladder every 2 hours for distention; an in-and-out catheterization can be performed for women unable to void on their own. Alternatively, a Foley catheter may be inserted during the first stage of labor to reduce the need for multiple in-and-out catheterizations, which can increase the risk of urinary

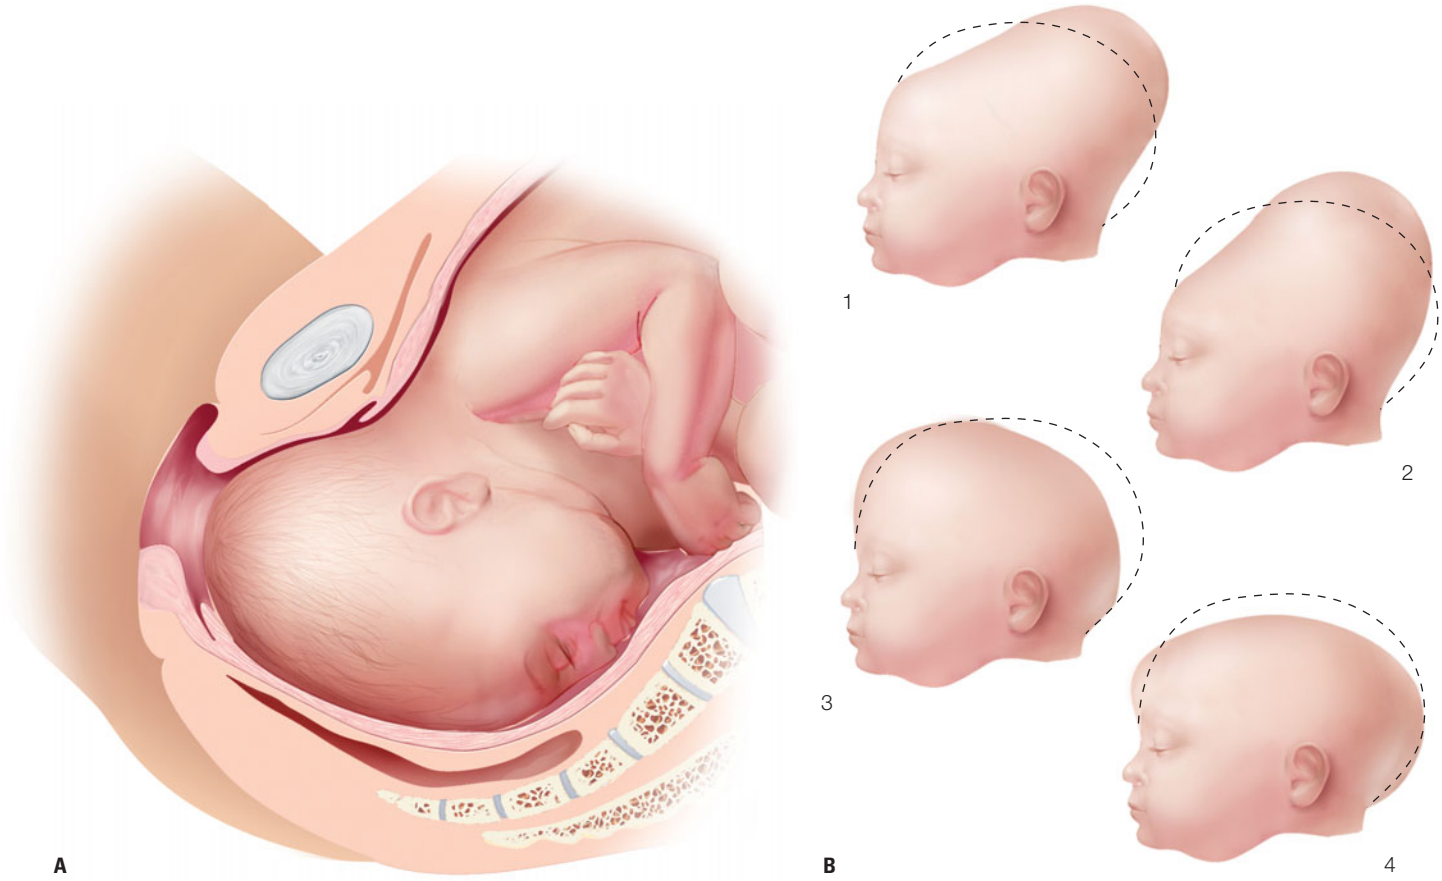

Figure 27-2 ■ Effects of labor on the fetal head. A. Caput succedaneum formation. The presenting portion of the scalp area is encircled by the cervix during labor, causing swelling of the soft tissue. B. Molding of the fetal head in cephalic presentations: (1) occiput anterior, (2) occiput posterior, (3) brow, (4) face.

tract infections. The catheter should be removed before maternal pushing.

Ongoing evaluation for symptoms of infection should be performed, especially for prolonged labors. These symptoms include fever, chills, foul-smelling amniotic fluid, and fetal tachycardia. Vaginal examinations should be kept to a minimum to reduce the incidence of infections.

The laboring woman needs information about the hypotonic labor pattern and the possible implications for herself and her baby. It is particularly important to address the couple's concerns and questions with clear, accurate information. They need to be informed of progress and possible treatment measures. Disadvantages and treatment alternatives also need to be discussed and understood by the woman and her support person.

Evaluation

Expected outcomes of nursing care include the following:

- The woman and her partner understand the labor pattern and its possible implications.
- The woman and her partner are able to cope with the labor.
- The woman's comfort increases and her anxiety decreases.
- The woman experiences a more effective labor pattern.

Care of the Woman and Fetus at Risk for Precipitous Labor and Birth

Precipitous labor and birth occurs when the entire process of labor and birth occurs within 3 hours. The most common causes are abnormally low resistance in maternal soft tissues, which allows for rapid cervical dilatation and fetal descent, and abnormally strong uterine contractions (Cunningham et al., 2010). In precipitous labor, cervical dilatation is 5 cm or more per hour in the primigravida and up to 10 cm per hour for the multigravida.

Precipitous labor and birth and precipitous birth are not the same. A precipitous birth is a sudden, and often unattended, birth. See chapter 24 ∞ for a discussion of precipitous birth and nurse-attended births. The incidence of precipitous birth in the United States is about 2% (Battista & Wing, 2007).

Risks of Precipitous Labor and Birth

Maternal risks of precipitous labor include the following (Cunningham et al., 2010):

- Loss of coping abilities
- Anxiety and fear

- Lacerations of the cervix, vagina, and perineum caused by rapid descent and birth of the fetus
- Postpartum hemorrhage caused by undetected lacerations or inadequate uterine contractions after birth

Fetal-neonatal implications include the following:

- Nonreassuring fetal status or hypoxia from decreased uteroplacental circulation caused by intense uterine contractions
- Meconium stained fluid that can result in meconium aspiration
- Brachial plexus injuries caused by rapid descent and uncontrolled birth
  - Low Apgar scores (see chapter 24 ∞)
  - Intracranial trauma from rapid birth and delivery

Clinical Therapy

Any woman with a history of precipitous labor requires close medical monitoring and preparation for precipitous birth to facilitate a safe outcome for the mother and fetus. Women with a history of precipitous birth should be closely monitored for cervical effacement and dilatation in the final weeks of pregnancy. An induction can be scheduled to control the birth environment and prevent complications that can occur with an unattended birth. Drugs such as magnesium sulfate or other tocolytic agents have not proven to be effective in these circumstances (Cunningham et al., 2010).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

During the intrapartal nursing assessment, the nurse can identify a woman at increased risk of precipitous labor (for example, a previous history of precipitate or short labor places a woman at risk). During the labor, accelerated cervical dilatation and fetal descent and intense contractions with little uterine relaxation between contractions are indicative of precipitous labor. During labor one or both of the following factors may indicate potential problems:

- Accelerated cervical dilatation (more than 2 cm/hr in multigravidas or more than 1.2 cm/hr in primiparous women) and rapid fetal descent (more than 2 cm/hr in a multiparous and more than 1.2 cm hour in a primiparous woman)
- Intense uterine contractions with less than 60 seconds of relaxation between contractions

Nursing diagnoses that may apply to the woman with precipitous labor include the following:

- ***Risk for Injury*** related to rapid labor and birth
- ***Acute Pain*** related to rapid labor process
- ***Anxiety*** related to rapid labor progress

Nursing Plan and Implementation

If the woman has a history of precipitous labor, it is imperative that the nurse establish rapport quickly because the nurse and woman may be involved in another precipitous labor and birth, and the situation has the potential to be tense. The physician or certified nurse-midwife (CNM) should be notified of the woman's status immediately. Rapport and support from the nurse will enhance all other interventions. The nurse closely monitors the woman's contractions and cervical dilatation, and an emergency birth pack is kept near the bed. The nurse stays in constant attendance if at all possible, assists the woman to a comfortable position, and provides a quiet environment. The nurse provides information and support before and after the birth. See chapter 24 ∞ for a discussion of nurse-managed birth.

The fetus is monitored for signs of hypoxia and other indications of nonreassuring fetal status such as late decelerations. If meconium staining of the amniotic fluid is present, the fetal nares and mouth will be suctioned just after the head is born (before the birth of the shoulders) to prevent the baby from drawing more meconium-stained fluid into the lungs with the first breath. After the birth of the baby, the cords will be visualized and additional suctioning carried out as needed. The neonatologist or nursery staff should be present for immediate care of the infant.

Evaluation

Expected outcomes of nursing care include the following:

- The woman and her baby are closely monitored during labor, and a safe birth occurs.
- The couple feels support and enhanced comfort during labor and birth.
- The woman maintains optimal comfort.

CLINICAL JUDGMENT

Case Study: Kim Hahn

Kim Hahn presents in labor with a fetal heart tracing demonstrating the following: baseline fetal heart rate (BL FHR) of 140 with variability of 6 to 10 beats/min. When you compare the fetal heart rate (FHR) with the uterine contractions, you note there is a slowing of the FHR at the time of the contraction and that the FHR tracing looks like the contraction curve, but it is upside down.

Critical Thinking

Based on the tracing, what would you do?

See www.nursing.pearsonhighered.com for possible responses.

Care of the Woman with Postterm Pregnancy

Postterm pregnancy is one that extends more than 294 days or 42 completed weeks past the first day of the last menstrual period. It is important to understand that 42 completed weeks refers to the completion of 42 weeks, meaning that the 7th day has elapsed. The incidence of postterm pregnancy is approximately 10% of all pregnancies in the United States (Norwitz, Snegovskikh, & Caughey, 2007). Most causes of postterm pregnancies are related to inaccurate pregnancy dating. Postterm pregnancy has been associated with primiparity, previous postterm pregnancy, placenta sulfatase deficiency, fetal anencephaly, male fetus, maternal obesity, and genetic predisposition (Caughey, Snegovskikh, & Norwitz, 2008).

A frequent cause of inaccurate pregnancy dating is error in determining the time of ovulation and conception according to

the first day of the last menstrual period. This error can be corrected by performing an ultrasound scan in early pregnancy. A first-trimester scan is the most accurate ultrasonic gestational age assessment. During the first trimester, the crown-rump length (CRL) is used. In second-trimester ultrasound, which is less accurate, the biparietal diameter of the fetal head is measured and then compared with conventional dating tables (Caughey, Nicholson, & Washington, 2008). First trimester dating reduces the number of estimated postterm pregnancies and decreases unnecessary interventions (Caughey et al., 2008).

Maternal Risks

Although postterm pregnancy does not pose any significant risk to the woman during the pregnancy, the labor and birth process may be affected. In many instances, labor is induced. Because postterm pregnancy is associated with an increased incidence of large-for-gestational-age (LGA) or macrosomic (weight in excess of 4000 g) fetuses, vaginal birth is frequently associated with the use of forceps or vacuum extractor. Women who deliver postterm fetuses are more likely to encounter perineal damage because of the increased size of the fetus. Maternal hemorrhage may also occur. Cesarean birth rates are doubled in postterm pregnancies. Cesarean births are associated with endometritis, hemorrhage, and thromboembolitic disease (Cunningham et al., 2010). Many women experience anxiety and are emotionally fatigued as their estimated date of birth (EDB) passes. Normal discomforts associated with late pregnancy persist that can lead to irritability and loss of sleep.

> "When I went over my due date, I felt so anxious and overwhelmed. I was mentally prepared to carry my baby until a certain date, but once that date was reached, I felt unable to deal with all of the discomforts of pregnancy. I couldn't sleep well. I was uncomfortable eating, walking, even putting on my shoes. Well-wishing friends and family would call and say, "Haven't you had that baby yet?" The calls just made it worse. I can't tell you how relieved I was when labor started, and I knew I would soon meet my new baby"

Fetal-Neonatal Risks

True postterm pregnancies are frequently associated with placental changes that cause a decrease in the uterine-placental-fetal circulation. The perinatal mortality rate after 42 weeks is twice that of term infants and increases sixfold during the 43rd gestational week (Beckmann et al., 2008). This decrease reduces the blood supply, oxygen, and nutrition for the fetus. Oligohydramnios (decreased amount of amniotic fluid) is frequently present and may increase the risk of umbilical cord compression (because the cord does not have as much fluid to float in). In such cases, the fetus is more likely to be small-for-gestational-age (SGA) or may lag behind the expected growth curve and experience growth alterations because of decreased nutrition associated with decreased uteroplacental-fetal circulation. If uteroplacental-fetal circulation is not compromised, the fetus continues to gain weight until the 42nd week; therefore, the fetus is often LGA and macrosomic. The LGA or macrosomic fetus has a higher incidence of birth trauma or shoulder dystocia (difficulty or inability to deliver the baby's shoulders). Macrosomia is also associated with prolonged labor, increased risk of cesarean birth, and cephalopelvic disproportion (CPD) (Cunningham et al., 2010). During labor, the postterm fetus may have meconium staining of the amniotic fluid, which can be associated with nonreassuring fetal status and meconium aspiration at birth (Cunningham et al., 2010). Some infants born after the 42nd week of pregnancy may have low umbilical artery pH and lower 5-minute Apgar scores (Norwitz et al., 2007). Many practitioners now favor delivering women once they reach 41 weeks gestation to avoid some of these complications (Norwitz et al., 2007).

Approximately 20% of all postterm infants experience *dysmaturity syndrome,* which is associated with uteroplacental insufficiency (resembling intrauterine growth restriction), meconium aspiration, and short-term neonatal complications (Gabbe et al., 2007). Neonatal complications associated with postterm pregnancies include hypoglycemia seizures and respiratory distress. These fetuses frequently experience nonreassuring fetal heart tracings in the antepartum and intrapartum periods.

Clinical Therapy

When the 40th week of gestation is completed and birth has not occurred, most practitioners begin using the nonstress test (NST), biophysical profile (BPP), or a modified BPP (ultrasound measurement of the amniotic fluid volume plus an NST) as assessment tools. While there is no consensus on the frequency of antenatal surveillance, many practitioners use twice-weekly testing providing the amniotic fluid level is normal. Any time that tests indicate fetal problems or there is decreased amniotic fluid volume, induction of labor is recommended (Cunningham et al., 2010).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

When the woman is admitted into the birthing area, it is important to establish the EDB and ascertain the type of antenatal testing that has been completed. During labor, ongoing assessments of the fetal heart rate (FHR) by continuous electronic fetal monitoring (EFM) are important to identify reassuring characteristics (lack of decelerations, accelerations with fetal movement) and to determine the presence of variable decelerations or late decelerations so that corrective actions may be taken. When amniotic membranes rupture, the nurse assesses the fluid for the presence of meconium. Ongoing assessments of labor progress (contractions, progressive cervical dilatation and effacement, and fetal descent) may provide clues to the presence of a macrosomic fetus because labor may be lengthened and fetal descent may not occur.

Possible nursing diagnoses for the woman with postterm pregnancy include the following:

- ***Fear*** related to the unknown outcome for the baby
- ***Compromised Family Coping*** related to concern regarding the status of the baby
- ***Risk for Injury (Fetus)*** related to the birth of a macrosomic infant
- ***Risk for Injury (Mother)*** related to perineal trauma
- ***Acute Pain*** related to the birthing process

Nursing Plan and Implementation

Community-Based Nursing Care

If the woman has not been assessing fetal activity every day, the nurse teaches her how to do it so that she can identify inadequate fetal movement and contact her healthcare provider (see chapter 21 ∞ for further discussion of techniques to detect fetal movement). The nurse encourages the woman to keep all appointments for BPPs and other testing and provides information regarding the postterm pregnancy and the antenatal testing that will be indicated. In addition, the nurse addresses the implications and associated risks for the baby, as well as possible treatment plans, and provides the woman and her partner opportunities to ask questions and clarify information. Most antenatal testing is performed by the nurse who must be knowledgeable regarding the testing procedures, interpretation of results, and collaboration with the physician or certified nurse-midwife (CNM).

Hospital-Based Nursing Care

In the birth setting, the response of the fetus during labor is assessed carefully. Continuous electronic monitoring of the FHR is important to determine whether reassuring characteristics are present and to detect variable decelerations, especially if oligohydramnios is present. If variable decelerations are present, the laboring woman's position is changed to attempt to take pressure off the umbilical cord, and the FHR is reevaluated. When an amnioinfusion is performed to increase the volume of fluid or to dilute meconium-stained fluid, the nurse assists with the procedure and monitors the infusion and the response of the FHR. (See chapter 28 ∞ for further discussion.)

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to explain the implications of the postterm pregnancy.
- The woman and her partner and family feel supported and able to cope with the labor and birth.
- Fetal problems are identified quickly.

Care of the Woman and Fetus at Risk Because of Fetal Malposition

Persistent occiput posterior (OP) position of the fetus is the most common fetal malposition and occurs when the head remains in the direct OP position throughout labor. In early labor approximately 15% of fetuses are in OP position, although only 5% remain in that position at the time of birth (Cunningham et al., 2010). This position may be normal in some races, particularly those in which women tend to have small pelves or in women with anthropoid pelves. The position is related to transverse narrowing of the midpelvis. For a fetus in an OP position to rotate to an occiput anterior (OA) position, it must rotate 135 degrees (right-occiput-posterior [ROP] to right-occiput-transverse [ROT] to right-occiput-anterior [ROA] to OA) (see Figure 22-8 ∞ on page 536), and in most cases this rotation is accomplished. In others, however, it is not. Labor progress may cease or the fetus may be born in a posterior position.

Maternal-Fetal-Neonatal Risks

The woman usually experiences intense pain in the small of her back throughout the labor, unless the baby rotates. At birth, if the fetus remains in a posterior position, the woman may suffer a third- or fourth-degree perineal laceration or extension of a midline episiotomy. There is no increased risk of fetal mortality because of the OP position unless labor is protracted or an operative birth is performed. There is a higher incidence of operative vaginal deliveries in fetuses who fail to rotate from the OP position. Maternal risks of OP malposition include the following (Ridley, 2007):

- Higher rates of cesarean birth
- Prolonged first and second stage of labor
- Oxytocin augmentation
- Anal sphincter injury
- Severe perineal lacerations
- Episiotomy
- Blood loss greater than 500 ml
- Postpartum infection
- Accidental lacerations of the lower uterine segment during cesarean
- Instrument delivery

Clinical Therapy

Medical treatment focuses on close monitoring of both maternal and fetal status and labor progress to determine whether vaginal or cesarean birth is the safer method. Prenatally, use of a hands and knees position twice daily has been helpful in correcting the persistent OP position if it is diagnosed prenatally (Hunter, Hofmeyr, & Kulier, 2007). According to Cunningham et al. (2010), vaginal birth is possible via:

1. Spontaneous birth.
2. Forceps-assisted birth with the occiput directly posterior.
3. Forceps rotation of the occiput to the anterior position and birth (Scanzoni maneuver [Figure 27-3 ■]).
4. Manual rotation to the anterior position followed by spontaneous or forceps-assisted birth (Figure 27-4 ■).

If the pelvis has larger diameters and the perineal muscles are relaxed, as found in grand multiparity (a woman who has had five or more children), the fetus may have no particular problem emerging spontaneously in the OP position. If, however, the perineum is rigid, the second stage of labor may be prolonged. A prolonged second stage is one that lasts over an hour in multiparas and 2 hours or more in nulliparas.

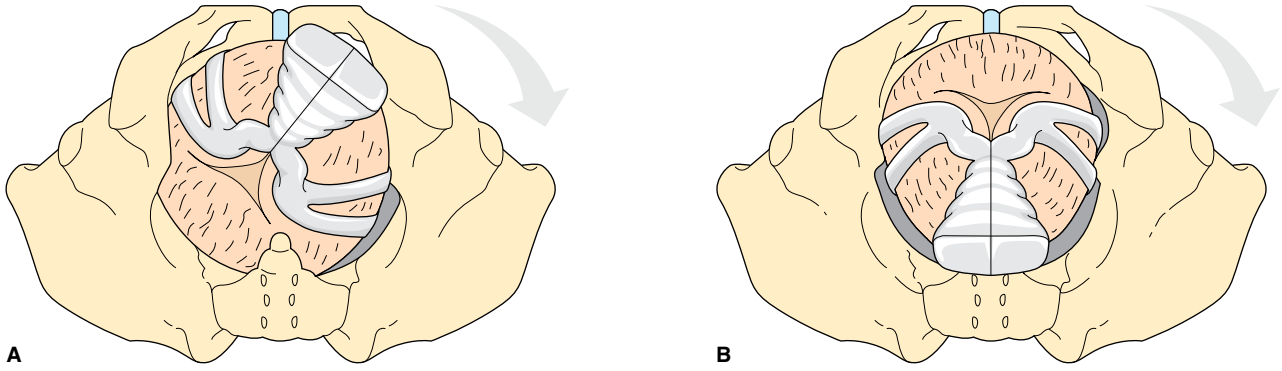

Figure 27-3 ■ Scanzoni maneuver, anterior rotation. A. Forceps are applied to the fetal head, which is in ROP position. Fetal head is then rotated 45 degrees to ROT, then another 45 degrees to ROA, then a final 45 degrees to OA. B. The fetal position has now changed from ROP to OA for a total rotation of 135 degrees. The forceps are now upside down, so they are removed and reapplied to provide the traction necessary for a forceps-assisted birth.

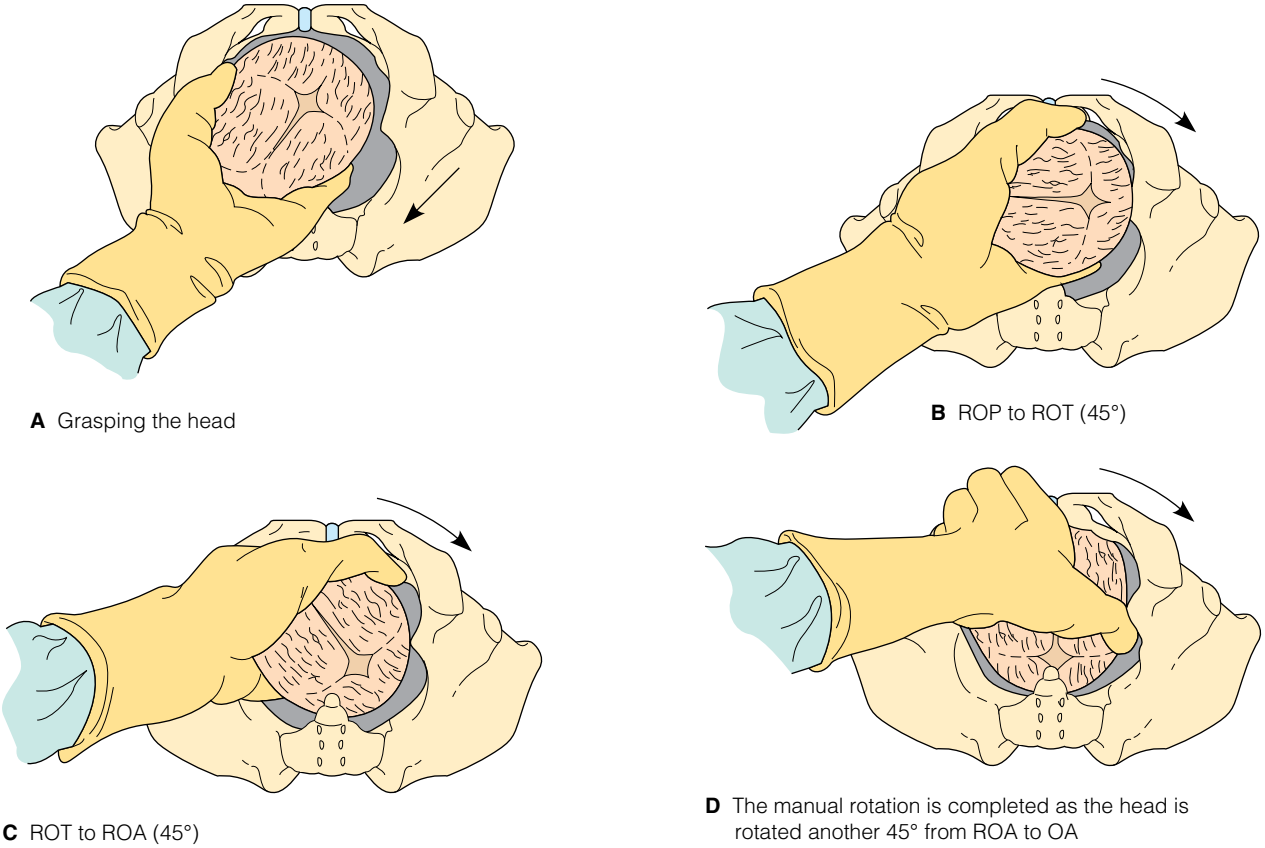

Figure 27-4 ■ Manual rotation of ROP to OA. A. The physician's left hand is inserted into the vagina and the back of the fetal head is grasped. B. The head is flexed and then rotated 45 degrees to ROT. C. The head is rotated another 45 degrees to ROA. D. The manual rotation is completed as the head is rotated another 45 degrees from ROA to OA. During the manual rotation, the physician's other hand is placed on the maternal abdomen, and the body is turned in the same direction as the head by applying pressure to the fetal breech or shoulders.

In the event of a prolonged second stage with arrest of descent due to the OP position, a forceps or manual rotation may be done if no cephalopelvic disproportion (CPD) is present. Forceps rotation has been associated with neonatal high cervical spinal cord injuries in the past. For this reason, obstetricians may choose to perform a cesarean birth (Cunningham et al., 2010). In cases of CPD, cesarean is always the preferred mode of birth. Of women with a persistent OP position, 60% will deliver via cesarean. These account for 12% of all cesarean births performed for dystocia (Cunningham et al., 2010).

RESEARCH EVIDENCE IN PRACTICE

Maternal Positions and Fetal Occiput Posterior Malposition

CLINICAL QUESTION

Can maternal position during labor affect fetal occiput posterior malposition?

RESEARCH EVIDENCE

The occiput posterior fetal position is present in 10% to 20% of fetuses at the beginning of labor. Persistence of this malposition is associated with a host of maternal and fetal problems, including increased rates of neonatal mortality. Frequently, the mother laboring with a fetal occiput posterior position complains of back pain during labor. In most cases, the fetus spontaneously rotates into the occiput anterior position during labor. If it does not, risks for both mother and baby can be reduced if interventions are applied to rotate the fetus into a desirable position for birth.

A systematic review of the research literature, combined with information from obstetric textbooks and expert consultation, revealed only weak evidence that the hands-and-knees position was associated with correction of the occiput posterior malposition. However, regardless of whether the fetal position changed, mothers reported this position was comfortable and relieved backache.

One randomized controlled trial studied the effects of the hands-and-knees position on fetal malposition and additional outcomes. Similarly, fetal rotation to the occiput anterior position was greater in the group that used the hands-and-knees position, but only marginally so. However, additional outcomes were achieved in greater numbers with this maternal position, including back pain reduction, less perineal trauma, higher Apgar scores, and shorter length of labor.

A systematic review of multiple randomized trials involving nearly 3000 mothers revealed that the most effective maternal position may be Sims on the same side as the fetal spine. This position was associated with a significant rate of rotation to occiput anterior, as well as shorter labor and a lower rate of cesarean births.

WHAT QUESTIONS REMAIN UNANSWERED?

Some of these studies suggested rocking motions and abdominal stroking may be an effective addition to maternal positioning. Are these possible additional nursing interventions that may support fetal rotation?

WHAT IS BEST PRACTICE?

Most fetuses that present in the occiput posterior position will spontaneously rotate during labor. For those that do not, use of Sims position on the same side as the fetal spine may help the fetus rotate to occiput anterior. The hands-and-knees position may provide some support for fetal rotation, but will likely be most helpful when the baby is appropriately positioned but the mother is experiencing back pain.

CRITICAL THINKING

How can the nurse support the laboring mother in finding a comfortable, yet appropriate, position?

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The first sign of OP position is intense back pain in the first stage of labor. The back pain is caused by the fetal occiput compressing the sacral nerves. Other signs and symptoms may include a dysfunctional labor pattern, a prolonged active phase, secondary arrest of dilatation, or arrest of descent. Further assessment may reveal a depression in the maternal abdomen above the symphysis pubis. Fetal heart rate (FHR) may be heard far laterally on the maternal abdomen, and on vaginal examination the nurse will find the wide diamond-shaped anterior fontanelle in the anterior portion of the pelvis. This fontanelle may be difficult to feel because of molding of the fetal head. Leopold's maneuvers should also be performed to detect positional changes (see chapter 23 ∞ and Figure 23-7 ∞ on page 571).

Intrapartum ultrasound is another effective tool for detecting fetal malposition (Ridley, 2007). Nursing diagnoses that may apply to women with persistent OP position include the following:

- ***Acute Pain*** related to back discomfort secondary to occiput-posterior position
- ***Ineffective Coping*** related to persistent back pain

Nursing Plan and Implementation

Changing maternal posture has been used for many years to enhance rotation of OP or occiput transverse (OT) to OA. The woman may be placed on one side and then asked to move to the other side as the fetus begins to rotate. This side-lying position may promote rotation; it also enables the support person to apply counterpressure on the sacral area to decrease discomfort (Ridley, 2007). A knee-chest position provides a downward slant to the vaginal canal, directing the fetal head downward on descent and is often effective in rotating the fetus. In addition to maintaining a hands-and-knees position on the bed, the woman may do pelvic rocking, and the support person may perform firm stroking motions on the abdomen. The stroking begins over the fetal back and swings around to the other side of the abdomen. After the fetus has rotated, the woman lies in Sims' position on the side opposite the fetal back. In addition to assuming these positions, the woman may want to sit on the toilet, walk around the room, stand beside the bed and lean forward with her hands on the bed and do the pelvic rock, rest in a whirlpool, or lie on her side in the bed. The use of a birthing ball (see Figure 24-4 ∞ on page 609) has also been helpful in rotating the fetal head.

Evaluation

Expected outcomes of nursing care include the following:

- The woman's discomfort is decreased.

- The woman and her partner apply comfort measures and position changes that assist her.
- The woman's coping abilities are strengthened.
- The woman and her partner state that they feel supported and encouraged.

Care of the Woman and Fetus at Risk Because of Fetal Malpresentation

In a normal cephalic presentation, the occiput is the presenting part and the head is flexed with the chin on the chest (Figure 27-5A ■). Three cephalic malpresentations are possible: military (sinciput), brow, and face (Figure 27-5B–D ■). The fetal body straightens out in these malpresentations from the classic fetal position to an S-shaped position. Of these, the military presentation is probably the least difficult for the woman and fetus. In most cases, as soon as the head reaches the pelvic floor, flexion occurs and a vaginal birth results. Thus, of the cephalic malpresentations, only brow and face are discussed here.

In addition to the cephalic malpresentations, the breech, shoulder (transverse lie), and compound presentations can cause significant difficulty during labor. These malpresentations are also discussed in this chapter.

Brow Presentation

Brow presentations are the least common of all presentations, with an incidence of 1 in 670 births to 1 in 3433 births (Gabbe et al., 2007). In a brow presentation, the forehead of the fetus becomes the presenting part. The fetal head is slightly extended instead of flexed, with the result that the fetal head enters the birth canal with the widest diameter of the head (occipitomental) foremost (Figure 27-5C). Although no specific cause can be identified, proposed causes include high parity, placenta previa, uterine anomaly, hydramnios, fetal anomaly, low birth weight, cephalopelvic disproportion, and large fetus (Bashiri, Burstein, Bar-David, et al., 2008). Primiparity is a protective factor (Bashiri et al., 2008).

In labors in which a brow presentation exists, 33% to 50% will result in a prolonged labor or a secondary arrest of labor (Gabbe et al., 2007). Cesarean birth is preferred in the presence of cephalopelvic disproportion (CPD) or failure of a

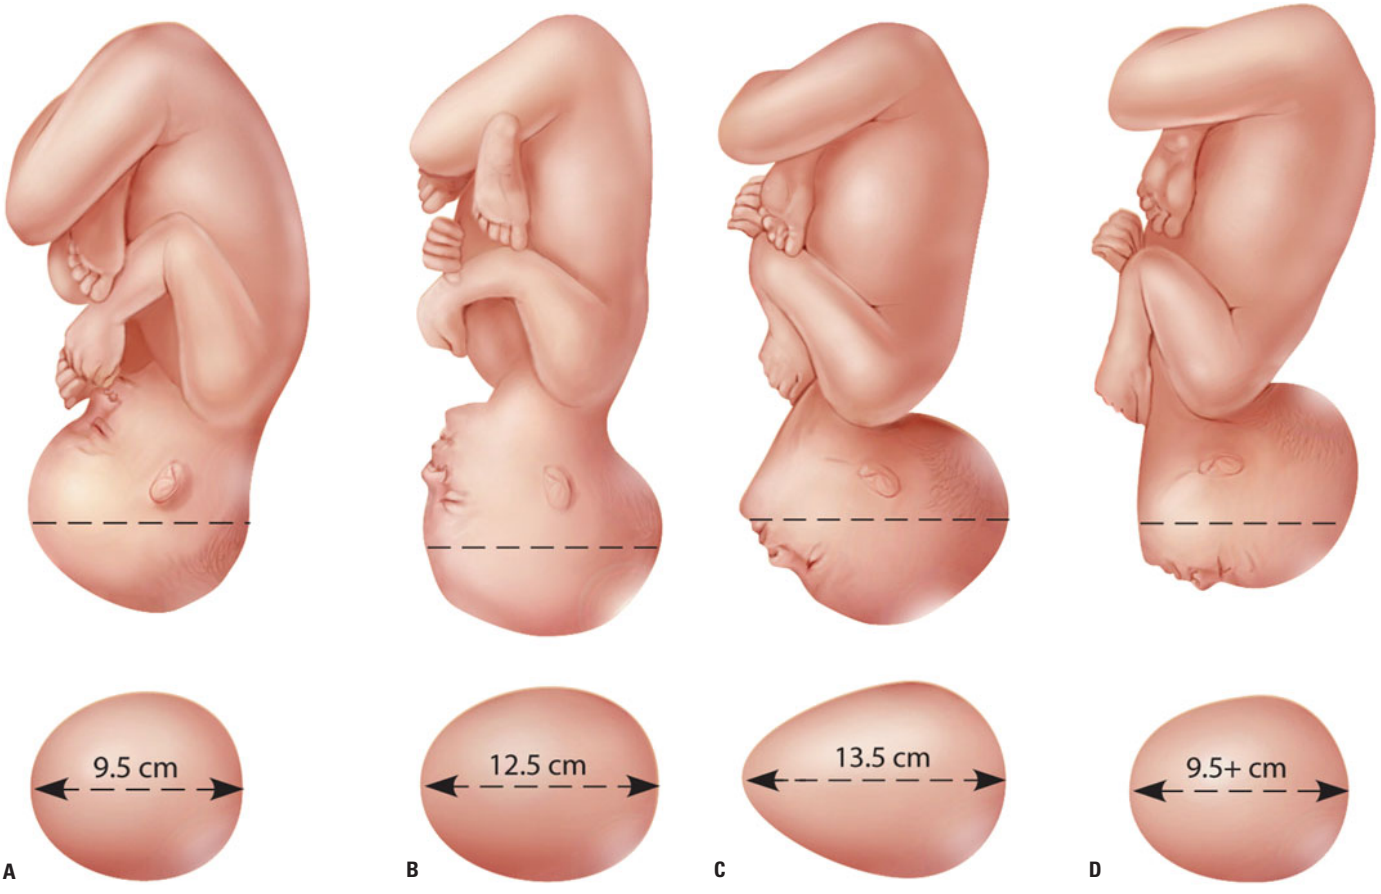

Figure 27-5 ■ Types of cephalic presentations. A. The occiput is the presenting part because the head is flexed and the fetal chin is against the chest. The largest anteroposterior (AP) diameter that presents and passes through the pelvis is approximately 9.5 cm. B. Military (sinciput) presentation. The head is neither flexed nor extended. The presenting AP diameter is approximately 12.5 cm. C. Brow presentation. The largest diameter of the fetal head (approximately 13.5 cm) presents in this situation. D. Face presentation. The AP diameter is 9.5 cm.

brow presentation to convert to a normal vertex or face presentation. If a vaginal birth is attempted, the woman will probably have an episiotomy and may require extension of the episiotomy at the moment of birth.

Fetal mortality is increased because of injuries received during the birth. Trauma during the birth process can include cerebral and neck compression and damage to the trachea and larynx.

Clinical Therapy

Active medical intervention is not necessary as long as cervical dilatation and fetal descent are occurring. If labor progress is slow, clinical pelvimetry findings and ultrasound to determine the presence of fetal anomalies are important. Brow presentations should be managed expectedly because a cesarean birth is most frequently warranted (Zayed, Amarin, Obeidat, et al., 2008). Oxytocin may be used with caution to correct an inadequate labor pattern. Use of forceps or manual conversion is contraindicated (Zayed et al., 2008). If problems occur, cesarean birth is indicated.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Leopold's maneuvers suggest a brow presentation when both the chin and occiput are palpable. A brow presentation may be detected on vaginal examination by palpation of the diamond-shaped anterior fontanelle and orbital ridges (Figure 27-6 ■).

Nursing diagnoses that may apply to brow presentation include the following:

- ***Anxiety*** or ***Fear*** related to outcome for fetus
- ***Deficient Knowledge*** related to lack of information about possible maternal-fetal effects of brow presentation
- ***Risk for Injury (Fetus)*** related to pressure on fetal structures secondary to brow presentation

Nursing Plan and Implementation

Nursing management of the brow presentation includes close observation of the woman for labor aberrations and of the fetus for signs of nonreassuring fetal status. The fetus should be observed closely during labor for signs of hypoxia as evidenced by late decelerations.

The nurse may need to explain the position of the fetus to the laboring couple or to interpret what the physician or certified nurse-midwife (CNM) has told them. The nurse should stay close at hand to reassure the couple, inform them of any changes, and assist them with labor-coping techniques.

In both brow and face presentations, the appearance of the newborn may be affected. The couple may need help in beginning the attachment process because of the newborn's facial appearance. After the infant is inspected for gross abnormalities, the pediatrician and nurse can assure the couple that the facial edema and excessive molding are only temporary and will subside in a few days.

Evaluation

Expected outcomes of nursing care include the following:

- The woman and her partner understand the implications and associated problems of brow presentation.
- The mother and her baby have a safe labor and birth.
- The woman and her baby initiate the bonding process.

Face Presentation

In a face presentation, the face of the fetus is the presenting part. The fetal head is hyperextended even more than in the brow presentation. Face presentation occurs frequently in multiparous women or women with a pendulous abdomen. Women with a contracted pelvis account for 10% to 40% of all face presentations. Fetal factors include macrosomia or a nuchal cord around the neck. The presence of anencephaly accounts for one third, and fetal malformations, such as thyroid goiter and soft tissue tumors of the fetal neck, are also common in face presentations. The incidence of face presentation is about 1 in 500 births overall or 0.2% of all births (Gabbe et al., 2007). There is an identified fetal or maternal cause in 90% of cases.

The risks of CPD and prolonged labor are increased with face presentation. As with any prolonged labor, the chance of infection is increased.

The fetus may develop edema, making vaginal examination for placement of heart rate electrodes difficult. If a fetal scalp electrode is applied, it should be placed on the mentum. After

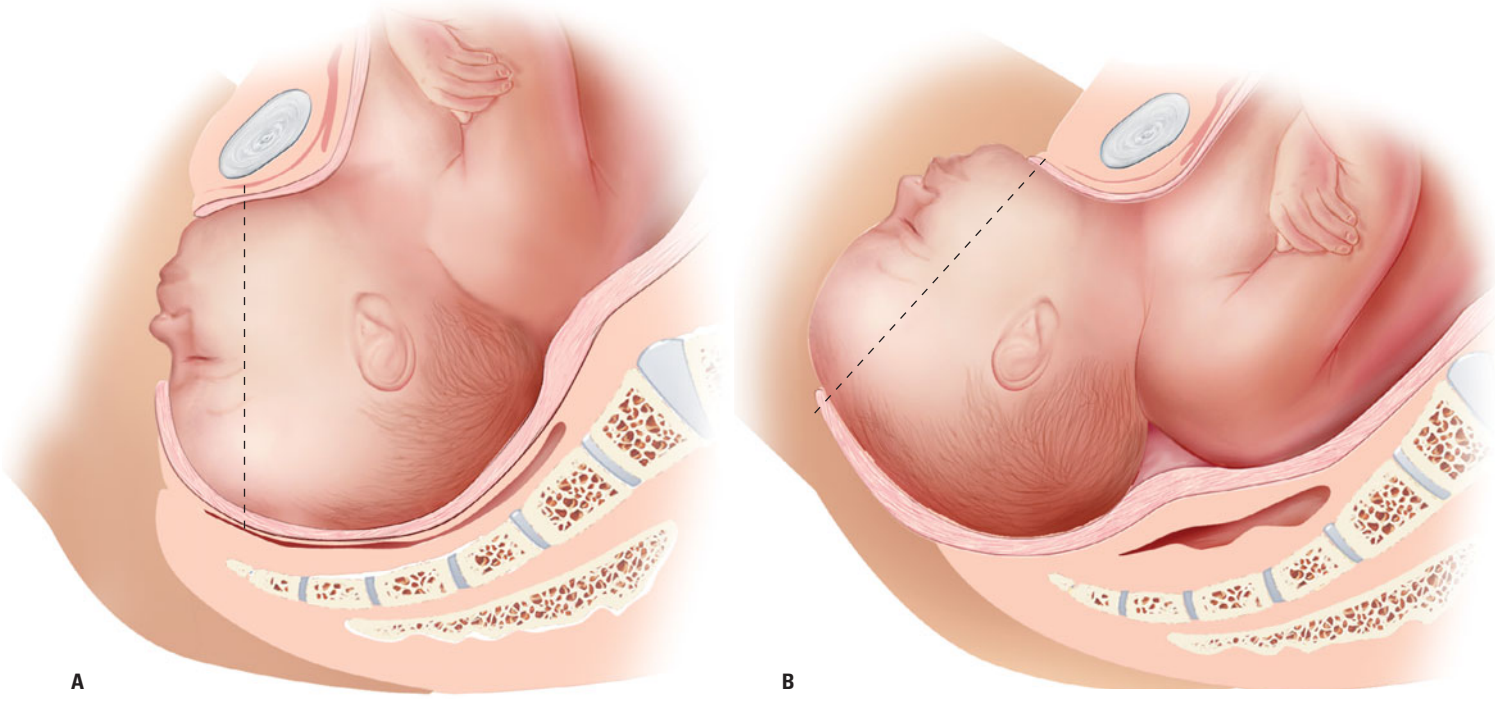

Figure 27-7 ■ Face presentation. Mechanism of birth in mentoanterior position. A. The submentobregmatic diameter at the outlet. B. The fetal head is born by movement of flexion.

birth the edema gives the newborn an unusual appearance. As with the brow presentation, the neck and internal structures may swell as a result of trauma received during descent. Petechiae, swelling, and facial bruising are often seen in the superficial layers of the facial skin because of the birth trauma. The perinatal mortality rate is 2% to 3% not including nonviable malformations and extreme prematurity (Gabbe et al., 2007).

Clinical Therapy

If no CPD is present, the mentum (chin) is anterior, and the labor pattern is effective, the objective of medical treatment is a vaginal birth (Figure 27-7 ■). The success rate of vaginal delivery is 70% to 80%. Oxytocin may be administered as needed for hypotonic labor patterns. Attempts at manual rotation should not be made, because this increases perinatal mortality and maternal morbidity (Creasy, Resnik, Iams, et al., 2009). Mentum posteriors can become wedged on the anterior surface of the sacrum (Figure 27-8 ■). In this case as well as in the presence of CPD, cesarean is the preferred method of birth.

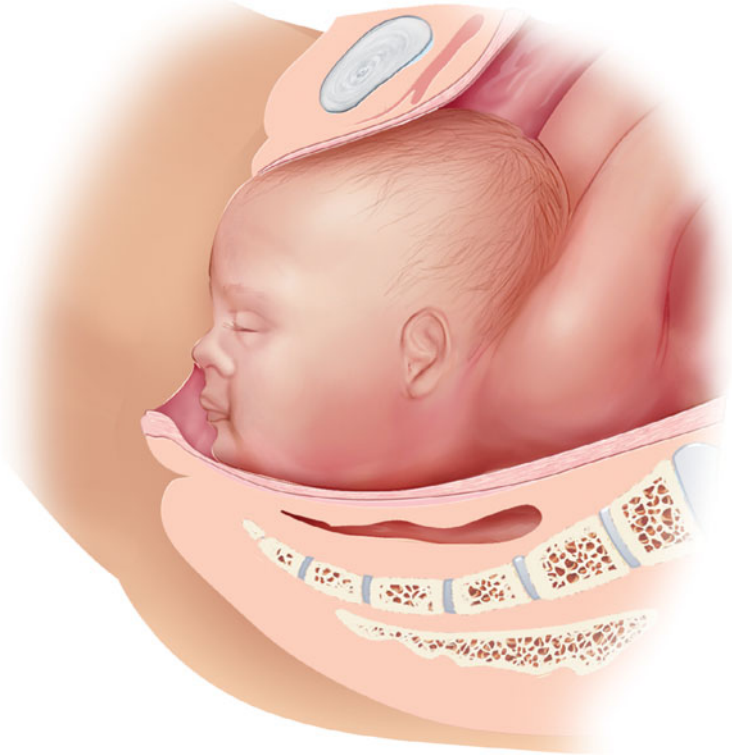

Figure 27-8 ■ Face presentation. Mechanism of birth in mentoposterior position. Fetal head is unable to extend farther. The face becomes impacted.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

When performing Leopold's maneuvers, the nurse finds that the back of the fetus is difficult to outline, and a deep furrow can be palpated between the hard occiput and the fetal back (Figure 27-9 ■). Fetal heart tones can be heard on the side where the fetal feet are palpated. It may be difficult to determine by vaginal examination whether a breech or a face is presenting, especially if facial edema is already present. During the vaginal examination, palpation of the saddle of the nose and the gums should be attempted. When assessing engagement, the nurse needs to remember that the face has to be deep within the pelvis before the biparietal diameter has entered the inlet. The majority

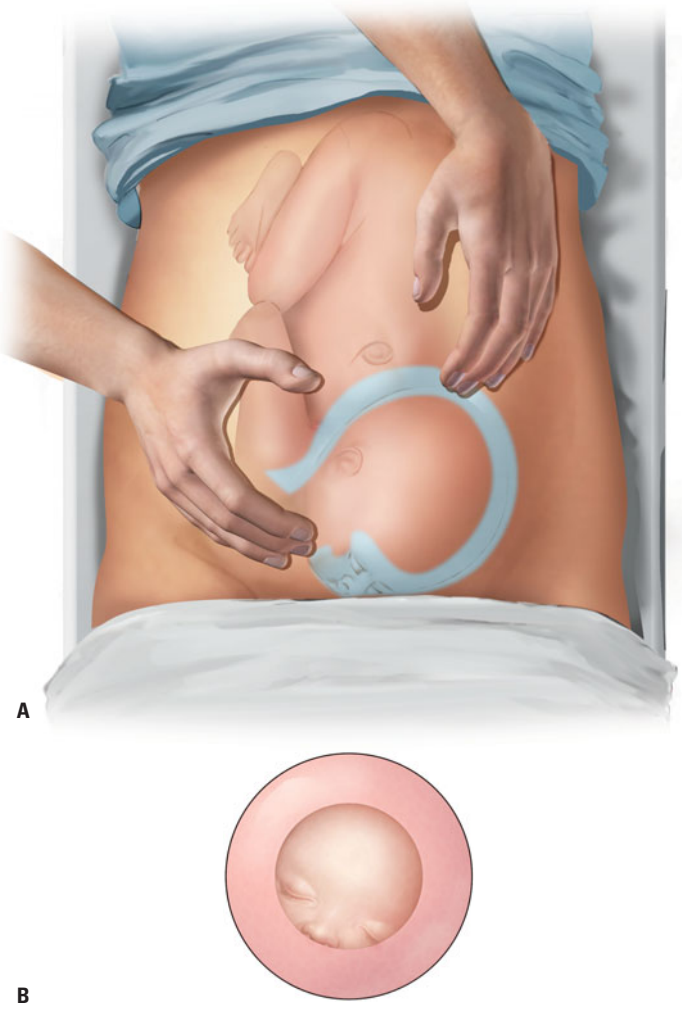

Figure 27-9 ■ Face presentation. A. Palpation of the maternal abdomen with the fetus in right mentum posterior (RMP). B. Vaginal examination may permit palpation of facial features of the fetus.

of face presentations are diagnosed via vaginal exam later in labor, and some are not diagnosed until the time of birth (Gabbe et al., 2007).

Nursing diagnoses that may apply to the woman with a fetus in face presentation include the following:

- ***Fear*** related to unknown outcome of the labor and appearance of the baby
- ***Risk for Injury*** to the newborn's face related to edema secondary to the birth process

Nursing Plan and Implementation

Nursing interventions are the same as for the brow presentation.

Evaluation

Expected outcomes of nursing care include the following:

- The woman and her partner understand the implications and problems of face presentation.
- The mother and her baby have a safe labor and birth.
- The woman and her baby initiate the bonding process.

Breech Presentation

Breech presentation is the most common malpresentation, with an overall incidence of approximately 4% of births. The incidence of breech presentation is directly related to gestational age: at 25 to 26 weeks' gestation, the incidence is about 25%, but by 32 weeks, the incidence has decreased to 7% (Beckmann et al., 2008).

Frank breech is the most common type of breech (especially at term) and is characterized by flexed hips and extended knees. It occurs in about 50% to 70% of breech births (Figure 27-10A ■). Single or double footling breech (incomplete breech), characterized by one or both hips extended and a foot presenting, accounts for about 10% to 30% of breech births (Figure 27-10B ■) and occurs more frequently in preterm fetuses. The remaining 5% to 10% of breech presentations are complete breech presentations (Figure 27-10C ■) (Beckmann et al., 2008).

Breech presentation is most frequently associated with placenta previa, implantation of the placenta in either cornual area, hydramnios, high parity, oligohydramnios, hydrocephaly, anencephaly, previous breech presentation, uterine anomalies, pelvic tumors, multiple gestation, and fetal anomalies (Cunningham et al., 2010). Because the presenting part does not completely fill the space in the lower uterine segment, once membranes rupture, cord prolapse is more likely. The incidence of cord prolapse is more likely in a breech presentation. Infants born after breech presentation have higher infant mortality and neonatal complications. Factors associated with breech presentation include a decreased muscle tone in the fetus and an abnormal fetal motor ability. Breech fetuses are more likely to have neuromuscular disorders. Children who presented in breech presentation scored lower on motor functioning during the first 5 years of life than children who had presented in cephalic presentation (Creasy et al., 2009). These birth defects can be associated with factors that caused the breech presentation (birth defects or intrauterine growth restriction) or with damage that occurred during birth (Rubio et al., 2009).

Head trauma during vaginal birth is more likely in breech presentation because it does not allow for the slow molding that occurs in a cephalic presentation as the fetal head moves through the birth canal. The head is the largest and least resilient part of the fetal body. It is the last to come through the maternal pelvis in breech presentations; thus molding does not occur. In the case of a preterm breech, a single or double footling and the torso may emerge through a cervix that is not completely dilated, leaving the larger head entrapped by the cervix. Entrapment may also occur with cesarean birth if the incision is inadequate or uterine relaxation is less than optimum. Vaginal breech birth also carries higher risks of meconium aspiration and fetal asphyxia (ACOG, 2006).

Studies have demonstrated that planned cesarean births of breech fetuses had a lower risk of perinatal morbidity and mortality than planned vaginal births (ACOG, 2006). The American College of Obstetricians and Gynecologists now recommends that the mode of birth for a single fetus should be based on the healthcare provider's experience and expertise and notes there is a decrease of expertise in this area of obstetrics. The mother should be informed that there are more com-

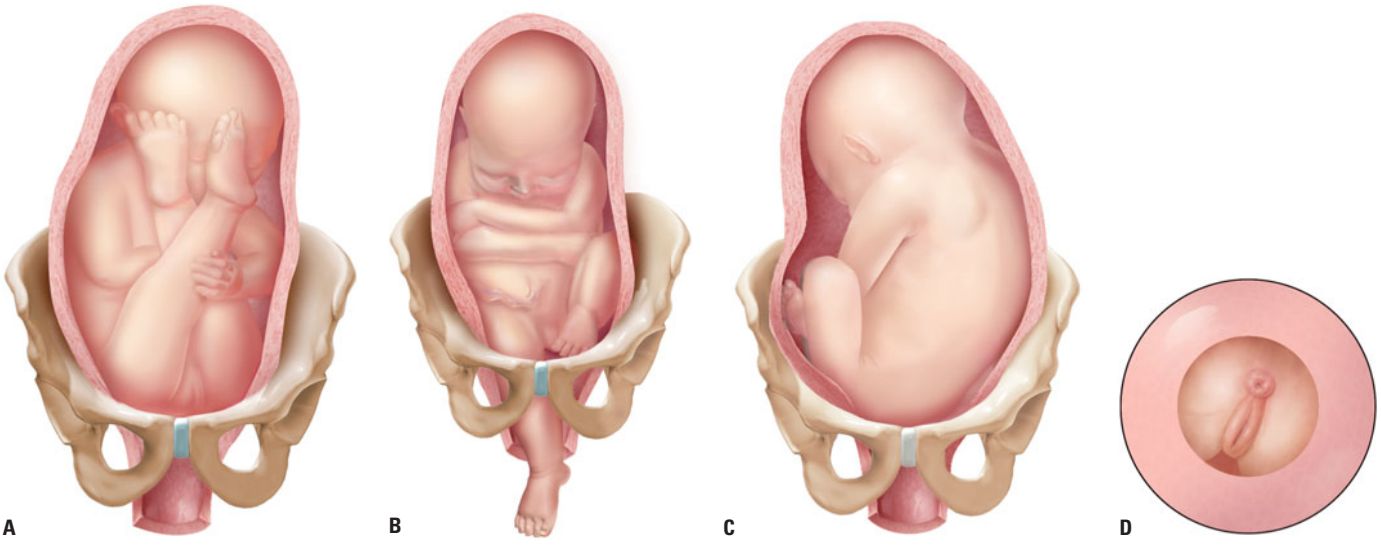

Figure 27-10 ■ Breech presentation. A. Frank breech. B. Incomplete (footling) breech. C. Complete breech in left sacral anterior (LSA) position. D. On vaginal examination, the nurse may feel the anal sphincter. The tissue of the fetal buttocks feels soft.

plications associated with planned vaginal breech delivery than with planned cesarean birth in these fetuses (ACOG, 2006).

Clinical Therapy

An external cephalic version (ECV) is usually attempted at 37 to 38 weeks' gestation. The ECV, which is discussed in detail in chapter 28 ∞, can reduce breech presentation by 50% (Beckmann et al., 2008).

Complementary and alternative therapies have also been used with some success. *Moxibustion* is a traditional Chinese medicine (TCM) technique in which certain herbs are burned close to the skin near a particular acupressure or acupuncture point, thus stimulating the point and allowing energy to flow through it. To promote version in breech presentations, mugwort is burned close to acupoint BL67, located beside the outer corner of the fifth toenail. The heat and pungency of the burning mugwort stimulates the pressure point, much like acupressure or acupuncture does, and energy is released. It is believed that the effect of moxibustion increases fetal activity. Moxibustion has been shown to decrease the need for ECV and reduce the use of oxytocin before and during labor (Gibbs et al., 2008).

Maternal positioning exercises can also be utilized to facilitate the rotation of the fetus. The mother should be advised to assume a position where her hips are higher than her torso, which can give the fetus ample room to move into a cephalic presentation. The mother should be encouraged to perform these exercises 2 or 3 times daily. Once she feels a large movement, however, she should be advised to discontinue the exercises until a care provider has determined if the desirable position has been achieved.

If the version is unsuccessful or the fetus spontaneously turns back into a breech presentation, the physician will evaluate the possibility of a vaginal birth or plan a cesarean birth. Many physicians recommend a cesarean birth when a breech presentation is detected, especially if the woman is nulliparous because breech births have higher mortality and morbidity rates as well as an increased incidence of cord prolapse, birth trauma, and fetal cervical spinal cord injuries due to hyperextension of the head (Beckmann et al., 2008). Contraindications for labor and vaginal birth include the following:

- Fetal weight less than 1500 g or more than 3800 g
- Hyperextension of the fetal neck of more than 90 degrees
- Extension of the fetal arms over the head
- Anomalies, such as hydrocephalus
- Diminished maternal pelvic measurements

If a vaginal birth is being attempted, narcotic agents or an epidural block may be used for pain relief. Epidural anesthesia may be advantageous during the latter portion of labor because it will help prevent the pushing sensation the woman may feel before complete dilatation. If the woman pushes before cervical dilatation is complete, the fetal body may be expelled and the head entrapped. At the time of birth the physician may have an assistant available in case forceps are needed. Once the fetal body is born, an assistant supports the fetal body as the physician applies Piper forceps to assist in birth of the fetal head (called the *aftercoming head*) (Cunningham et al., 2010).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

At times, the nurse is the first person to recognize a breech presentation. On palpation using Leopold's maneuvers, the nurse feels the hard vertex in the fundus and can perform ballottement of the head independently of the fetal body. The wider sacrum is palpated in the lower part of the abdomen. If the sacrum has not descended, on ballottement the entire fetal body will move. Furthermore, fetal heart tones (FHTs) are usually auscultated above the umbilicus. Passage of meconium from compression of the infant's intestinal tract during descent may occur.

The nurse is particularly alert for a prolapsed umbilical cord, especially in single or double footling breeches, because there is space between the cervix and presenting part through which the cord can slip. If the infant is small and the membranes rupture, the danger is even greater. This is one reason why any woman admitted to the birthing area with a history of ruptured membranes should not ambulate until a full assessment, including vaginal examination, is performed.

Nursing diagnoses that may apply to breech presentation include the following:

- ***Readiness for Enhanced Self-Health Management*** related to an expressed desire to understand the implications of the procedure
- ***Risk for Injury (Fetus)*** due to head entrapment from a planned vaginal breech birth

Nursing Plan and Implementation

During labor, the fetus is at increased risk for prolapse of the cord. Some agency protocols may therefore call for continuous electronic fetal monitoring (EFM) even though there are no current research studies to support the use of EFM. Since women with a breech presentation are at an increased risk for a prolapsed umbilical cord, maternal ambulation is usually not recommended until the presenting part is well engaged. Ongoing assessments of contractions, cervical dilatation, effacement, and fetal descent are also important to monitor labor progress. Emotional support and sharing of information are critical to the childbearing woman and her support person. They need to be kept apprised of the labor's current status as well as the possible treatment plans so they can continue to make informed choices.

During a vaginal birth, the nurse continues to assess the fetal heart rate (FHR) and to provide encouragement and support for the couple. Piper forceps need to be readily available to the physician; the nurse may assist the physician if the forceps are needed for the birth.

Evaluation

Expected outcomes of nursing care include the following:

- The woman and her partner can describe the implications and associated problems with breech presentation.
- The mother and baby have a safe labor and birth.
- Major complications are recognized early, and corrective measures are instituted.

Shoulder Presentation (Transverse Lie) of a Single Fetus

It is not uncommon in multiple gestations for one or more of the fetuses to be in a transverse lie. An incidence of transverse lie of a single fetus is approximately 1 in 300 term births (Cunningham et al., 2010). The infant's long axis lies across the woman's abdomen, and on inspection the contour of the maternal abdomen appears widest from side to side (Figure 27-11 ■).

Maternal conditions associated with a transverse lie are grand multiparity with lax uterine musculature (the most common cause); obstructions such as bony dystocia, placenta previa, neoplasms, and fetal anomalies; hydramnios; and preterm fetus.

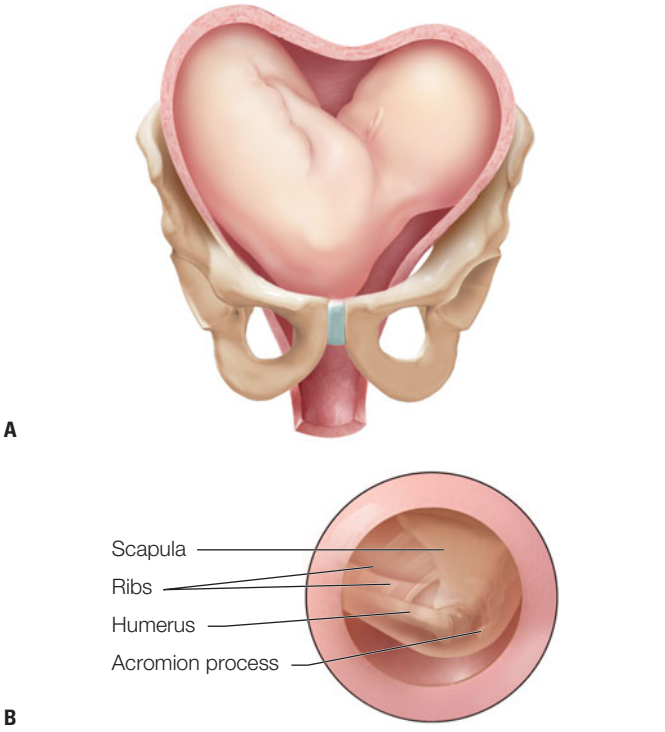

Figure 27-11 ■ Transverse lie. A. Shoulder presentation. B. On vaginal examination, the nurse may feel the acromion process as the fetal presenting part.

Vaginal birth is impossible with a transverse lie. Labor should not be allowed to continue, and a cesarean birth is done quickly. Frequently a vertical incision is made in the uterus because the fetal head and fetal feet lie in the upper portion of the uterus; a low transverse incision may lead to difficulties in extracting the fetus (Cunningham et al., 2010).

If labor is allowed to continue, the fetal shoulder will be forced down into the pelvis and the fetus will become impacted. With no relief, uterine rupture may occur (Cunningham et al., 2010).

Clinical Therapy

Transverse lie may be diagnosed using Leopold's maneuvers and can then be confirmed by ultrasound. At the time of the ultrasound examination, it is important to confirm fetal position, fetal biparietal diameters (to confirm gestational age), and location of the placenta and to carry out an examination for the presence of fetal anomalies and structural abnormalities of the uterus such as leiomyoma (fibroid tumor) or adnexal tumors.

Management varies, depending on the length of gestation, because many transverse lies convert to either cephalic or breech presentation by term (38 weeks). If the fetus is still in a transverse lie at term, an ECV may be done if (1) there is no contraindication to vaginal birth (for example, a fetal anomaly, complete placenta previa, or a structural problem in the uterus), and (2) fetal pulmonary lung maturity is confirmed either by ultrasound measurements or by amniocentesis for assessment of phospholipids (2:1 lecithin/sphingomyelin [L/S] ratio and the

presence of phosphatidylglycerol). An ECV is most likely to be successful close to term. Spontaneous version will likely occur if performed before 37 weeks. The use of tocolytics for the procedure may be helpful for nulliparas. The fetus is assessed with a nonstress test (NST) or biophysical profile (BPP) before the procedure. If the version is successful, the woman may be induced if she is at term and her cervix is favorable. However, scientific studies do not support immediate induction as a routine to minimize the chance the fetus will return to the original position (Gabbe et al., 2007).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse can identify a transverse lie by inspection and palpation of the abdomen, by auscultation of FHTs in the midline of the abdomen (not conclusive), and by vaginal examination.

On palpation, no fetal part is felt in the fundal portion of the uterus or above the symphysis pubis. The head may be palpated on one side and the breech on the other. FHTs are usually auscultated just below the midline of the umbilicus. On vaginal examination, if a presenting part is palpated, it is the ridged thorax or possibly an arm that is compressed against the chest. Women with a transverse lie may report less shortness of breath, pelvic pressure, and urinary frequency than other women because pressure is not exerted on the diaphragm and the bladder.

Nursing diagnoses that may apply when transverse lie is present include the following:

- ***Risk for Impaired Gas Exchange*** related to decrease in blood flow secondary to cord compression associated with prolapsed cord
- ***Risk for Powerlessness*** related to unknown outcome
- ***Fear*** related to unknown outcome of birth

Nursing Plan and Implementation

The primary nursing actions are to help evaluate the fetal presentation and to provide information and support to the couple. If an ECV has been accomplished and an induction is started, the nurse completes all interventions related to the induction (see the discussion in chapter 28 ∞). If transverse lie is discovered when the woman is admitted to the birthing unit in labor, the nurse provides information regarding the need for either an ECV or a cesarean birth and assists with preparation for the birth. If an ECV is not performed or is unsuccessful, a cesarean birth will be performed. Before the cesarean, the nurse watches for rupture of membranes and the possibility of prolapse of the umbilical cord. (See chapter 28 ∞ for further information regarding teaching with cesarean birth.)

Evaluation

Expected outcomes of nursing care include the following:

- The transverse lie is recognized promptly, and crucial assessments are completed.
- Measures to perform an ECV or a cesarean birth are completed.
- The mother and baby have a safe birth.
- The couple can describe the implications and associated problems of transverse lie.

Compound Presentation

A compound presentation is one in which there are two presenting parts. It can occur when the pelvic inlet is not totally occluded by the primary presenting part. If the prolapsed part is a hand, the birth is generally not difficult. Sometimes the hand slips back, and occasionally it is born alongside the head. This may increase the chance of laceration. Cesarean birth is indicated in the presence of uterine dysfunction or nonreassuring fetal status (Cunningham et al., 2010).

Care of the Woman and Fetus at Risk Because of Macrosomia

Fetal **macrosomia** is defined as weight of more than 4000 g. It is important to remember that the mean birth weight varies throughout the world. For instance, mean birth weight in Sweden is 3490 g, whereas in Pakistan the mean birth weight is 2770 g. In Latino cultures, "fat" babies are more desirable and are viewed as more healthy. Nurses working with Latino women may encounter resistance if counseling is focused on preventing a large baby. Instead, nurses should stress the importance of the baby's health status (Simpson & Creehan, 2007). The definition of macrosomia will thus differ according to the ethnic group being discussed.

A woman who is obese is twice as likely to have a macrosomic fetus (Hillier et al., 2008). Obesity has been defined in a number of ways. For a complete discussion on maternal obesity, see chapter 18 ∞. There is also an association between macrosomia and both pregestational and gestational diabetes. Increased maternal glucose levels have also been shown to increase fetal weight (Hillier et al., 2008). Other risk factors include postterm pregnancy, multiparity, grand multiparity, previous macrosomic infant, previous shoulder dystocia, male sex, and maternal birth weight.

A woman's pelvis that is adequate for an average-sized fetus may be disproportionately small for an oversized fetus. Distention of the uterus causes overstretching of the myometrial fibers, which may lead to dysfunctional labor and an increased incidence of postpartal hemorrhage. If the oversized fetus is not able to descend, the chance of uterine rupture during labor increases. Vaginal birth poses an increased risk of perineal lacerations and extensions of an episiotomy. The mother is also at risk for postpartum hemorrhage and puerperal infection. The incidence of vacuum and forceps birth increases with fetal size.

The most significant complication in macrosomia is *shoulder dystocia,* which is an obstetric emergency. However, shoulder dystocia may occur with fetuses weighing less than 4000 g, and risk factors are not reliable predictors. Following birth of the head, the anterior shoulder of the macrosomic fetus may not emerge either spontaneously or with gentle traction

(Cunningham et al., 2010). If shoulder dystocia is not managed correctly, permanent injury to the baby may result. **Brachial plexus injury** is an injury due to improper or excessive traction applied to the fetal head during birth that results in damage to the network of nerves that send signals from the spine to the shoulder, arm, and hand.

Other injuries that may occur include fractured clavicles, meconium aspiration, asphyxia, hypoglycemia, polycythemia, and hyperbilirubinemia. Other neurologic damage to the fetus can also occur.

In addition, macrosomic infants are more likely to become obese in childhood and adolescence. These children are also at risk to develop diabetes later in life (Landon, Catalano, & Gabbe, 2007).

Clinical Therapy

The occurrence of the maternal and fetal problems associated with macrosomic infants may be somewhat lessened by identifying macrosomia before the onset of labor. The diagnosis is not precise. There is good evidence to show that estimating fetal size with ultrasound is no more accurate than a clinical estimate from Leopold's maneuvers (Heywood, Magann, Rich, et al., 2008; Magliore & Copel, 2007). However, ultrasound is usually employed as an assessment measure in diagnosing macrosomia. If a large fetus is suspected, the maternal pelvis should be evaluated carefully. An estimation of fetal size can be made by palpating the crown-rump length (CRL) of the fetus in utero, but the greatest errors in estimation occur on both ends of the spectrum—the macrosomic fetus and the very small fetus. Whenever the uterus appears excessively large, hydramnios, an oversized fetus, or a multiple pregnancy must be considered.

Labor and vaginal birth for a fetus greater than 4500 g may warrant a cesarean birth to reduce the risks associated with vaginal births. The best method of birth for a fetus weighing 4000 to 4500 g is debated. If a vaginal birth is attempted and difficulty extracting the shoulders occurs during the birth, the obstetrician or certified nurse-midwife (CNM) may direct the woman to sharply flex her thighs up against her abdomen (McRoberts maneuver). This position is thought to change the maternal pelvic angle and therefore reduce the force needed to extract the shoulders, thereby decreasing the incidence of brachial plexus stretching and clavicular fracture (Figure 27-12A–C ■). The maternal head should be lowered and the nurse applies suprapubic pressure directly over the symphysis pubis to aid release of the anterior shoulder. Fundal pressure (pressure exerted at the top of the maternal fundus) should not be performed, because this can further wedge the shoulder against the suprapubic bone.

In addition, the obstetrician or CNM may incorporate other interventions, such as checking the placement of the shoulder, performing an episiotomy, and using the Woods Screw maneuver (which consists of rotating the anterior shoulder 180 degrees to the posterior position). In cases where these interventions fail, the obstetrician or CNM may electively break the clavicle to facilitate extraction of the shoulders.

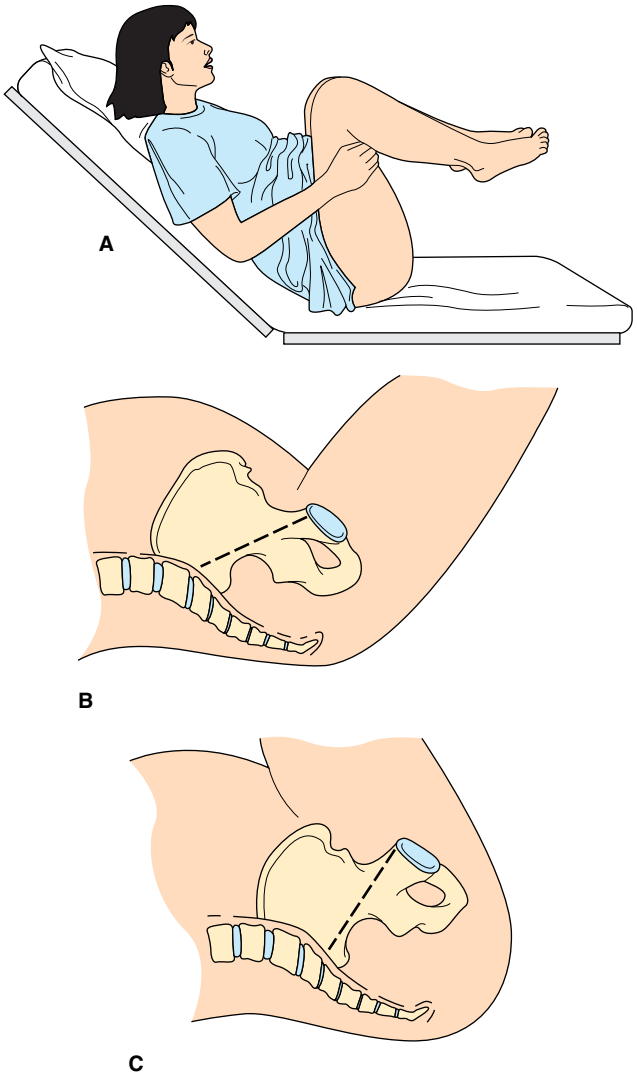

Figure 27-12 ■ McRoberts maneuver. A. The woman flexes her thighs up onto her abdomen. B. The angle of the maternal pelvis before McRoberts maneuver. C. The angle of the pelvis with McRoberts maneuver.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse assists in identifying factors associated with macrosomic infants. During the intrapartum period, the risk factors include slow descent of the fetus and prolonged second stage. Because women with these risk factors are prime candidates for dystocia and its complications, the nurse frequently assesses the fetal heart rate (FHR) for nonreassuring heart rate patterns, which may indicate fetal stress; evaluates the rate of cervical dilatation; and assesses fetal descent.

Nursing diagnoses that may apply to the woman with a macrosomic fetus include the following:

- ***Risk for Injury*** to the fetus related to trauma during the birth process

- ***Risk for Infection*** related to traumatized tissue secondary to maternal tissue damage during birth
- ***Risk for Injury*** to the mother related to perineal trauma associated with macrosomic birth

Nursing Plan and Implementation

The nurse monitors labor closely for a dysfunctional pattern, assessing FHR and reporting any sign of labor dysfunction or nonreassuring heart rate patterns to the physician or CNM. The nurse notes any arrest of descent, excessive molding of the fetal head, or the presence of caput succedaneum, which can also indicate a large fetus or cephalopelvic disproportion (CPD).

The nurse provides support for the laboring woman and her partner and information regarding the implications and possible associated problems. The nurse can provide the couple with directions for proper positioning at the time of birth to facilitate extraction of the shoulders. If the nurse anticipates a possible shoulder dystocia, additional staff should be notified and appropriate support personnel for the newborn should be informed. During the birth, the nurse continues to provide support and encouragement to the couple. Informing the woman that possible suprapubic pressure may be needed can help reduce anxiety for the couple.

After the birth, the nurse inspects the newborn for cephalhematoma, Erb palsy (caused by overstretching of the brachial plexus and damage to C_5, C_6, C_7), and fractured clavicles (exhibited by nonmovement of one arm or palpation of the clavicle to detect an irregularity of the bone structure) and informs the admission nursery of any problems. The newborn will need to be observed closely for cerebral and neurologic damage.

Postpartum, the nurse checks the uterus for potential atony and the maternal vital signs for deviations suggesting hypovolemic shock. Frequent fundal checks should be performed to evaluate the woman for postpartum bleeding. If postpartum hemorrhage occurs, intravenous (IV) or intramuscular (IM) Pitocin should be administered to stimulate contraction of the uterus.

Evaluation

Expected outcomes of nursing care include the following:

- The woman and her partner can describe the implications of macrosomia and possible associated problems.
- The mother and baby have a safe labor and birth.

Care of the Woman and Fetus in the Presence of Nonreassuring Fetal Status

When the oxygen supply is insufficient to meet the physiologic demands of the fetus, a nonreassuring fetal status may result. *Nonreassuring fetal status* is the term used to identify data describing the fetal status. Previously, the term fetal distress was used; however, its use implied an ill fetus despite the fact that the condition is often transient, not chronic.

A variety of factors may contribute to a nonreassuring fetal status. The most common are related to cord compression and uteroplacental insufficiency associated with placental abnormalities and preexisting maternal or fetal disease. If the resultant hypoxia persists and metabolic acidosis follows, the situation can be life threatening to the fetus.

The most common initial signs of nonreassuring fetal status are meconium-stained amniotic fluid (in a vertex presentation) and changes in the fetal heart rate (FHR). The presence of ominous FHR patterns, such as late or severe variable decelerations, decrease in or lack of variability, and progressive acceleration in the FHR baseline, are indicative of hypoxia. Fetal scalp blood samples demonstrating a pH value of 7.2 or less provide a more sophisticated indication of fetal problems and are generally obtained when questions about fetal status arise. (See chapter 23 ∞.)

Clinical Therapy

When there is evidence of possible nonreassuring fetal status, treatment centers on relieving the hypoxia and minimizing the effects of anoxia on the fetus. Initial interventions include changing the mother's position, increasing infusion rates of intravenous fluids, and administering oxygen by mask at 6 to 10 L per minute. If electronic fetal monitoring (EFM) has not yet been used, it is usually instituted at this time. If oxytocin is in use, it should be discontinued. Fetal scalp stimulation can be performed. Fetal scalp blood samples can be taken. If EFM is ineffective, the certified nurse-midwife (CNM) or physician may utilize internal monitoring devices to more accurately assess FHR changes. Figure 27-13 ■ depicts intrapartum management of nonreassuring fetal status heart rate patterns.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse reviews the woman's prenatal history to anticipate the possibility of nonreassuring fetal status. When the membranes rupture, it is important to assess FHR and to observe for meconium staining. A sterile vaginal examination should be performed to rule out cord prolapse. As labor progresses, the nurse is particularly alert for even subtle changes in the FHR pattern and the fetal scalp pH, if available. Reports by the mother of increased or greatly decreased fetal activity may also be associated with nonreassuring fetal status. For further discussion of FHR patterns and characteristics, see evaluation of fetal status during labor in chapter 23 ∞.

Nursing diagnoses that may apply in the presence of nonreassuring fetal status include the following:

- ***Decreased Cardiac Output (Fetus)*** related to decreased uteroplacental perfusion secondary to maternal hypotension, decreased blood volume, or vasoconstriction with preeclampsia
- ***Anxiety*** related to knowledge of nonreassuring fetal status

Nursing Plan and Implementation

Staff members may become so involved in assessing fetal status and initiating corrective measures that they fail to give explanations and emotional support to the woman, her partner, and other family members. It is imperative that the nurse provide both full

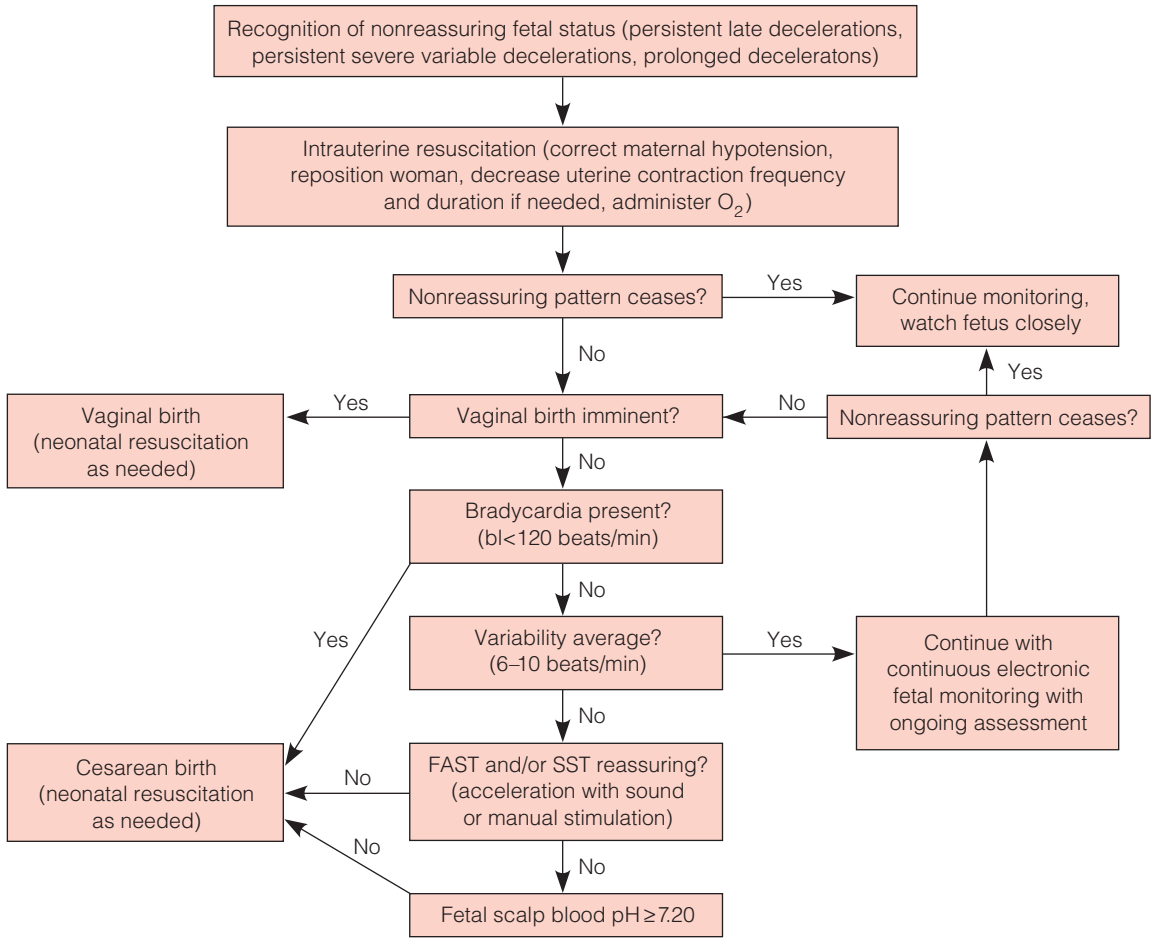

Figure 27-13 ■ Intrapartum management of nonreassuring fetal status.

Note: bl = baseline; FAST = fetal acoustic stimulation test; SST = scalp stimulation test.

Source: From Zuspan, F. P., & Quilligan, E. J. Handbook of obstetrics, gynecology, and primary care. *Copyright 1998, Mosby; reprinted with permission from Elsevier Science.*

explanations of the problem and comfort to the couple. In many instances, if birth is not imminent, the woman must undergo cesarean birth. Anticipation of this surgery may cause fear and frustration for the couple, especially if they were committed to a shared, prepared birth experience.

Evaluation

Expected outcomes of nursing care include the following:

- The woman and her family become less anxious and more able to cope with their situation.
- The FHR remains in normal range, or, alternatively, supportive measures maintain the FHR as normal as possible.

Care of the Woman Experiencing Placental and Umbilical Cord Problems

Placenta Problems

Problems of the placenta can be divided into those that are developmental and those that are degenerative. Developmental problems of the placenta include placental lesions, succenturiate placenta, circumvallate placenta, and battledore placenta (Table 27-3). Degenerative changes include infarcts and placental calcification.

Succenturiate Placenta

In *succenturiate placenta,* one or more accessory lobes of fetal villi have developed on the placenta, with vascular connections of fetal origin (see Table 27-3). Vessels from the major to the minor lobe(s) are supported only by the membranes, thus increasing the risk of the minor lobe's being retained during the third stage of labor.

The gravest maternal danger is postpartal hemorrhage if this minor lobe is severed from the placenta and remains in the uterus. All placentas should be examined closely for intactness. If vessels appear to be severed at the margin of the placenta, the uterus should be explored for retained placental tissue. This condition is not usually diagnosed until after the birth of the placenta.

Fetal/newborn implications can be life threatening if the vascular connections rupture between the placenta lobes because a fatal fetal hemorrhage can result. Examination of the fetal membrane following birth may reveal a small hole with vessels running toward it. This is another indication of a retained lobe (Gibbs et al., 2008). At birth, the infant should be inspected for

TABLE 27-3 Placental and Umbilical Cord Variations

PLACENTAL VARIATION	MATERNAL IMPLICATIONS	FETAL-NEONATAL IMPLICATIONS	
Succenturiate Placenta			
One or more accessory lobes of fetal villi will develop on the placenta.	Postpartal hemorrhage from retained lobe	None, as long as all parts of the placenta remain attached until after birth of the fetus	Circumvallate Placenta			
A double fold of chorion and amnion form a ring around the umbilical cord, on the fetal side of the placenta.	Increased incidence of late abortion, antepartal hemorrhage, and preterm labor	Intrauterine growth restriction, prematurity, fetal death	Battledore Placenta			
The umbilical cord is inserted at or near the placental margin.	Increased incidence of preterm labor and bleeding	Prematurity, fetal stress	Velamentous Insertion of the Umbilical Cord			
The vessels of the umbilical cord divide some distance from the placenta in the placental membranes.	Hemorrhage if one of the vessels is torn	Fetal stress, hemorrhage

pallor, cyanosis, retractions, tachypnea, tachycardia, and feeble pulse. The infant's cry will be weak and the muscle tone flaccid.

Circumvallate Placenta

In *circumvallate placenta,* the fetal surface of the placenta is exposed through a ring opening around the umbilical cord (see Table 27-3). The vessels descend from the cord and end at the margin of the ring instead of coursing through the entire surface area of the placenta. The ring is composed of a double fold of amnion and chorion with some degenerative decidua and fibrin between. The cause of this condition is unknown. Maternal-fetal problems include an increased incidence of late abortion or fetal death, antepartal hemorrhage, prematurity, and abnormal maternal bleeding during or following the third stage of labor, resulting from improper placental separation or shearing of membranes from the placenta.

Battledore Placenta

In *battledore placenta,* the umbilical cord is inserted at or near the placental margin (see Table 27-3). As a result, all fetal vessels transverse the placental surface in the same direction. The chances of preterm labor are high because of interference with fetal circulation and nutrition. Nonreassuring fetal status or bleeding during labor is also likely because of cord compression or vessel rupture.

Placental Infarcts and Calcifications

As the placenta grade matures (previously discussed in chapter 26 ∞), the placenta may develop infarcts and calcifications. They become significant if they cover a large enough area to interfere with the uterine-placental-fetal exchange. Altered exchange can also occur with certain maternal disease processes, such as hypertension. Infarcts are most often seen in cases of severe preeclampsia and in women who smoke.

Umbilical Cord Abnormalities

Umbilical cord abnormalities include congenital absence of an umbilical artery, insertion variations, cord length variations, and knots and loops of the cord. Insertion variations include velamentous insertion and vasa previa, and cord length problems include long and short cords.

Congenital Absence of Umbilical Artery

Absence of an umbilical artery may have serious fetal implications. The incidence of all types of fetal anomalies is 33% and 74% in infants born with two-vessel cords (Gibbs et al., 2008).

Immediately after the umbilical cord is cut, it should be inspected to determine whether the correct number of vessels is present. If an artery is absent, the nurse should examine the newborn closely for anomalies and gestational age problems and alert the attending pediatrician.

Insertion Variations

In a *velamentous insertion,* the vessels of the umbilical cord divide some distance from the placenta in the placental membranes (see Table 27-3). Velamentous insertions occur more frequently in multiple gestations than in singletons. Other placental anomalies, such as succenturiate placenta, often accompany this condition. The velamentous insertion is more easily compressed or kinked during pregnancy or labor because of the lack of Wharton's jelly to protect it. If the vessels become torn during labor, fetal hemorrhage can occur, and the blood can escape from the vagina. When fetal hemorrhage occurs, it results in fetal heart rate (FHR) abnormalities.

When the vessels of a velamentous insertion transverse the internal os and appear in front of the fetus, a vasa previa has occurred. Fetal hemorrhage with asphyxia is likely to result because as the fetal blood escapes out of the vagina the hemorrhage will probably be diagnosed as maternal.

Cord Length Variations

The average length of the umbilical cord is 55 cm. Although short cords rarely cause complications directly, they have been associated with umbilical hernias in the fetus, abruptio placentae, and cord rupture. Long cords tend to twist and tangle around the fetus, causing transient variable decelerations. A long cord rarely causes fetal death, however, because it is generally not pulled tight until descent at the time of birth. With a long cord and an active fetus, one or more true knots can result. Again, these knots usually are not pulled tight enough to cause fetal stress until the infant has been born, and the cord can then be clamped and cut.

Clinical Therapy

The goals of medical treatment are to prevent serious fetal complications and to examine the newborn for anomalies that coexist with umbilical cord abnormalities.

Any vaginal bleeding during labor warrants continuous monitoring of the fetus, preferably with an external electronic monitor. Any signs of nonreassuring heart rate patterns should be reported immediately. In the presence of bleeding, laboratory tests may be used to differentiate fetal from maternal red blood cells. Fetal hemorrhage is resolved by terminating the pregnancy vaginally or through cesarean birth and by correcting neonatal anemia. Expediting the birth, whether vaginally or surgically, is paramount when a severe nonreassuring heart rate pattern is apparent. Following the birth, the pediatric team identifies and treats any neonatal complications or anomalies.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Umbilical abnormalities may not become evident until the birth of the fetus. During labor the nurse should observe for signs of nonreassuring fetal status and excessive bleeding (with velamentous insertion and vasa previa).

Nursing diagnoses that may apply include the following:

- ***Risk for Impaired Gas Exchange (Fetus)*** related to decreased blood flow secondary to placental abnormalities
- ***Deficient Knowledge*** regarding information about placental abnormalities related to an expressed desire to understand the implications of the finding

Nursing Plan and Implementation

The nurse is alert for an unusual amount of bleeding during the labor and birth. Following the birth, the placenta is inspected for abnormalities. Examination of the placenta by a pathologist may be indicated.

Often any mild or moderate variable deceleration can be successfully managed by the nurse. Repositioning of the woman often alleviates pressure on the cord if this is the reason for the deceleration.

Evaluation

Expected outcomes of nursing care include the following:

- The mother and baby have a safe labor and birth.
- The woman's bleeding is assessed quickly, and corrective measures are taken.
- The family is able to cope successfully with fetal or neonatal anomalies, if they exist.

Care of the Woman and Fetus with a Prolapsed Umbilical Cord

An umbilical cord that precedes the fetal presenting part is known as a **prolapsed umbilical cord**. It occurs when the cord falls or is washed down through the cervix into the vagina and becomes trapped between the presenting part and the maternal pelvis. The incidence of cord prolapse is 3% of vertex presentations and 3.7% of all breech presentations. It can also occur in compound presentations. Because of this entrapment, the vessels carrying blood to and from the fetus are compressed. In rare circumstances a prolapsed cord may be visible at the lower edge of the vagina. In other cases, the umbilical cord lies beside or just ahead of the fetal head; this is called *occult cord prolapse.*

Any time that the pelvic inlet is not completely filled by the fetus or the presenting part is not firmly against the cervix, and the membranes rupture, the umbilical cord can be washed down into the birth canal in front of the presenting part (Figure 27-14 ■).

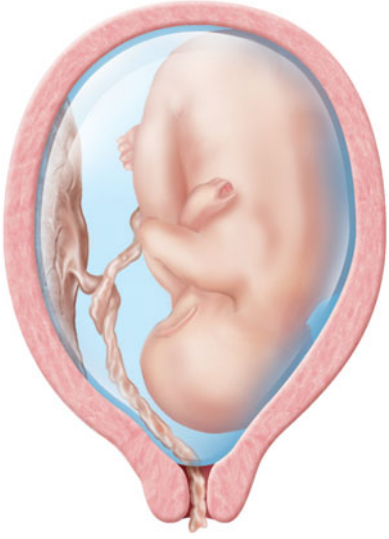

Figure 27-14 ■ Prolapse of the umbilical cord.

Figure 27-15 ■ Knee-chest position is used to relieve cord compression during cord prolapse emergency.

The incidence of prolapse of the cord is 20 times greater with abnormal axis lie (Cunningham et al., 2010)—especially footling breech and shoulder presentations—low birth weight, a multipara with more than five previous births, multiple gestation, polyhydramnios, unengaged presenting part, obstetric manipulation (amniotomy), and the presence of a long cord (longer than 80 cm). Approximately 50% of cord prolapses occur in the second stage of labor. An additional 47% of cord prolapses occur as a result of some obstetric intervention, such as amniotomy, application of fetal scalp electrode, intrapressure catheter, or external cephalic version (Nasser et al., 2006).

Maternal-Fetal-Neonatal Risks

Although a prolapsed cord does not directly precipitate physical alterations in the woman, her immediate concern for the baby creates enormous stress. The woman may need to deal with some unusual interventions, a cesarean birth, and, in some circumstances, death of the fetus.

The fetus is affected because compression of the umbilical cord occludes blood flow through the umbilical vessels. Bradycardia (baseline fetal heart rate [BL FHR]) below 110 beats per minute) and persistent variable decelerations may develop. If labor is occurring, the cord is compressed further with each contraction. If the pressure on the cord is not relieved, the fetus will die.

Clinical Therapy

Preventing the occurrence of cord prolapse is the preferred medical approach. For all laboring women with a history of ruptured membranes, bed rest is usually indicated until engagement with no cord prolapse has been documented. When prolapse does occur, it is usually discovered by the nurse, and relieving the compression of the cord by pushing back the presenting part (discussed shortly) is critical for the fetus. It is also effective to place the woman in a knee-to-chest position to relieve pressure on the cord (Figure 27-15 ■). The method of birth will most likely be cesarean unless a vaginal birth is imminent.

Application: Umbilical Cord Prolapse

Care Plan Activity: Prevention of Cord Prolapse

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

In the intrapartal area, the nurse reviews the nursing history and ascertains whether the woman is likely to be at risk for prolapse

of the cord. Particularly when the presenting part is not engaged and spontaneous or artificial rupture of the membranes occurs, the nurse observes the perineum and assesses the FHR for bradycardia and severe, recurrent, variable decelerations. In addition, the pulsing cord could also be the presenting part, even in cases where dilatation and effacement have not yet occurred.

Nursing diagnoses that may apply to the woman with a prolapsed cord include the following:

- ***Risk for Impaired Gas Exchange (Fetus)*** related to decreased blood flow secondary to compression of the umbilical cord
- ***Fear*** related to unknown outcome

Nursing Plan and Implementation

Because there are few outward signs of cord prolapse, each pregnant woman is advised to call her physician or certified nurse-midwife (CNM) when the membranes rupture and to go immediately to the office, clinic, or birthing facility. A sterile vaginal examination determines whether there is danger of cord prolapse. If the presenting part is well engaged, the risk is minimal and ambulation may be encouraged. If the presenting part is not well engaged, bed rest is recommended to prevent cord prolapse. Maintaining bed rest after rupture of membranes can lead to conflict if the laboring woman and her partner wish to utilize ambulation. The nurse can ease this situation by helping communication between the physician or CNM and the couple.

If membranes have not yet ruptured when the woman arrives at the facility, at the time of spontaneous rupture or amniotomy the fetal heart rate (FHR) should be monitored by electronic fetal monitoring (EFM) or auscultated for at least a full minute and again at the end of a contraction and after a few contractions. In the presence of cord prolapse, EFM tracings show baseline bradycardia or severe, moderate, or prolonged nonperiodic decelerations. If these patterns are found, the nurse performs a vaginal examination.

If a loop of cord is discovered, the nurse's gloved fingers are left in the vagina, and the presenting part is pushed upward to lift the fetal part off the cord and relieve cord compression until the physician or CNM arrives. This is a lifesaving measure. Oxygen is administered, and FHR is monitored by EFM to see if the cord compression is adequately relieved (baseline will rise above 110 beats per minute, and variable decelerations are lessened or relieved). The nurse may also feel pulsation in the cord; however, in some instances a pulsation cannot be felt, and FHR can be detected only by EFM. A large-gauge intravenous cannula is inserted and intravenous fluids should be initiated. Anesthesia and neonatology services should be notified of impending birth.

In some cases, another nurse may insert an indwelling bladder catheter and, using a sterile asepto syringe or infusion device, fill the bladder with approximately 500 ml of warmed, sterile normal saline. The filled bladder lifts the fetal head upward and relieves pressure on the umbilical cord. Filling her bladder and maintaining the woman in a side-lying position may be all that is needed to relieve the pressure on the cord. If the bladder is not filled, the force of gravity can be incorporated. In this instance, the nurse maintains pressure on the presenting part and instructs the woman to bring her knees to her chest or adjusts the bed to the Trendelenburg position. The nurse maintains pressure on the presenting part while the woman is transported to the birthing or operating room in this position. The nurse maintains this position until the fetus is born via cesarean birth.

Evaluation

Expected outcomes of nursing care include the following:

- The FHR remains in normal range with supportive measures.
- The fetus is born safely.
- The woman and her partner feel supported.
- The woman and her partner understand the problem and the corrective measures that are undertaken.

Care of the Woman and Fetus at Risk Because of Anaphylactoid Syndrome of Pregnancy (Amniotic Fluid Embolism)

Anaphylactoid syndrome of pregnancy or **amniotic fluid embolism** occurs when a bolus of amniotic fluid, fetal cells, hair, or other debris enters the maternal circulation and then the maternal lungs. The cause of this obstetric emergency is unknown but has a 60% to 80% mortality rate (Moore, 2008). It is the second leading cause of maternal deaths, resulting in 5% to 10% of all maternal deaths per year in the United States. It occurs in 1 in 8000 to 1 in 30,000 pregnancies (Moore, 2008). Because amniotic fluid embolism is a rare complication, a national registry was initiated in 1988 to collect retrospective data for analysis.

Clinical Therapy

When an amniotic fluid embolism is suspected, intravenous access is obtained as quickly as possible. The crash cart is accessed and on hand so supplies are readily available if a code is indicated. The mother is stabilized and an emergency cesarean birth is warranted. Symptoms generally occur rapidly so a quick response is imperative. Diagnosis is made by symptomology by the physician. Symptoms include shortness of breath, hypoxia, cyanosis, and cardiovascular and respiratory collapse (Creasy et al., 2009). Supportive nursing measures include preparations for an emergency birth and transfer of the mother to the intensive care unit after surgery is completed.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Nursing diagnoses that may apply to the woman with a prolapsed cord include the following:

- ***Risk for Impaired Gas Exchange (Fetus)*** related to decreased blood flow secondary to maternal hypoxia

- ***Risk for Impaired Gas Exchange (Mother)*** related to decreased blood flow secondary to amniotic fluid embolism
- ***Fear*** related to unknown outcome

Nursing Plan and Implementation

In the absence of the physician or certified nurse-midwife (CNM), the nurse administers oxygen under positive pressure until medical help arrives. An intravenous line is quickly established. If respiratory and cardiac arrest occurs, cardiopulmonary resuscitation (CPR) is initiated immediately. The obstetrician and anesthesiologist should be called immediately. If a perinatologist and/or hospital intensivist is on staff, they should also be called.

The nurse readies the equipment necessary for blood transfusion and for the insertion of the central venous pressure (CVP) line. As the blood volume is replaced, using fresh whole blood to provide clotting factors, the CVP is monitored frequently. In the presence of cor pulmonale, fluid overload could easily occur. The fetus is continually monitored. In women who are unresponsive to CPR, an emergent cesarean birth should be performed in an effort to save the fetus. CPR is continued throughout the cesarean procedure.

Evaluation

- The mother is treated with appropriate interventions to achieve stabilization.
- The fetus is delivered safely via cesarean birth.
- The family is informed and supported during emergency procedures.

Care of the Woman with a Uterine Rupture

Uterine rupture is a nonsurgical disruption of the uterine cavity. The incidence of uterine rupture is approximately 1 in 2000 births (Gabbe et al., 2007). A complete rupture is one in which the endometrium, myometrium, and serosa have separated. An *incomplete or partial rupture* is one in which not all layers, but some, have been disrupted. The extent of maternal and fetal distress is proportional to the degree of rupture. Rupture preceding labor is rare. It is most commonly associated with a previous uterine incision that ruptures during the labor process. It can also be caused from uterine manipulation (such as a version), an operative vaginal delivery, abdominal trauma, interval of birth between deliveries less than 18 months, postpartum fever during a previous cesarean birth, or a one-layer closure performed with a previous cesarean birth (Gabbe et al., 2007).

Clinical Therapy

Uterine rupture can only be diagnosed via a surgical incision, but suspected uterine rupture is based on maternal and fetal symptomology. If the rupture is accompanied by vaginal bleeding, the nurse initiates a pad count to keep track of bleeding. Preparations are made for an emergency birth and neonatology services are obtained if available in the practice setting. Neonatal resuscitation should be anticipated.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

A nonreassuring fetal heart rate is commonly the earliest warning sign of a possible uterine rupture. It is sometimes associated with variable or late decelerations, followed by bradycardia (Gabbe et al., 2007). Upon palpation, there may be loss of a fetal station since the presenting part is no longer being held in place by the uterine wall. Maternal symptoms include constant abdominal pain, uterine tenderness, change in uterine shape, cessation of contractions, hematuria, and signs of shock. Uterine rupture can be suspected clinically but is confirmed surgically.

Nursing Plan and Implementation

When a nonreassuring fetal pattern is identified, the physician or certified nurse-midwife (CNM) is immediately contacted. Risk factors for uterine rupture should be reviewed. Women with a previous history of cesarean birth or uterine surgery are at risk for uterine rupture. Maternal signs and symptoms should be assessed, including pain, bleeding, and hematuria. Leopold's maneuvers and maternal vital signs should be performed. Birth via cesarean is warranted. The nurse prepares the woman for an emergency cesarean birth. The anesthesiologist should be called immediately. Blood should be typed and matched for possible transfusion. An additional intravenous line using an 18 gauge or larger cannula is placed. During the cesarean birth, the degree of rupture is assessed. If the uterus is unable to be repaired or if the mother is hemodynamically unstable, a hysterectomy is performed.

Nursing diagnosis for women experiencing a uterine rupture include the following:

- ***Risk for Impaired Gas Exchange (Fetus)*** related to decreased blood flow secondary to uterine rupture
- ***Risk for Impaired Gas Exchange (Mother)*** related to decreased blood flow secondary to uterine rupture
- ***Fear*** related to unknown outcome
- ***Anxiety*** related to emergency procedures and unknown fetal outcome
- ***Impaired Individual Coping*** due to emergent situation secondary to uterine rupture.

Evaluation

- The mother remains hemodynamically stable throughout emergency cesarean birth.
- The fetus retains optimal oxygenation until a safe birth is achieved.

Care of the Woman with Cephalopelvic Disproportion

The birth passage includes the maternal bony pelvis, beginning at the pelvic inlet and ending at the pelvic outlet, and the maternal soft tissues within these anatomic areas. A contracture (narrowing) in any of the described areas can result in **cephalopelvic disproportion (CPD)**. Abnormal fetal presentations and positions occur in CPD as the fetus moves to accommodate passage through the maternal pelvis.

TABLE 27-4 Clues to Contractures of Maternal Pelvis

- Diagonal conjugate less than 11.5 cm (contracture of inlet), outlet less than 8 cm (contracture of outlet)
- Unengaged fetal head in early labor in primigravidas (consider contracture of inlet, malpresentation, or malposition)
- Hypotonic uterine contraction pattern (consider contracted pelvis)
- Deflexion of fetal head (fetal head not flexed on fetal chest; may be associated with occiput posterior)
- Uncontrollable pushing before complete dilatation of cervix (may be associated with occiput posterior)
- Failure of fetal descent (consider contracture of inlet, midpelvis, or outlet)
- Edema of anterior portion (lip) of cervix (consider obstructed labor at the inlet)

The gynecoid and anthropoid pelvic types are usually adequate for vertex birth, but the android and platypelloid types predispose to CPD. Certain combinations of types also can result in pelvic diameters inadequate for vertex birth. (See chapter 10 ∞ for a description of the types of pelves and their implications for childbirth.) Clues that may lead to suspicion of contractures of the maternal pelvis are presented in Table 27-4. Women with a history of pelvic fractures may also be at risk for CPD (Cunningham et al., 2010).

Types of Contractures

There are two types of contractures: contractures of the inlet and contractures of the outlet.

Contractures of the Inlet

The pelvic inlet is contracted if the shortest anterior-posterior diameter is less than 10 cm or the greatest transverse diameter is less than 12 cm. The anterior-posterior diameter may be approximated by measuring the diagonal conjugate, which in the contracted inlet is less than 11.5 cm. Clinical and x-ray pelvimetry are used to determine the smallest anterior-posterior diameter through which the fetal head must pass.

The treatment goal is to allow the natural forces of labor to push the biparietal diameter of the fetal head beyond the potential interspinous obstruction. Although forceps may be used, they cause difficulty because pulling on the head destroys flexion and because they further diminish the available space. A bulging perineum and crowning indicate that the obstruction has been passed.

Contractures of the Outlet

An interischial tuberous diameter of less than 8 cm constitutes an outlet contracture. Outlet and midpelvic contractures frequently occur simultaneously. Whether vaginal birth can occur depends on the woman's interischial tuberous diameters and the fetal posterosagittal diameter.

Implications of Pelvic Contractures

Labor is prolonged and protracted in the presence of CPD, and premature rupture of the membranes (PROM) can result from the force of the unequally distributed contractions being exerted on the fetal membranes. In obstructed labor (the fetus is not able to pass through the birth canal), uterine rupture can also occur. With delayed descent, necrosis of maternal soft tissues can result from pressure exerted by the fetal head. Eventually, necrosis can cause fistulas from the vagina to other nearby structures. Difficult forceps-assisted births can also result in damage to maternal soft tissue.

If the membranes rupture and the fetal head has not entered the inlet, there is a danger of cord prolapse. Extreme molding of the fetal head can result. Traumatic forceps-assisted births can damage the fetal skull and CNS.

Clinical Therapy

Fetopelvic relationships can be assessed by comparing the estimated weight of the fetus as obtained by ultrasound measurements to pelvic measurements obtained by a manual examination before labor and by computed tomography (CT). Occasionally, in high-risk centers magnetic resonance imaging (MRI) is used to identify adequacy of pelvic diameters.

When the pelvic diameters are borderline or questionable, a trial of labor (TOL) may be advised. In this process the woman continues to labor, and careful assessments of uterine contractions, cervical dilatation, and fetal descent are made by the certified nurse-midwife (CNM) or physician and nurse. As long as there is continued progress, the TOL continues. If progress ceases, the decision for a cesarean birth is made.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The adequacy of the maternal pelvis for a vaginal birth should be assessed intrapartally as well as antepartally. During the intrapartal assessment, the size of the fetus and its presentation, position, and lie must also be considered. (See chapter 23 ∞ for intrapartal assessment techniques.)

The nurse should suspect CPD when labor is prolonged, cervical dilatation and effacement are slow, and engagement of the presenting part is delayed or lack of fetal descent occurs.

Nursing diagnoses that may apply include the following:

- ***Deficient Knowledge*** related to lack of information about implications of CPD
- ***Fear*** related to unknown outcome of labor

Nursing Plan and Implementation

Nursing actions during the TOL are similar to care during any labor, with the exception that the assessments of cervical dilatation and fetal descent are done more frequently. Contractions should be monitored and the labor progress charted. The fetus should also be monitored frequently. Any signs of fetal stress are reported to the physician or CNM immediately.

The woman may be positioned in a variety of ways to increase the pelvic diameters. Sitting or squatting increases the outer diameters and may be effective in instances where there is failure of or slow fetal descent. Changing from one side to the other or maintaining a hands-and-knees position may assist the fetus in occiput posterior (OP) position to change to an occiput anterior (OA) position. The woman may instinctively

want to assume one of these positions. If not, the nurse may encourage a change of position. Women with an epidural may use position changes with adequate support.

A couple may need help in coping with the stresses of complicated labor. The nurse should keep the couple informed of what is happening and explain the procedures that are being used. This should reassure the couple that measures are being taken to resolve the problem.

Evaluation

Expected outcomes of nursing care include the following:

- The woman's fear is lessened.
- The woman has additional knowledge regarding the problems, implications, and treatment plans.

Care of the Woman at Risk Because of Complications of Third and Fourth Stages of Labor

Common complications of the third and fourth stages of labor include retained placenta, lacerations, and placenta accrete (Cunningham et al., 2010).

Retained Placenta

Retention of the placenta beyond 30 minutes after birth is termed **retained placenta**. It occurs in 2% to 3% of all vaginal births. Bleeding as a result of a retained placenta can be excessive. If placenta expulsion does not occur, a manual removal of the placenta by the physician or certified nurse-midwife (CNM) is attempted. In women who do not have an epidural in place, intravenous sedation may be required because of the discomfort caused by the procedure. Retained placenta may be a symptom of an accreta, increta, or percreta (to be discussed shortly). Failure to retrieve the placenta via manual removal usually necessitates surgical removal by curettage. If the woman does not have an epidural in place, the procedure can be performed under general anesthesia.

Lacerations

Lacerations of the cervix or vagina may be present when bright red vaginal bleeding persists in the presence of a well-contracted uterus. The incidence of lacerations is higher among childbearing women who are young, are nulliparous, have an epidural block, undergo forceps-assisted or vacuum-assisted birth, or undergo an episiotomy. Vaginal and perineal lacerations are often categorized in terms of degree:

- First-degree laceration is limited to the fourchette, perineal skin, and vaginal mucous membrane.
- Second-degree laceration involves the perineal skin, vaginal mucous membrane, underlying fascia, and muscles of the perineal body; it may extend upward on one or both sides of the vagina.
- Third-degree laceration extends through the perineal skin, vaginal mucous membranes, and perineal body and involves the anal sphincter; it may extend up the anterior wall of the rectum.
- Fourth-degree laceration is the same as the third degree but extends through the rectal mucosa to the lumen of the rectum; it may be called a third-degree laceration with a rectal wall extension.

Placenta Accreta

In **placenta accreta**, the chorionic villi attach directly to the myometrium of the uterus. Two other types of placental adherence are **placenta increta**, in which the myometrium is invaded, and **placenta percreta**, in which the myometrium is penetrated. These placenta adherent disorders can be life threatening. The adherence itself may be total, partial, or focal, depending on the amount of placental involvement. The incidence of placenta accreta is 1 in 2500 births (Cunningham et al., 2010). Placenta accreta is the most common type of adherent placenta. Previous cesarean births increase the risk of placenta accreta. This is of concern with the rapidly rising cesarean section rate within the United States.

The primary complication of placenta accreta is maternal hemorrhage and failure of the placenta to separate following birth of the infant. An abdominal hysterectomy may be the necessary treatment, depending on the amount and depth of involvement. Chapter 39 ∞ discusses hemorrhage following birth.

The at-risk conditions during labor discussed in this chapter can, in some cases, lead to fetal demise. See chapter 38 ∞ for an in-depth discussion of caring for the family experiencing perinatal loss.

FOCUS YOUR STUDY

- Intense anxiety; fear; loss of orientation to person, place, or time; or other inappropriate behaviors may be associated with an underlying psychologic disorder that results in difficulties with coping.
- Hypotonic labor patterns begin normally and then progress to infrequent, less intense contractions. If there are no contraindications, oxytocin is administered intravenously as treatment.
- Precipitous labor and birth is extremely rapid labor and birth that lasts less than 3 hours. It is associated with an increased risk to the mother and newborn infant.
- Postterm pregnancy is one that extends more than 294 days, or 42 weeks, past the first day of the last menstrual period.
- The occiput-posterior position of the fetus prolongs the labor process, causes severe back discomfort in the laboring woman, and predisposes her to vaginal and perineal trauma and lacerations during birth.
- The types of fetal malpresentations include face, brow, breech, and shoulder.
- A fetus or newborn weighing more than 4000 g is termed *macrosomic.* Macrosomia may lead to problems during labor and birth and in the early neonatal period.
- Prolapsed umbilical cord results when the umbilical cord precedes the fetal presenting part. When this occurs, pressure is placed on the umbilical cord, and blood flow to the fetus is diminished.
- Anaphylactoid syndrome of pregnancy or amniotic fluid embolism occurs when a bolus of amniotic fluid enters the maternal circulation and then enters the maternal lungs. Maternal mortality is very high with this complication.
- Uterine rupture occurs when the layers of the uterine cavity are separated by a nonsurgical event and requires an emergency cesarean birth be performed immediately.
- Cephalopelvic disproportion occurs when there is a narrowed diameter in the maternal pelvis. The narrowed diameter is called a contracture, and it may occur in the pelvic inlet, midpelvis, or outlet. If pelvic measurements are borderline, a trial of labor may be attempted. Failure of cervical dilatation or fetal descent would then necessitate a cesarean birth.
- Third- and fourth-stage complications usually involve a hemorrhage. Causes of hemorrhage include lacerations of the birth canal or cervix, retained placenta, and placenta accreta.
- Nonreassuring fetal status is indicated by persistent late decelerations, persistent severe variable decelerations, and prolonged decelerations. If fetal stress is recognized and treated appropriately, the fetus may be spared any permanent damage.

CRITICAL THINKING IN ACTION

Source: George Dodson/Pearson Education.

June Dice, a 25-year-old G3, P1011, is admitted to labor and delivery at 38 weeks with a moderate amount of dark red vaginal bleeding. June's prenatal history is significant for late prenatal care (20 weeks' gestation by ultrasound) and cocaine abuse. An ultrasound is done upon admission that demonstrates a marginal placenta abruption. You place June on the fetal monitor and observe a fetal heart rate baseline of 146 to 155 with accelerations to 166 with fetal movement. There are occasional mild variable decelerations with a quick return to baseline. Contraction pattern is interpreted as an irritable uterus. An intravenous infusion with Ringer's lactate is started with a #18 intracath. June's vital signs are within normal limits. Her hematocrit is 29%. You assist the physician with a vaginal exam to rupture membranes and insert a fetal scalp electrode and intrauterine pressure catheter. A small amount of light, yellow-green amniotic fluid is observed. The exam shows June is 4 cm dilated, 50% effaced, vertex at –1 station. You follow protocol and start an oxytocin induction/augmentation. June is asking why oxytocin is needed.

1. Explain the goal of labor induction/augmentation in response to June's question.
2. Explain potential risk factors associated with oxytocin induction of labor.
3. You observe a nonreassuring fetal heart rate of 144 to 150 with decreased variability, and persistent late decelerations with each contraction. What interventions would you immediately take?
4. What supportive actions are taken to decrease the risk of hypofibrinogenemia?
5. What complications might be present in the newborn at birth?

See www.nursing.pearsonhighered.com for possible responses.

CHAPTER 28

Birth-Related Procedures

With our first baby I suddenly had to have a cesarean. Everything happened so fast, but our son was OK, and that's all that mattered. With our second baby, I wanted to try for a vaginal birth but nevertheless I was afraid. I don't know what I would have done without my nurse. She stayed with me the whole time I labored and kept giving me support. She explained everything, so I knew what was happening. I felt safe. I had a beautiful baby girl after 8 hours of labor. Everything went well postpartally, and I am so glad I was able to avoid another cesarean. We don't plan to have another baby, but if we did, I wouldn't be so afraid.

LEARNING OUTCOMES

1. Describe the impact of selected procedures on the childbearing woman and her family or support system.
2. Contrast the methods of external cephalic version and internal version and the related nursing management.
3. Discuss the use of amniotomy in current maternal-newborn care.
4. Compare methods for inducing labor, explaining their advantages and disadvantages.
5. Discuss the use of transcervical intrapartum amnioinfusion.
6. Describe the types of episiotomies performed, the rationale for each, and the associated nursing interventions.
7. Summarize the indications for forceps-assisted birth, types of forceps that may be used, complications, and related interventions.
8. Discuss the use of vacuum extraction, including indications, procedure, complications, and related nursing management.
9. Explain the indications for cesarean birth, impact on the family unit, preparation and teaching needs, and associated nursing management.
10. Discuss vaginal birth following cesarean birth.

KEY TERMS

Amnioinfusion (AI) *740*
Amniotomy *736*
Cervical ripening *728*
Cesarean birth *748*
Episiotomy *741*
External cephalic version (ECV) *725*
Forceps-assisted birth *743*
Labor augmentation *731*
Labor induction *731*
Podalic version *725*
Vacuum extraction *745*
Vaginal birth after cesarean (VBAC) *752*

Most births occur without the need for operative obstetric intervention. In some instances, however, obstetric procedures are necessary to maintain the safety of the woman and the fetus. The most common obstetric procedures are electronic fetal monitoring, version, amniotomy, induction of labor, episiotomy, cesarean birth, and vaginal birth following a previous cesarean birth.

Generally, women are aware of the possible need for an obstetric procedure during their labor and birth, and many women accept whatever procedure is recommended based on the belief that the caregiver knows what is needed and that it is in the baby's best interest. However, some women expect to have a "natural" birth experience and do not desire or anticipate any medical intervention. These women may feel disappointed or even guilty when an unanticipated obstetric procedure is needed. The nurse can provide information regarding any procedure to enhance the understanding of the woman and her partner of what is proposed, the anticipated benefits and possible risks, and any possible alternative treatments.

The nurse must provide emotional support to the woman and her family to assist them in accepting the unanticipated procedure. Although the physical responses to interventions are constantly monitored and documented, it is especially important for nurses to continually assess and document the family's emotional responses to interventions. Many times it is the nurse who plays a key role in emotional support and teaching. The importance of this role is just as imperative to any physical care that the nurse performs for the laboring woman and her family.

Care of the Woman During Version

Version, or turning the fetus, is a procedure used to change the fetal presentation by abdominal or intrauterine manipulation. The most common type of version is **external cephalic version (ECV)** in which the fetus is changed from a breech, transverse, or oblique lie to a cephalic presentation by external manipulation of the maternal abdomen (Figure 28-1 ■). The success rates for version are the highest for transverse presentations. Overall, success rates for version average 60% (Cunningham et al., 2010). Successful ECVs decrease the chances of nonvertex and cesarean births.

The other type of version, called a **podalic version** (also called an *internal version*), is used only with the second twin during a vaginal birth. In an internal version, the obstetrician places a hand inside the uterus, grabs the fetus's feet, and then turns the fetus from a transverse or noncephalic presentation to a breech presentation (Figure 28-2 ■). The fetus is then born in a breech presentation. This maneuver is used only when the second twin is not in a cephalic position. It is considered superior to an external cephalic version because it causes fewer decelerations (Cunningham et al., 2010). Some obstetricians may elect to have the second twin be born by cesarean if the twin is not in a cephalic presentation.

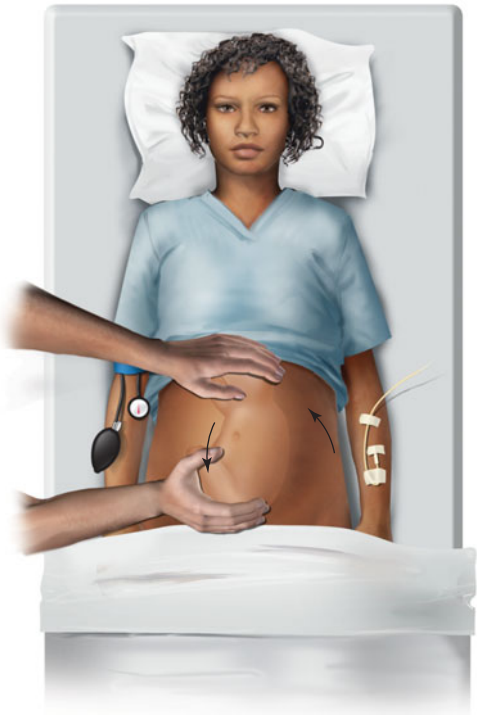

Figure 28-1 ■ External (or cephalic) version of the fetus. A new technique involves applying pressure to the fetal head and buttocks so that the fetus completes a "backward flip" or "forward roll."

External Cephalic Version

If breech or shoulder presentation (transverse lie) is detected in the later weeks of pregnancy, an external cephalic version (ECV) may be attempted. The version is usually done after 36 to 37 weeks' gestation because most fetuses still in breech presentation at this time will not spontaneously change back to a vertex presentation. This provides time for the fetus to assume a vertex position spontaneously. In addition, if complications arise from the procedure, the risk of prematurity is eliminated. Even when ECV is successful, there is some evidence that the stress of the procedure may increase the rate of intrapartum cesarean births. Breech fetuses have been shown to have smaller head circumferences, lower birth weight, and lower fetoplacental ratios. Fetuses that were previously breech tend to have higher rates of nonreassuring fetal status and dystocia. These mothers may also have a smaller pelvis, which may be the cause of the breech presentation in the first place (Creasy, Resnik, Iams, et al., 2008). Factors associated with higher success rates include higher parity, adequate amniotic fluid, lack of fetal engagement, transverse lie, a palpable fetal head, and a relaxed uterus (Cunningham et al., 2010; Kok et al., 2008). Factors associated with higher failure rates include nulliparity, advanced dilatation, fetal weight less than 2500 g, anterior placenta, a low station, maternal obesity, decreased amniotic fluid volume, and anterior or posterior positioning of the fetal spine (Cunningham et al., 2010).

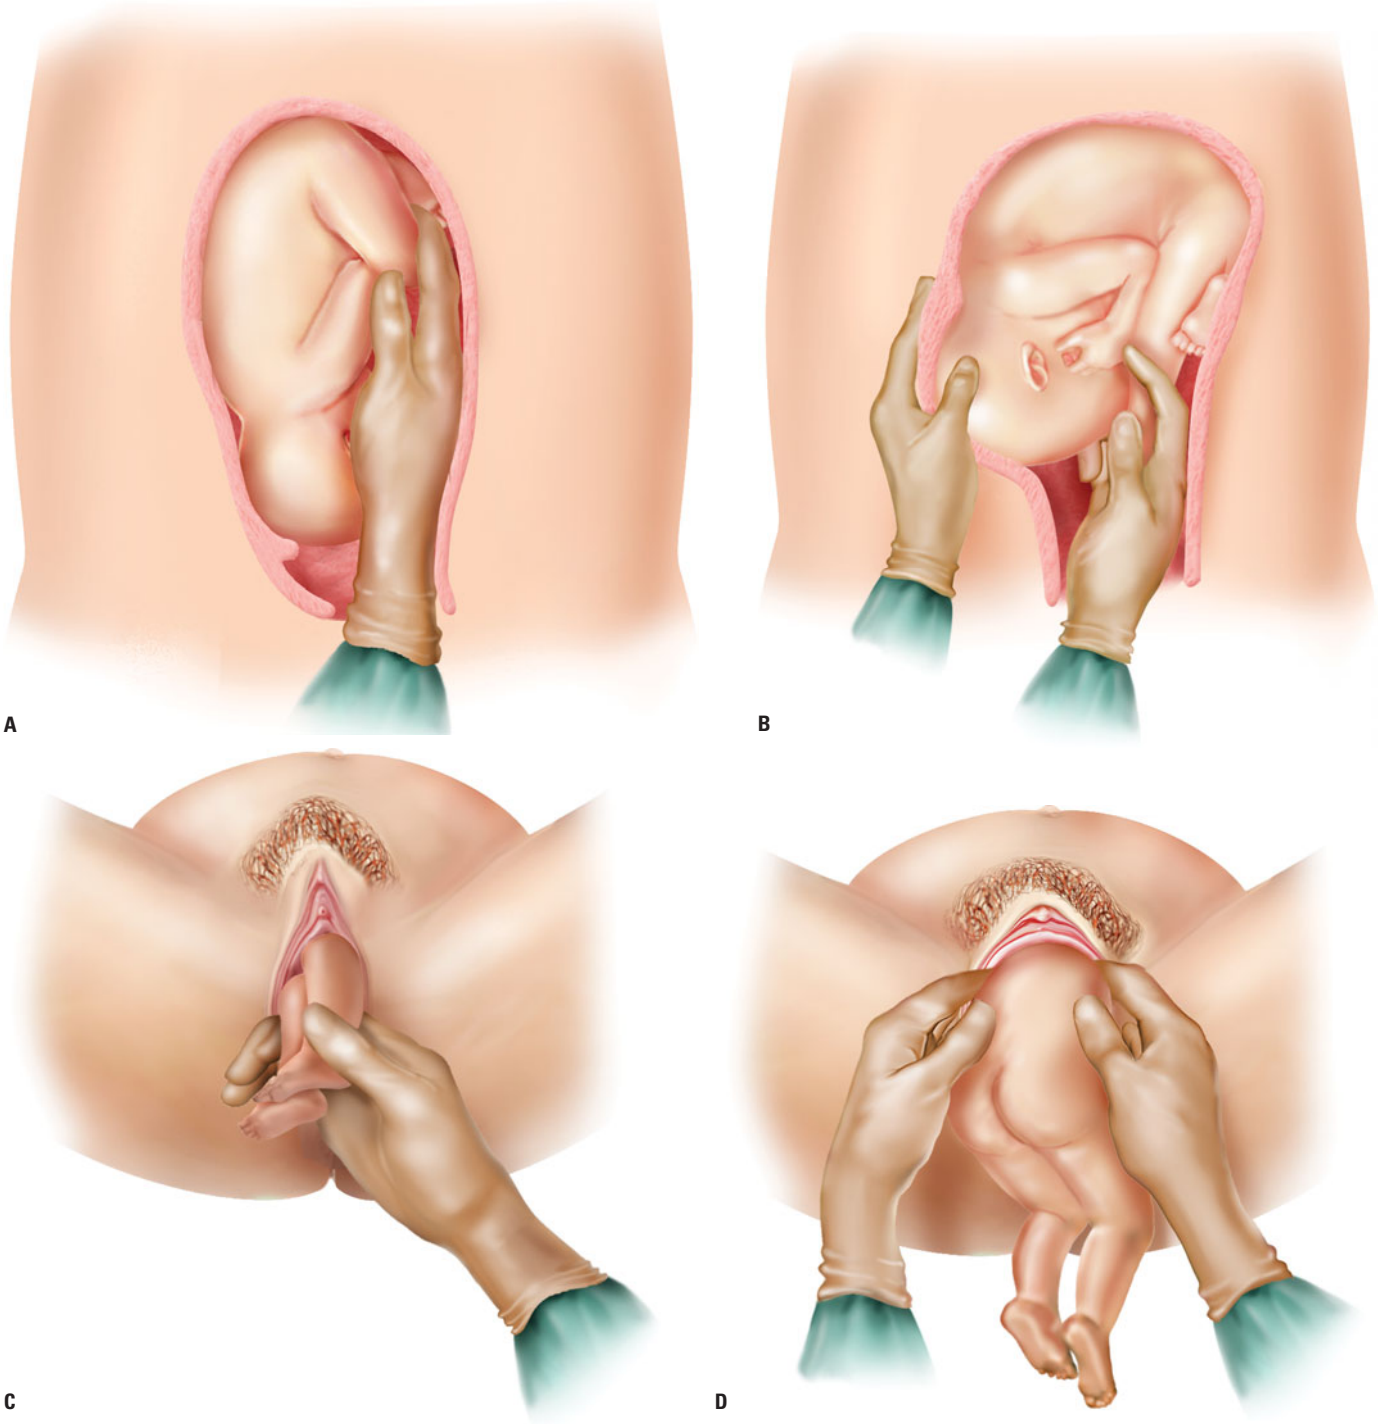

Figure 28-2 ■ Use of podalic version and extraction of the fetus to assist in the vaginal birth of the second twin. A. The physician reaches into the uterus and grasps a foot. Although a vertex birth is always preferred in a singleton birth, in this instance of assisting in the birth of a second twin it is not possible to grasp any other fetal part. The fetal head would be too large to grasp and pull downward, and grasping the fetal arm would result in a transverse lie and make vaginal birth impossible. B. While applying pressure on the outside of the abdomen to push the baby's head up toward the top of the uterus with one hand, the physician pulls the baby's foot down toward the cervix. C. Both feet have been pulled through the cervix and vagina. D. The physician now grasps the baby's trunk and continues to pull downward on the baby to assist the birth.

Criteria for External Version

The following criteria should be met before performing ECV (Creasy et al., 2008):

- A single fetus (also called a singleton) must be present. If a multiple gestation exists, a variety of concerns preclude an external version. For example, a cesarean rather than vaginal birth may need to be considered, and the fetuses might become entangled during a version.
- The fetal breech is not engaged. Once the presenting part is engaged, it is difficult, if not impossible, to do a version.
- An adequate amount of amniotic fluid must exist. The amniotic fluid helps ease movement of the fetus and provides adequate room for the umbilical cord to float without being compressed.
- A reactive nonstress test (NST) should be obtained immediately before performing the version. A reactive NST indicates fetal well-being.
- The fetus must be 36 to 37 or more weeks' gestation. A version may be accompanied by complications that require immediate birth by cesarean. If gestation is less than 37 weeks, a preterm birth would result.

(*Note:* Occasionally, a physician may do an external version while the woman is in early labor before the presenting part has become engaged.)

Contraindications for External Version

Absolute contraindications to ECV include the following (Cunningham et al., 2010):

- ***Suspected intrauterine growth restriction.*** The fetus has been stressed and amniotic fluid may be decreased.
- ***Fetal anomalies.*** This category includes major abnormalities.
- ***Presence of an abnormal fetal heart rate (FHR) tracing.*** A nonreassuring FHR pattern might indicate that the fetus is already stressed and other action needs to be taken.
- ***Rupture of the membranes.*** Rupture of the membranes would result in an inadequate amount of amniotic fluid.
- ***Cesarean birth indicated anyway.*** ECV should not be attempted if there is a contraindication to vaginal delivery.
- ***Maternal problems.*** Maternal problems include gestational diabetes that has required insulin, uncontrolled chronic hypertension, preeclampsia, or maternal cardiac disease.
- ***Amniotic fluid abnormalities.*** Oligohydramnios (amniotic fluid index less than 5 cm) makes the fetus difficult to maneuver and increases risk of umbilical cord compression. Hydramnios (amniotic fluid index greater than 25 cm) stretches the uterine walls, increasing pressure and decreasing the chance the fetus will remain in a cephalic presentation.

Relative contraindications to ECV include the following:

- ***Previous lower uterine segment cesarean birth.*** Prior scarring of the uterus may increase the risk of uterine tearing or uterine rupture.
- ***Nuchal cord.*** A nuchal cord may tighten around the fetal neck and decrease circulation to the fetus.
- ***Multiple gestation.***
- ***Evidence of uteroplacental insufficiency.***
- ***Significant third trimester bleeding.***
- ***Uterine malformation.***

External Version Procedure

The external version is accomplished in a birthing unit, rather than an outpatient setting, in case further intervention (such as emergency cesarean birth) is necessary. There have been no reported fetal deaths from the procedure since 1980. The risk of major complications resulting from an ECV has been reported as 1% to 2%. A systematic review with a total of 2503 women in 11 studies of adverse outcomes of ECV found no increased risk of antepartum fetal death, uterine rupture, placental abruption, prelabor rupture of membranes, or cord prolapse (Nassar et al., 2006).

The woman is instructed to fast for 8 hours preceding the version in case a cesarean birth needs to be performed because of complications. The physician uses ultrasound to confirm the presence of a single fetus, the amount of amniotic fluid, the location of the placenta, the position of the umbilical cord, and that a breech presentation still exists. Maternal vital signs are assessed, and continuous electronic fetal monitoring (EFM) is done to evaluate the fetal heart rate (FHR), to obtain a reactive NST, and to evaluate the presence of uterine activity. Blood work may be drawn, including a complete blood count (CBC) and a blood type and antibody screen (if not already available). The physician explains the procedure and the patient signs a consent form.

An intravenous line is established for medication administration and in case of difficulties. A beta-mimetic agent (a subcutaneous dose of terbutaline) or intravenous infusion of magnesium sulfate (if a beta-mimetic agent is contraindicated because of a medical condition) is administered to achieve uterine relaxation. Occasionally, some physicians do not use a beta-mimetic agent during the version. However, it greatly enhances the comfort of the woman. The use of epidural and spinal analgesia has been found to increase success rates, although further research is needed (Cunningham et al., 2010; Weiniger et al., 2007).

The woman is placed in a supine or slight Trendelenburg position. Once uterine relaxation is achieved, the maternal abdomen is copiously covered with warmed ultrasound gel to decrease excessive manipulation and friction, and the physician grasps the fetal breech between the index finger and the thumb. First the presenting part is gently pushed upward or lifted out of the maternal pelvis by exerting pressure over the skin on the maternal abdomen. If the fetal breech can be lifted out, then the breech and head are rotated or moved out in opposite directions. In most cases, a direction similar to a forward roll is attempted initially. If that is not successful, a roll in the opposite direction is attempted. The procedure should be concluded when any of the following occur: the fetal head is moved to a head-down position; repeated failures have occurred; the woman has indicated that the procedure has become too painful or stressful; or signs of maternal or fetal problems occur, including a nonreassuring FHR pattern (Cunningham et al., 2010). The intravenous tocolytic agent is

discontinued, and frequently the fetus is held in the new presentation by either the physician or the nurse until the uterus regains tone. In the event of a failed version, a repeat attempt can be made within a week if the procedure was well tolerated by the woman and her fetus. The risk of maternal-fetal hemorrhage is 2.4% (Boucher, Marquette, Varin, et al., 2008). (See chapter 20 ∞). Ultrasound is performed to confirm the fetal position. A vaginal examination may be performed to evaluate cervical dilatation and fetal descent; however, there is no evidence to support the routine practice of immediate induction of labor to minimize reversion (American College of Obstetricians and Gynecologists (ACOG), 2008). Spontaneous reversion can also occur, but the risk is decreased with term gestations compared with earlier gestations (ACOG, 2008).

External cephalic version has been the subject of several recent systematic evidence reviews. A recent review of interventions (tocolysis, vibroacoustic stimulation of the fetus, epidural or spinal anesthesia, and amnioinfusion) to facilitate ECV in term infants found routine tocolysis was likely to increase the success rates of ECV (Collaris & Tan, 2009).

A recent evidence review of the efficacy of moxibustion to assist in turning a baby from its breech position found positive results. Moxibustion is a type of Chinese medicine that involves burning an herb close to the skin. Evidence was found to support its use in correcting a breech presentation, and it was noted that moxibustion may be beneficial in reducing the need for ECV (Li, Hu, Wang, et al., 2009).

NURSING CARE MANAGEMENT

The nurse begins by ensuring that the expectant woman understands the procedure, knows that the procedure may be uncomfortable or very painful, and realizes that she can tell the physician to stop if the pain is too great.

The possibility of failure of the ECV and the slight risk of a cesarean birth if the fetus exhibits a nonreassuring fetal status should also be discussed. Before the version, the nurse explains the procedure and possible outcomes, then completes initial maternal and fetal assessments, provides ongoing evaluation of FHR, and performs the NST. The nurse obtains blood work and alerts the obstetrical team regarding the procedure in the rare event that a cesarean birth should be necessary. The nurse provides psychologic support through reassurance and continuous explanations throughout the procedure. The nurse continues to monitor maternal blood pressure and pulse about every 2 minutes throughout the period of time the beta-mimetic agent is used and for about 30 minutes after. The FHR is monitored for approximately 1 to 2 hours following the ECV. The nurse also assesses the maternal-fetal response to the tocolytic agent. The nurse continues to provide information by reiterating aftercare instructions, such as monitoring for uterine contractions, being aware of fetal movement (fetal kick counts), and recognizing signs of reversion (excessive movement or a sensation described as the fetus "turning around").

Care of the Woman During Cervical Ripening

Induction of labor may be necessary or beneficial in certain clinical situations. When the cervix is unfavorable, the use of cervical ripening agents increase the likelihood of a successful induction of labor (see Bishop Score and Table 28-3 ∞ on page 732). Misoprostol (Cytotec) and formulations of Prostaglandin E_2 (PGE_2) gel for **cervical ripening** (softening and effacing the cervix) are drugs that may be used for the pregnant woman at or near term when there is a medical or obstetric indication for induction of labor. Mechanical methods designed to ripen the cervix employ the use of balloon catheters to encourage mechanical dilatation.

Use of Misoprostol (Cytotec)

Misoprostol (Cytotec) is a synthetic PGE_1 analogue that can be used to soften and ripen the cervix and to induce labor. It is available as a tablet that is inserted into the vagina, or it can be taken orally or sublingually. The use of Cytotec for cervical ripening has fluctuated. Cytotec was widely used in the 1990s for cervical ripening and induction of labor until several reports showed an increase in the rates of uterine rupture. However, there is now a large body of research that supports its safety and efficacy when used appropriately (ACOG, 2009b). Cytotec is approved by the U.S. Food and Drug Administration (FDA) for prevention of peptic ulcer disease and has had special labeling for indication of cervical ripening and induction of labor since 2002 (ACOG, 2009b).

Research has shown that Cytotec used in ripening the cervix and inducing labor is more effective than oxytocin or prostaglandin agents and is less costly. Women who receive Cytotec to induce labor typically deliver within 24 hours of administration. The use of Cytotec is also associated with lower cesarean birthrates. When compared with women who have been induced using prostaglandin agents or oxytocin, the adverse outcomes do not differ among the three methods (ACOG, 2009b). Most adverse maternal and fetal outcomes associated with misoprostol have been associated with doses beyond the recommended 25 mcg. Misoprostol intravaginally has been found to be as efficacious or superior to dinoprostone gel (Cunningham et al., 2010). Guidelines for misoprostol induction include (ACOG, 2009a):

- The initial dosage should be 25 mcg.
- Recurrent administration should not exceed dosing intervals of more than 3 to 6 hours.
- Pitocin should not be administered less than 4 hours after the last Cytotec dose.
- Cytotec should only be administered where the uterine activity and fetal heart rate (FHR) can be monitored continuously for an initial observation period.

Contraindications for Cytotec include the following (AAP/ACOG, 2007):

- Nonreassuring FHR tracing.
- Frequent uterine contractions of moderate intensity.

DRUG GUIDE Dinoprostone (Cervidil) Vaginal Insert

PREGNANCY RISK CATEGORY: C

OVERVIEW OF MATERNAL-FETAL ACTION

Dinoprostone is a naturally occurring form of prostaglandin E_2. Dinoprostone can be used at term to ripen the cervix and can stimulate the smooth muscle of the uterus to enhance uterine contractions. A single vaginal insert may be used to ripen the cervix and then oxytocin can be administered 30 minutes later (Forest Pharmaceuticals, 2006).

ROUTE, DOSAGE, FREQUENCY

The vaginal insert contains 10 mg of dinoprostone. The insert is placed transversely in the posterior fornix of the vagina, and the patient is kept supine for 2 hours but then may ambulate. The dinoprostone is released at approximately 0.3 mg/hr over a 12-hour period. The vaginal insert should be removed by pulling on the retrieval string upon onset of uterine contractions or after 12 hours (Forest Pharmaceuticals, 2006).

CONTRAINDICATIONS

- Patient with known sensitivity to prostaglandins
- Presence of nonreassuring fetal status
- Unexplained bleeding during pregnancy
- Strong suspicion of cephalopelvic disproportion
- Patient already receiving oxytocin
- Patient with six or more previous term pregnancies
- Patient who is not anticipated to be able to give birth vaginally

Dinoprostone vaginal insert should be used with CAUTION in patients with ruptured membranes, a fetus in breech presentation, presence of glaucoma, or history of asthma (Forest Pharmaceuticals, 2006).

MATERNAL SIDE EFFECTS

Uterine hyperstimulation with or without nonreassuring fetal status has occurred in a very small number (2.8% to 4.7%) of patients. Less than 1% of patients have experienced fever, nausea, vomiting, diarrhea, or abdominal pain (Forest Pharmaceuticals, 2006).

EFFECTS ON FETUS/NEWBORN

Nonreassuring fetal heart rate patterns

NURSING CONSIDERATIONS

- Assess for presence of contraindications.
- Monitor maternal vital signs, cervical dilatation, and effacement carefully.
- Monitor fetal status for presence of reassuring fetal heart rate pattern (baseline 110–160 beats/min, presence of short-term variability, average variability presence of accelerations with fetal movement, absence of late or variable decelerations).
- Remove vaginal insert if uterine hyperstimulation, sustained uterine contractions, nonreassuring fetal status, or any other maternal adverse actions occur.

Source: Forest Pharmaceuticals. (2006). *Cervidil manufacturer's fact sheet.* St. Louis: Forest Pharmaceuticals.

- Prior cesarean section or uterine scar.
- Placenta previa.
- Undiagnosed vaginal bleeding.

Use of Prostaglandin Agents (Cervidil, Prepidil)

The two most commonly used types of prostaglandin gel are Prepidil and Cervidil. Prepidil gel contains 0.5 mg dinoprostone (a form of prostaglandin E_2 for intracervical application) and is placed intracervically. Cervidil is packaged in an intravaginal insert that resembles a 2-cm-square piece of cardboard-like material. It is placed in the posterior vagina and is left in place to provide a slow release of 10 mg dinoprostone at a rate of 0.3 mg/hr over 12 hours (Cunningham et al., 2010). See Drug Guide: Dinoprostone (Cervidil) Vaginal Insert and Drug Guide: Dinoprostone (Prepidil).

Advantages and Disadvantages of Prostaglandin Administration

The advantage of Cervidil is that it can be removed easily if uterine hyperstimulation occurs (Beckmann et al., 2010). Both preparations have been demonstrated to cause cervical ripening, shorter labor, and lower requirements for oxytocin during labor induction. Vaginal birth is achieved within 24 hours for most women. The incidence of cesarean birth is reduced when prostaglandin agents are used before labor induction (Cunningham et al., 2010).

Risks of prostaglandin administration include uterine hyperstimulation, nonreassuring fetal status, higher incidence of postpartum hemorrhage, and uterine rupture that can occur even in the absence of a previous uterine incision (Creasy et al., 2008). Contraindications to labor induction are found in Table 28-1. Women with a previous uterine incision should not receive prostaglandin agents, as the risk of uterine rupture is greatly increased (ACOG, 2009b). Prostaglandin should be used with caution in women with compromised cardiovascular, hepatic, or renal function and in women with asthma or glaucoma (Creasy et al., 2008).

TABLE 28-1 Contraindications to Labor Induction or Augmentation

- Vasa previa or complete placenta previa
- Transverse fetal lie
- Umbilical cord prolapse
- Previous classical cesarean delivery
- Active genital herpes infection
- Previous myomectomy entering the endometrial cavity

DRUG GUIDE Dinoprostone (Prepidil)

PREGNANCY RISK CATEGORY: C

OVERVIEW OF MATERNAL-FETAL ACTION

Dinoprostone is a synthetically prepared form of prostaglandin E_2. Dinoprostone can be given at term and acts directly on the myometrial fibers to stimulate uterine contractility. Dinoprostone directly softens the cervix, relaxing smooth muscle in the cervix itself, and assists the uterus in producing coordinated contractions with lower doses of pitocin (Wilson, Shannon, & Shields, 2010).

ROUTE, DOSAGE, AND FREQUENCY

Prepidil is packaged as a single-dose syringe that contains 0.5 mg of dinoprostone in a 2.5 ml viscous gel. The package contains two soft plastic catheters that are used for intracervical administration. The plastic catheter is introduced into the external cervical os for placement. The catheters come in two different lengths and have a shield to prevent instillation of the medication into the internal os. The medication can be placed directly during a digital examination, or a speculum can be used to visualize the cervix. The woman is placed in a reclining position and bed rest is maintained to prevent the medication from leaking from the vagina. The woman should be monitored using electronic fetal monitoring for at least 30 minutes and up to 2 hours after placement to assess the contraction pattern and the fetal status. Prepidil may be repeated every 6 hours up to 3 doses. Pitocin should not be administered for at least 6 to 12 hours because the effects of dinoprostone can be heightened when oxytocin is administered (Wilson et al., 2010).

CONTRAINDICATIONS

- Known sensitivity to prostaglandins
- Presence of nonreassuring fetal status
- Unexplained vaginal bleeding during pregnancy
- Current use of oxytocin
- Grandmultiparous women with more than six previous term vaginal births
- Known contraindications for vaginal birth
- Suspected cephalopelvic disproportion
- Previous surgical scar on uterus

Dinoprostone should be used with caution in women with a history of asthma; ruptured membranes; or renal, hepatic, or cardiovascular disease (Wilson et al., 2010).

MATERNAL SIDE EFFECTS

Uterine hyperstimulation can occur, resulting in a nonreassuring fetal heart rate pattern. Rarely, fever, nausea, vomiting, and diarrhea have also been noted to occur. In the past, women who have had a previous cesarean birth and have been given dinoprostone have had a uterine rupture as a result.

EFFECTS ON FETUS/NEWBORN

Nonreassuring fetal heart rate patterns.

NURSING CONSIDERATIONS

- Assess fetal status before administration.
- Assess for contractions.
- Monitor vital signs, cervical changes, and potential side effects.
- Monitor for reassuring fetal status (fetal heart rate of 110–160, presence of variability, accelerations with fetal movement, absence of late or variable decelerations).
- Report uterine hyperstimulation, sustained uterine contractions, nonreassuring fetal status, or adverse maternal reactions to physician or certified nurse-midwife (CNM) immediately.
- Use caution in handling this product to prevent contact with skin. Wash hands thoroughly with soap and water after administration.

Prostaglandin Agent Insertion Procedure

It is recommended that prostaglandin gel be used only in a hospital birthing unit and that an obstetrician be readily available in case an emergency cesarean birth is needed. The use of prostaglandin E (PGE) in outpatient settings and birth centers is currently under study. When Prepidil is used, it is introduced by means of a prefilled syringe with a catheter attached to the hub. The catheter is inserted through the vagina and into the endocervix, where the gel is injected. The catheter has a small shield at the top so that the gel cannot be deposited above the internal os. Dinoprostone is available as a gel that may be placed in a diaphragm and applied to the cervix and as a suppository that is placed in the posterior fornix of the vagina.

When Cervidil is used, the vaginal insert is placed in the posterior vagina. The woman should be instructed to call the nurse if it becomes dislodged so it can be reinserted. The woman is then monitored so her contractions and the fetus can be assessed. If hyperstimulation does occur, the insert can be removed. If active labor is established, the insert should also be removed. Women who receive Cytotec typically remain in the acute care setting, and oxytocin is started to facilitate birth.

Mechanical Methods of Cervical Ripening and Labor Induction

Mechanical methods to ripen the cervix or induce labor, such as balloon catheters and extra-amniotic saline infusion (EASI), can be used as an alternative or in conjunction with other agents. Advantages of mechanical agents for cervical ripening are similar efficacy when compared to hormonal agents, less costly, lower incidence of systemic side effects, and less incidence of uterine hyperstimulation (Cunningham et al., 2010).

Balloon catheters have been used for cervical ripening for many years to promote mechanical dilatation. A Foley catheter with a 25-ml to 80-ml balloon is passed through the undilated cervix and then inflated. The weighted balloon applies pressure on the internal os of the cervix and acts to ripen the cervix. This technique can be used alone or in conjunction with other induc-

tion methods, such as vaginal misoprostol, intravenous Pitocin, or extra-amniotic saline infusion where additional saline is inserted into the Foley bulb, which is pulled snugly against the cervical os (Cunningham et al., 2010).

One study examined cervical ripening after Foley catheter insertion and found that the mean change in Bishop Score (see the discussion of Bishop Score on p. 732) was 3.56 after placement of a Foley bulb catheter. The average time from Foley bulb expulsion until birth was 8 hours and 27 minutes which indicates that Foley bulb induction is a safe and effective means to induce cervical ripening (Marciniak, Leszczyńska-Gorzelak, Bartosiewicz, et al., 2010). A systematic review of the evidence of mechanical methods of cervical ripening and induction found that in women with an unfavorable cervix, Foley catheter placement prior to induction with oxytocin significantly reduced the duration of labor and reduced the risk of a cesarean section (Gelber & Sciscione, 2006).

NURSING CARE MANAGEMENT

Physicians, certified nurse-midwives (CNMs), and labor and delivery nurses who have had special education and training may administer agents for cervical ripening. Maternal vital signs are assessed for a baseline, and an electronic fetal monitor is applied for at least 30 minutes to obtain an external tracing of uterine activity, fetal heart rate (FHR) pattern, and a reactive nonstress test (NST). If a nonreactive test is obtained, consultation with the physician or CNM is required. After the gel, intravaginal insert, or tablet is inserted, the woman is instructed to remain lying down with a rolled blanket or hip wedge under her right hip to tip the uterus slightly to the left for the first 30 to 60 minutes to maintain the cervical ripening agent in place. Gel may leak from the endocervix. The nurse monitors the woman for uterine tachysystole (hyperstimulation of the uterus) and FHR abnormalities (changes in baseline rate, variability, and presence of decelerations) for 30 minutes to 2 hours if a prostaglandin gel agent is used (ACOG, 2009b). If tachysystole of the uterus greater than five contractions in 10 minutes occurs, the woman is positioned on her left side and oxygen is administered if fetal stress is noted. The administration of a tocolytic agent (such as a subcutaneous injection of 0.25 mg terbutaline) should be considered if the uterine hyperstimulation pattern continues. The gel may be removed if hyperstimulation, severe nausea, vomiting, or tachysystole develops (Wilson et al., 2010). Treatment with antiemetics, antipyretics, and antidiarrheal agents usually is not indicated. Women who receive Cervidil or Cytotec tend to remain in the acute care setting so the contraction pattern and fetal status can be monitored continuously for an initial observation period (ACOG, 2009b).

Women undergoing induction via balloon catheters do not need continuous fetal monitoring. The nurse can perform intermittent monitoring along with the maternal vital signs. The nurse should also assess the location of the catheter to ensure the catheter has not become displaced. This can be achieved by marking the catheter tubing at the introitus and noting whether movement has occurred. After the catheter is inserted, the woman should remain in a recumbent position. Vaginal examinations should not be performed. A bedpan should be used as ambulation should be avoided.

Care of the Woman During Induction or Augmentation of Labor

The American College of Obstetricians and Gynecologists (ACOG) defines **labor induction** as the stimulation of uterine contractions before the spontaneous onset of labor, with or without ruptured fetal membranes, for the purpose of accomplishing birth (ACOG, 2009b). **Labor augmentation** refers to the artificial stimulation of uterine contractions when spontaneous contractions have failed to result in progressive cervical dilation or the descent of the fetus (ACOG, 2009b).

Induction or augmentation may be indicated in the presence of the following (ACOG, 2009b):

- Maternal medical conditions (diabetes mellitus, hypertensive disorders, renal disease, chronic pulmonary disease, antiphospholipid syndrome)
- Preeclampsia, eclampsia
- Premature rupture of membranes (PROM)
- Chorioamnionitis
- Fetal demise
- Postterm pregnancy
- Fetal compromise (severe fetal growth restriction, isoimmunization, oligohydramnios, nonreassuring antepartal testing (poor biophysical profile score)
- Risk of rapid labor or extensive distance from the hospital setting
- Mild abruptio placentae
- Nonreassuring fetal heart rate (FHR)

Contraindications to Labor Induction or Augmentation

All contraindications to spontaneous labor and vaginal birth are contraindications to the induction or augmentation of labor (see Table 28-1).

Before induction is attempted, appropriate assessment must indicate that both the woman and fetus are ready for the onset of labor. Assessment of the individual patient and the clinical situation should be considered. This includes evaluation of fetal maturity and cervical readiness. In order to reduce the likelihood of delivery of a late-preterm infant, confirmation of a gestational age of at least 39 weeks should be ascertained.

The gestational age of the fetus is best evaluated by accurate menstrual dating, ultrasound visualization of the gestational sac between 5 and 6 weeks' gestation, and quickening at 18 to 20 weeks. Serial ultrasounds are helpful in validating gestational age. When needed, amniotic fluid studies for lecithin/sphingomyelin (L/S) ratio and phosphatidylglycerol are also beneficial in assessing fetal lung maturity (see chapter 21 ∞). See Table 28-2 for confirmation of gestational age to ensure a term infant.

TABLE 28-2 Confirmation of Gestational Age

- Ultrasound measurement at less than 20 weeks gestation supports gestational age of 39 weeks or greater.
- Fetal heart tones have been documented as present for at least 30 weeks by Doppler ultrasonography.
- It has been 36 weeks since a positive serum or urine human chorionic gonadotropin pregnancy test result.

TABLE 28-3 Prelabor Status Evaluation Scoring System

	ASSIGNED VALUE: BISHOP SCORE			
FACTOR	**0**	**1**	**2**	**3**
Cervical dilatation	Closed	1–2 cm	3–4 cm	5 cm or more
Cervical effacement	0% to 30%	40% to 50%	60% to 70%	80% or more
Fetal station	−3	−2	−1, 0	+1, or lower
Cervical consistency	Firm	Moderate	Soft	
Cervical position	Posterior	Midposition	Anterior	

Source: Bishop, E. H. (1964). Pelvic scoring for elective inductions. Obstetrics and Gynecology, 24, *266.*

Bishop Score

The findings on vaginal examination will help determine whether cervical changes favorable for induction have occurred. Bishop (1964) developed a prelabor scoring system that is still helpful in predicting the inducibility of women (Table 28-3). Components evaluated are cervical dilatation, effacement, consistency, and position, as well as the station of the fetal presenting part. A score of 0, 1, 2, or 3 is given to each assessed characteristic. The higher the total score for all the criteria, the more likely that labor will occur. The lower the total score, the higher the failure rate. A favorable cervix is the most important criterion for a successful induction (Cunningham et al., 2010). The presence of a cervix that is anterior, soft, 50% effaced, and dilated at least 2 cm, with the fetal head at +1 station or lower (Bishop score of 9), is favorable for successful induction (Bishop, 1964). Low Bishop scores have been correlated with prolonged labors and a higher incidence of cesarean births (Cunningham et al., 2010).

Fetal fibronectin (fFN) assay has been suggested as a biochemical marker for predicting impending term labor and successful labor induction. The presence of fetal fibronectin in the cervicovaginal secretions has been associated with successful induction of labor; however, in a review of factors that predict labor induction success, fFN was not found to be superior to Bishop score in predicting labor induction success (Droulez, Girard, Dumas, et al., 2008).

Methods of Inducing or Augmenting Labor

When the cervix is favorable, the most frequently used methods of induction or augmentation are stripping the amniotic membranes, amniotomy, intravenous oxytocin (Pitocin) infusion, and complementary methods. Amniotomy is discussed later in this section.

Stripping the Membranes

A nonpharmacologic method of induction or augmentation frequently used by physicians and certified nurse-midwives (CNMs) is called *stripping* (or *sweeping*) *the amniotic membranes.* The CNM or physician inserts a gloved finger as far as possible into the internal cervical os and rotates the finger 360 degrees, twice. This motion separates the amniotic membranes that are lying against the lower uterine segment and internal os from the distal part of the lower uterine segment. The stripping or sweeping is thought to release prostaglandin F_{2oc} (PGF_{2oc}) from the amniotic membranes or prostaglandin E_2 (PGE_2) from the cervix. A systematic review of the membrane sweeping studies found that membrane sweeping tended to promote the onset of labor, reducing the risk for postterm pregnancy and other methods of induction of labor (Hill et al., 2008). Women should be advised that this procedure can cause discomfort. In addition, uterine contractions, cramping, and a bloody discharge can occur after the procedure is performed. Although the procedure is not 100% effective as a labor induction method, if labor is initiated, it typically begins within 24 to 48 hours. As an augmentation method, stripping of the membranes can be performed in the birthing room in an attempt to strengthen contractions without the need for oxytocin administration. If contractions fail to become adequate, however, oxytocin may need to be considered.

Oxytocin Infusion

Intravenous administration of oxytocin is an effective method of initiating uterine contractions. Contraction frequency is only a partial assessment of uterine activity; the duration and intensity of contractions are also important measures of the quality of a contraction. The goal is to achieve an adequate uterine contraction pattern without producing tachysystole. Normal contraction activity is described as five contractions or less in 10 minutes, averaged over a 30-minute window. More than five contractions in 10 minutes (averaged over a 30-minute window) constitutes tachysystole (ACOG, 2009b).

When augmentation is needed because of an arrest of labor or failure of the presenting part to descend, oxytocin is given intravenously to achieve a desirable labor pattern with strong contractions that will result in cervical dilatation and fetal descent. Typically, augmentation is warranted if there are fewer than three contractions in a 10-minute period or if the intensity is less than 25 mm Hg as indicated by an internal uterine pressure catheter during the active phase of labor. An assessment of the maternal pelvis, fetal station, and fetal position is performed before starting the oxytocin infusion. In addition, cephalopelvic disproportion should be ruled out because it is a contraindication. The other contraindications for labor augmentation are the same as for labor induction.

A primary bottle of intravenous fluid is prepared and used to start and maintain the infusion. This avoids the risk of infusing a large dose of oxytocin as the line is begun and provides addi-

tional fluids while the oxytocin solution is being kept at a low infusion rate. After the infusion is started, the oxytocin solution is piggybacked into the primary tubing port closest to the catheter insertion. This allows only a small amount of oxytocin to back flow into the tubing and ensures greater dosage accuracy. The oxytocin should be administered with a device that permits precise control of the flow rate. Oxytocin for induction of labor should not be administered intramuscularly or without the aid of an intravenous electric pump. Over the past few years, differences in opinion regarding oxytocin dosage have surfaced.

Ten to 20 units of oxytocin (Pitocin) are added to 1 L of a secondary line of isotonic intravenous fluid (usually 5% dextrose in balanced saline solution—for example, 5% dextrose in lactated Ringer's solution). The resulting mixture will contain 10 or 20 milliunits of oxytocin per milliliter (1 milliunit/min/6 milliunit/hr or 2 milliunit/min/12 milliliters/hr), and the prescribed dose can be calculated easily. Some facilities are now using 30 units of oxytocin (Pitocin) per 500 ml of intravenous fluid to reduce the risk of pulmonary edema in the postpartum period. Other dilutions can also be used. Other dosage concentrations are presented in the following Drug Guide: Oxytocin (Pitocin). It is imperative that the nurse be familiar with the specific dosage used within the institution to avoid medication errors.

DRUG GUIDE Oxytocin (Pitocin)

OVERVIEW OF OBSTETRIC ACTION

Oxytocin (Pitocin) exerts a selective stimulatory effect on the smooth muscle of the uterus and blood vessels. Oxytocin affects the myometrial cells of the uterus by increasing the excitability of the muscle cell, increasing the strength of the muscle contraction, and supporting propagation of the contraction (movement of the contraction from one myometrial cell to the next). Its effect on the uterine contraction depends on the dosage used and on the excitability of the myometrial cells. During the first half of gestation, there is little excitability of the myometrium, and the uterus is fairly resistant to the effects of oxytocin. However, from midgestation on, the uterus responds increasingly to exogenous intravenous oxytocin. Cautious use of diluted oxytocin administered intravenously at term results in a slow rise of uterine activity.

The circulatory half-life of oxytocin is 3 to 5 minutes. It takes approximately 40 minutes for a particular dose of oxytocin to reach a steady-state plasma concentration (Wilson et al., 2010).

The effects of oxytocin on the cardiovascular system can be pronounced. Blood pressure initially may decrease but after prolonged administration increase by 30% above the baseline. Cardiac output and stroke volume increase. With doses of 20 milliunits/min or above, oxytocin exerts an antidiuretic effect decreasing free water exchange in the kidney and markedly decreasing urine output.

Oxytocin is used to induce labor at term and to augment uterine contractions in the first and second stages of labor. Oxytocin may also be used immediately after birth to stimulate uterine contraction and thereby control uterine atony.

ROUTE, DOSAGE, FREQUENCY

For induction of labor: Add 10 units of Pitocin (1 ml) to 1000 ml of intravenous solution. (The resulting concentration is 10 mU oxytocin per 1 ml of intravenous fluid.) Using an infusion pump, administer IV, starting at 0.5–1 milliunit/min and increase by 1–2 milliunits/min every 40–60 minutes. Alternatively, start at 1–2 milliunits/min and increase by 1 milliunit/min every 15 minutes until a good contraction pattern (every 2–3 minutes and lasting 40–60 seconds) is achieved.

MATERNAL CONTRAINDICATIONS

- Severe preeclampsia-eclampsia
- Predisposition to uterine rupture (in nullipara over 35 years of age, multigravida 4 or more, overdistention of the uterus, previous major surgery of the cervix or uterus)
- Cephalopelvic disproportion
- Malpresentation or malposition of the fetus, cord prolapse
- Preterm infant
- Rigid, unripe cervix; total placenta previa
- Presence of nonreassuring fetal status

MATERNAL SIDE EFFECTS

Hyperstimulation of the uterus results in hypercontractility, which in turn may cause the following:

- Abruptio placentae
- Impaired uterine blood flow, leading to fetal hypoxia
- Rapid labor, leading to cervical lacerations
- Rapid labor and birth, leading to lacerations of cervix, vagina, or perineum, uterine atony; fetal trauma
- Uterine rupture
- Water intoxication (nausea, vomiting, hypotension, tachycardia, cardiac arrhythmia) if oxytocin is given in electrolyte-free solution or at a rate exceeding 20 milliunits/min; hypotension with rapid IV bolus administration postpartum

EFFECT ON FETUS-NEWBORN

- Fetal effects are primarily associated with the presence of hypercontractility of the maternal uterus. Hypercontractility decreases the oxygen supply to the fetus, which is reflected by irregularities or decrease in fetal heart rate (FHR).
- Hyperbilirubinemia (Wilson et al., 2010) when administered for augmentation of labor
- Trauma from rapid birth

NURSING CONSIDERATIONS

- Explain induction or augmentation procedure to patient.
- Apply fetal monitor, and obtain 15- to 20-minute tracing and nonstress test (NST) to assess FHR before starting IV oxytocin.
- For induction or augmentation of labor, start with primary IV, and piggyback secondary IV with oxytocin and infusion pump.
- Ensure continuous monitoring of the fetus and uterine contractions.
- The maximum rate is 40 milliunits/min (Blackburn, 2007). Not all protocols recommend a maximum dose. When indicated, the maximum dose is generally between 16 and 40 milliunits/min. Decrease oxytocin by similar increments once labor has

(continued)

DRUG GUIDE **Oxytocin (Pitocin)** continued

progressed to 5–6 cm dilatation. Protocols may vary from one agency to another.

0.5 milliunit/min = 3 ml/hr
1.0 milliunit/min = 6 ml/hr
1.5 milliunit/min = 9 ml/hr
2 milliunit/min = 12 ml/hr
4 milliunit/min = 24 ml/hr
6 milliunit/min = 36 ml/hr
8 milliunit/min = 48 ml/hr
10 milliunit/min = 60 ml/hr
12 milliunit/min = 72 ml/hr
15 milliunit/min = 90 ml/hr
18 milliunit/min = 108 ml/hr
20 milliunit/min = 120 ml/hr

- Assess FHR, maternal blood pressure, pulse, frequency and duration of uterine contractions, and uterine resting tone before each increase in the oxytocin infusion rate.
- Record all assessments and IV rate on monitor strip and on patient's chart.
- Record oxytocin infusion rate in milliunits/min and ml/hr (e.g., 0.5 milliunits/min [3 ml/hr]).
- Record on monitor strip all patient activities (such as change of position, vomiting), procedures done (amniotomy, sterile vaginal examination), and administration of analgesic agents to allow for interpretation and evaluation of tracing.
- Assess cervical dilatation as needed.
- Apply nursing comfort measures.
- Discontinue IV oxytocin infusion and infuse primary solution when (1) nonreassuring fetal status is noted (bradycardia, late or variable decelerations; (2) uterine contractions are more frequent than every 2 minutes; (3) duration of contractions exceeds more than 60 seconds; or (4) insufficient relaxation of the uterus between contractions or a steady increase in resting tone are noted (Blackburn, 2007). In addition to discontinuing IV oxytocin infusion, turn patient to side, and if nonreassuring fetal status is present, administer oxygen by tight face mask at 7–10 L/min; notify physician.
- Maintain intake and output record.

For Augmentation of Labor

Prepare and administer IV Pitocin as for labor induction. Increase rate until labor contractions are of good quality. The flow rate is gradually increased at no less than every 30 minutes to a maximum of 10 milliunits/min (Blackburn, 2007). In some settings or in a situation when limited fluids may be administered, a more concentrated solution may be used. When 10 units Pitocin are added to 500 ml IV solution, the resulting concentration is 1 milliunit/min = 3 ml/hr. If 10 units Pitocin are added to 250 ml IV solution, the concentration is 1 milliunit/min = 1.5 ml/hr.

For Administration After Expulsion of Placenta

- One dose of 10 units of Pitocin (1 ml) is given intramuscularly or 10 units to 20 units is added to IV fluids for continuous infusion.
- Assess, maternal vital signs.
- Record all assessments and IV rate on patient's chart. Record oxytocin infusion rate in milliunits/min and ml/hr (e.g., 0.5 milliunits/min [3 ml/hr]).
- Apply nursing comfort measures or pharmacologic agents for afterbirth pain associated with pitocin administration.
- Maintain intake and output record.

CLINICAL TIP

Attach the IVPB Pitocin to the medication port closest to the insertion site. If the Pitocin needs to be turned off quickly, there will be little left to infuse through the primary IV line.

ACOG (2009b) cites the use of both a low-dose and a high-dose regimen. The low-dose regimen uses a starting dose of 0.5 to 2 milliunits/min with increases of 1 to 2 milliunits/min every 15 to 40 minutes until an adequate labor pattern is established. The high-dose regimen has a starting dose of up to 6 milliunits/min with incremental increases of 3 to 6 milliunits/min every 20 to 40 minutes. If tachysystole arises with the high-dose regimen, the incremental dose is reduced to 3 milliunits/min; if tachysystole is recurrent, the incremental dose is reduced to 1 milliunit/min. Higher dose regimens have been associated with a shorter labor, less incidence of dystocia, lower cesarean birthrates, and a lower incidence of chorioamnionitis (ACOG, 2009b).

Oxytocin induction is not without some associated risks; however, most side effects are dose-related. The most common side effect of oxytocin administration is tachysystole of the uterus (with or without FHR changes), resulting in uterine contractions that are too frequent (more often than every 2 minutes), uterine contractions that are too intense, or an increased uterine resting tone. Category 2 or 3 FHR tracing changes have been associated with tachysystole (ACOG 2009b).

Other risks include uterine rupture and water intoxication.

Researchers continue to investigate a new method of labor induction with pulsatile oxytocin administration by a computer-controlled pump.

COMPLEMENTARY AND ALTERNATIVE THERAPIES

In addition to the allopathic cervical ripening and induction methods previously discussed, there are a variety of more "natural" and noninvasive methods that CNMs tend to suggest or administer either in the home setting or in tertiary care centers. These methods include the following: sexual intercourse/lovemaking; self or partner stimulation of the woman's nipples and breasts; the use of herbs, such as blue/black cohosh, evening primrose oil, and red raspberry leaves; the use of homeopathic solutions, such as caulophyllum or pulsatilla; castor oil; enemas; and acupressure/acupuncture.

RESEARCH EVIDENCE IN PRACTICE

The Relationship Between Labor Induction and Cesarean Birth

CLINICAL QUESTION

Is there an association between labor induction and subsequent cesarean birth?

RESEARCH EVIDENCE

Induction of labor carries with it a cascade of inherent risks. Induction requires an intravenous access line, continuous fetal monitoring, confinement to bed, amniotomy, and the use of pharmacologic agents, each with its own potential for adverse effects. Labor induction is often employed based on medical indications that may preclude a natural labor process. However, some mothers choose elective induction of labor, and currently this is at an all-time high in the United States.

The evidence that links induction of labor and cesarean birth is strong under certain conditions. Induction and cesarean birth appears to be associated most strongly in primiparous mothers. In a retrospective study of more than 62,000 births, the association of labor induction and cesarean birth was evaluated while accounting for demographic variables such as socioeconomic status and location of birth. In this study, cesarean births were associated with labor induction, but only in primiparous women. This relationship is even stronger when the induction is elective. In a retrospective study of more than 1300 women, elective labor induction increased the risk of a cesarean birth by 50% among primiparous women. The association between elective induction and cesarean birth has been demonstrated in multiparous women as well. One large study of more than 11,000 births showed a strong correlation between elective labor induction and cesarean birth.

The association is not apparent when induction is medically indicated. In one study that evaluated only risk-based labor induction in a population of 100 women, cesarean birth was not associated with labor induction. In these mothers, the induction was associated with better birth outcomes.

WHAT QUESTIONS REMAIN UNANSWERED?

Why is this association strongest in primiparous women? Are there factors that could mediate the risk of cesarean birth when labor is induced in primiparous women?

WHAT IS BEST PRACTICE?

When compared with risk-based labor induction, elective labor induction is associated with higher rates of cesarean birth. Risk-based labor induction is not; better outcomes are achieved when induction follows standard medical indications. Primiparous women are at highest risk of cesarean birth, but are particularly so when the induction is not risk-related.

CRITICAL THINKING

What physiologic characteristics of primiparous mothers make them at higher risk of cesarean birth after labor induction? How can the nurse counsel mothers about the risks of elective labor induction?

Although not widely described in nursing and medical textbooks, the use of complementary and alternative medicine (CAM) has risen dramatically. It is estimated that 38% of adults and 12% of children use CAM regularly (National Center for Complementary and Alternative Medicine, 2009). Natural methods are very effective and are frequently the preferred choice of many CNMs and their patients. It is important for nursing students, nurses, and consumers to be aware of all aspects of pregnancy care.

Sexual intercourse is a logical method of stimulating cervical ripening and uterine contractions; female orgasm stimulates uterine contractions, and the male ejaculate contains a rich source of natural prostaglandins (Tan, Andi, Azmi, et al., 2006). Breast and nipple stimulation are also a frequent part of lovemaking, and this stimulates the release of endogenous oxytocin, which in turn stimulates the uterus to contract. Until recently, most literature about sexual intercourse and lovemaking during pregnancy has focused on the possible harmful effects that may arise; however, new research regarding sexual intercourse as a method of labor induction found sexual intercourse will initiate labor and prevent the incidence of postterm gestation (Tan et al., 2006). Sexual intercourse is not used to augment labor.

Nipple stimulation for cervical ripening may be done at term or to augment labor. Nipple stimulation is found to increase endogenous oxytocin and stimulate uterine contractions. It also has been found to initiate spontaneous labor (Cunningham et al., 2010). There are multiple suggested methods, including manual manipulation and use of the electric breast pump. A recent systematic review of clinical trials comparing breast stimulation for third trimester cervical ripening or induction of labor to other or no interventions found that breast stimulation increased the likelihood that women would go into labor. Breast stimulation therefore is not recommended in high-risk women and care should be taken to monitor uterine contractility because hyperstimulation can occur (Creasy et al., 2008).

Herbal preparations such as blue and black cohosh, evening primrose oil, and red raspberry leaf teas are used for both cervical ripening and induction of labor. Although extensive scientific data are not available for many of these preparations, they have been widely used to promote uterine contractions and stimulate and augment labor (Bayles, 2007).

One of the more widely studied herbal preparations is evening primrose oil (*Oenothera biennis*). It has been widely used for centuries by midwives as a means of softening the cervix, vagina, and perineum to facilitate the onset of labor. Evening primrose oil

Case Study: Patient Undergoing Labor Induction

contains a fatty acid called gamma linolenic acid, which is converted into a prostaglandin compound. Prostaglandins play a key role in ripening the cervix so labor can begin. Women can be advised to begin evening primrose oil supplementation after 38 weeks of pregnancy. The route of delivery is oral or intravaginally. There are a variety of dosing protocols. Side effects are rare but can include headaches, nausea, or skin rashes. Women who experience side effects should be counseled to discontinue the supplement unless advised otherwise by their CNM or physician (Knoche, Selzer, & Smolley, 2008).

Homeopathic solutions, such as caulophyllum, cimicifuga, pulsatilla, and others, are used for cervical ripening and induction of labor. There are no current guidelines for their use in augmenting labor. The midwife or physician needs thorough personal knowledge of homeopathic remedies or ongoing consultation with a homeopathic physician.

Case Plan Activity: Patient with Pitocin for Labor Augmentation

Castor oil has been used for many years but has not been studied frequently as a method of labor induction and augmentation. The method by which castor oil stimulates uterine contractions is not understood, but is thought to be a result of the release of prostaglandin E_2 as a consequence of increased peristalsis and diarrhea after ingestion of the drug (Knoche et al., 2008). Although some studies have examined the effectiveness of castor oil, further research is needed to determine the effectiveness of this method (Kavanagh, Kelly, & Thomas, 2009).

Acupressure and acupuncture are not as accepted in the United States as in other countries. However, the rising interest in and use of holistic practices and alternative medicine is prompting a closer look at acupuncture as a method of inducing and augmenting labor and relieving labor pain. In acupuncture, sterile needles are inserted into the body at specific predetermined sites to elicit a desired response, such as initiation of contractions or relief of pain. A systematic review of evidence regarding acupuncture and induction of labor found that women who underwent acupuncture were less likely to require other methods of induction (Moleti, 2009). Although acupuncture requires extensive education and training, some CNMs can work with an acupressurist/acupuncturist to learn manual massage of acupuncture and acupressure points, shiatsu, and other touch techniques.

NURSING CARE MANAGEMENT

No matter which induction or augmentation method is used, close observation and accurate assessments are mandatory to provide safe, optimal care for both woman and fetus. The nurse obtains maternal vital signs (temperature, pulse, respirations, and blood pressure) before beginning an oxytocin infusion. Induction protocols also recommend obtaining a 20- to 30-minute electronic fetal monitor recording demonstrating a reassuring FHR and a reactive nonstress test (NST) and contraction status before the infusion is started. Patient teaching includes the purpose and procedure for the induction, as well as a review of the care that will be provided, including assessments and comfort measures. A Nursing Care Plan for Induction of Labor appears on pp. 737–738.

During the oxytocin infusion, an obstetrician should be readily accessible to manage any complication that occurs (AAP & ACOG, 2007). A fetal monitor is used to provide continuous data. Women may ambulate if a portable or walking monitor is available.

Women who are undergoing alternative methods of induction also need continuous assessment and nursing support. For women who have entered labor after stripping of the amniotic membranes, a normal labor pattern should ensue. Intermittent external fetal monitoring can be used if the fetus is reactive and the maternal vital signs are within normal parameters. Women should be advised that they may continue to have a blood-tinged discharge from the procedure. Women who have their membranes stripped are less likely to go past their due dates. The nurse continues to assess the contraction pattern, including the frequency, intensity, and duration of the contractions.

Women who choose to use nipple stimulation as a means of inducing labor should be continuously monitored with the external fetal monitor while the electric breast pump is in use. Release of oxytocin stimulated by breast pumping can result in surges of oxytocin release, which can lead to nonreassuring fetal status. Some fetuses who are unable to tolerate the release of oxytocin from breast pumping may react without stress to intravenous oxytocin administration, as this results in a small amount of oxytocin being released in a controlled manner.

In cases where homeopathic or herbal remedies have been used to induce labor, normal intermittent monitoring and assessment of maternal vital signs can be performed. If oxytocin is to be administered, the nurse should inform the physician or CNM of what has been given, the dose, the last time administered, and the immediate effects that were achieved. An assessment is performed before administration of pharmacologic substances.

Expected outcomes of nursing care include the following:

- The woman and family are fully informed; understand the induction process; are able to relate the advantages, disadvantages, risks, and possible outcomes; and have had an opportunity to have their questions answered.
- The woman's labor is successfully induced.
- The labor progresses at a normal rate and maternal vital signs remain in normal range.
- The fetal status remains reassuring throughout the labor period.

Care of the Woman During an Amniotomy

Amniotomy is the artificial rupture of the amniotic membranes (AROM). It is probably the most common procedure performed in obstetrics. Because the amniotomy requires that an instrument be inserted through the cervix, at least 2 cm of cervical dilatation must be present. The amniotomy may be performed as a method of induction of labor (to stimulate the beginning of labor), or it

NURSING CARE PLAN For Induction of Labor

INTERVENTION	RATIONALE
1. Nursing diagnosis: Risk for Injury related to hyperstimulation of uterus caused by induction of labor **Goal:** Progression of labor without difficulty or complications	
■ Obtain a baseline for maternal blood pressure, pulse, respirations, temperature, and pain level.	■ Pitocin induction can affect the cardiovascular system. Blood pressure may initially be decreased. If the induction is prolonged the blood pressure may increase by 30%. Respirations can become elevated because of pain sensation, anxiety, or physiologic causes. Temperature is obtained to monitor for infection. The pain level is assessed continuously to determine if pain medication is warranted or changes in vital signs are caused by maternal discomfort.
■ Place patient on external fetal monitor for 20 minutes to obtain a baseline for fetal heart rate (FHR) and variability.	■ Assesses for fetal well-being. Normal FHR ranges from 110 to 160 beats/min. Variability measuring three to five fluctuations in 1 minute is documented as average. Continuous electronic fetal monitoring (EFM) is performed during a Pitocin induction.
■ Perform nonstress test.	■ A nonstress test is performed to assess the fetal heart rate in response to fetal movement. Accelerations of fetal heart rate with fetal movement may indicate the fetus has adequate oxygenation and an intact central nervous system. A reactive nonstress test indicates there were at least two accelerations of 15 beats/min above baseline, lasting 15 seconds in a 20-minute period.
■ Insert IV line and begin primary infusion with 1000 ml of electrolyte solution.	■ An electrolyte solution such as lactated Ringer's is used for the primary solution. A primary IV allows continuous intravenous access and fluid infusion in the event the Pitocin drip needs to be discontinued.
■ Piggyback Pitocin solution into primary IV tubing, via pump, in the port closest to the IV insertion site.	■ Pitocin is mixed in 1000 ml of an electrolyte solution (usually 5% dextrose in lactated Ringer's solution) and piggybacked to main IV line. A pump is used to ensure dosage accuracy.
■ Begin Pitocin infusion per agency protocol.	■ The rate to be used is determined by physician or CNM orders or agency protocol.
■ Monitor infusion pump and connections.	■ This ensures adequate dosing. Early identification of problems with the infusion site, the piggyback connection, or flow rate will minimize effects on uterine contractions and FHR. If a problem is found, correct and restart infusion at the beginning dose.
■ Monitor and evaluate maternal blood pressure and pulse before each increase in the Pitocin infusion rate.	■ Prolonged inductions may increase the blood pressure by 30%. The Pitocin infusion rate should not be advanced if maternal hypertension or hypotension is present or if there are any radical changes in pulse rate.
■ Evaluate urine output.	■ There is an antidiuretic effect with dosages of Pitocin above 20 milliunits/min. This level decreases free water exchange in the kidneys, therefore markedly decreasing urine output.
■ Evaluate and document fetal heart rate before each increase in Pitocin infusion rate.	■ During Pitocin infusion, fetal heart rate should range between 110 and 160 beats/min. Hypercontractility of the maternal uterus may cause nonreassuring fetal status. Fetal bradycardia may occur along with a decrease in variability, leading to fetal hypoxia. Fetal tachycardia may also occur. If persistent fetal bradycardia or fetal tachycardia occurs, the Pitocin is discontinued.
■ Evaluate and document contraction pattern before each increase of the Pitocin infusion rate.	■ Contractions every 2 to 3 minutes, lasting 40 to 60 seconds with moderate intensity, are considered adequate. Cervical dilatation progresses an average of 1.2 cm/hr to 1.5 cm/hr (0.5 in./hr to 0.6 in./hr) during the active phase of labor.
■ Increase Pitocin infusion dosage until adequate contractions are achieved or the maximum dose per agency protocol is reached.	■ Pitocin may be increased every 20 to 40 minutes until an adequate contraction pattern is achieved.

(continued)

NURSING CARE PLAN For Induction of Labor continued

INTERVENTION	RATIONALE
■ Evaluate contraction frequency, duration, and intensity before increasing the infusion rate. Discontinue Pitocin infusion and infuse primary solution if signs of hyperstimulation of the uterus are detected.	■ Signs of hyperstimulation include contraction frequency less than 2 minutes, duration exceeding 60 seconds, and increased resting tone. Hyperstimulation of the uterus puts the patient at risk for abruptio placentae and uterine rupture.
■ Initiate treatment measures to reverse the effects of Pitocin infusion if fetal tachycardia or bradycardia occurs.	■ When the FHR falls outside the normal range (110 to 160 beats/min), treatment measures should be initiated. To reverse the effects of Pitocin, immediately discontinue Pitocin, infuse primary solution, administer oxygen by tight face mask at 7 to 10 L/min, place patient in side-lying position, and notify physician or CNM.

EXPECTED OUTCOME: Contractions will increase in frequency, duration, and intensity. An increase in cervical dilatation, effacement, and intensity will be achieved. The uterus will remain soft between contractions.

may be done to augment labor. A meta-analysis of 12 studies found that if an amniotomy is performed along with early oxytocin administration, the labor will probably be shortened and the incidence of cesarean birth is reduced (Wei et al., 2009). Amniotomy may also be performed during labor to allow access to the fetus in order to apply an internal fetal heart monitoring electrode to the scalp, to insert an intrauterine pressure catheter, or to obtain a fetal scalp blood sample for acid–base determination.

The decision to perform an amniotomy should include the patient. The evidence for advantages and disadvantages should be presented to the patient. Ideally such a discussion would not occur during a vaginal examination (Smyth, Aldred, & Markham, 2007).

Advantages and Disadvantages of Amniotomy

Amniotomy as a method of labor induction has the following advantages:

1. The contractions elicited are similar to those of spontaneous labor.
2. There is usually no risk of hypertonus or rupture of the uterus, as with intravenous oxytocin induction.
3. The woman does not require the same intensive monitoring as with intravenous oxytocin induction.
4. Electronic fetal monitoring (EFM) is facilitated because, once the membranes are ruptured, a fetal scalp electrode may be applied, an intrauterine catheter may be inserted, and scalp blood sampling for pH determinations may be done to assist in evaluating a fetal heart rate (FHR) pattern.
5. The color and composition of amniotic fluid can be evaluated.
6. Amniotomy is a less costly procedure compared to other methods of induction.

The disadvantages of amniotomy are as follows (Smyth, Aldred, & Markham, 2007):

1. Once an amniotomy is done, the risk for infection begins to rise if labor proceeds beyond 24 hours because microorganisms can now invade the intrauterine cavity and cause amnionitis.
2. The danger of a prolapsed cord is increased once the membranes have ruptured, especially if the fetal presenting part is not firmly pressed down against the cervix.
3. Compression and molding of the fetal head are increased because of loss of the cushioning effect of the amniotic fluid for the fetal head during uterine contractions.
4. Fetal injury can occur if the amniohook causes a laceration on the presenting part.
5. Bleeding can occur if an undiagnosed vasa previa is present.
6. Severe variable decelerations can occur, which increases the likelihood of a cesarean birth.
7. The intervention can cause an increase in pain making labor more difficult to manage.

Amniotomy Procedure

Before an amniotomy is performed, the fetus is assessed for presentation, position, station, and FHR. Unless the fetal head is well engaged in the pelvis, some practitioners do not advocate an amniotomy because of the danger of prolapsed cord (refer to chapter 27 ∞ for discussion of prolapsed cord). Other risks are abruptio placentae (because of rapid decompression of the uterus with the rapid loss of amniotic fluid), infection (because of the introduction of organisms into the cervix and intrauterine cavity), and amniotic fluid embolus (because of rapid decompression of the uterus and small amounts of fluid entering the maternal vascular system from under the edge of the placenta). These complications may also be associated with spontaneous rupture of membranes (SROM).

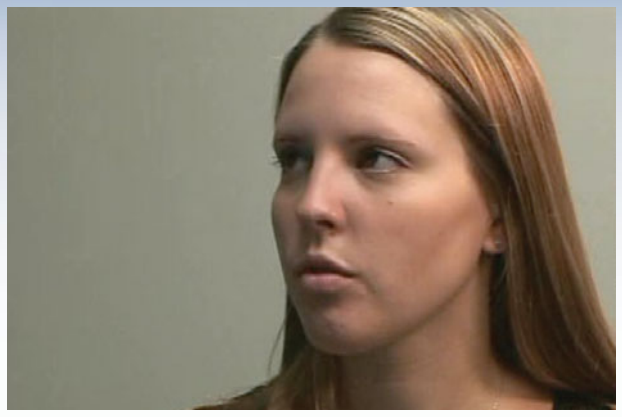
While performing a sterile vaginal examination, the physician or certified nurse-midwife (CNM) introduces an amnihook (or other rupturing device) into the vagina, through the cervix, and against the amniotic membrane, which is in front of the fetal presenting part. A small tear is made in the amniotic membrane. Following rupture of the membrane, amniotic fluid is allowed to escape slowly.

Through the Eyes of a Nurse
Labor Induction

Family's Experience

"I can't take it anymore! I can't sleep; I can't bend over; I am exhausted! I have contractions all of the time. We sit and time them, and just when we think it is time to call and come to the hospital, they space out and go away! I am miserable; I just want to get this over. I really want to be induced at this point. I can't take it, I really can't!"

Her husband is concerned as well. "We have been to the hospital twice. She is having contractions on the (electronic fetal) monitor but they keep sending us home. She is crying and miserable. She is up all night and can't rest. What are the dangers of inducing her?"



Nurse's Response

"What you are feeling is very typical at this stage of pregnancy. It is often uncomfortable at the end stages of pregnancy. We can certainly let the nurse-midwife know that you would like to consider an induction.

"There are a variety of factors to consider. It is important to determine if there are any contraindications to induction and to review the risks with you. You are overdue, which is one of the indications for induction. The midwife will need to examine your cervix to determine if your cervix is ripe or favorable for induction. You can also explore whether you would like to try complementary methods first or if you would like to schedule a medical induction where oxytocin is administered."

Nurse's Actions and Rationale

The nurse provides reassurance that her feelings and the physical discomforts that she is experiencing are normal at this stage in pregnancy. The nurse explains that there are some contraindications to induction and that these need to be reviewed with the healthcare provider. Table 28-1 lists absolute contraindications to induction. The midwife will perform a vaginal examination to determine if the woman's cervix is favorable for induction. The Bishop score (see Table 28-3) is a measure of prelabor status criteria that is commonly used to determine if induction is likely to be successful. A score of 9 indicates that labor will most likely occur if induction is attempted.

NURSING CARE MANAGEMENT

The nurse explains the procedure to the woman. The fetal presentation, position, and station are assessed because amniotomy is usually delayed until engagement has occurred (to decrease the risk of a prolapsed cord when the fluid is expelled). The woman is positioned in a semireclining position and draped to provide privacy. Disposable underpads and/or towels are placed under the woman's buttocks to absorb the amniotic fluid. The FHR is assessed just before and immediately after the amniotomy, and the two FHR assessments are compared. If there are marked changes, the nurse should check for prolapse of the cord. The amniotic fluid is inspected for amount, color, odor, and the presence of meconium or blood. While wearing disposable gloves, the nurse cleanses and dries the perineal area and changes the disposable underpads. The nurse advises the woman that fluid will continue to be expelled from her vagina. Frequent pericare and pad changes should be done to increase patient comfort. Because there is now an open pathway for organisms to ascend into the uterus, strict sterile technique must be observed during vaginal examinations. In addition, the number of vaginal examinations must be kept to a minimum to reduce the chance of introducing an infection, and the woman's temperature should be monitored every 2 hours. Bed rest is maintained unless the presenting part is engaged and is firmly against the cervix (to decrease the risk of prolapsed cord). The nurse needs to provide information about the amniotomy and the expected effects. Some couples may worry that all the amniotic fluid will be gone and that they will experience a "dry birth." It is important for them to know that amniotic fluid is constantly produced.

Amnioinfusion

Care of the Woman During Amnioinfusion

Amnioinfusion (AI) is a technique by which a volume of warmed, sterile, normal saline or Ringer's lactate solution is introduced into the uterus through the use of an intrauterine pressure catheter (IUPC). AI can be used intrapartally to increase the volume of fluid when oligohydramnios is present and the physician wants either to prevent the possibility of variable decelerations by increasing the volume of amniotic fluid or to treat nonperiodic decelerations that are already occurring. The AI increases the volume of fluid, relieving pressure on the umbilical cord and promoting increased perfusion to the fetus. When AI is used for this indication or for prolonged decelerations in fetal heart rate (FHR) patterns, the abnormal FHR pattern is usually relieved in 20 to 30 minutes (Beckmann et al., 2010).

Amnioinfusion has also been used for meconium dilution in the presence of medium to heavy meconium staining. Debate has ensued regarding the effectiveness of this regimen. A recent systematic review of randomized controlled trials of AI for thick, meconium-stained amniotic fluid found no evidence that AI reduced the incidence of meconium aspiration syndrome (Xu, Hofmeyr, Roy, et al., 2007). The possibility that the meconium had already entered the fetal tracheobronchial tree before the onset of labor or that affected fetuses have been exposed to prolonged periods of nonreassuring fetal status are other factors that may contribute to the review's findings (Xu et al., 2007). Even with these findings, some practitioners continue to administer AIs in the presence of moderate to severe meconium staining. Further research is needed to examine these factors.

Contraindications to AI include patients with a contraindication to vaginal delivery, amnionitis, hydramnios, uterine hypertonus, multiple gestation, known fetal anomaly, uterine anomaly, nonreassuring fetal status requiring immediate birth, nonvertex presentation, scalp pH below 7.2, placenta previa, vasa previa, or abruptio placentae (Cunningham et al., 2010). AI can also be associated with rare serious risk factors, including umbilical cord prolapse, amniotic fluid embolism, and uterine rupture (Beckmann et al., 2010).

There is no one accepted protocol for AI. However, most procedures involve infusing a bolus of from 250 to 500 ml of warmed normal saline through an intrauterine catheter using an infusion pump over 20 to 30 minutes and repeated until the indication resolves. Other protocols include a bolus followed by a constant administration of 180 cc of warmed saline until birth occurs (Queenan, Spong, & Lockwood, 2007).

NURSING CARE MANAGEMENT

The nurse is frequently the first person to detect changes in FHR associated with cord compression or to observe thick, meconium-stained amniotic fluid. When cord compression is suspected, the immediate intervention is to assist the laboring woman to another position in an effort to relieve the compression and to apply O_2 via face mask (see chapter 27 ∞ for further discussion). If this intervention is not successful, an amnioinfusion may be considered. The nurse helps with the AI and monitors the woman's vital signs (blood pressure, pulse, and respiration) and contraction status (frequency, duration, intensity, resting tone, and associated maternal discomfort). Fetal heart rate (FHR) is monitored by continuous electronic fetal monitoring (EFM). The nurse should provide ongoing information to the laboring woman and her partner and answer questions as they arise. Comfort measures and positioning are very important because AI requires the woman to be on bed rest.

The AI should not cause pain or discomfort for the laboring woman other than the need for bed rest. The nurse needs to ensure that the fluid infused is being expelled from the woman's vagina. This is achieved with frequent examination of the woman's sanitary pad or an absorbent pad that is placed beneath her buttocks. The woman should be advised that fluid will leak from her vagina. The nurse should change absorbent pads and provide pericare on a regular basis.

Care of the Woman During an Episiotomy

An **episiotomy** is a surgical incision of the perineal body. Traditionally, some physicians and certified nurse-midwives (CNMs) performed episiotomies to prevent damage to the periurethra, perineum, anal sphincter, and rectum from lacerations during the birth; to prevent damage to the posterior wall of the vagina; to prevent jagged tears from lacerations; to reduce mechanical and metabolic risk to the fetus/newborn; to protect the maternal bladder; and to prevent future perineal relaxation. However, more recent research indicates that routine episiotomy use is driven by local professional norms, experience in training, and individual practitioner preference rather than the needs of the individual woman at the time of delivery (Frankman, Wang, Bunker, et al., 2009).

Although the incidence of episiotomies in the United States has declined, it is still performed in slightly greater than one third of all vaginal births (Frankman et al., 2009). Typically, nurse-midwives tend to perform fewer episiotomies than physicians. Residents and hospital-based physicians tend to perform fewer routine episiotomies than physicians in private practice (Frankman et al., 2009).

Even though the procedure is very common, its routine use has been questioned. The most current research indicates that there are no maternal advantages in performing routine episiotomies (Viswanathan et al., 2009). Research suggests that, rather than protecting the perineum from lacerations, the presence of an episiotomy makes it more likely that the woman will have deep perineal tears. It has also been suggested that perineal lacerations heal more quickly in the absence of episiotomy (Frankman et al., 2009). Major perineal trauma (extension to or through the anal sphincter) is *more* likely to occur if a midline episiotomy is performed. It is estimated that one in five women will experience an anal sphincter injury as a result of a vaginal delivery (Viswanathan et al., 2009). Women who are allowed to tear spontaneously have less sexual dysfunction than women who have undergone episiotomies (Frankman et al., 2009).

Additional complications associated with an episiotomy are blood loss, infection, pain, and perineal discomfort that may continue for days or weeks past birth, including dyspareunia (painful intercourse). Flatal incontinence (uncontrollable passage of gas) has also been reported (Cunningham et al., 2010). There are no scientific data to support the beliefs that episiotomies yield a shorter second stage, improved Apgar scores, or a decrease in perinatal asphyxia (Viswanathan et al., 2009). In light of the debate over the value of episiotomy, it is now suggested that the procedure be used selectively to facilitate birth in the presence of maternal or fetal stress or when a shoulder dystocia is anticipated. There is debate on whether episiotomies should be performed to create more room in the presence of a breech presentation, multiple gestation, or a large-for-gestational-age infant (greater than 4000 g), or for the use of an instrument (forceps or vacuum extractor) to assist birth. Some researchers argue that midline episiotomy and vacuum-assisted birth should be avoided when a large baby is anticipated. Although many practitioners perform episiotomies when an instrument is being used to assist birth, new research suggests this may result in more third- and fourth-degree extensions (Frankman et al., 2009).

Risk Factors That Predispose Women to Episiotomy

Overall factors that place a woman at increased risk for an episiotomy are primigravid status, large or macrosomic fetus, occiput-posterior position, use of forceps or vacuum extractor, shoulder dystocia, and white race (Frankman et al., 2009). Other factors that predispose a woman to episiotomy may be mitigated by nurses and physicians or CNMs. These include the following:

- Use of lithotomy position or other recumbent position (causes excessive perineal stretching)
- Encouraging or requiring sustained breath holding during second-stage pushing (causes excessive perineal stretching, can adversely affect blood flow in the mother and fetus, and encourages the woman to be responsive to caregiver directions rather than to her own urges to push spontaneously)
- Arbitrary time limit placed by the physician or CNM on the length of the second stage

Nursing advocacy is needed to promote selective rather than routine episiotomies. The nurse can begin by encouraging pregnant women to read about prenatal perineal preparation and to talk with the physician or CNM about their personal beliefs and the incidence of episiotomy in their practice. Nurses can share current research with nursing colleagues through staff meetings and explore and strongly encourage nursing care interventions that avoid the lithotomy position. The woman should be encouraged to respond to her body's urges to push during the second stage. Just as patients ask physicians and CNMs about their episiotomy philosophy and incidence, patients may ask labor and birthing nurses to provide information about their actions to help decrease episiotomy rates. It is imperative that each nurse continue to stay current about new information and research in order to maintain current practice standards.

Episiotomy Procedure

The episiotomy is performed with a sharp scissors that has rounded points, just before birth, when approximately 3 to 4 cm of the fetal head is visible during a contraction (Cunningham et al., 2010). There are two types of episiotomy: midline and mediolateral (Figure 28-3 ■). A midline episiotomy is performed along the median raphe of the perineum. It extends down from the vaginal orifice to the fibers of the rectal sphincter. This type of episiotomy avoids muscle fibers and major blood vessels because it divides the insertions of the superficial perineal muscles (Blackburn, 2007). A midline episiotomy is preferred if the perineum is of adequate length and no difficulty is anticipated during the birth, because it entails less blood loss, is easy to repair, and heals with less discomfort for the mother. The major disadvantage is that a tear of the midline incision may extend through the anal sphincter and rectum (Blackburn, 2007).

In the presence of a short perineum, macrosomia, and instrument-assisted birth (use of forceps or vacuum extractor),

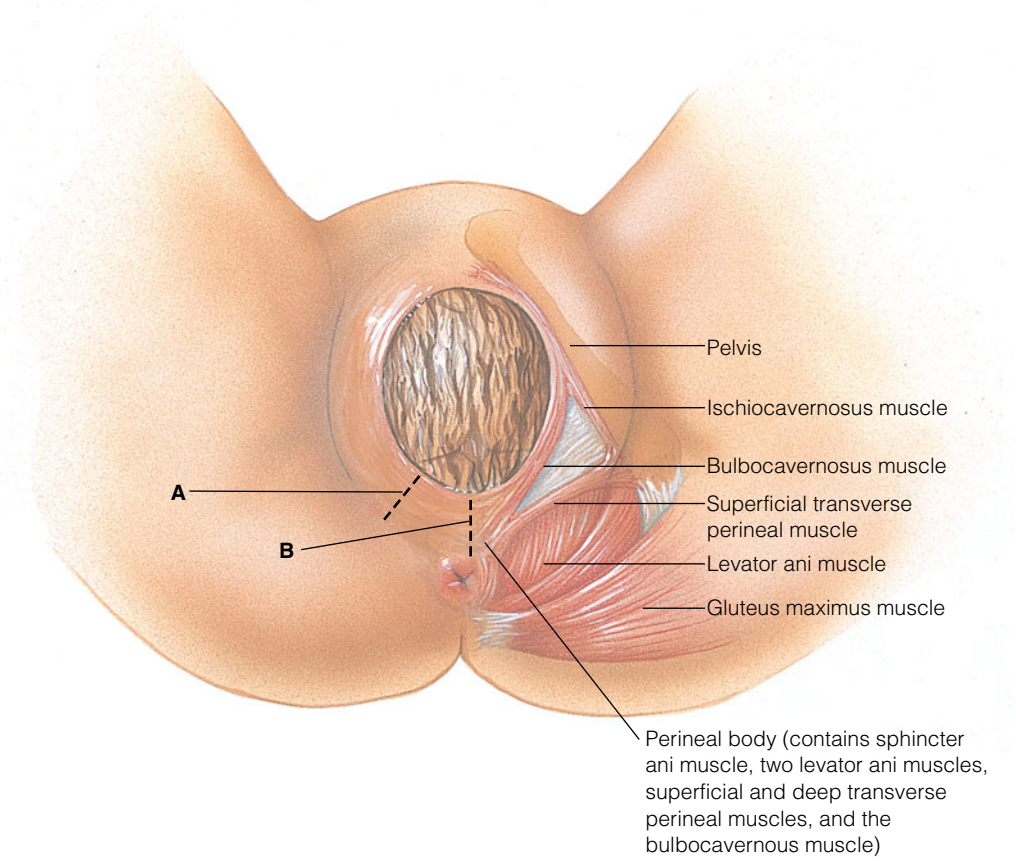


Figure 28-3 ■ The two most common types of episiotomies are midline and mediolateral. A. Right mediolateral. B. Midline.

a mediolateral episiotomy provides more room and decreases the possibility of a traumatic extension into the rectum. The mediolateral episiotomy begins in the midline of the posterior fourchette (to avoid incision into the Bartholin's gland) and extends at a 45-degree angle downward to the right or left (the direction depending on the handedness of the clinician). The mediolateral episiotomy may be complicated by greater blood loss, a longer healing period, and more postpartal discomfort (Frankman et al., 2009).

The episiotomy is usually performed with regional or local anesthesia but may be performed without anesthesia in emergency situations. It is generally suggested that as crowning occurs, the distention of the tissues causes numbing. Adequate anesthesia must be given for the repair.

Repair of the episiotomy (episiorrhaphy) and any lacerations is performed either during the period between birth of the baby and before expulsion of the placenta or after expulsion of the placenta. Many providers wait until after expulsion of the placenta in case a manual removal of the placenta or a uterine exploration is indicated (Blackburn, 2007).

NURSING CARE MANAGEMENT

The woman needs to be supported during the episiotomy and the repair because she may feel some pressure sensations. It is not uncommon for the woman to feel a "pulling" or "tugging" sensation. In the absence of adequate anesthesia, she may feel pain. Placing a hand on her shoulder and talking with her can provide comfort and distraction from the repair process. If the woman is having more discomfort than she can comfortably handle, the nurse needs to act as an advocate in communicating the woman's needs to the physician or CNM. At all times, the woman needs to be the one who decides whether the amount of discomfort is tolerable, and she should never be told, "This doesn't hurt." She is the person experiencing the discomfort, and her evaluation needs to be respected. If there are just a few (three to five) stitches left, she may choose to forgo more local anesthesia, but she should be given the choice. For women with severe pain or anxiety, intravenous medication such as Fentanyl or Nubain can be administered for both pain and anxiety control.

The nurse notes the type of episiotomy on the birth record. This information should also be included in a report to the postpartum nurse so that adequate assessments can be made and relief measures can be instituted if necessary.

Pain relief measures may begin immediately after birth with application of an ice pack to the perineum. For optimal effect, the ice pack should be applied for 20 to 30 minutes and removed for at least 20 minutes before being reapplied. This is advisable because the ice causes vasoconstriction; however, if the ice pack is left in place more than 30 minutes, vasodilation and subsequent edema may occur. The perineal tissues should be assessed frequently to prevent injury from the ice pack. The episiotomy site is inspected every 15 minutes during the first

hour after the birth for redness, swelling, tenderness, and hematomas. As a part of postpartal care, the mother will need instruction in perineal hygiene care and comfort measures. (See chapter 36 ∞ for additional discussion of relief measures for the immediate postpartum period.)

It is important for nurses to recognize that perineal pain continues for a period of time. Women who experience prolonged pain tend to have other problems, such as breastfeeding difficulties and depression, and are more reluctant to reestablish sexual activity. Risk factors for subsequent lacerations include use of repeat episiotomy and instrument-assisted births.

DEVELOPING CULTURAL COMPETENCE

Canadian Orthodox Jewish Women

Although many North American women have specific beliefs and expectations for childbirth, other cultural or religious groups may not verbalize specific requests or ideas for their labor experience. Canadian Orthodox Jewish women typically do not express their preferences but instead depend on their healthcare practitioner to make decisions regarding procedures that may be indicated. They typically view healthcare providers as authority figures and participate less in their own healthcare decision making.

Care of the Woman During Forceps-Assisted Birth

Forceps are designed to assist the birth of a fetus by providing traction or by providing the means to rotate the fetal head to an occiput-anterior position. In medical literature and practice, **forceps-assisted birth** is also known as *instrumental delivery, operative delivery,* or *operative vaginal delivery.* There are many different types of forceps, each with special functions. For example, Piper forceps are designed to be used with a breech presentation (buttocks as presenting part); they are applied after the birth of the body, when the fetal head is still in the birth canal and assistance is needed. In conversational language, Piper forceps are said to be applied to the aftercoming head. All other forceps are used in situations when the fetus is in a cephalic (head down) presentation. In such situations, the forceps are applied to the sides of the head. The type of forceps used is determined by the physician assisting with the birth.

Criteria for Forceps Application

ACOG has classified the definitions of forceps applications into three categories: outlet, low, and midforceps. Criteria for *outlet forceps* application are as follows (Cunningham et al., 2010):

1. Forceps are applied when the fetal skull has reached the pelvic floor and is at or on the perineum. (There is bulging of the perineum.)
2. The scalp is visible between contractions without separating the labia. (Earlier in labor, as the woman pushes during the contraction, the fetal scalp may be visible, but when the pushing effort ceases, the scalp recedes and is no longer visible. This criterion indicates that the scalp remains visible even when the woman is not pushing.)
3. The sagittal suture is not more than 45 degrees from the midline. The sagittal suture is the anterior-posterior suture on the top of the fetal head. At this point in a spontaneous birth, extension has almost been completed, external rotation is beginning, and the sagittal suture is between the midline and 45 degrees from the midline. (For example, think of a clock face. If 12:00 is the maternal symphysis pubis and the fetus is in left occiput anterior (LOA), the sagittal suture and the occiput are between 12:00 and 1:30.) (See chapter 22 ∞.) The important aspect of this criterion is that with outlet forceps, the fetal head is moving naturally from extension to external rotation, and the forceps are being used to guide or lift the head out.

The criterion for *low forceps* application is that the leading edge (presenting part) of the fetal skull must be at a station of plus 2 (+2) or below (for example, +3) but not on the pelvic floor. The rotation (internal rotation, which is part of the cardinal movements) of the fetal head is less than 45 degrees (right or left occiput anterior to occiput anterior, or right or left occiput posterior to occiput posterior) (Cunningham et al., 2010).

The criterion for *midforceps* application is that the fetal head must be engaged (largest diameter of the head reaches or passes through the pelvic inlet), but the leading edge (presenting part) of the fetal skull is above a plus 2 (+2) station (for example +1, 0, −1, −2). When midforceps are used, the goal is to apply traction, and, frequently, to rotate the head and facilitate the vaginal birth.

High forceps are not indicated in current obstetric practice. A woman whose fetus is at a station of −3 or is above the pelvic inlet should give birth by cesarean. Types of forceps are depicted in Figure 28-4 ■.

Indications for Use of Forceps

Indications for the use of forceps include the presence of any condition that threatens the mother or fetus and that can be relieved by birth. Conditions that put the woman at risk include heart disease, acute pulmonary edema or pulmonary compromise, certain neurologic conditions, intrapartal infection, prolonged second stage, or exhaustion. Fetal conditions include premature placental separation, prolapsed umbilical cord, and nonreassuring fetal status. Forceps may be used electively to shorten the second stage of labor and spare the woman's pushing effort (when exhaustion or heart disease is present) or when regional anesthesia has affected the woman's motor innervation, and she cannot push effectively. In the past, outlet forceps have been used to protect the head of a preterm infant during birth; however, the advantages of this practice are now being questioned (Cunningham et al., 2010).

Risk factors for a forceps- or vacuum-assisted birth (discussion to follow) are as follows (Cunningham et al., 2010):

- Nulliparity
- Maternal age (35 and over)
- Maternal height of less than 150 cm (4 ft 11 in)
- Pregnancy weight gain of more than 15 kg (33 lb)

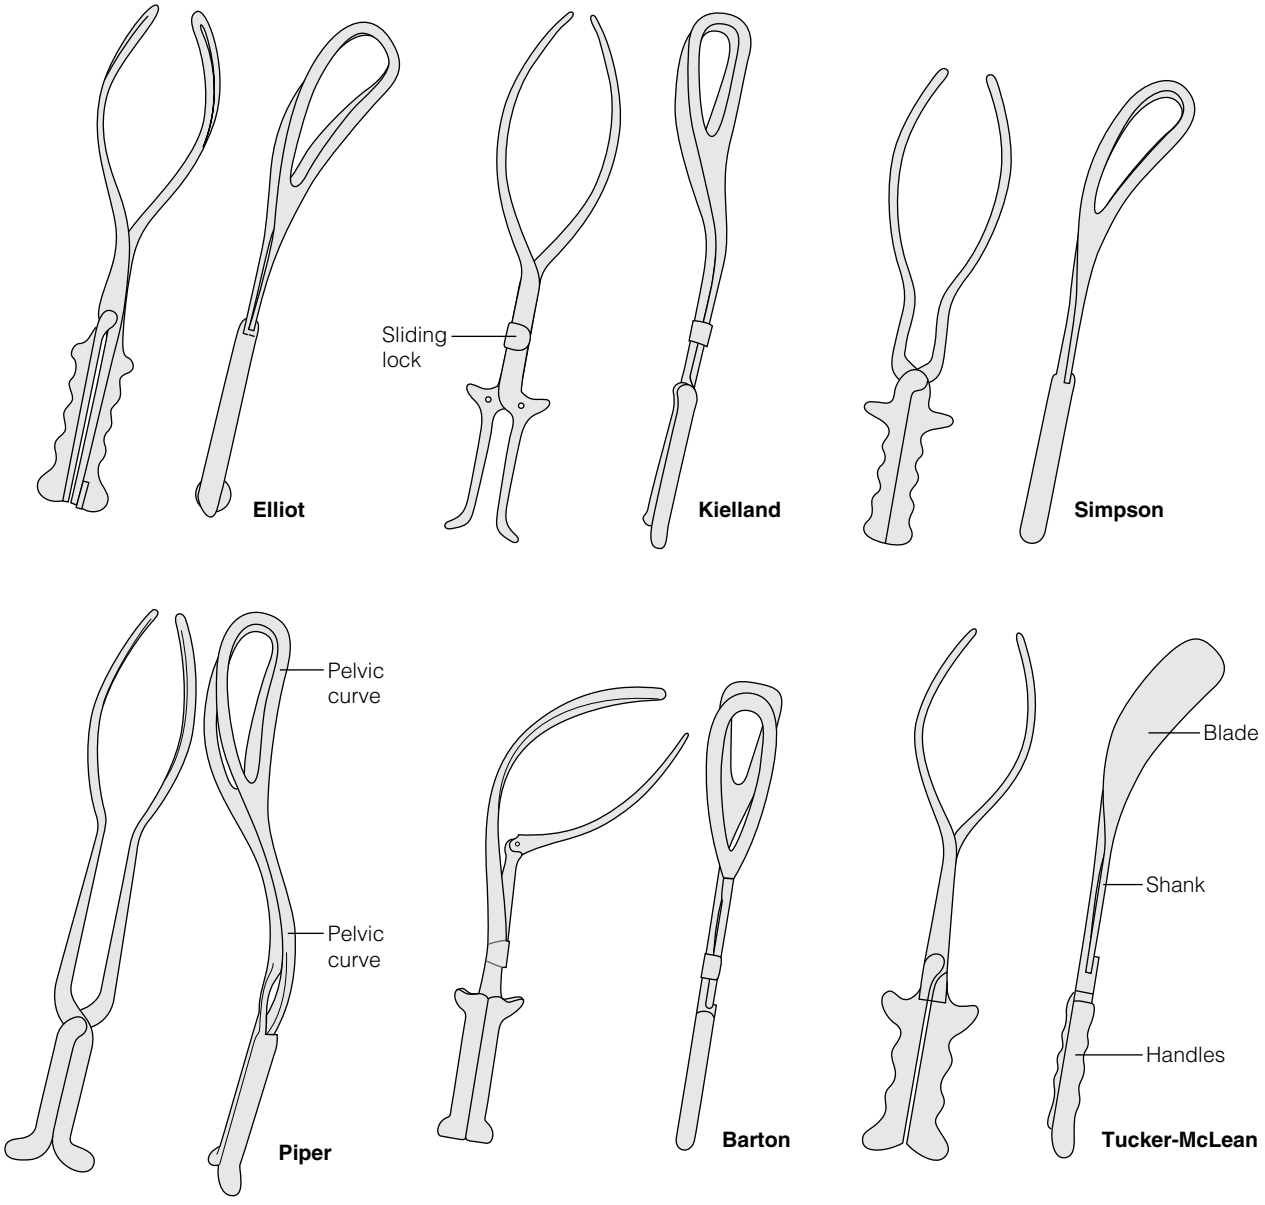

Figure 28-4 ■ Forceps are composed of a blade, shank, and handle and may have a cephalic and pelvic curve. (Note labels on Piper and Tucker-McLean forceps.) The blades may be fenestrated (open) or solid. The front and lateral views of these forceps illustrate differences in blades, open and closed shanks, and cephalic and pelvic curves. Elliot, Simpson, and Tucker-McLean forceps are used as outlet forceps. Kielland and Barton forceps are used for midforceps rotations. Piper forceps are used to provide traction and flexion of the aftercoming head (the head comes after the body) of a fetus in breech presentation.

- Postdate gestation (41 weeks or more)
- Epidural anesthesia
- Infant presentation other than occipitoanterior
- Presence of dystocia
- Presence of a midline episiotomy
- Abnormal fetal heart rate (FHR) tracing

Neonatal and Maternal Risks

Some newborns may develop a small area of ecchymosis or edema, or both, along the sides of the face as a result of forceps application. Caput succedaneum or cephalhematoma (and subsequent hyperbilirubinemia) may occur as well as transient facial paralysis. Other reported complications include low Apgar scores, retinal hemorrhage, corneal abrasions, ocular trauma, other trauma (Erb's palsy, fractured clavicle), elevated neonatal bilirubin levels, and prolonged infant hospital stay (Cunningham et al., 2010).

Maternal risks may include trauma such as lacerations of the birth canal, periurethral lacerations, and extensions of a median episiotomy into the anus, resulting in increased bleeding, bruising, hematomas, and pelvic floor injuries (Beckmann et al., 2010). Women who give birth with the assistance of forceps are more likely to have a third- or fourth-degree laceration and report more perineal pain and sexual problems in the postpartum period (Cunningham et al., 2010). In addition, an increase in postpartum infections, cervical lacerations, and prolonged hos-

pital stays has been reported (Cunningham et al., 2010). Women who have given birth with forceps may also experience urinary and rectal incontinence, anal sphincter injury, and postpartum metritis (Cunningham et al., 2010).

Prerequisites for Forceps Application and Birth

It is very important that all of the prerequisites be met before the forceps procedure is attempted. The prerequisites are as follows (Cunningham et al., 2010):

- The physician must be knowledgeable about the advantages and disadvantages of different types of forceps and their use.
- The cervix must be completely dilated.
- The fetal head must be engaged and the station, presentation, and exact position of the head must be known. The fetus should be in a vertex or a face presentation with the chin anterior.
- Amniotic membranes must be ruptured to allow a firm grasp on the fetal head.
- The type of pelvis should be identified, because certain pelvic types do not permit rotation. In addition, there must be no disproportion between the fetal head and the maternal pelvis.
- Maternal bladder should be empty.
- There must be no obstructions to the birth below the fetal head, such as an incurving coccyx that will not allow the fetus to pass or a disproportion between the size of the head and the outlet or the midpelvis.
- Adequate anesthesia must be given for the type of forceps procedure that is anticipated. For instance, low forceps may be done with a pudendal block; however, midforceps or a rotation of more than 45 degrees requires an epidural, spinal-epidural, or general anesthesia.

Trial or Failed Forceps Procedure

The use of forceps or vacuum may be considered when the clinician believes a successful outcome can occur. In a trial forceps procedure, the physician attempts to use forceps with the knowledge that there could be a degree of cephalopelvic disproportion. A complete setup for immediate cesarean birth needs to be available before the forceps are applied. If a good application cannot be obtained or if no descent occurs with the application, a vacuum technique can be attempted. If this yields no descent, then a cesarean birth is the method of choice.

NURSING CARE MANAGEMENT

The nurse directs nursing care measures toward the variable(s) that may be positively affected by specific nursing interventions. For instance, dystocia may be corrected by changing maternal position, ambulation, rocking, frequent bladder emptying, and so on. FHR abnormalities may be affected by utero-placental-fetal circulation, so the nurse could support ambulation (if not contraindicated), frequent position changes, intake of adequate fluids, and monitoring to detect early FHR changes.

If a forceps-assisted birth is required, the nurse explains the procedure briefly to the woman. With adequate regional anesthesia, the woman should feel some pressure but no pain. The nurse encourages her to avoid pushing during application of the forceps (Figure 28-5 ■ depicts the application). The nurse monitors contractions and advises the physician when one is present because traction is applied only with a contraction. During the contraction, as the forceps are applied, the nurse again advises the woman to avoid pushing. With each contraction, *after the forceps are in place,* the physician provides traction on the forceps as the woman pushes. It is not uncommon to observe mild bradycardia as traction is applied to the forceps. This bradycardia results from head compression and is transient.

Following birth, the newborn is assessed for facial edema, bruising, caput succedaneum, cephalhematoma, corneal abrasion, and any sign of cerebral edema. In the fourth stage, the nurse assesses the woman for perineal swelling, bruising, hematoma, excessive bleeding, and hemorrhage. In the postpartum period it is important to assess for signs of infection if lacerations occurred during the procedure (Beckmann et al., 2010).

The nurse answers questions and reiterates explanations provided, reviews nursing assessments of the woman and her newborn, and provides opportunities for the woman and family to ask further questions. Some women may feel a sense of loss or failure as a result of needing forceps for birth. The nurse provides reassurance to the woman and her family.

Care of the Woman During Vacuum Extraction

Vacuum extraction is an obstetric procedure used by physicians and certified nurse-midwives (CNMs) to assist the birth of a fetus by applying suction to the fetal head. The vacuum extractor accounts for 68% of all operative vaginal births. Its use has increased by 41% since 1990 and continues to rise (Cunningham et al., 2010). The vacuum extractor is composed of a soft suction cup attached to a suction bottle (pump) by tubing. The suction cup, which comes in various sizes, is placed against the occiput of the fetal head. Care must be taken to ensure that no cervical or vaginal tissue is trapped under the cup. The pump is used to create negative pressure (suction) of approximately 50 to 60 mm Hg in a stepwise sequence or rapid application. An artificial caput ("chignon") is formed as the fetal scalp is pulled into the cup. The physician or CNM then applies traction in coordination with uterine contractions. The fetal head should descend with each contraction until it emerges from the vagina (Figure 28-6 ■).

Research indicates that negative suction applied for more than 10 minutes is associated with a greater incidence of scalp injury. The longer the duration of suction, the more likely the newborn will have scalp injury. Although there are no data on the duration of use, ACOG advises a 30-minute time limit (Simpson & Creehan, 2008). Many practitioners limit the time to 20 minutes. Although there are no specifications on the number of attempts, failure to descend with multiple attempts is an indicator that a cesarean birth may be needed. In addition, if more than three "pop-offs" occur (the suction cup pops off the

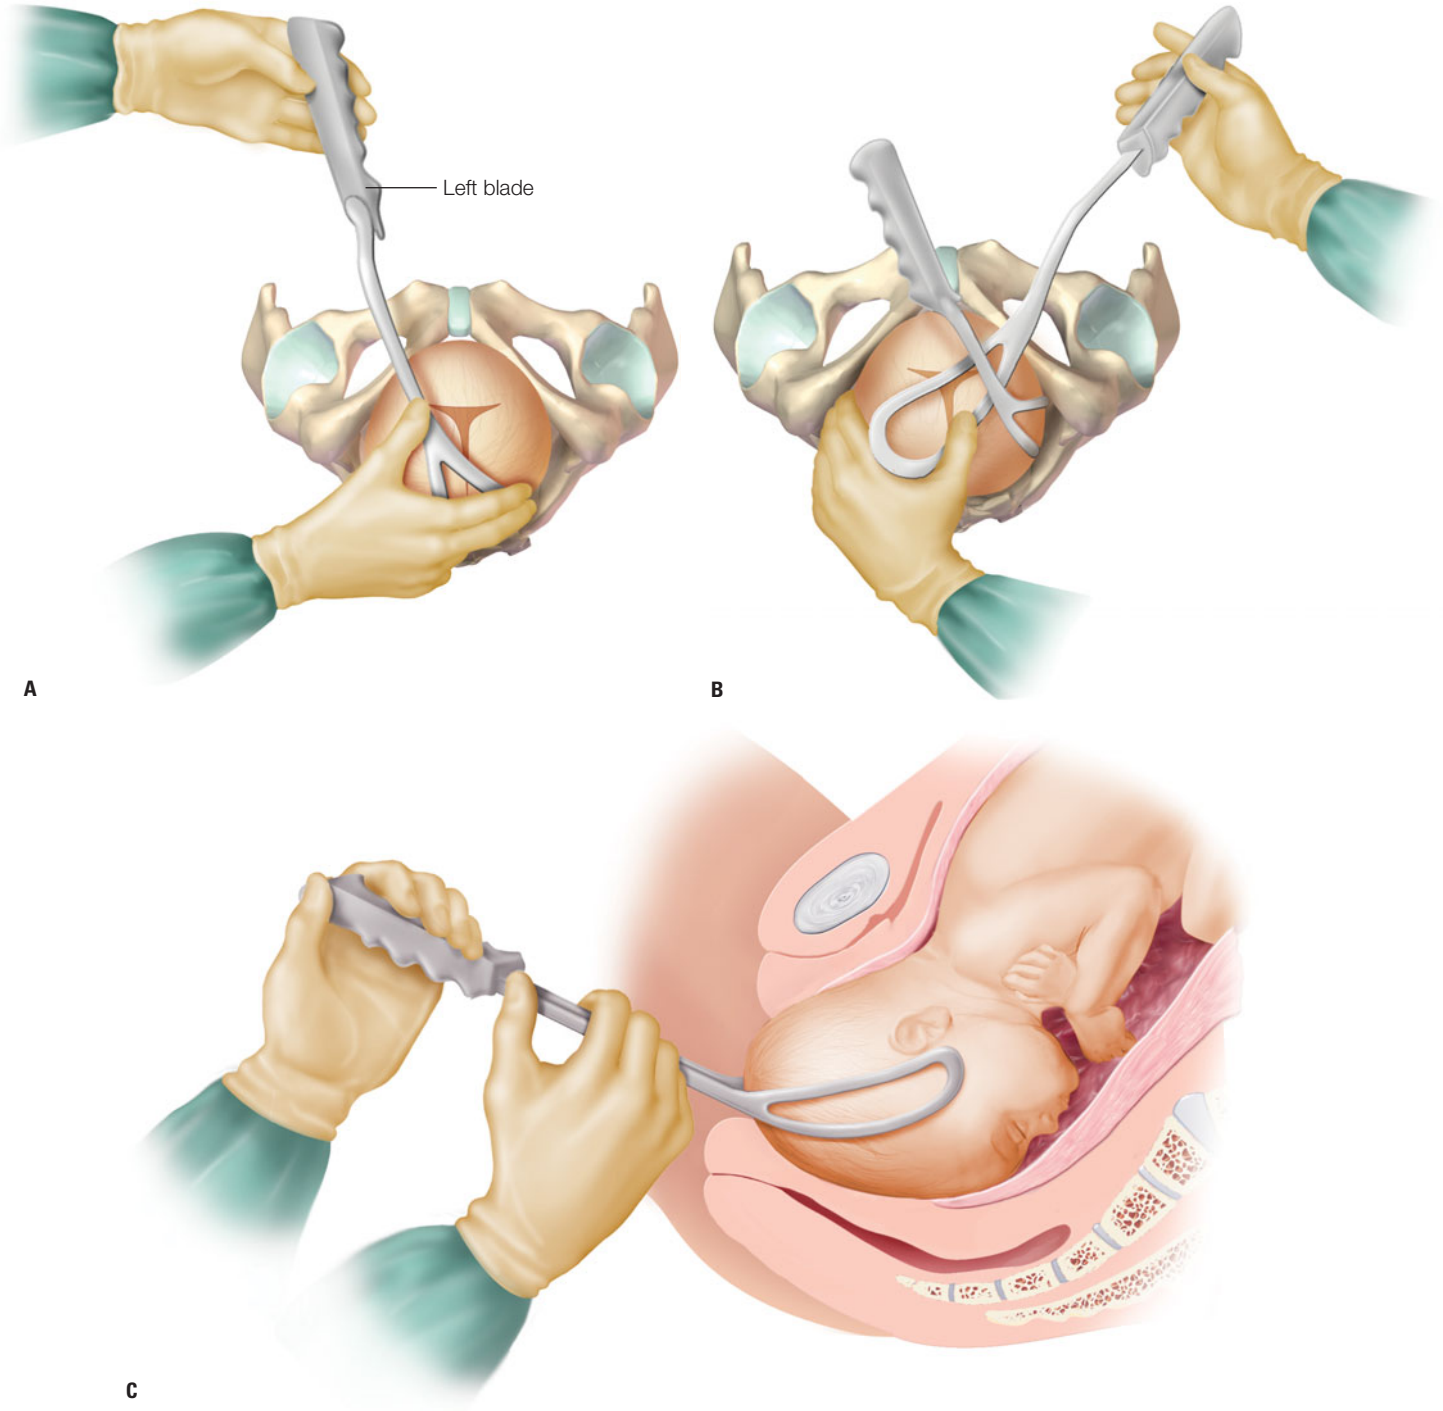

Figure 28-5 ■ Application of forceps in occiput-anterior (OA) position. A. The left blade is inserted along the left side wall of the pelvis over the parietal bone. B. The right blade is inserted along the right side wall of the pelvis over the parietal bone. C. With correct placement of the blades, the handles lock easily. During uterine contractions, traction is applied to the forceps in a downward and outward direction to follow the birth canal.

fetal head), the procedure should be discontinued. The most common indication for the use of the vacuum extractor is a prolonged second stage of labor or nonreassuring heart rate pattern. Vacuum extraction is also used to relieve the woman of pushing effort, or when analgesia or fatigue interferes with her ability to push effectively, or in cases of nonreassuring fetal status when prompt birth is indicated. The vacuum extractor is preferred to forceps in cases of borderline cephalopelvic disproportion (CPD), when successful passage of the fetal head requires all potential space inside the vaginal canal. True CPD is an absolute contraindication to vacuum extraction. Other contraindications include nonvertex presentations, maternal or suspected fetal coagulation defects, known or suspected hydrocephalus, and fetal scalp trauma (Cunningham et al., 2010). Relative contraindications include suspected fetal macrosomia, high fetal station, face or breech presentation, gestation less than 34 weeks, incompletely dilated cervix, and previous fetal scalp blood sampling (Cunningham et al., 2010).

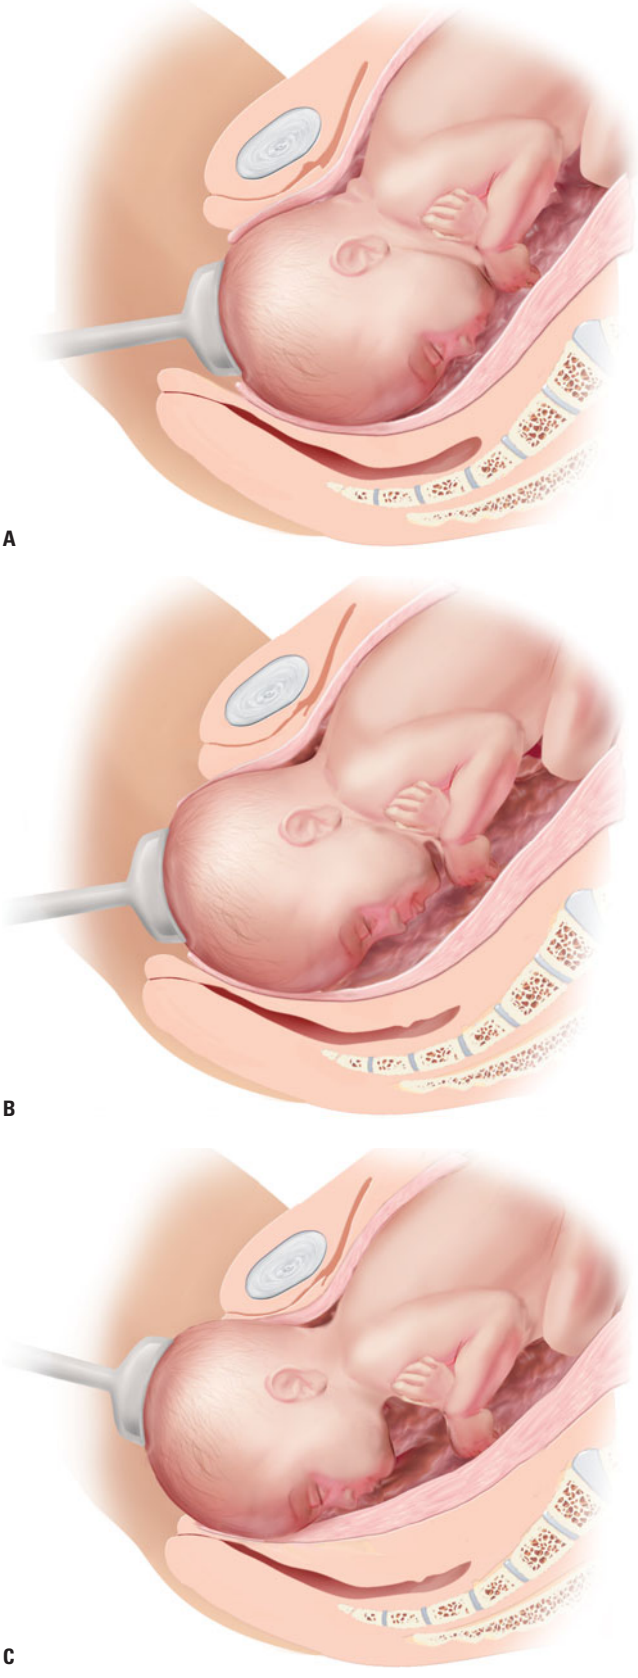

Figure 28-6 ■ Vacuum extractor traction. A. The cup is placed on the fetal occiput, creating suction. Traction is applied in a downward and outward direction. B. Traction continues in a downward direction as the fetal head begins to emerge from the vagina. C. Traction is maintained to lift the fetal head out of the vagina.

Neonatal complications include scalp lacerations, bruising, subgaleal hematomas, cephalhematomas, intracranial hemorrhages, subconjunctival hemorrhages, neonatal jaundice, fractured clavicle, Erb's palsy, damage to the sixth and seventh cranial nerves, retinal hemorrhage, and fetal death. In addition, there is an increased incidence of shoulder dystocia (Cunningham et al., 2010). There appear to be more neonatal complications and injuries with use of a metal suction cup device than with soft cup devices. In the presence of a preterm gestation, risk of periventricular-intraventricular hemorrhage (PV-IVH) has been a concern, and some studies provide conflicting recommendations. Maternal complications include perineal trauma, edema, third- and fourth-degree lacerations, postpartum pain, and infection (Simpson & Creehan, 2008). Women who give birth with the aid of a vacuum extractor report more sexual difficulties in the postpartum period. Maternal genital tract and anal sphincter injuries occur less frequently with the vacuum extractor than with forceps.

In 1998, the U.S. Food and Drug Administration (FDA) released a health advisory statement that vacuum extraction can cause serious or fatal complications. Twelve deaths and nine serious injuries occurred between 1994 and 1998. The FDA recommended caution in using rocking movements when using the device. They also recommended that pediatricians be alerted when a vacuum-assisted birth occurred so the infant can be closely monitored for related injuries. In addition, the following guidelines are recommended when a birth is facilitated by a vacuum extractor (Cunningham et al., 2010):

1. The criteria used to evaluate the appropriateness of a forceps birth should also be used to determine the appropriateness of a vacuum birth (station).
2. The same indications and contraindications should be used for both forceps and vacuum births.
3. The presenting part must be vertex and must be at 0 station or below.
4. Vacuum-assisted births should be performed only by an experienced practitioner.
5. The procedure should be terminated immediately if descent does not occur or if the vacuum device pops off more than three times.

NURSING CARE MANAGEMENT

There are different types of vacuum extractors. The nurse must be familiar with the types used within the birthing setting and learn the pressure limits of each type.

The nurse should inform the woman about what is happening during the procedure. If adequate regional anesthesia has been administered, the woman feels only pressure during the procedure. The nurse pumps the vacuum to the appropriate level to provide suction by the physician or CNM. The fetal heart rate (FHR) is auscultated at least every 5 minutes or assessed by continuous electronic fetal monitoring (EFM). The parents need to be informed that the caput (chignon) on the baby's head will disappear within 2 to 3 days.

The nurse continues to assess the newborn for complications such as bruising, newborn jaundice, cephalhematomas, intracranial hemorrhage, and retinal hemorrhages.

Care of the Family During Cesarean Birth

Cesarean birth is the birth of the infant through an abdominal and uterine incision. Cesarean birth is one of the oldest surgical procedures known. Until the 20th century, cesareans were primarily equated with an attempt to save the fetus of a dying woman. As the maternal and perinatal morbidity and mortality rates associated with cesarean birth steadily decreased throughout the 20th century, the rate of cesarean births increased. In 1965, cesarean births constituted 4.5% of all births and progressed to a high of 32.3% in 2008 (Hamilton, Martin, & Ventura, 2010). The cesarean birthrate has risen by 50% since 1996 (Hamilton et al., 2010). In some countries, the incidence has been much lower throughout the 20th century; however, many countries have seen a consistent rise in their cesarean delivery rate. In 2005, the cesarean delivery rate in Australia had risen to 29% (Brennan, Robson, Murphy, et al., 2009). Bolivia has one of the lowest cesarean birthrates in the world, accounting for only 5% of all births. Sweden and the Netherlands have maintained cesarean birthrates of 10% for decades. Many Latin American countries also have low rates, including Peru with a cesarean birthrate below 10%, and Honduras with a rate of 12%. England and Canada have rates below 20%. However, some countries, such as Chile, have rates as high as 40% (Brennan et al., 2009). The rising international cesarean rate is concerning given that the World Health Organization has proposed that a rate greater than 10% to 15% is not justifiable in any region of the world (Brennan et al., 2009).

The rising cesarean birthrate has created marked concern among various practitioner groups. ACOG created a task force in 2000 to address concerns regarding the rise in cesarean birthrates. The committee recommended two benchmarks to be achieved by 2010: a primary cesarean rate of 15.5% for women who were greater than 37 gestational weeks with a cephalic singleton presentation, and a vaginal birthrate of 37% in women who have had one previous cesarean birth after 37 gestational weeks (Cunningham et al., 2010).

Many factors affect the cesarean birthrate, and they need to be considered in discussions about decreasing the current rate in the United States. These factors include a rising number of nulliparous women, who are at an increased risk for cesareans, giving birth; a rise in the maternal age, which is associated with a higher incidence of cesarean birth; changing philosophies regarding the best method of birth with a breech presentation; interpretations of electronic fetal monitoring (EFM) tracings; a decrease in the use of forceps and vacuum extractors to facilitate a vaginal birth; and a dramatic rise in obesity, another risk factor for cesarean birth. Other risks include changing practice related to vaginal birth after cesarean birth, increased use of epidural anesthesia, physician convenience, and type of provider (Cunningham et al., 2010). Interestingly, some women are now requesting a primary cesarean birth because of fear of labor, convenience, and concern about pelvic floor damage that could result in long-term medical complications (Michaluk, 2009).

One of the most significant healthcare factors dominating the 21st century is the concern related to medical malpractice litigation. Failure to perform a cesarean birth is one of the most common malpractice claims in obstetrical practice. Although there is no association between performing a cesarean birth and a reduction in childhood neurologic problems, including a decline in neonatal seizures or cerebral palsy, fear of litigation remains a driving force in obstetrical practice (ACOG, 2009a). The malpractice crisis has become so grave that some certified nurse-midwives (CNMs) and physicians are abandoning obstetrical practice because of fear of litigation and high malpractice premiums.

Indications

Cesarean births are performed in the presence of a variety of maternal and fetal conditions. Commonly accepted indications include complete placenta previa, cephalopelvic disproportion (CPD), placental abruption, active genital herpes, umbilical cord prolapse, failure to progress in labor, proven nonreassuring fetal status, and benign and malignant tumors that obstruct the birth canal. Indications that are more controversial include breech presentation, previous cesarean birth, major congenital anomalies, cervical cerclage, severe Rh isoimmunization, and maternal preference for cesarean birth. The majority of cesarean births performed in the United States are done because of a previous cesarean birth and dystocia (Cunningham et al., 2010).

Maternal Mortality and Morbidity

Cesarean births have a higher maternal mortality rate than vaginal births. In the United States, women undergoing a cesarean birth have a fourfold risk of death when compared with women who give birth vaginally (Lothian, 2006). In England, emergency cesarean birth has a ninefold risk of death when compared with vaginal delivery, and elective cesarean births have a threefold risk (Cunningham et al., 2010). Perinatal morbidity is also considerably higher in women who have had a cesarean. Common postoperative complications include infection, reactions to anesthesia agents, blood clots, and bleeding. Women who have had a cesarean birth are twice as likely to be rehospitalized within 60 days of birth when compared with women who have had a vaginal birth. Other sources of maternal morbidity that are directly associated with cesarean birth include ureteral injury, bladder laceration, and wound infection (Cunningham et al., 2010).

Surgical Techniques

Cesarean birth requires both a skin and a uterine incision, which are not necessarily the same type of incision.

Skin Incisions

The skin incision for a cesarean birth is either transverse (Pfannenstiel) or vertical and is not indicative of the type of incision made into the uterus. The type of skin incision is determined by time factor, patient preference, cosmetic reasons, or physician preference.

The transverse incision is made across the lowest and narrowest part of the abdomen. Because the incision is made just below the pubic hair line, it is almost invisible after healing. Other advantages of this type of incision include less bleeding and better

healing. The limitations of this type of skin incision are that it does not allow for extension of the incision if needed. Because it usually requires more time, this incision is used when time is not of the essence (e.g., with failure to progress and no fetal or maternal stress). This type of incision may result in suboptimal visualization, especially in obese women. This type of incision may also develop more scar tissue if subsequent surgeries, such as repeat cesarean, are performed (Creasy et al., 2008).

The vertical (infraumbilical midline) incision is made between the navel and the symphysis pubis. This incision is quicker and is therefore preferred in cases of nonreassuring fetal status when rapid birth is indicated, with preterm or macrosomic infants, or when the woman is obese (Creasy et al., 2008).

Uterine Incisions

The type of uterine incision depends on the need for the cesarean. The choice of incision affects the woman's opportunity for a subsequent vaginal birth and her risks of a ruptured uterine scar with a subsequent pregnancy.

The two major locations of uterine incisions are the lower uterine segment and the upper segment of the uterine corpus (Figure 28-7 ■).

The most common lower uterine segment incision is a transverse incision (Figure 28-7A), which is preferred for the following reasons (Cunningham et al., 2010):

1. The lower segment is the thinnest portion of the uterus and involves less blood loss.
2. It requires only moderate dissection of the bladder from underlying myometrium.
3. It is easier to repair, although repair takes longer.
4. The site is less likely to rupture during subsequent pregnancies.
5. There is a decreased chance of adherence of bowel or omentum to the incision line.

The disadvantages include the following:

1. It takes longer to make a transverse incision.
2. It is limited in size because of the presence of major blood vessels on either side of the uterus.
3. It has a greater tendency to extend laterally into the uterine vessels.

Types of Incisions

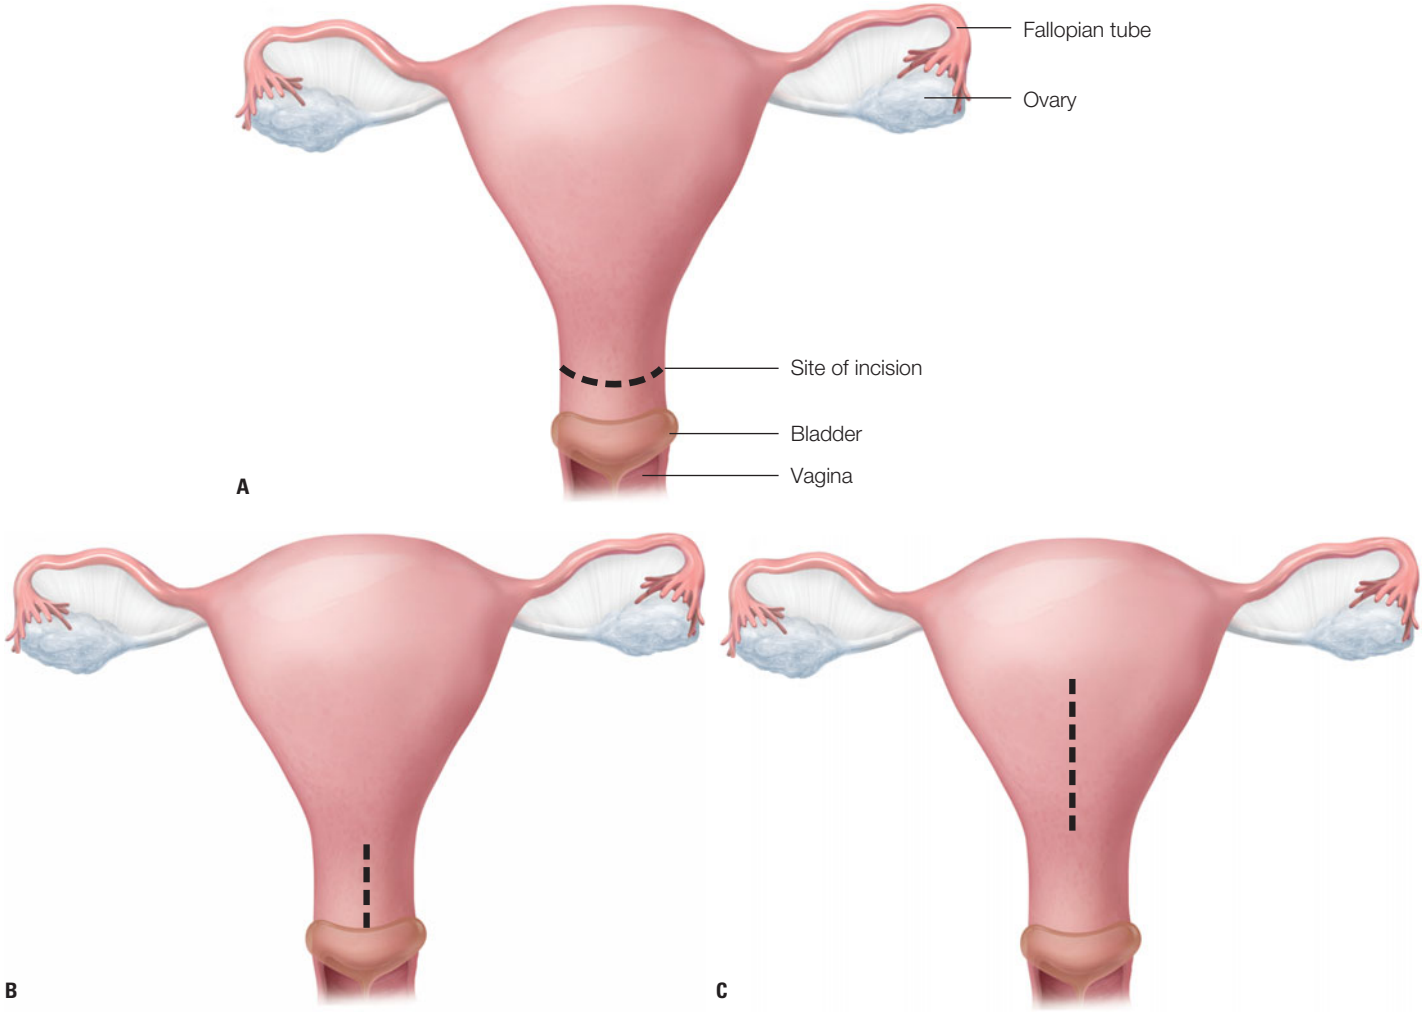

Figure 28-7 ■ Uterine incisions for a cesarean birth. A. This transverse incision in the lower uterine segment is called a Kerr incision. B. The Sellheim incision is a vertical incision in the lower uterine segment. C. This view illustrates the classic uterine incision that is done in the body (corpus) of the uterus. The classic incision was commonly done in the past and is associated with increased risk of uterine rupture in subsequent pregnancies and labor.

Application: Cesarean Birth

4. The incision may stretch and become a thin window, but it usually does not create problems clinically until subsequent labor ensues.

The lower uterine segment vertical incision is preferred for multiple gestation, abnormal presentation, if the woman has had no labor, and for preterm and macrosomic fetuses (Figure 28-7B).

Disadvantages of this incision are as follows:

1. The incision may extend downward into the cervix.
2. More extensive dissection of the bladder is needed to keep the incision in the lower uterine segment.
3. If the incision extends upward into the upper segment, hemostasis and closure are more difficult.
4. The vertical incision carries a higher risk of rupture with subsequent labor. Consequently, once a vertical incision is performed, future births need to be via cesarean.

One other incision, the classic incision, was the method of choice for many years but it is used infrequently now (Figure 28-7C). This vertical incision was made into the upper uterine segment. More blood loss resulted, and it was more difficult to repair. Most important, it carried an increased risk of uterine rupture with subsequent pregnancy, labor, and birth, because the upper uterine segment is the most contractile portion of the uterus.

The primary indications for a classical incision include a very small fetus in breech presentation when the lower uterine segment is not thinned out, morbid maternal obesity that precludes safe access to the lower uterine segment, a macrosomic fetus in transverse position with the shoulder impacted in the birth canal, inability to expose the lower uterine segment because of scarring of the maternal bladder associated with previous surgery, myoma in the lower uterine segment, cervical cancer, and placenta percreta (Cunningham et al., 2010). Students should recognize that these situations are very rare and that classical uterine incisions are rarely performed.

Analgesia and Anesthesia

There is no perfect anesthesia for cesarean birth. Each has its advantages, disadvantages, possible risks, and side effects. Goals for analgesia and anesthesia administration include safety, comfort, and emotional satisfaction for the patient. See chapter 25 ∞.

NURSING CARE MANAGEMENT

Preparation for Cesarean Birth

Because nearly one out of every three births is a cesarean, preparing the woman and family for this possibility is an integral part of prenatal education (Hamilton et al., 2010). Nurses should encourage all pregnant women and their partners to discuss with their obstetrician or CNM what approach would be taken in the event of a cesarean. They can also discuss their needs and desires as a couple under those circumstances. Their preferences may include the following:

- Participating in the choice of anesthetic
- Presence of the father (or significant other) during the procedures in the recovery or postpartum room
- Audio or video recording and/or photographing of the birth
- Delayed instillation of eye drops to promote eye contact between parent and infant in the first hour after birth
- Physical contact or holding the newborn while on the operating room table or in the recovery room (If the mother cannot hold the newborn, the father can hold the baby for her.)
- Breastfeeding immediately after the surgery has been completed
- Preparation that may be done, such as abdominal prep, insertion of an indwelling bladder catheter, and starting an intravenous infusion and epidural placement
- Description or viewing of the operating room
- Types of anesthesia for birth and analgesia available postpartum
- Sensations that may be experienced
- Roles of significant others
- Interaction with the newborn
- Immediate recovery phase
- Postpartum phase

Preparing the woman for surgery involves more than the procedures of establishing intravenous lines and a urinary indwelling catheter or doing an abdominal prep. As discussed previously, good communication skills are essential in assisting the couple. Therapeutic use of touch and eye contact (if culturally acceptable and possible) do much to maintain reality orientation and control. These measures reduce anxiety for the woman during the stressful preparatory period.

If the cesarean birth is scheduled and not an emergency, the nurse has ample time for preoperative teaching. The woman needs to practice her turning, coughing, and deep breathing. It is helpful if she is taught to splint her abdominal muscles when she coughs. An informed consent for surgery needs to be signed.

To prepare the woman for the surgery, she is given nothing by mouth. To reduce the likelihood of serious pulmonary damage should aspiration of gastric contents occur, antacids may be administered within 30 minutes of surgery. If epidural anesthesia is used, the nurse may assist with the procedure, monitor the woman's blood pressure and response, and continue EFM. An abdominal and perineal prep is done, and an indwelling catheter is inserted to prevent bladder distention. For women receiving epidural anesthesia, it may be more comfortable to place the Foley catheter after the epidural has been placed. An intravenous line is started with a needle of adequate size to permit blood administration, and preoperative medication may be ordered. The pediatrician, neonatologist, or neonatal intensive care unit should be notified and adequate preparation made to receive the infant. The nurse should make sure that the infant warmer is functional and that appropriate resuscitation equipment is available.

The nurse assists in positioning the woman on the operating table. Fetal heart rate (FHR) should be ascertained before surgery and during preparation because fetal hypoxia can result from aortocaval compression. The operating table may be adjusted so it slants slightly to one side, or a wedge (folded blanket or towels)

may be placed under the right hip. The uterus should be displaced about 15 degrees from the midline. This helps relieve the pressure of the heavy uterus on the vena cava and lessens the incidence of vena caval compression and supine maternal hypotension. The woman is strapped onto the table to prevent falls or injuries from occurring during the surgery. If a cauterization device is being used, the grounding source is secured on the woman's leg after the device has been checked to make sure it is in working order. The suction should be in working order, and the urine collection bag should be positioned under the operating table to ensure proper urinary drainage. Auscultation or electronic monitoring of the FHR needs to continue until immediately before the surgery. A last-minute check is done to ensure that the fetal scalp electrode has been removed if the fetus was internally monitored. The nurse should continue to provide reassurance and describe the various procedures being performed, along with a rationale, to ease anxiety and give the woman a sense of control.

Before beginning the procedure, a count of all instruments that will be used during the operative procedure is performed and recorded. Typically, this count is repeated three times throughout the operation to ensure that no instruments are left in the woman's abdomen. The nurse is responsible for ensuring that the instrument count is correct. In the event the count is not correct or if a count was not done initially because of emergency circumstances, a portable x-ray screening is performed to ensure no instruments remain in the maternal abdomen.

Preparation for Repeat Cesarean Birth

When a couple is anticipating a repeat cesarean birth, they have time to reflect on their past experiences, analyze and synthesize the new information they are given, and prepare for the experience. Couples who have had previous negative experiences need an opportunity to describe what they felt contributed to these events. They should be encouraged to identify what they would like to have altered and to list interventions that would make the experience more positive. Those who have had positive experiences need reassurance that their needs and desires will be met in the same manner. In addition, the nurse should provide an opportunity for the couple to discuss any fears or anxieties. Some women undergoing an elective repeat cesarean birth may continue to grieve the loss of the ideal birth experience or continue to exhibit mixed emotions regarding their choices for the birth. These women need reassurance and support throughout the birth process.

Preparation for Emergency Cesarean Birth

The period preceding surgery must be used to its greatest advantage. If possible, the couple needs some time for privacy to assimilate the information given to them and to ask for additional information. It is imperative that caregivers use their most effective communication skills. The nurse must address what the couple may anticipate during the next few hours. Asking the couple, "What questions do you have about the decision?" gives the couple an opportunity for further clarification. The nurse can prepare the woman in stages, giving her information and the rationale for each procedure before commencing. Before carrying out a procedure, it is essential to tell the woman (1) what is going to happen, (2) why it is being done, and (3) what sensations she may experience. This allows the woman to be informed and to consent to the procedure. The woman experiences a sense of control and therefore less helplessness and powerlessness.

Supporting the Father/Partner

Every effort should be made to include the father/partner or support person in the cesarean birth experience. When the father or support person attends the cesarean birth, he or she must wear a surgical gown and mask as do others in the operating suite. The father or support person can sit on a stool placed beside the woman's head to provide physical touch, visual contact, and verbal reassurance to his partner.

Many support persons worry about their own reactions to the operative procedure. A sterile drape is placed between the woman's head and the sterile field. The nurse can advise the support person that this can be used as a partition if he or she does not wish to view the procedure itself. The nurse should encourage support persons to eat if possible before the surgery. Most fathers or support persons who fear "fainting" or "feeling queasy" do not have difficulties in the operating room and frequently forget these fears as they are swept away in the excitement of the birth.

Other measures, such as the following, can be taken to promote the participation of the father or partner who chooses not to be present in the delivery room:

- Allowing the father or partner to be near the operating room, where he can hear the newborn's first cry
- Encouraging the father/partner to carry or accompany the infant to the nursery for the initial assessment
- Involving the father/partner in postpartal care in the recovery room

In the event that a support person cannot be with the woman during the cesarean birth, such as in situations involving emergencies, the nurse may obtain consent from the woman before the surgery and then provide updates to the support person to alleviate undue fear and anxiety.

Immediate Postpartum Recovery Period

After birth, the nurse assesses the Apgar score and completes the initial assessment and identification procedures as after a vaginal birth. Every effort must be made to assist the parents in bonding with the infant. If the mother is awake, one of her arms should be freed to enable her to touch and stroke the infant. The baby can be given to the father to hold until she or he must be taken to the nursery.

The nurse caring for the postpartal woman should check her vital signs every 5 minutes until they are stable, then every 15 minutes for an hour, then every 30 minutes until she is discharged to the postpartal unit. The nurse should remain with the woman until she is stable.

The dressing and perineal pad must be checked every 15 minutes for at least an hour, and the fundus should be gently palpated to determine whether it is remaining firm. The fundus may be palpated by placing a hand to support the incision. Intravenous oxytocin is usually administered to promote the contractility of the

uterine musculature. If the woman has had general anesthesia, she should be positioned on her side to facilitate drainage of secretions, turned, and assisted with coughing and deep breathing every 2 hours for at least 24 hours. If she has received a spinal or epidural anesthetic, the level of anesthesia should be checked every 15 minutes. It is important to monitor intake and output and to observe the urine for bloody tinge, which could mean surgical trauma to the bladder. The physician prescribes medication to relieve the mother's pain and nausea, and this should be administered as needed. Some physicians use a single dose of epidural morphine (5 to 7.5 mg) for postsurgical pain relief. Facilitation of parent-infant interaction following birth and postpartum care is discussed in chapter 36 ∞.

Care of the Woman Undergoing Vaginal Birth After Cesarean

In the late 1980s there was an increasing trend to have a trial of labor and **vaginal birth after cesarean (VBAC)** birth in cases of nonrecurring indications for a cesarean (for example, twins, umbilical cord prolapse, placenta previa, nonreassuring fetal status). This trend was influenced by consumer demand and studies that support VBAC as a viable and safe alternative. Recent media reports have reintroduced the debate regarding the safety of VBACs resulting in a decrease in the number of VBACs in the United States.

The American College of Obstetricians and Gynecologists (ACOG) guidelines state that the following aspects should be met when identifying candidates for a trial of labor (Cunningham et al., 2010):

- One previous cesarean birth and a low transverse uterine incision
- An adequate pelvis
- No other uterine scars or previous uterine rupture
- A physician who is able to do a cesarean needs to be available throughout active labor
- In-house anesthesia personnel are available for emergency cesarean births if warranted

Recent debate and research have led to a considerable rise in cesarean births and a significant reduction in women attempting VBACs. In the late 1980s, a movement to increase vaginal births after a previous cesarean birth was advocated because of the increases in morbidity, mortality, and costs associated with cesarean births. This resulted in a decline in the cesarean birthrate and a rise in the VBAC rates. Research in the 1990s, however, changed this trend when reports of rising numbers of uterine ruptures were reported in women attempting VBACs. Although the absolute risks of VBAC are small, there is a 0.1% to 0.7% risk of uterine rupture when women attempt a trial of labor after previously undergoing a cesarean birth (Algert, Morris, Simpson, et al., 2008). The significance is that, in the studies, there were no uterine ruptures in the group of women who had undergone an elective repeat cesarean birth. There is uncertainty about whether a trial of labor after cesarean (TOLAC) increases the risk of perinatal death compared to babies born by elective repeat cesarean section (ERCS). Some studies have found an increased perinatal death rate in babies in the TOLAC groups compared to those in the ERCS group (Richter, Bergmann, & Dudenhausen, 2008). These findings, combined with nonmedical factors (rising malpractice premiums for providers, accessibility to an institution that provides VBAC services, provider attitudes), are primarily responsible in the decline of VBACs in the United States since the 1990s. Other risks associated with VBAC are included in Table 28-4.

Although VBACs remain controversial, success rates for VBAC have been encouraging. Women whose previous cesarean was performed because of nonrecurring indications have been reported to have approximately a 60% to 80% chance of success with VBAC (Harper & Macones, 2008). Women whose previous cesarean was performed for breech presentation had the highest success rates for VBAC (91%). Women who had a previous cesarean birth for nonreassuring fetal status had an 84% success rate, whereas a woman diagnosed with previous dystocia had a 67% success rate. Women who were previously diagnosed with dystocia before 5-cm dilatation had a 67% success rate, whereas women who had previously progressed to 6 to 9 cm had a 73% success rate. Women who had been labeled as having dystocia in the second stage had a 75% success rate (Cunningham et al., 2010).

NURSING CARE MANAGEMENT

The nursing care of a woman undergoing VBAC varies according to institutional protocols. Generally, if the woman is at very low risk (has had one previous cesarean with a lower uterine segment incision), her blood count, type, and screen are obtained on admission; a heparin lock is inserted for intravenous access if needed; continuous electronic fetal monitoring (EFM) is used; and clear fluids may be taken. If the woman is at higher risk, NPO status should be maintained, and, in addition to the care listed, an intrauterine catheter may be inserted to monitor intrauterine pressures during labor.

Supportive and comfort measures are very important. The woman may be excited about this opportunity to experience labor and vaginal birth, or she may be hesitant and frightened about the possibility of complications. The nurse provides information and encouragement for the laboring woman and her partner.

TABLE 28-4 Complications Associated with VBAC

- Uterine rupture
- Uterine dehiscence
- Hysterectomy
- Uterine infection
- Maternal death
- Neonatal death
- Antepartum stillbirth
- Intrapartum stillbirth
- Transfusion
- Hypoxic ischemic encephalopathy

FOCUS YOUR STUDY

- An external (or cephalic) version may be done after 37 weeks' gestation to change a breech presentation to a cephalic presentation, thereby making a lower risk vaginal birth more possible.
- The version is accomplished with the use of tocolytic agents to relax the uterus. An internal (podalic) version is used only when needed during the vaginal birth of a second twin.
- Amniotomy (AROM) is performed to hasten labor. The risks are prolapse of the umbilical cord and infection.
- Prostaglandin E_2 may be used before an induction of labor to soften the cervix (called cervical ripening). These agents are inserted into the vagina to make the cervix more favorable for induction.
- Labor is induced for many reasons. The methods include amniotomy, stripping of the membranes, intravenous oxytocin infusion, and alternative and complementary methods. Nursing responsibilities are heightened during an induced labor.
- Amnioinfusions are used in cases of oligohydramnios or nonperiodic decelerations to increase the volume of amniotic fluid, which relieves cord compression and promotes perfusion to the fetus.
- An episiotomy may be performed just before birth of the fetus. Current evidence shows a limited number of indications for its use.
- Forceps-assisted birth can be accomplished using outlet forceps, low forceps, or midforceps. Outlet forceps are the most common and are associated with few maternal-fetal complications. Midforceps are associated with more complications but, when needed, are an important aid to birth.
- A vacuum extractor is a soft, pliable cup attached to suction that can be applied to the fetal head and used in much the same way as forceps.
- Approximately one in three births is accomplished by cesarean. The nurse has a vital role in providing information, support, and encouragement to the couple participating in a cesarean birth.
- Vaginal birth after cesarean (VBAC) carries a low risk of uterine rupture; however, many physicians perform repeat cesarean births out of fear of malpractice issues. Overcoming the old fears of uterine rupture is a high priority for both the parents and the medical and nursing community.

CRITICAL THINKING IN ACTION

Source: George Dodson/Pearson Education.

Betsy Jones, a 28-year-old G1 PO is at 39 weeks' gestation, and her husband present to you in the labor suite for an external cephalic version procedure by her obstetrician. You introduce yourself and review her prenatal record for any significant risk factors or contraindications to the version procedure. Her prenatal chart is significant in that the fetus has been in a persistent frank breech position. You encourage Betsy and her husband to express their understanding and expectations of the procedure. You discuss certain criteria to be met prior to the procedure and obtain vital signs as follows: T 98.8°F, P 88, R 14, BP 110/80, urine screening negative for sugar, albumin, and ketones. You place Betsy on the external electronic fetal monitor, which demonstrates a fetal heart rate baseline of 140 to 152 with moderate long-term variability. There are no contractions observed by the monitor or Betsy. After explaining how to record fetal movement on the monitor, you proceed with an NST.

1. Explain the contraindications to the version procedure.
2. Discuss the criteria that should be met prior to performing external version.
3. How would you explain to Betsy and her husband what to expect during the version procedure?
4. What support would you give Betsy during the procedure?
5. Explain postversion discharge teaching.

CHAPTER 29

Physiologic Responses of the Newborn to Birth

The incredible attributes of the newborn have a major purpose. They prepare the baby for interaction with the family and for life in the world.

—Marshall H. Klaus & Phyllis H. Klaus, *The Amazing Newborn*

LEARNING OUTCOMES

1. Summarize the respiratory and cardiovascular changes that must occur for the newborn to successfully transition to extrauterine life.
2. Compare the various factors that modify the newborn's blood values to the corresponding results.
3. Relate the process of thermogenesis in the newborn and the major mechanisms of heat loss to the challenge of maintaining newborn thermal stability.
4. Explain the steps involved in the conjugation and excretion of bilirubin in the newborn.
5. Discuss the reasons a newborn may develop hyperbilirubinemia and the nursing interventions that can decrease the probability or the severity of jaundice.
6. Delineate the functional abilities of the newborn's gastrointestinal tract and liver.
7. Relate the development of the newborn kidney to the newborn's ability to maintain adequate fluid and electrolyte balance.
8. Describe basic newborn immunologic responses.
9. Explain the physiologic and behavioral characteristics of newborn neurologic functioning including the patterns of behavior, during periods of reactivity.
10. Describe the normal sensory/perceptual abilities and behavioral states present in the newborn period.

KEY TERMS

Active acquired immunity *775*
Alveolar surface tension *759*
Brown adipose tissue (BAT) *768*
Cardiopulmonary adaptation *760*
Conduction *767*
Convection *767*
Evaporation *767*
Fetal breathing movements (FBM) *757*
Functional residual capacity (FRC) *758*
Habituation *778*
Lung compliance *759*
Meconium *774*
Neonatal transition *757*
Neutral thermal environment (NTE) *766*
Orientation *778*
Passive acquired immunity *775*
Periodic breathing *761*
Periods of reactivity *777*
Physiologic anemia of the newborn *765*
Physiologic jaundice *770*
Radiation *767*
Self-quieting ability *778*
Surfactant *757*
Thermogenesis *768*
Total serum bilirubin *769*

The newborn period is the time from birth through the 28th day of life. During this period, the newborn undergoes physiologic adaptation from intrauterine to extrauterine life. The nurse needs to be knowledgeable about a newborn's normal physiologic and behavioral adaptations and be able to recognize alterations from normal transition.

The first few hours of life, in which the newborn stabilizes respiratory and circulatory functions, are called **neonatal transition**. All other newborn body systems change their level of functioning or become established over a longer period of time during the neonatal period.

Respiratory Adaptations

To begin life as a separate being, the baby must immediately establish respiratory functioning and ventilation. Adequate respiratory gas exchange in conjunction with marked circulatory changes are radical and rapid changes crucial to successful transition to extrauterine life.

Intrauterine Factors Supporting Respiratory Function

Even before the significant respiratory events occur at birth, certain intrauterine factors also enhance the newborn's ability to breathe. Adequate fetal lung development allows the newborn to expand his or her lungs and exchange oxygen and carbon dioxide gases. Even before birth the fetus practices breathing movements that aid in developing lung tissue and strengthening respiratory muscles, allowing him or her to breathe immediately after birth.

Fetal Lung Development

The respiratory system is in a continuous state of development during fetal life, and lung development continues into early childhood. During the first 20 weeks of gestation, lung development is limited to the differentiation of pulmonary, vascular, and lymphatic structures. At 20 to 24 weeks, alveolar ducts begin to appear, followed by primitive alveoli at 24 to 28 weeks. During this time, the alveolar epithelial cells begin to differentiate into type I cells (structures necessary for gas exchange) and type II cells (structures that provide for the synthesis and storage of surfactant). **Surfactant** is composed of surface-active phospholipids (lecithin and sphingomyelin), which are critical for alveolar expansion and stability.

At 28 to 32 weeks of gestation, the number of type II cells increases further, and surfactant is produced by a choline pathway within them. Surfactant production by this pathway peaks at about 35 weeks of gestation and remains high until term, paralleling late fetal lung development. At this time, the lungs are structurally developed enough to maintain good lung expansion and adequate exchange of gases although a fetus born at this gestation may need intensive care to survive.

Clinically, the peak production of lecithin—one component of surfactant—corresponds closely to the marked decrease in incidence of idiopathic respiratory distress syndrome for babies born after 35 weeks' gestation. Production of sphingomyelin—the other component—remains constant during gestation. The newborn born before the lecithin/sphingomyelin (L/S) ratio is 2:1 will have varying degrees of respiratory distress. (See discussion of L/S ratio in chapter 21 ∞ and chapter 34 ∞.)

Fetal Breathing Movements

The newborn's ability to breathe air immediately after birth appears to result from **fetal breathing movements (FBM)**, the intrauterine practice respiratory movements that begin around the 17th to 20th week of gestation. In this respect, breathing can be seen as a continuation of an intrauterine process; the lungs convert from a fluid-filled organ to an air-filled organ capable of gas exchange.

These breathing movements are essential for developing the chest wall muscles and the diaphragm and, to a lesser extent, for regulating lung fluid volume and resultant lung growth.

Initiation of Breathing

To maintain life, two significant changes must take place immediately after birth for the lungs to begin adequate functioning:

1. Pulmonary ventilation must be established through lung expansion.
2. A marked increase in the pulmonary circulation must occur.

The first breath of life—the gasp in response to mechanical, reabsorptive, chemical, thermal, and sensory changes associated with birth—initiates the serial opening of the alveoli. So begins the transition from a fluid-filled environment to extrauterine life as an independent functioning newborn. Figure 29-1 ■ summarizes the initiation of respiration.

Mechanical Events

During the latter half of gestation, the fetal lungs continuously produce fluid. This fluid production expands the lungs almost completely, filling the air spaces. Some of the lung fluid moves up into the trachea and out into the amniotic fluid. The amniotic fluid is then swallowed by the fetus.

In preparation for birth, lung fluid production normally decreases and fetal breathing movement decreases 24 to 36 hours before the onset of true labor (Knuppel, 2007). However, approximately 80 to 100 ml of fluid remains in the respiratory passages of a normal term fetus at the time of birth. Excess fluid must be removed from the alveolar spaces after birth for effective gas exchange to occur (Ramachandrappa & Jain, 2008). As the fetus experiences labor, there is a fetal gasp and active exhalation that initiates the removal of fluid from the lungs (Rosenberg, 2007). During the vaginal birthing process the fetal chest is compressed, increasing intrathoracic pressure and squeezing a small amount of fluid out of the lungs. At delivery, the chest wall recoils, creating negative intrathoracic pressure, which is thought to produce a small, passive inspiration of air that replaces the fluid that was squeezed out. The significance of the "thoracic squeeze" is controversial, and it is now thought that the process of labor is primarily responsible for the initial movement of lung fluid out of the lungs (Rosenberg, 2007).

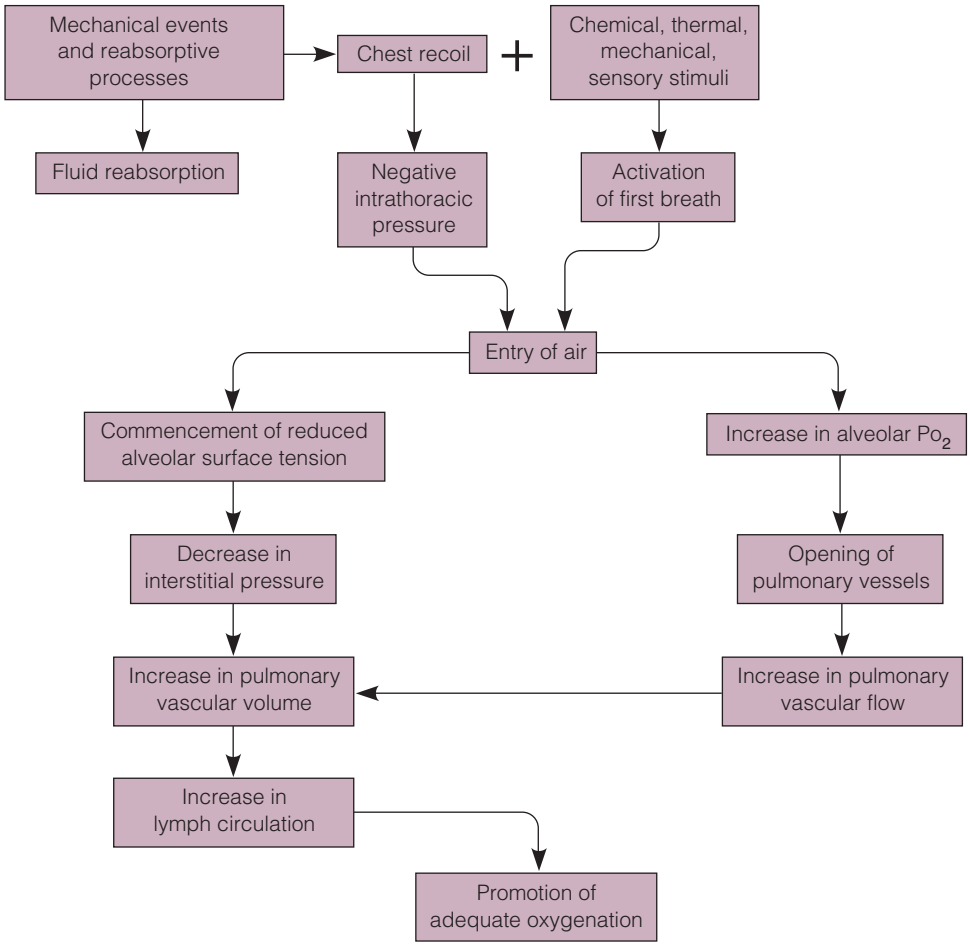

Figure 29-1 ■ Initiation of respiration in the newborn.

After this first inspiration, the newborn exhales and cries against a partially closed glottis, creating a positive intrathoracic pressure. The high positive intrathoracic pressure distributes the inspired air throughout the alveoli and begins the establishment of **functional residual capacity (FRC)**, the amount of air remaining in the lungs at the end of a normal expiration. The higher intrathoracic pressure also increases absorption of lung fluid via the capillaries and lymphatic system. The negative intrathoracic pressure created when the diaphragm moves down with inspiration causes lung fluid to flow from the alveoli across the alveolar membranes into the pulmonary interstitial tissue.

At birth the alveolar epithelium is temporarily more permeable. This, combined with decreased cellular resistance at the onset of breathing, may facilitate passive liquid absorption. With each succeeding breath, the lungs continue to expand, stretching the alveolar walls and increasing the alveolar volume. Protein molecules are too large to pass through capillary walls. The presence of more protein molecules in the pulmonary capillaries than in the interstitial tissue creates oncotic pressure. This pressure draws the interstitial fluid into the capillaries and lymphatic tissue to balance the concentration of protein. Lung expansion helps the remaining lung fluid move into the interstitial tissues. As pulmonary vascular resistance decreases, pulmonary blood flow increases, and more interstitial fluid is absorbed into the bloodstream. In the healthy term newborn, lung fluid moves rapidly into the interstitial tissue but may take several hours to move into the lymph and blood vessels. Figure 29-2 ■ depicts the changes in fetal lung fluid with the first and subsequent breaths. Most of the lung fluid is reabsorbed within 2 hours after birth, and it is completely absorbed within 12 to 24 hours after birth (Rosenberg, 2007).

Although the initial chest compression and recoil should clear the airways of accumulated fluid and permit further inspiration, most clinicians feel it is wise to suction mucus and fluid from the newborn's mouth, nose, and throat. They use a bulb syringe or mucus trap attached to suction as soon as the newborn's head and shoulders are born and again as the newborn adapts to extrauterine life and stabilizes (see Procedure 24-1 ∞ on page 622 and chapter 24 ∞).

Newborns may have problems clearing the fluid in the lungs and beginning respiration for a variety of reasons:

- The lymphatic system may be underdeveloped, thus decreasing the rate at which the fluid is absorbed from the lungs.
- Complications that occur before or during labor and birth can interfere with adequate lung expansion and cause failure to decrease pulmonary vascular resistance, resulting in decreased pulmonary blood flow. Excess fluid must exit the alveoli and pulmonary blood flow must increase to match

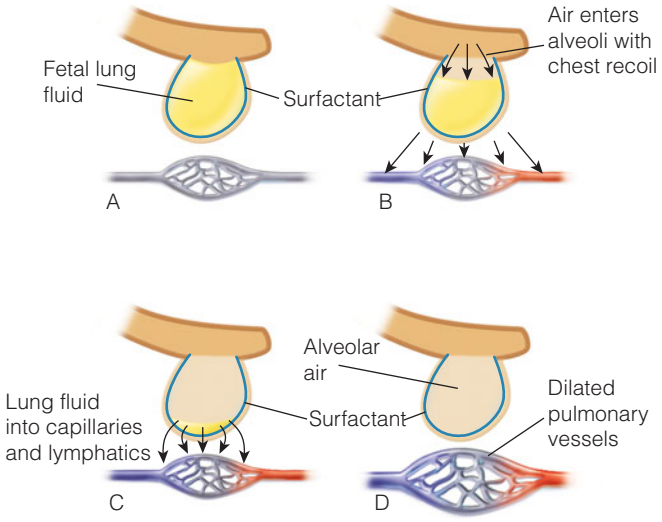

Figure 29-2 ■ Process of absorption of fetal lung fluid during breathing after birth. A. Fetal alveoli filled to functional residual capacity with fetal lung fluid. Fetal lung fluid is produced by the alveoli, fills the airways, and eventually enters the amniotic fluid. B. After fetal chest compression, one third of the fetal lung fluid is squeezed out, allowing air to enter passively as the chest recoils. C. With each subsequent breath, the lungs expand, facilitating the movement of the remaining fetal lung fluid into the capillaries and lymphatic system. Pulmonary blood flow is increasing. D. Normal alveoli after removal of fetal lung fluid and dilatation of pulmonary arteries. Surfactant has lined the inside of the alveoli to prevent collapse.

ventilation with perfusion. These complications include inadequate compression of the chest wall in a very small newborn (small for gestational age [SGA] or very low birth weight [VLBW]) because the immature muscular development causes an overly compliant chest well. Other complications include the absence of the chest wall compression in the newborn delivered by cesarean birth, respiratory depression secondary to maternal analgesia or anesthesia agents, or aspiration of amniotic fluid, blood, or meconium.

Chemical Stimuli

An important chemical stimulator that contributes to the onset of breathing is transitory asphyxia of the fetus and newborn. The first breath is an inspiratory gasp, the result of central nervous system reaction to sudden pressure, temperature change, and other external stimuli (Knuppel, 2007).

This first breath is triggered by normal chest recoil as well as the chemical factors of an elevation in PCO_2 (hypercapnia), decrease in pH (acidosis), and decrease in PO_2 (hypoxia), which are the natural results of normal vaginal labor and birth and cessation of placental gas exchange when the cord is clamped. These stressors, present in all newborns to some degree, stimulate the aortic and carotid chemoreceptors, initiating impulses that trigger the respiratory center in the medulla. Although this brief period of asphyxia is a significant stimulator, prolonged asphyxia is abnormal, depresses respiration, and causes a decrease in pulmonary blood flow. Another chemical factor involves hormonal changes during the labor and delivery process. The levels of prostaglandin, a hormone that suppresses respiration, fall with the clamping of the umbilical cord, thus increasing the infant's respiratory drive (Ramachandrappa & Jain, 2008).

Thermal Stimuli

A significant decrease in ambient temperature after birth—from 37°C to 21–23.9°C (98.6°F to 70–75°F) results in sudden chilling of the moist newborn (Blackburn, 2007). The cold stimulates skin sensory receptors and the newborn responds with rhythmic respirations. Normal temperature changes that occur at birth are apparently within acceptable physiologic limits. Excessive cooling, however, may result in profound respiratory depression and evidence of cold stress (see chapter 34 ∞ for discussion of cold stress).

Sensory Stimuli

During intrauterine life, the fetus is in a dark, sound-dampened, fluid-filled environment and is nearly weightless. After birth the newborn experiences light, sounds, and the effects of gravity for the first time. As the fetus moves from a familiar, comfortable, quiet environment to one of sensory abundance, a number of physical and sensory influences help respiration begin and be sustained after birth. They include the numerous tactile, auditory, visual, and painful stimuli of birth and the normal handling after delivery. Joint movement results in enhanced proprioceptor stimulation to the respiratory center to sustain respirations. Thoroughly drying the newborn and placing him or her in skin-to-skin contact with the mother's chest and abdomen provides stimulation in a far more comforting way and also decreases heat loss.

CLINICAL TIP

Historically, slapping the buttocks or heels of the newborn was a common way to stimulate breathing, but today the emphasis is on gentle physical contact. Thoroughly drying the newborn and placing the baby in skin-to-skin contact with the mother's chest and abdomen will provide ample external stimulation for the first breaths in a far more comforting way. These actions will also decrease heat loss and promote mother-infant bonding.

Factors Opposing the First Breath

Three major factors may oppose the initiation of respiratory activity: (1) the contracting force between moist surfaces of the alveoli—called **alveolar surface tension**; (2) viscosity of lung fluid within the respiratory tract, which is influenced by surfactant levels; and (3) the ease with which the lung is able to fill with air—called **lung compliance**.

Alveolar surface tension is the contracting force between the moist surfaces of the alveoli. This tension, which is necessary for healthy respiratory function, would cause the small airways and alveoli to collapse after each inspiration if surfactant were not present. Surfactant is important because it reduces surface tension of the fluid lining the alveoli permitting the alveoli to expand. Surfactant stabilizes the alveoli and prevents them from completely collapsing with each expiration and thus promotes lung expansion. Similarly, surfactant promotes lung compliance, the ability of the lung to fill with air easily. When

surfactant is decreased, compliance is also decreased, and the pressure needed to expand the alveoli with air increases.

Resistive forces of the fluid-filled lung, combined with the small radii of the airways, necessitates pressures of 30 to 40 cm of water pressure, which are needed to open the lung initially (Niermeyer & Clarke, 2011).

The first breath usually establishes FRC that is 30% to 40% of the fully expanded lung volume. This FRC allows alveolar sacs to remain partially expanded on expiration, decreasing the need for continuous high pressures for each of the following breaths. Subsequent breaths require only 6 to 8 cm H_2O pressure to open alveoli during inspiration. Thus, the first breath of life is usually the most difficult.

Cardiopulmonary Physiology

The onset of respiration stimulates cardiovascular system changes necessary for successful transition to extrauterine life, hence the term **cardiopulmonary adaptation**. As air enters the lungs, PO_2 rises in the alveoli, which stimulates the relaxation of the pulmonary arteries and triggers a decrease in the pulmonary vascular resistance. As pulmonary vascular resistance decreases, the vascular flow in the lung increases very rapidly and achieves 100% normal flow volume at 24 hours of life. This delivery of greater blood volume to the lungs contributes to the conversion from fetal circulation to newborn circulation.

After pulmonary circulation is established, blood is distributed throughout the lungs, although the alveoli may or may not be fully open. For adequate oxygenation to occur, the heart must deliver sufficient blood to functional open alveoli. Shunting of blood is common in the early newborn period. Bidirectional blood flow, or right-to-left shunting through the ductus arteriosus, may divert a significant amount of blood away from the lungs, depending on the pressure changes of respiration, crying, and the cardiac cycle. This shunting of blood away from the lungs in the newborn period is also responsible for the unstable transitional period in cardiopulmonary function.

Oxygen Transport

The transportation of oxygen to the peripheral tissues depends on the type of hemoglobin in the red blood cell (RBC). In the fetus and newborn, a variety of hemoglobin types exist with the most significant being fetal hemoglobin (HbF) and adult hemoglobin (HbA). Approximately 70% to 90% of hemoglobin in the fetus and newborn is HbF. The greatest difference between HbF and HbA relates to the transport of oxygen. The oxygen-carrying capacity of fetal hemoglobin is lower than that of adult hemoglobin. Although each gram of HbF carries less oxygen, it has a greater affinity for the oxygen molecules it carries. At any given arterial oxygen level, HbF has a greater oxygen saturation than HbA. Thus the oxygen-hemoglobin dissociation curve for HbF lies to the left of that for HbA (Figure 29-3 ■). HbF's greater affinity for oxygen benefits the fetus and newborn because it facilitates oxygen transfer across the placenta and into the newborn's tissues. In utero, the fetus has an arterial oxygen tension (PaO_2) between 30 and 40 mm Hg. Because of the nature of the HbF as depicted in the curve, small changes in fetal PaO_2 result in a great amount of oxygen

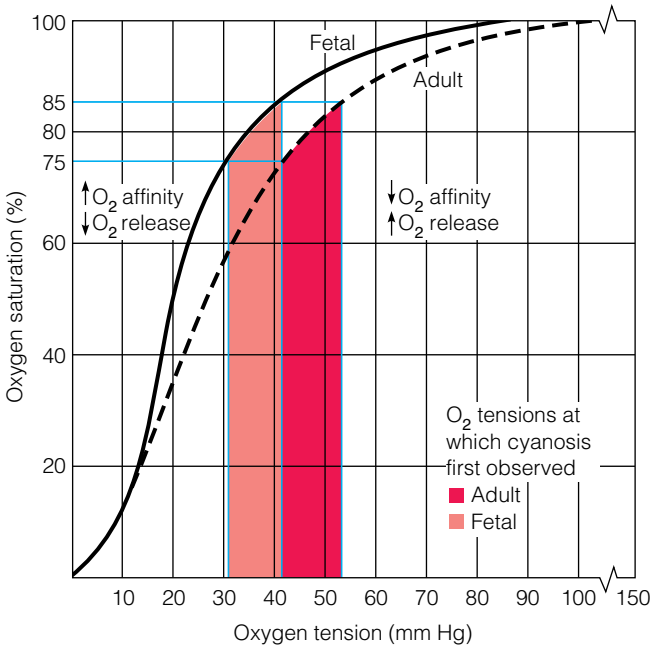

Figure 29-3 ■ Fetal oxygen-hemoglobin dissociation curve.

loading in the placenta or unloading to the tissues as compared with the adult. HbF's greater affinity for oxygen also requires that a lower tissue oxygen level exist before oxygen unloading than is required by HbA. Because of this phenomenon, the newborn will have both a lower arterial oxygen level and lower oxygen saturation than the adult before cyanosis becomes clinically apparent.

In addition to the specific characteristics of HbF, other conditions affect the transport of oxygen. Alkalosis (increased pH) and hypothermia can result in less oxygen being available to the body tissues, whereas acidosis, hypercarbia, and hyperthermia can result in less oxygen being bound to hemoglobin and more oxygen being released to the body tissues. Therefore, as blood is perfusing active tissues that are producing acids and carbon dioxide, hemoglobin's affinity for oxygen decreases, allowing oxygen unloading and carbon dioxide and acid uptake. This blood is then transferred to the placenta or the lungs, where its higher carbon dioxide and acid content results in uploading of these waste products from hemoglobin and the uptake of oxygen to be transferred to the tissues.

Other factors that regulate oxygen delivery to the tissues are oxygen-carrying capacity and cardiac output. The oxygen-carrying capacity of blood is defined as the product of the hemoglobin concentration and the maximum amount of oxygen that 1 g of hemoglobin can hold when it is fully saturated. The amount of oxygen bound to hemoglobin divided by the oxygen-carrying capacity yields a percentage that signifies oxygen saturation. Oxygen saturation usually reaches a value between 96% and 98% after several hours of life. Although HbF can hold only 1.26 ml of oxygen per gram of hemoglobin, compared with 1.34 ml of oxygen per gram of HbA, the newborn's hemoglobin level at birth (17 g/dl) is substantially

greater than in adults (13 g/dl). Therefore, the absolute oxygen-carrying capacity of fetal blood (21.42 vol %) is greater than in adult blood (17.42 vol %) and allows the fetus to tolerate the relatively hypoxic intrauterine environment.

A significant reduction in the oxygen-carrying capacity results in an increased cardiac output to compensate for hemoglobin's decreased oxygen concentration. Lastly, cardiac output of the fetus and newborn is relatively greater per body weight than in the adult, which contributes to the rapid delivery of oxygenated blood to tissues with high metabolic demands.

Maintaining Respiratory Function

The ability of the lung to maintain oxygenation and ventilation (the exchange of oxygen and carbon dioxide) is influenced by such factors as lung compliance and airway resistance. Lung compliance is influenced by the elastic recoil of the lung tissue and by anatomic differences in the newborn. The newborn has a relatively large heart and mediastinal structures that reduce available lung space. Also, the newborn chest is equipped with weak intercostal muscles, a rigid rib cage with horizontal ribs, and a high diaphragm that restricts the space available for lung expansion. The large abdomen further encroaches on the diaphragm to decrease lung space. Another factor that limits ventilation is airway resistance, which depends on the radii, length, and number of airways. Airway resistance is increased in the newborn when compared with adults.

Characteristics of Newborn Respiration

The normal newborn respiratory rate is 30 to 60 breaths per minute (Tappero & Honeyfield, 2009). Initial respirations may be largely diaphragmatic, shallow, and irregular in depth and rhythm. The abdomen's movements are synchronous with chest movements. Breathing patterns in newborns can be irregular and variable. Periodic breathing is common in preterm infants, but can also be seen in term infants. **Periodic breathing** is defined as "pauses in respiratory movements that last for up to 20 seconds alternating with breathing" (Blackburn, 2007). Periodic breathing is rarely associated with differences in skin color or heart rate changes, and it has no prognostic significance. Tactile or other sensory stimulation stimulates the respiratory center and converts periodic breathing patterns to normal breathing patterns during neonatal transition. With deep sleep, the pattern is reasonably regular. Periodic breathing occurs with rapid eye movement (REM) sleep, and grossly irregular breathing is evident with motor activity, sucking, and crying. Cessation of breathing lasting more than 20 seconds is defined as *apnea* and is abnormal in term newborns. Apnea may or may not be associated with changes in skin color or heart rate (drop below 100 beats per minute [beats/min]). Apnea always needs to be further evaluated.

Newborns tend to be obligatory nose breathers because the nasal route is the primary means of air entry. This is because of the high position of the epiglottis and the position of the soft palate (Blackburn, 2007). Although many term newborns can breathe orally when nasally occluded, nasal obstructions can cause respiratory distress. Any obstruction will cause some degree of respiratory distress, so it is important to keep the throat and nose clear. Immediately after birth and for about the next 2 hours, respiratory rates of 60 to 70 breaths per minute (breaths/min) are normal. Some cyanosis and acrocyanosis are normal for several hours; thereafter the infant's color improves steadily. If respirations drop below 20 or exceed 60 per minute when the baby is at rest, or if dyspnea, central cyanosis, nasal flaring, chest wall retractions, or expiratory grunting occur, the clinician should be notified. Any increased use of the intercostal muscle (retractions) may indicate respiratory distress. (See Respiratory Distress Syndrome in chapter 34 ∞ and Table 34-1 ∞ on page 948 for signs of respiratory distress.)

Cardiovascular Adaptations

As described earlier, the onset of respiration triggers increased pulmonary blood flow after birth. This greater blood volume contributes to the conversion from fetal circulation to neonatal circulation.

Fetal-Newborn Transitional Physiology

During fetal life, blood with the highest oxygen content is directed to the heart and brain. Blood in the descending aorta is less oxygenated and supplies the kidneys and intestinal tract before it is returned to the placenta. Limited amounts of blood, pumped from the right ventricle toward the lungs, enter the pulmonary vessels. In the fetus, increased pulmonary resistance forces most of the blood through the ductus arteriosus into the descending aorta (Table 29-1). See the fetal heart animation on www.nursing.personhighered.com.

TABLE 29-1 Fetal and Neonatal Circulation

SYSTEM	FETAL	NEONATAL
Pulmonary blood vessels	Constricted with very little blood flow (high pulmonary vascular resistance); lungs not expanded and fluid-filled.	Vasodilatation and increased blood flow (decreasing pulmonary vascular resistance); lungs expanded; increased PaO_2 stimulates vasodilation.
Systemic blood vessels	Dilated with low peripheral vascular resistance; blood mostly in placenta.	Arterial pressure rises due to cord clamping with loss of placental reservoir; increased systemic blood volume causes increased peripheral vascular resistance.
Ductus arteriosus	Large with no tone; blood flow from pulmonary artery to aorta (right to left shunting).	Reversal of blood flow. Now from aorta to pulmonary artery (left to right shunting) because of increased left atrial pressure and increased systemic vascular pressures. Ductus is sensitive to increased PaO_2 and a decline in circulating prostaglandins and begins to constrict.
Foramen ovale	Patent with large blood flow from right atrium to left atrium.	Increased pressure in left atrium attempts to reverse blood flow and shuts one-way valve.

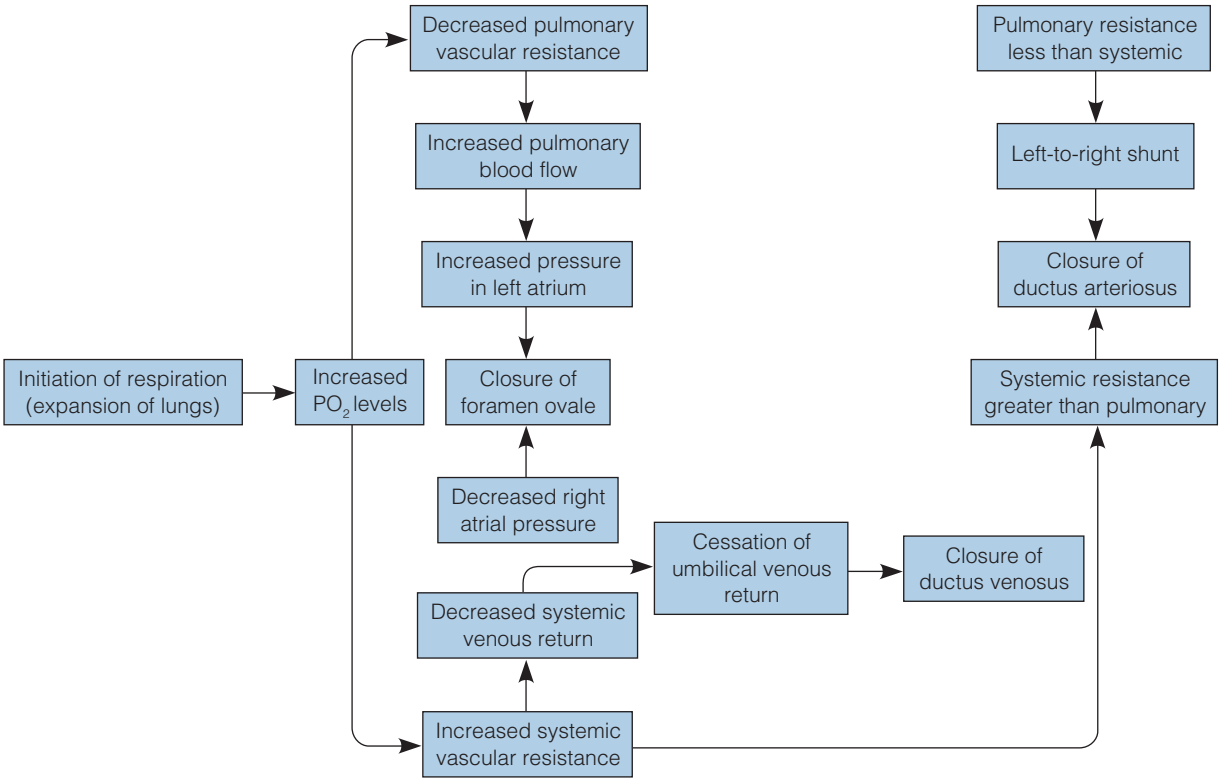

Figure 29-4 ■ Transitional circulation: Conversion from fetal to neonatal circulation.

Marked changes occur in the cardiovascular system at birth. Expansion of the lungs with the first breath decreases the pulmonary vascular resistance and increases pulmonary blood flow. Pressure in the left atrium increases as blood returns from the pulmonary veins. Pressure in the right atrium drops, and systemic vascular resistance increases as umbilical venous flow is halted when the cord is clamped. These physiologic mechanisms mark the beginning of transition from fetal to neonatal circulation and show the interplay of the cardiovascular and respiratory systems (Figure 29-4 ■).

Five major areas of change in cardiopulmonary adaptation (Figure 29-5 ■) are the following:

1. ***Increased aortic pressure and decreased venous pressure.*** Clamping of the umbilical cord eliminates the placental vascular bed and reduces the intravascular space. Consequently, aortic (systemic) blood pressure increases. At the same time, blood return via the inferior vena cava decreases, resulting in decreased right atrial pressure and a small decrease in pressure within the venous circulation.
2. ***Increased systemic pressure and decreased pulmonary artery pressure.*** With the loss of the low-resistance placenta, systemic resistance increases, resulting in greater systemic pressure. At the same time, lung expansion increases pulmonary blood flow, and the increased blood PO_2 associated with initiation of respirations dilates pulmonary blood vessels. The combination of vasodilation and increased pulmonary blood flow decreases pulmonary artery resistance. As the pulmonary vascular beds open, the systemic vascular pressure increases, enhancing perfusion of the other body systems.
3. ***Closure of the foramen ovale.*** Closure of the foramen ovale is a function of changing atrial pressures. In utero, pressure is greater in the right atrium, and the foramen ovale is open after birth, shunting blood from the right atrium to the left. Decreased pulmonary resistance and increased pulmonary blood flow increase pulmonary venous return into the left atrium, thereby increasing left atrial pressure slightly. The decreased pulmonary vascular resistance and the decreased umbilical venous return to the right atrium also cause a decrease in right atrial pressure. The pressure gradients across the atria are now reversed, with left atrial pressure greater, and the foramen ovale is functionally closed 1 to 2 hours after birth. However, a slight right-to-left shunting may occur in the early neonatal period. Any increase in pulmonary resistance or right atrial pressure, such as occurs in crying, acidosis, cold stress, or induced hypoxia, may cause the foramen ovale to reopen, causing a right-to-left shunt. Anatomical closure of the foramen ovale occurs within 30 months (Blackburn, 2007).
4. ***Closure of the ductus arteriosus.*** Initial elevation of the systemic vascular pressure above the pulmonary vascular pressure increases pulmonary blood flow by reversing the flow through the ductus arteriosus. Blood now flows from the aorta into the pulmonary artery. Furthermore, although the presence of oxygen causes the pulmonary arterioles to dilate, an increase in blood PO_2 triggers the opposite response in the ductus arteriosus—it constricts.

In utero the placenta produces prostaglandin E_2 (PGE_2), which causes ductus vasodilation. With the loss of the placenta and increased pulmonary blood flow, PGE_2 levels drop, leaving the active constriction by PO_2 unopposed. If the lungs fail to expand or if PO_2 levels drop, the ductus remains patent. Functional closure in the well newborn starts at 10 to 15 hours after birth, and fibrosis of the ductus occurs within 4 weeks after birth (Blackburn, 2007).

5. ***Closure of the ductus venosus.*** Although the mechanism of initiating closure of the ductus venosus is not known, it appears to be related to mechanical pressure changes that result from severing of the cord, redistribution of blood, and cardiac output. Closure of the ductus venosus forces perfusion of the liver. Fibrosis of the ductus venosus occurs within 2 months, at which time it becomes known as the ligamentum venosum. Figure 29-6 ■ depicts the changes in blood flow and oxygenation as the fetal cardiopulmonary circulation adapts to extrauterine life.

Characteristics of Cardiac Function

Evaluation of the newborn's heart rate, blood pressure, heart sounds, and cardiac workload provides data for evaluating cardiac function.

Heart Rate

Shortly after the first cry and the start of changes in cardiopulmonary circulation, the newborn heart rate can accelerate to 180 beats/min. The average resting heart rate in the first week of life is 110 to 160 beats/min in a healthy full-term newborn but may vary significantly during deep sleep or active awake states. In full-term newborns, the heart rate may drop to a low of 80 to 100 beats/min during deep sleep (Creehan, 2008).

Apical pulse rates should be obtained by auscultation for a full minute, preferably when the newborn is asleep. The heart rate should be evaluated for abnormal rhythms or beats. Peripheral pulses of all extremities should also be evaluated to detect any inequities or unusual characteristics (Creehan, 2008). While radial pulses are usually readily found, pedal pulses can be difficult to palpate in the newborn. Additionally, brachial and femoral pulses are usually easily palpated in the well newborn.

Blood Pressure

Case Study: Normal Range of Newborn's Vital Signs

The blood pressure tends to be highest immediately after birth, and then it descends to its lowest level at about 3 hours of age. By 4 to 6 days of life, the blood pressure rises and plateaus at a level approximately the same as the initial level. Blood pressure is sensitive to the changes in blood volume that occur in the transition to newborn circulation. Figure 29-7 ■ diagrams this response. Peripheral perfusion pressure is a particularly sensitive indicator of the newborn's ability to compensate for alterations in blood volume before changes in blood pressure. Capillary refill should be less than 2 to 3 seconds when the skin is blanched.

Blood pressure values during the first 12 hours of life vary with the birth weight and gestational age. The average mean blood pressure is 5 to 55 mm Hg in full term, resting newborns over 3 kg during the first 12 hours of life (Thureen, Deacon, Hernandez, et al., 2005). In the preterm newborn, the average mean blood pressure varies according to weight and degree of illness. Crying may cause an elevation of 20 mm Hg in both the systolic and diastolic blood pressure; thus accuracy is more likely in the quiet newborn. The measurement of blood pressure is best accomplished by using the Doppler technique, with a size- and weight-appropriate cuff over the brachial artery.

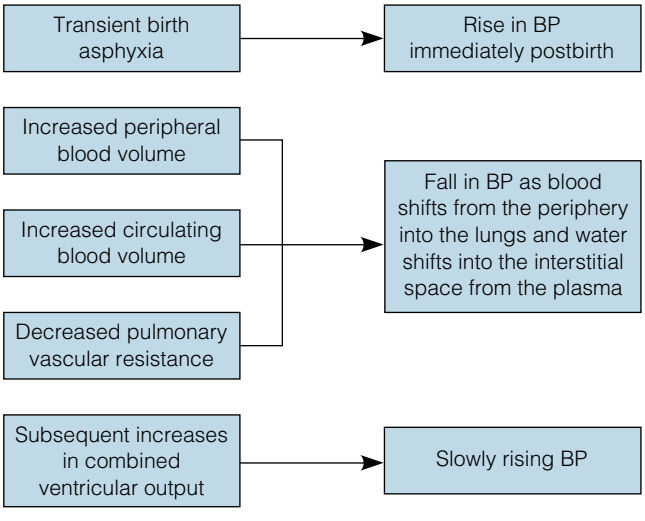

Figure 29-7 ■ Response of blood pressure (BP) to changes in neonatal blood volume.

Heart Murmurs

Murmurs are usually produced by turbulent blood flow through a narrowed opening. Murmurs may be heard when blood flows across an abnormal valve or across a stenosed valve, when there is an atrial or ventricular septal defect, or when there is increased flow across a normal valve. In newborns, 90% of all murmurs are transient and *not associated with anomalies*. Cardiac murmurs are often present in the initial newborn period as transition from fetal to neonatal circulation occurs. These murmurs heard in the transition period mean less than at any other time (Cloherty, Eichenwald, & Stark, 2008). They usually involve incomplete closure of the ductus arteriosus or foramen ovale. Soft murmurs may be heard as the pulmonary branch arteries increase their blood flow from 7% to 50% of the combined ventricular output during transition, causing a physiologic peripheral pulmonary stenosis. Clicks may normally be heard at the lower left sternal border as the great vessels dilate to accommodate systolic blood flow in the first few hours of life. Because of the current practice of early discharge, murmurs associated with ventricular septal defect and patent ductus arteriosus are often not detected until the first well-baby checkup at 4 to 6 weeks of age. Consequently, newborns with serious cardiac anomalies may or may not exhibit murmurs. Oftentimes hearing a murmur is the most common means of recognizing cardiac disease.

Cardiac Workload

Before birth the right ventricle does approximately two thirds of the cardiac work resulting in increased size and thickness of the right ventricle at birth. After birth the left ventricle must assume a larger share of the cardiac workload, and it progressively increases in size and thickness. This may explain why right-sided heart defects are better tolerated than left-sided ones and why left-sided defects rapidly become symptomatic after birth.

In the newborn, right ventricular output reflects systemic venous return, and left ventricular output reflects pulmonary venous return. Systemic blood volume and pulmonary blood volume are not equal in the newborn. The newborn's combined cardiac output (left and right ventricular) is greater per unit of body weight than it will be in later childhood.

Hematopoietic Adaptations

Fetal blood flowing through the umbilical vein in utero is 50% oxygen saturated; this relative hypoxia causes increased amounts of erythropoietin to be secreted, resulting in active erythropoiesis (an increase in nucleated red blood cells and reticulocytes). Erythropoiesis is regulated by the hormone erythropoietin, which is produced postnatally in the kidneys. Levels of erythropoietin rise in response to hypoxia and anemia. After birth, the increases in oxygen saturation and arterial oxygen levels shut off the produc-

tion of erythropoietin. In the first days of life, hemoglobin (the major iron-containing component of the red blood cell [RBC]) concentration may rise 1 to 2 g/dl above fetal levels as a result of placental transfusion, low oral fluid intake, and diminished extracellular fluid volume. By 1 week postnatally, peripheral hemoglobin is comparable to fetal blood counts. Then the hemoglobin level declines progressively thereafter during the first 2 months after birth. This initial decline in hemoglobin creates a phenomenon known as **physiologic anemia of the newborn** (Blackburn, 2007). The lowest hemoglobin level is reached at about 3 months of age, called the physiologic nadir. The newborn usually tolerates this physiologic state without any clinical difficulties. A factor that influences the degree of physiologic anemia is the nutritional status of the newborn. Supplies of vitamin E, folic acid, and iron may be inadequate given the amount of growth in the later part of the first year of life. Hemoglobin values fall, mainly from a decrease in red cell mass rather than from the dilutional effect of increasing plasma volume. The fact that red cell survival is lower in newborns than in adults, and that red cell production is less, also contributes to this anemia. Neonatal RBCs have a lifespan of 80 to 100 days, approximately two thirds of an adult's RBC lifespan. Erythropoiesis resumes normally when levels of erythropoietin rise in response to low hemoglobin levels and tissue oxygen needs (Blackburn, 2007). Once erythropoiesis resumes, iron stores will be used to produce new RBCs. Most infants require supplemental iron to maintain adequate iron stores.

Leukocytosis is a normal finding because the stress of birth stimulates increased production of neutrophils during the first few days of life. Neutrophils then decrease to 35% of the total leukocyte count by 2 weeks of age. Lymphocytes play a role in antibody formation and eventually become the predominant type of leukocyte, and the total white blood count falls. Blood volume of the term infant is estimated to be 85 ml/kg of body weight (Bagwell, 2007). For example, a 3.6 kg (8 lb) newborn has a blood volume of about 306 ml. Blood volume varies according to the amount of placental transfusion received during the expulsion of the placenta as well as other factors, including the following:

1. ***Delayed cord clamping and the normal shift of plasma to the extravascular spaces.*** Newborn hemoglobin and hematocrit values are higher when a placental transfusion occurs at birth. Placental vessels contain about 75 to 125 ml of blood at term, most of which can be transfused into the newborn through the umbilical vein by holding the newborn below the level of the placenta and by delaying clamping of the cord (Figure 29-8 ■). Blood volume increases by 61% with delayed cord clamping (Bagwell, 2007). The increase is reflected by a rise in hemoglobin level and an increase in the hematocrit. For greatest accuracy, the initial hemoglobin and

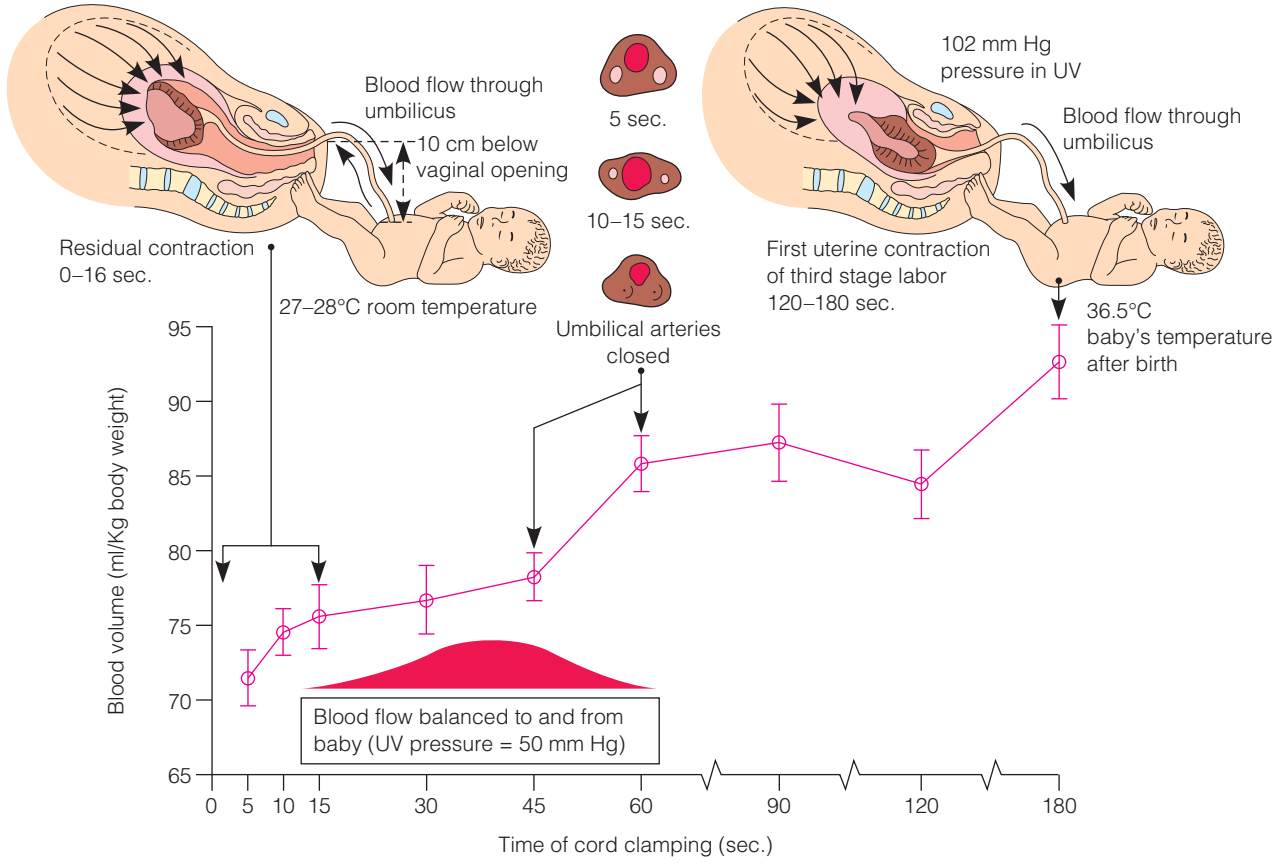

Figure 29-8 ■ Schematic illustration of the mechanisms in placental transfusion (normal term births) through the umbilical vein. The mean neonatal blood volume at 30 minutes is plotted against the time of cord clamping after birth (mean + 1 SE, data from 114 full-term infants). Note episodic, stepwise increments in blood volume at 10, 60, and 180 seconds.

TABLE 29-2 Normal Term Newborn Cord Blood Values

LABORATORY DATA	NORMAL RANGE
Hemoglobin	14–20 g/dl
Hematocrit	43%–63%
WBC	10,000–30,000/mm^3
WBC differential	
Neutrophils	40%–80%
Lymphocytes	20%–40%
Monocytes	3%–10%
Platelets	150,000–350,000/mm^3
Reticulocytes	3%–7%
Blood volume	82.3 ml/kg (third day after early cord clamping), 92.6 ml/kg (third day after delayed cord clamping)
Sodium	129–144 mEq/l
Potassium	3.4–9.9 mEq/l
Chloride	103–111 mEq/l
Bicarbonate	18–23 mEq/l
Carbon dioxide	13–29 mmol/l
Calcium	8.2–111 mg/dl
Glucose	45–96 mg/dl
Total protein	4.8–7.3 g/dl

Source: Adapted from Fanaroff, A. A., & Martin, R. J. (Eds.). (2006). Neonatal-perinatal medicine *(8th ed., pp. 1801, 1810). St. Louis, MO: Mosby.*

hematocrit levels should be measured in the cord blood; however, this is not common practice. In term newborns, a delay in clamping the umbilical cord appears to offer protection from anemia without harmful effects (Mercer, Erickson-Owens, Graves, et al., 2007). In preterm or small-for-gestational-age (SGA) newborns, delay in cord clamping may have risks. It can speed and worsen symptoms of hyperbilirubinemia and cause hypervolemia.

2. ***Gestational age.*** There appears to be a positive association between gestational age, RBC numbers, and hemoglobin concentration.
3. ***Prenatal or perinatal hemorrhage.*** Significant prenatal or perinatal bleeding decreases the hematocrit level and causes hypovolemia.
4. ***Site of the blood sample.*** Hemoglobin and hematocrit levels are significantly higher in capillary blood than in venous blood. Sluggish peripheral blood flow creates red blood cell stasis, thereby increasing RBC concentration in the capillaries. Consequently, blood samples taken from venous blood sites are more accurate than those from capillary sites.

The concentration of serum electrolytes in the blood indicates the fluid and electrolyte status of the newborn. See Table 29-2 for normal electrolyte and blood values of the normal term newborn.

Temperature Regulation

Temperature regulation is the maintenance of thermal balance by losing heat to the environment at a rate equal to heat production. It is a critical function necessary for survival and optimum health in the infant. Newborns are *homeothermic;* they attempt to stabilize their internal (core) body temperatures within a narrow range in spite of significant temperature variations in their environment. At birth, the fetus moves from a warm, moist intrauterine environment to the relatively colder, drier extrauterine environment. The newborn's temperature may fall 2°C to 3°C after birth mainly because of evaporative losses; this triggers cold-induced metabolic responses and heat production. Term newborns can increase their metabolic rate by 200% to 300% after birth in an attempt to accelerate heat production (Blackburn, 2007).

Thermoregulation in the newborn is closely related to the rate of metabolism and oxygen consumption. Within a specific environmental range called the **neutral thermal environment (NTE)**, the rates of oxygen consumption and metabolism are minimal, and internal body temperature is maintained because of thermal balance (Brand & Boyd, 2010). For an unclothed full-term newborn, the NTE range is an ambient environmental temperature of about 32°C to 34°C (89.6°F to 93.2°F) within 50% relative humidity and adjusted according to the needs of individual infants (Brand & Boyd, 2010). Thus the normal newborn requires higher environmental temperatures to maintain a neutral thermal environment than adults.

Several newborn characteristics affect establishment of thermal stability.

- The newborn has less subcutaneous fat than an adult and a thin epidermis.
- Blood vessels of the newborn are closer to the skin than those of an adult. Therefore, the circulating blood is influenced by changes in environmental temperature and in turn influences the hypothalamic temperature-regulating center.
- The flexed posture of the term infant decreases the surface area exposed to the environment, thereby reducing heat loss.

A table listing neutral thermal environmental temperatures gives a recommended temperature range depending on the weight and age of the infant (see Application: Newborn Thermoregulation on www.nursing.pearsonhighered.com). Generally speaking, the smaller infants in each weight group will require a temperature in the higher portion of the temperature range. Within each time range, the younger the infant, the higher the temperature required. For example, the preterm or small-for-gestational-age (SGA) newborn has less adipose tissue and is hypoflexed, and therefore requires higher environmental temperatures to achieve a thermal neutral environment. A larger, well-insulated newborn may be able to cope with lower environmental temperatures. If the environmental temperature falls below the lower limits of the NTE, the newborn responds with increased oxygen consumption and raised metabolism, which results in greater heat production and decreased weight gain and growth. Prolonged exposure to the cold may result in depleted glycogen stores and acidosis. Oxygen consumption also increases if the environmental temperature is above the NTE.

Heat Loss

A newborn is at a distinct disadvantage in maintaining a normal temperature. With a large body surface in relation to mass and a limited amount of insulating subcutaneous fat, the full-

term newborn loses about four times as much heat as an adult does. The newborn's poor thermal stability is due primarily to excessive heat loss rather than to impaired heat production. Because of the risk of hypothermia and possible cold stress, minimizing heat loss in the newborn after birth is essential. (See Provision of Initial Newborn Care in chapter 24 ∞ and chapter 31 ∞ for nursing measures.)

Two major routes of heat loss are from the internal core of the body to the body surface and from the external body surface to the environment. Usually the core temperature is higher than the skin temperature, and the greater the difference in temperatures between core and skin, the more rapidly heat transfer occurs. The transfer is accomplished through an increase in oxygen consumption, depletion of glycogen stores, and metabolizing of brown fat. Heat loss from the body surface to the environment takes place in four ways—convection, radiation, evaporation, and conduction (Figure 29-9 ■).

- **Convection** is the loss of heat from the warm body surface to the cooler air currents. Air-conditioned rooms, air currents with a temperature below the infant's skin temperature, unwarmed oxygen by mask, and removal of the infant from an incubator for procedures increase convective heat loss of the newborn. The amount of heat transferred depends on the velocity of the moving air, the temperature difference between the air and the infant's skin, and the proportion of body surface area exposed.
- **Radiation** losses occur when body heat is transferred to cooler surfaces and objects not in direct contact with the body. The walls of a room or of an incubator are potential causes of heat loss by radiation, even if the ambient temperature of the incubator is within the neutral thermal range for the infant. Placing cold objects (such as ice for blood gases) onto the incubator or near the infant in the radiant warmer will increase radiant heat losses.
- **Evaporation** is the loss of heat incurred when water is converted to a vapor. The newborn is particularly prone to heat loss by evaporation immediately after birth (when the baby is wet with amniotic fluid) and during baths; thus drying the newborn is critical. Evaporation accounts for 25% of heat loss immediately after delivery (Brand & Boyd, 2010). Evaporation also occurs from expired air from the respiratory tract. Babies of lower gestational age have a higher incidence of evaporative heat loss because their skin is immature and they have a large body surface area to weight ratio. Radiant warming beds and bank phototherapy lights also accentuate evaporative loss.
- **Conduction** is the loss of heat to a cooler surface by direct skin contact. Chilled hands, cool scales, cold examination tables, and cold stethoscopes can cause heat loss by conduction. Even if objects are warmed to the incubator temperature, there still may be a significant temperature difference between the infant's core temperature and the ambient temperature. This difference results in heat transfer.

Once the infant has been dried after birth, the highest losses of heat generally result from radiation and convection. The newborn can respond to the cooler environmental temperature with adequate peripheral vasoconstriction, but this mechanism is less effective because of the minimal amount of fat insulation present, the large body surface, and ongoing thermal conduction. Because of these factors, minimizing the baby's heat loss

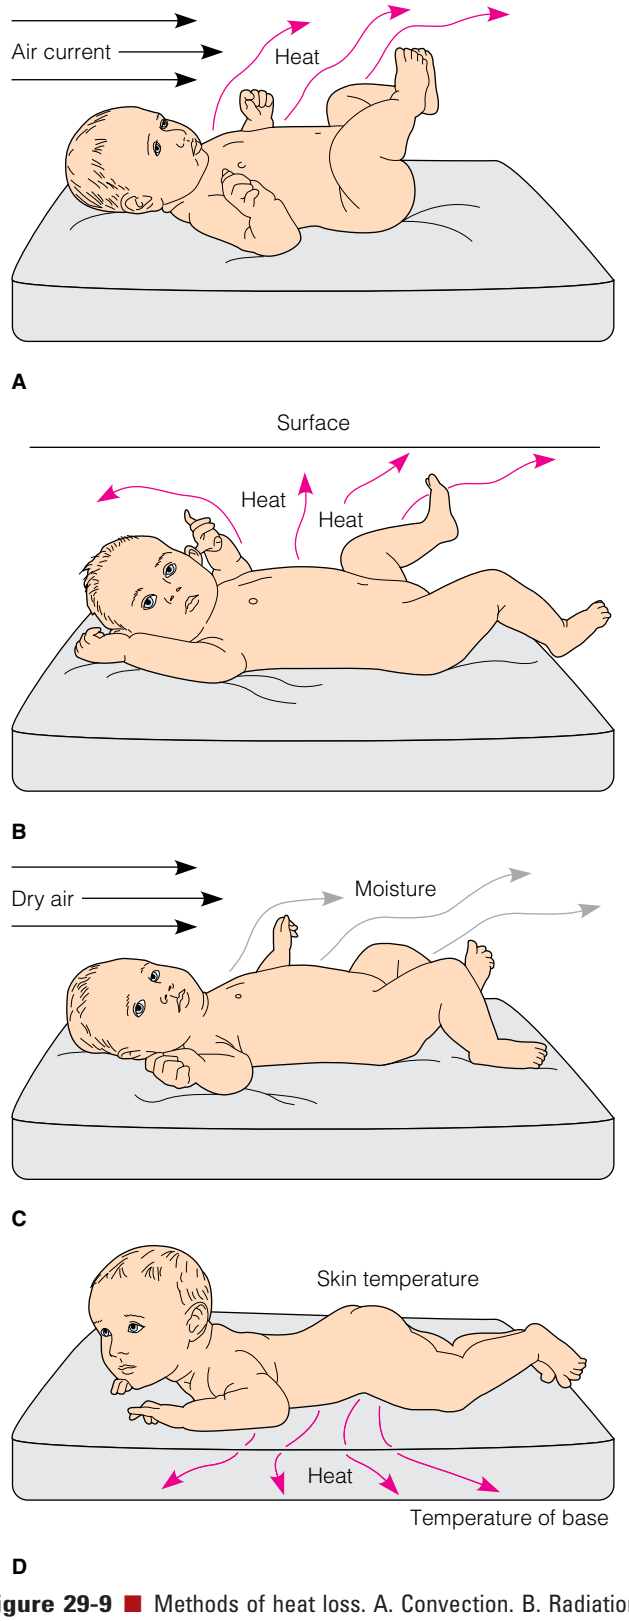

Figure 29-9 ■ Methods of heat loss. A. Convection. B. Radiation. C. Evaporation. D. Conduction.

and preventing hypothermia are imperative. Nursing measures for preventing hypothermia are described in chapter 31 ∞.

CLINICAL TIP

Bath time is when many newborns experience cold stress. To minimize the risk, always bathe infants in a warm room, gather all supplies prior to beginning the bath and pre-warming soaps or shampoos. Dry infants with warmed blankets and dress immediately. The infant's head accounts for a large portion of body surface area and has great capacity for heat loss, so placing a hat on the infant is an effective way to minimize heat loss. Placing infants skin to skin with mother after bathing is a good way to help them rewarm and maintain body temperature.

Most hospitalized infants are weighed daily. Placing unclothed infants on a cold scale can induce heat loss. A safer and more developmentally beneficial way to weigh an infant is by doing a "swaddled weight." Place blankets, diaper, hat, and infant clothing on the scale before calibrating the scale to zero. Then you will be able to dress and swaddle the infant for weighing and the scale will reflect only the infant's weight.

(This item omitted from WebBook edition)

Figure 29-10 ■ The distribution of brown adipose tissue (brown fat) in the newborn.

Heat Production (Thermogenesis)

When exposed to a cool environment, the newborn requires additional heat. The newborn has several physiologic mechanisms that increase heat production, or **thermogenesis**. These include increased basal metabolic rate, muscular activity, and chemical thermogenesis (also called *nonshivering thermogenesis [NST]*) (Rosenberg, 2007).

Nonshivering thermogenesis, an important mechanism of heat production unique to the newborn, is the major mechanism through which heat is produced. It occurs when skin receptors perceive a drop in environmental temperature and, in response, transmit sensations to stimulate the sympathetic nervous system. NST uses the newborn's stores of **brown adipose tissue (BAT)** (also called *brown fat*) to provide heat. BAT first appears in the fetus at 26 to 30 weeks' gestation and continues to increase until 2 to 5 weeks after the birth of a term infant, unless it is depleted by cold stress (Blackburn, 2007). Brown fat is deposited in the midscapular area, around the neck, and in the axillas, with deeper placement around the trachea, esophagus, abdominal aorta, kidneys, and adrenal glands (Figure 29-10 ■). BAT constitutes 2% to 7% of the newborn's total body weight (Blackburn, 2007). Brown fat receives its name from the dark color caused by its enriched blood supply, dense cellular content, and abundant nerve endings. These characteristics promote rapid metabolism, heat generation, and heat transfer to the peripheral circulation. The large numbers of brown fat cells increase the speed with which triglycerides are metabolized to produce heat but cause increased oxygen consumption and caloric output in the already compromised infant.

Shivering, a form of muscular activity common in the cold adult, is rarely seen in the newborn, although it has been observed at ambient temperatures of 15°C (59°F) or less (Polin et al., 2004). If the newborn does shiver, it means the newborn's metabolic rate has already doubled. The increase in muscular activity does little to produce the needed heat to meet the demands of true hypothermia. NST from BAT is the primary source of heat in the hypothermic newborn. Thermographic studies of newborns exposed to cold show an increase in the skin heat over the brown fat deposits in the newborn between 1 and 14 days of age (Polin et al., 2004). If an infant is SGA, intrauterine growth restricted, or premature, his or her brown fat stores will be inadequate to produce sufficient heat. Brown fat stores cannot be replenished once they are used.

An increase in basal metabolism as a result of hypothermia results in an increase in oxygen and glucose consumption. The normal term newborn is usually able to cope with the increase in oxygen requirements, but a decrease in the environmental temperature of 2°C, from 33°C to 31°C, is a drop sufficient to double the oxygen consumption of a term newborn and can cause the newborn to show signs of respiratory distress.

When exposed to cold, the preterm newborn may be unable to increase ventilation to the necessary level of oxygen consumption. (See chapter 34 ∞ for a discussion of cold stress.) Because oxidation of fatty acids depends on the availability of oxygen, glucose, and adenosine triphosphate (ATP), the newborn's ability to generate heat can be altered by pathologic events such as hypoxia, acidosis, and hypoglycemia or by medications that block the release of norepinephrine. The effect of certain drugs such as meperidine (Demerol) may also prevent metabolism of brown fat. Neonatal hypothermia prolongs as well as potentiates the effects of many analgesic and anesthetic drugs in the newborn.

Response to Heat

Sweating is the usual initial response of the term newborn to hyperthermia. The newborn sweat glands have limited function until after the fourth week of extrauterine life; heat is lost through peripheral vasodilation and evaporation of insensible water loss. Vasodilatation caused by overheating predisposes the infant to

DEVELOPING CULTURAL COMPETENCE

Newborn Baths in Jordan and Nigeria

In Jordan, the birth of a male infant is a much celebrated event. The newborn is bathed daily during the first week of life. During the final bath, salt is added to the water to help the newborn's skin adjust to the external environment and protect it from changes in the weather.

In Southeastern Nigeria, the *omugwo* is the practice of ritual of cares observed after the birth of a baby. Among the cares is a bathing regime for the newborn that includes physical exercises and routines like flexing the joints, holding the baby upside down, immersing the baby underwater, and even throwing the baby up in the air several times during bathing. These practices are thought to promote general health and physical strength, as well as promoting courage and fearlessness in the baby (Liamputtong, 2007).

hypotension. In term SGA infants, the onset of sweating is delayed; it is virtually nonexistent in preterm infants of less than 30 weeks' gestation because of the underdevelopment of the sweat glands. The term infant will be flaccid and assume a position of extension to facilitate heat loss (Blackburn, 2007). Oxygen consumption and metabolic rate also increase in response to hyperthermia. Severe hyperthermia can lead to death or to gross brain damage if the baby survives.

Hepatic Adaptations

The newborn's liver is frequently palpable 1 to 2 cm below the right costal margin at the midclavicular line (Tappero & Honeyfield, 2009). It is relatively large and occupies about 40% of the abdominal cavity. The newborn's liver plays a significant role in iron storage, carbohydrate metabolism, conjugation of bilirubin, and coagulation.

Iron Storage and Red Blood Cell Production

As red blood cells (RBCs) are destroyed after birth, their iron content is stored in the liver until needed for new RBC production. Newborn iron stores are determined by total body hemoglobin content and length of gestation. The term newborn has about 270 mg of iron at birth, and about 140 to 170 mg of this amount is in the hemoglobin. If the mother's iron intake has been adequate, enough iron will be stored to last until 5 months of age. After about 6 months of age, foods containing iron or iron supplements must be given to prevent anemia.

Carbohydrate Metabolism

At term, the newborn's cord blood glucose level is 15 mg/dl lower than maternal blood glucose level (Rosenberg, 2007). Neonatal carbohydrate reserves are relatively low. One third of this reserve is in the form of liver glycogen and are twice that of the adult. The newborn experiences an energy crunch at the time of birth with the cutting of the umbilical cord and resultant removal of the maternal glucose supply and the increased energy expenditure associated with the birth process and extrauterine life. Fuel sources are consumed at a faster rate because of the work of breathing, loss of heat when exposed to cold, activity, and activation of muscle tone.

Glucose is the main source of energy in the first 4 to 6 hours after birth. During the first 2 hours of life, the serum blood glucose level declines, then rises, and finally reaches a steady state by 3 hours after birth (Rosenberg, 2007).

The nurse may assess the glucose level on admission to the newborn nursery if risk factors or clinical symptoms are present, or per agency protocol. As stores of liver and muscle glycogen and blood glucose decrease, the newborn compensates by changing from a predominantly carbohydrate metabolism to fat metabolism. Energy is derived from fat and protein as well as from carbohydrates. The amount and availability of each of these "fuel substrates" depends on the ability of immature metabolic pathways (i.e., lacking specific enzymes or hormones) to function in the first few days of life.

Conjugation of Bilirubin

In the body, the breakdown of heme-containing proteins causes the production of bilirubin. Conjugation, or the changing of bilirubin into an excretable form, is the conversion of the yellow lipid-soluble pigment (unconjugated, indirect) into water-soluble pigment (excretable, direct). Unconjugated bilirubin is fat soluble, has a propensity for fatty tissues, is not in an excretable form, and is a potential toxin. Fetal unconjugated bilirubin crosses the placenta to be excreted, so the fetus does not need to conjugate bilirubin.

Total serum bilirubin is the sum of conjugated (direct) and unconjugated (indirect) bilirubin. Total bilirubin at birth is less than 3 mg/dl unless an abnormal hemolytic process has occurred in utero. After birth, the newborn's liver must begin to conjugate bilirubin. This produces a rise in serum bilirubin in the first few days of life. The unconjugated bilirubin formed, after RBCs are destroyed, is transported in the blood bound to albumin. The bilirubin is transferred into the hepatocytes and bound to intracellular proteins. These proteins determine the amount of bilirubin that is held in the liver cells for processing and consequently determine the amount of bilirubin uptake into the liver. The activity of uridine diphosphoglucuronosyl transferase (UDPGT) enzyme results in the attachment of unconjugated bilirubin to glucuronic acid (a product of liver glycogen), producing bilirubin glucuronides (conjugated, direct bilirubin). Direct (water soluble) bilirubin is excreted into the tiny bile ducts, then into the common duct and duodenum. The (direct) conjugated bilirubin then progresses down the intestines, where bacteria transform it into urobilinogen (urine bilirubin) and stercobilinogen. Stercobilinogen is not reabsorbed but is excreted as a yellow-brown pigment in the stools.

Even after the bilirubin has been conjugated and bound, it can be changed back to unconjugated bilirubin via the enterohepatic circulation. In the intestines, β-D-glucuronidase enzyme acts to split off (deconjugate) the bilirubin from bilirubin glucuronides if it is not first acted upon by gut bacteria to produce urobilinogen; the free bilirubin is reabsorbed through the intestinal wall and brought back to the liver via portal vein circulation. This recycling of the bilirubin and decreased ability to clear bilirubin from the system are prevalent in babies who have very high β-D-glucuronidase activity

levels as well as delayed bacterial colonization of the gut (such as with the use of antibiotics) and further increases the newborn's susceptibility to jaundice. The longer the direct bilirubin remains in the infant's gut, the greater chance it has of becoming deconjugated. Because of this, infants who establish gut motility and active stooling through early and frequent feedings are less likely to develop physiologic jaundice. Conjugation of bilirubin in newborns is depicted in Figure 29-11 ■.

The newborn liver has relatively less metabolic and enzymatic activity at birth and in the first few weeks of life than an adult liver. This reduction in hepatic activity, along with a relatively large bilirubin load, decreases the liver's ability to conjugate bilirubin and increases susceptibility to jaundice.

Physiologic Jaundice

Physiologic jaundice is caused by accelerated destruction of fetal RBCs, impaired conjugation of bilirubin, and increased bilirubin reabsorption from the intestinal tract. This condition does not have a pathologic basis, but rather is a normal biologic response of the newborn.

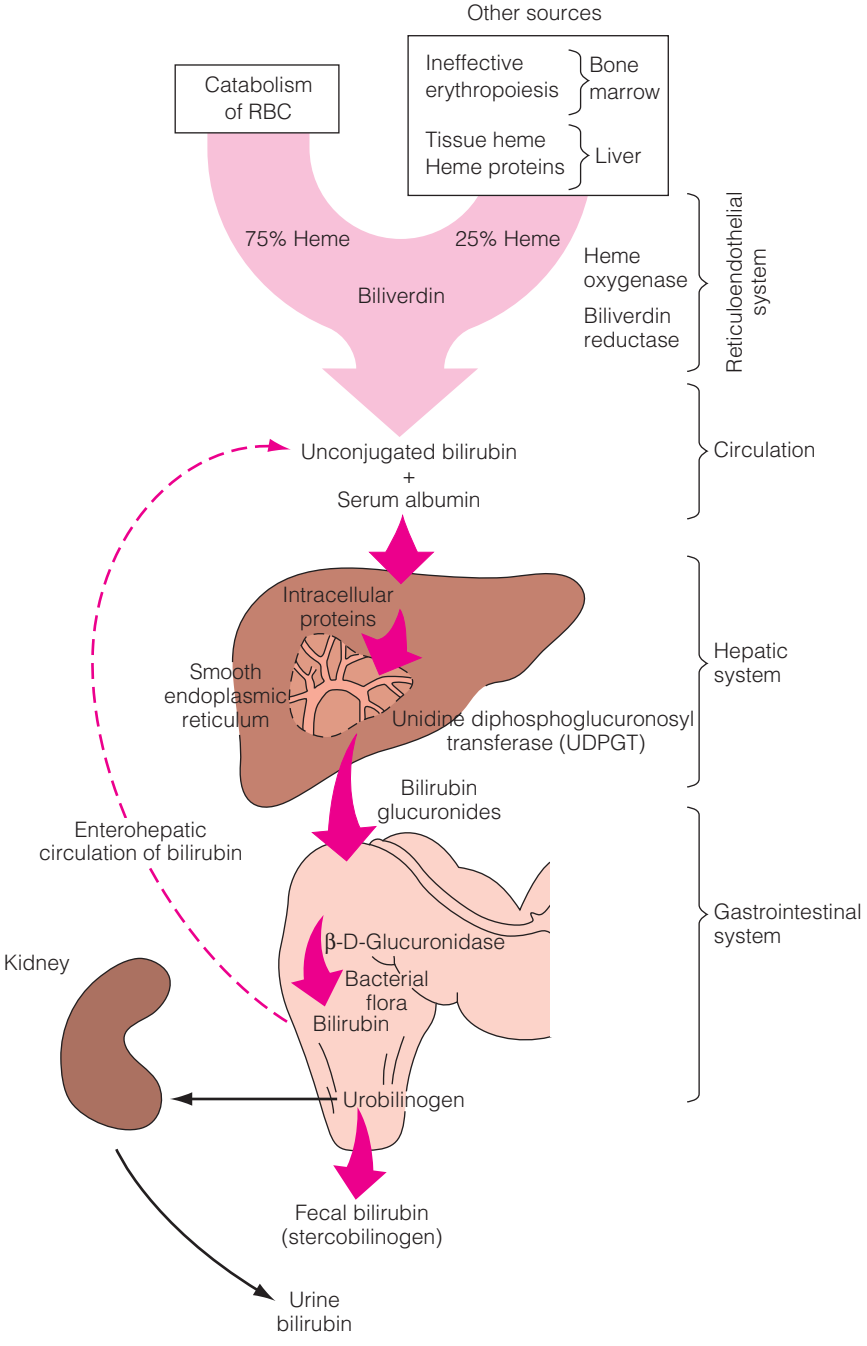

Figure 29-11 ■ Conjugation of bilirubin in newborns.

Maisels (2005) describes six factors—several of which can also be related to pathologic events—whose interactions may give rise to physiologic jaundice:

1. ***Increased amounts of bilirubin delivered to the liver.*** The increased blood volume due to delayed cord clamping combined with faster RBC destruction in the newborn leads to an increased bilirubin level in the blood. A proportionately larger amount of nonerythrocyte bilirubin is formed in the newborn. Therefore, newborns have two to three times greater production or breakdown of bilirubin. The use of forceps or vacuum extraction that sometimes causes facial bruising or cephalohematoma (entrapped hemorrhage), or any bruising of the newborn body can increase the amount of bilirubin to be handled by the liver.
2. ***Defective uptake of bilirubin from the plasma.*** If the newborn does not ingest adequate calories, the formation of hepatic intracellular binding proteins diminishes, resulting in higher levels of bilirubin.
3. ***Defective conjugation of the bilirubin.*** Decreased uridine diphosphoglucuronosyl activity, as in hypothyroidism, or inadequate caloric intake causes the intracellular binding proteins to remain saturated and results in greater unconjugated bilirubin levels in the blood. The fatty acids in maternal breast milk compete with bilirubin for albumin binding sites; this process is thought to impede bilirubin processing.
4. ***Defect in bilirubin excretion.*** Delay in introduction of bacterial flora and decreased intestinal motility can also delay excretion and increase enterohepatic circulation of bilirubin.
5. ***Inadequate hepatic circulation.*** Decreased oxygen supplies to the liver associated with neonatal hypoxia or congenital heart disease lead to a rise in the bilirubin level.
6. ***Increased reabsorption of bilirubin from the intestine.*** Reduced bowel motility, intestinal obstruction, or delayed passage of meconium increases the circulation of bilirubin in the enterohepatic pathway, resulting in higher bilirubin values.

About 50% of full-term and 80% of preterm newborns exhibit physiologic jaundice on about the second or third day after birth. The characteristic yellow color results from increased levels of unconjugated bilirubin, which are a normal product of RBC breakdown and reflect a temporary inability of the body to eliminate bilirubin. Serum levels of bilirubin are about 4 to 6 mg/dl before yellow coloration of the skin and sclera appears. The signs of physiologic jaundice appear *after* the first 24 hours postnatally. This differentiates physiologic jaundice from pathologic jaundice (see chapter 34 ∞), which is clinically seen at birth or within the first 24 hours of postnatal life. Major risk factors for developing severe hyperbilirubinemia in late preterm and term infants are total serum bilirubin (TSB) or transcutaneous bilirubin (TcB) level in the high-risk zone on the bilirubin nomogram (Figure 29-12 ■).

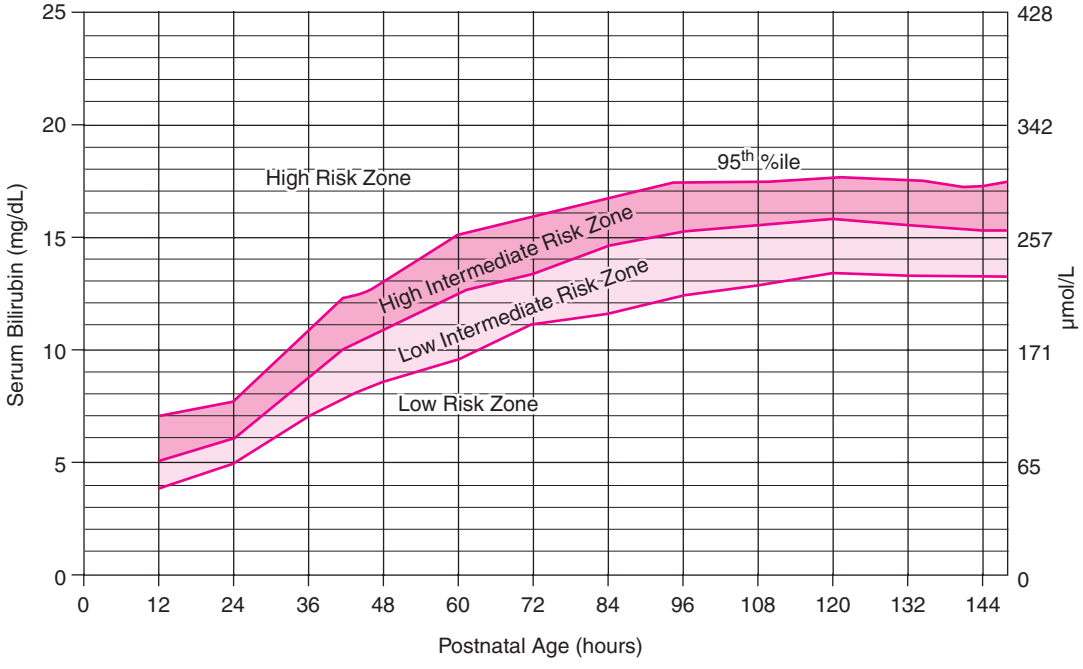

Figure 29-12 ■ Postnatal hour-specific bilirubin nomogram. Note: Nomogram for designation of risk in 2840 well newborns at 36 or more weeks' gestational age with birth weight of 2000 g or more or 35 or more weeks' gestational age and birth weight of 2500 g or more based on the hour-specific serum bilirubin values. The serum level was obtained before discharge, and the zone in which the value fell predicted the likelihood of a subsequent bilirubin level exceeding the 95th percentile (high-risk zone) as shown in Appendix 3, Table 4. Used with permission from Bhutani et al. See Appendix 1 for additional information about this nomogram, which should not be used to represent the natural history of neonatal hyperbilirubinemia.

Breastfeeding and Jaundice

Peak bilirubin levels are reached between days 3 and 5 in the full-term infant and between days 5 and 7 in the preterm infant. But these values are established for European and American Caucasian newborns. Chinese, Japanese, Korean, and Native American newborns have considerably higher bilirubin levels that are not as apparent and that persist for longer periods with no apparent ill effects (Maisels, 2005).

The nursery or postpartum room environment, including lighting, can hinder the early detection of the degree and type of jaundice. Pink walls and artificial lights mask the beginning of jaundice in newborns. Daylight assists the observer in early recognition by eliminating distortions caused by artificial light.

If jaundice is suspected, the nurse can quickly assess the newborn's coloring by pressing the skin, generally on the forehead or nose, with a finger. As blanching occurs, the nurse can observe the icterus (yellow coloring). The newborn develops jaundice in caudal progression, meaning that jaundice is first seen in the face and then travels down the trunk.

Several newborn care procedures will decrease the probability of high bilirubin levels:

- Maintain the newborn's skin temperature at 36.5°C (97.8°F) or above, because cold stress results in acidosis. Acidosis decreases available serum albumin-binding sites, weakens albumin-binding powers, and causes elevated unconjugated bilirubin levels.
- Monitor stool for amount and characteristics. Bilirubin is eliminated in the feces; inadequate stooling may result in reabsorption and recycling of bilirubin. Encourage early breastfeeding because the laxative effect of colostrum increases excretion of meconium and transitional stool.
- Encourage early feedings to promote intestinal elimination and bacterial colonization and to provide caloric and protein intake necessary for the formation of hepatic binding proteins.

If jaundice becomes apparent, nursing care is directed toward keeping the newborn well hydrated and promoting intestinal elimination. For specific nursing management and therapies, see Nursing Care Plan: Newborn with Hyperbilirubinemia on pages 969–971 in chapter 34 ∞.

Physiologic jaundice may be very upsetting to parents, and they will require emotional support and thorough explanation of the condition. If the baby is treated with phototherapy, a few additional days of hospitalization may be required, which may also be disturbing to parents. They can be encouraged to provide for the emotional needs of their newborn by continuing to feed, hold, and caress the infant. If the mother is discharged, the parents should be encouraged to return for feedings and telephone or visit whenever they wish. In many instances the mother, especially if she is breastfeeding, may elect to remain hospitalized with her newborn; the nurse should support this decision. If insurance limitations make this unrealistic, it may be possible to find an empty room for the discharged mother and her family to use while visiting the newborn. As an alternative to continued hospitalization, some newborns are treated with home phototherapy. (See Phototherapy in chapter 34 ∞ for more information.)

Breastfeeding Jaundice and Breast Milk Jaundice

Breastfeeding is implicated in jaundice in some newborns. *Breastfeeding jaundice* occurs in the first days of life in breastfed newborns. It appears to be associated with poor feeding practices and not with any abnormality in milk composition (McGrath & Hardy, 2011). It is related to inadequate fluid intake with some element of dehydration. Prevention of early breastfeeding jaundice includes encouraging frequent (every 2 to 3 hours) breastfeeding, avoiding supplementation, and accessing maternal lactation counseling.

In *breast milk jaundice,* the bilirubin rise is late onset and begins after the first week of life, when physiologic jaundice is waning. This type of jaundice may last from several weeks to several months. The level peaks at 5 to 10 mg/dl at 2 weeks of age and declines over the first several months of life (McGrath & Hardy, 2011).

In contrast to breastfeeding jaundice, breast milk jaundice is related to milk composition promoting increased bilirubin reabsorption from the intestine. Some women's breast milk may contain several times the normal concentration of certain free fatty acids. These free fatty acids may compete with bilirubin for binding sites on albumin and inhibit the conjugation of bilirubin or increase lipase activity, which disrupts the RBC membrane. Increased lipase activity enhances absorption of bile across the gastrointestinal tract membrane, thereby increasing the enterohepatic circulation of bilirubin. In the past it was thought that the breast milk of women whose newborns have breast milk jaundice contained an enzyme that inhibited glucuronyl transferase, but this hypothesis has not been proven (Thureen et al., 2005).

Newborns with breast milk jaundice appear well, and at present an absence of documented kernicterus (toxic levels of bilirubin in the brain) with this type of jaundice has not been documented. Temporary cessation of breastfeeding may be advised if bilirubin reaches presumed toxic levels of approximately 20 mg/dl or if the interruption is necessary to establish the cause of the hyperbilirubinemia. Most physicians believe that breastfeeding may be resumed once other causes of jaundice have been ruled out and as long as serum bilirubin levels remain below 20 mg/dl. In cases of breast milk jaundice, within 24 to 36 hours after breastfeeding is discontinued, the newborn's serum bilirubin levels begin to fall dramatically. With resumption of breastfeeding, the bilirubin concentration may show a slight rise of 2 to 3 mg/dl with a subsequent decline. Breastfeeding mothers need encouragement and support in their desire to breastfeed their infants, assistance and instruction regarding pumping and expressing milk during the interrupted breastfeeding period, and reassurance that nothing is wrong with their milk or their mothering abilities. Table 29-3 summarizes key factors in physiologic and breast milk jaundice.

CLINICAL TIP

Breastfeeding mothers need encouragement and support in their desire to breastfeed their infants, assistance and instruction about pumping and expressing milk during the interrupted breastfeeding period, and reassurance that nothing is wrong with their milk or mothering abilities.

TABLE 29-3 Jaundice

Physiologic Jaundice

- Physiologic jaundice occurs after the first 24 hours of life.
- During the first week of life, bilirubin should not exceed 13 mg/dl. Some pediatricians allow levels up to 15 mg/dl. See Figure 29-12 for the AAP Nomogram for Bilirubin risk for infants > 35 wks gestation.
- Bilirubin levels peak at 3 to 5 days in term infants.

Breast Milk Jaundice

- Bilirubin levels begin to rise about the fourth day after mature breast milk comes in.
- Peak of 5–10 mg/dl is reached at 2 to 3 weeks of age.
- It may be necessary to interrupt breastfeeding for a short period when bilirubin reaches 20 mg/dl.

Coagulation

The liver plays an important part in blood coagulation during fetal life and continues this function following birth. Coagulation factors II, VII, IX, and X (synthesized in the liver) are activated under the influence of vitamin K and therefore are considered vitamin K dependent. The absence of normal intestinal flora needed to synthesize vitamin K in the newborn gut results in low levels of vitamin K and creates a transient blood coagulation alteration between the second and fifth day of life. From a low point at about 2 to 3 days after birth, these coagulation factors rise slowly but do not approach adult levels until 9 months of age or later (Manco-Johnson, Rodden, & Hays, 2011). Other coagulation factors with low umbilical cord blood levels are XI, XII, and XIII. Fibrinogen and factors V and VII are near adult ranges.

Although newborn bleeding problems are rare, an injection of vitamin K (AquaMEPHYTON) is given prophylactically on the day of birth to combat potential clinical bleeding problems. (Hemorrhagic disease of the newborn is discussed in more depth in chapter 34 ∞.)

DEVELOPING CULTURAL COMPETENCE

Interpreting Illness Through Cultural Beliefs

Cultural beliefs lead mothers to interpret illness within their cultural framework, especially when left without clear and understood explanations (D'Avanzo & Geissler, 2008). For example, some Latina women believe that showing strong maternal emotions during pregnancy and during breastfeeding can be detrimental. They may blame jaundice in their newborn on "bili" associated with anger. Such maternal reactions can be lessened by careful explanations to the mothers about the diagnosis, prognosis, duration, and management options for jaundice, and possibility for recurrence.

Platelet counts at birth are in the same range as for older children, but newborns may manifest mild transient difficulty in platelet aggregation functioning. Phototherapy accentuates this platelet problem. Prenatal maternal therapy with phenytoin sodium (Dilantin) or phenobarbital also causes abnormal clotting studies and newborn bleeding in the first 24 hours after birth. Infants born to mothers receiving warfarin (Coumadin) compounds may bleed because these agents cross the placenta and accentuate existing vitamin K-dependent factor deficiencies. Transient neonatal thrombocytopenia may occur in infants born to mothers with severe hypertension or HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) (see chapter 20 ∞ for a discussion of HELLP) and in infants born to mothers who have idiopathic isoimmune thrombocytopenic purpura.

Gastrointestinal Adaptations

By 36 to 38 weeks of fetal life, the gastrointestinal tract is adequately mature, with the presence of enzymatic activity and the ability to transport nutrients.

Digestion and Absorption

The full-term newborn has adequate intestinal and pancreatic enzymes to digest most simple carbohydrates, fat, and proteins. The carbohydrates requiring digestion in the newborn are usually disaccharides (lactose, maltose, sucrose), which are split into monosaccharides (galactose, fructose, and glucose) by the enzymes of the intestinal mucosa. Lactose is the primary carbohydrate in the breastfeeding newborn and is generally easily digested and well absorbed. The only enzyme lacking at birth is pancreatic amylase, which remains relatively deficient during the first few months of life. Newborns have trouble digesting starches (changing more complex carbohydrates into maltose), so they should not eat them until after the first few months of life.

Although proteins require more digestion than carbohydrates, they are well digested and absorbed from the newborn intestine. The newborn digests and absorbs fats less efficiently because of the minimal activity of the pancreatic enzyme lipase. The newborn excretes 10% to 20% of the dietary fat intake, compared with 10% for the adult. The fat in breast milk is absorbed more completely by the newborn than is the fat in cow's milk because it consists of more medium-chain triglycerides and contains lipase. (See chapter 32 ∞ for a more detailed discussion of infant nutrition.)

By birth the newborn has experienced swallowing, gastric emptying, and intestinal propulsion. In utero, fetal swallowing is accompanied by gastric emptying and peristalsis of the fetal intestinal tract. By the end of gestation, peristalsis becomes much more active in preparation for extrauterine life. Fetal peristalsis is also stimulated by anoxia, causing the expulsion of meconium into the amniotic fluid in more mature or stressed fetuses.

Air enters the stomach immediately after birth. The small intestine is air filled within 2 to 12 hours, and the large bowel within 24 hours. The salivary glands are immature at birth, and little saliva is manufactured until the infant is about 3 months old. The newborn's stomach has a capacity of 50 to 60 ml. It empties intermittently, starting within a few minutes of the beginning of a feeding and ending between 2 and 4 hours after feeding. Bowel sounds are present within the first 30 to 60 minutes of birth and the newborn can successfully feed during this time. The newborn's gastric pH becomes less acidic about a week after birth and remains less acidic than that of adults for the next 2 to 3 months.

The cardiac sphincter is immature, as is neural control of the stomach, so some regurgitation may be noted in the neonatal period. Regurgitation of the first few feedings during the first day or two of life can usually be lessened by avoiding overfeeding and by burping the newborn well during and after the feeding.

When no other signs and symptoms are evident, vomiting is limited and ceases within the first few days of life. Continuous vomiting or regurgitation should be monitored closely and reported promptly as it may be indicative of a more serious problem. If the newborn has swallowed bloody or purulent amniotic fluid, lavage of the stomach may be indicated in the term newborn to relieve the problem. Bilious vomiting is abnormal and must be evaluated thoroughly because it might represent a condition that warrants prompt surgical intervention.

Adequate digestion and absorption are essential for newborn growth and development. If optimal nutritional support is available, postnatal growth ideally should parallel intrauterine growth. After 30 weeks of gestation the fetus gains 30 g per day and adds 1.2 cm (0.5 in.) to body length daily. To gain weight at the intrauterine rate, the term newborn requires 120 kcal/kg/day. Following birth, caloric intake is often insufficient for weight gain until the newborn is 5 to 10 days old. During this time there may be a weight loss of 5% to 10% in term newborns. A shift of intracellular water to extracellular space and insensible water loss account for the 5% to 10% weight loss. Thus failure to lose weight when caloric intake is inadequate may indicate fluid retention.

CLINICAL JUDGMENT

Case Study: Jonathon Sykes

Jonathon Sykes is a 5-day-old term male infant who has returned to the hospital for a lactation visit. Jonathon's birth weight was 3260 grams (7 pounds, 3 ounces) and his current weight is 2963 grams (6 pounds, 8 1/2 ounces). The lactation nurse is worried about this weight loss and shares her concerns with Jonathon's mother.

Critical Thinking

What would you tell Jonathon's mother about his weight loss since birth?

What are other questions you might ask Jonathon's mother about his daily habits?

Based on his birth weight, what is the appropriate number of kilocalories that Jonathon needs to grow?

See www.nursing.pearsonhighered.com for possible responses.

Elimination

Term newborns normally pass meconium within 8 to 24 hours of life—and almost always within 48 hours. **Meconium** is formed in utero from the amniotic fluid and its constituents, with intestinal secretions and shed mucosal cells. It is recognized by its thick, tarry, black (or dark green) appearance. Transitional (thinner brown to green) stools consisting of part meconium and part fecal material are passed for the next day or two, after which the stools become entirely fecal. Generally, the stools of a breastfed newborn are pale yellow (but may be pasty green); they are more liquid and more frequent than those of formula-fed newborns, whose stools are paler and often the consistency of peanut butter (Figure 29-13 ■). Frequency of bowel movement varies but initially ranges from one every 2 to 3 days to as many as 10 daily. Mothers should be counseled that this is not constipation as long as the bowel movement remains soft. Table 29-4 describes the progression of stools and other physiologic adaptations to extrauterine life.

Figure 29-13 ■ Newborn stool samples. A. Meconium stool. B. Transitional stool. C. Breast milk stool.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC.

TABLE 29-4 Physiologic Adaptations to Extrauterine Life

- Periodic breathing may be present.
- Desired skin temperature 36°C–36.5°C (96.8°F–97.7°F), stabilizes 4 to 6 hours after birth.
- Desired blood glucose level reaches 60–70 mg/dl by third postnatal day.
- Stools progress from:
  Meconium (thick, tarry, black; meconium plug may be expelled)
  Transitional stools (thin, brown to green)
  Breastfed infants (yellow gold, soft, or mushy)
  Formula-fed infants (pale yellow, formed, and pasty)

Urinary Adaptations

Kidney Development and Function

Certain physiologic features of the newborn's kidneys may affect the newborn's ability to handle body fluids and excrete urine:

1. The term newborn's kidneys have a full complement of functioning nephrons by 34 to 36 weeks of gestation.
2. The glomerular filtration rate of the newborn's kidneys is low in comparison with the adult rate. Because of this physiologic decrease in kidney glomerular filtration, the newborn's kidneys are unable to dispose of water rapidly when necessary.
3. The juxtamedullary portion of the nephron has limited capacity to reabsorb HCO_3 and H and concentrate urine (reabsorb water back into the blood) because the tubules are short and narrow. The limitation of tubular reabsorption can lead to inappropriate loss of substances present in the glomerular filtrate, such as amino acids, bicarbonate, glucose, sodium, potassium, chloride, phosphate, and urea.

The ability to concentrate urine fully is attained by 3 months of age. Feeding practices may affect the osmolarity of the urine but have limited effect on concentration of the urine.

Because the newborn has difficulty concentrating urine, the effect of excessive insensible water loss or restricted fluid intake is unpredictable. The newborn kidney is also limited in its dilutional capabilities. Concentrating and dilutional limitations of renal function are important considerations in monitoring fluid therapy to avoid dehydration and overhydration.

Characteristics of Newborn Urinary Function

Many newborns void immediately after birth, which is usually noticed in the birthing room. Among normal newborns, 93% void by 24 hours after birth, and 100% void by 48 hours after birth (Thureen et al., 2005). A newborn who has not voided by 36 hours should be assessed for adequacy of fluid intake, bladder distention, restlessness, and symptoms of pain. The appropriate clinical personnel should be notified if indicated.

TABLE 29-5 Newborn Urinalysis Values

- Protein less than 5–10 mg/dl
- WBC less than 2–3/hpf
- RBC 0
- Casts 0
- Bacteria 0
- Color pale yellow

The initial bladder volume is 6 to 44 ml of urine. Unless edema is present, normal urinary output is often limited, and the voidings are scanty until fluid intake increases. (The fluid of edema is eliminated by the kidneys, so infants with edema have a much higher urinary output.) The first 2 days postnatally, the newborn may void 2 to 6 times daily, with a urine output of 15 ml/kg/day. The newborn subsequently voids 5 to 25 times every 24 hours, with a volume of 25 ml/kg/day. Observation and documentation of adequate urinary output is necessary given the large number of term infants who have early hospital discharge.

Following the first voiding, the newborn's urine frequently appears cloudy (because of mucus content) and has a high specific gravity, which decreases as fluid intake increases. Occasionally, pink stains ("brick dust spots") appear on the diaper. These are caused by urates and are innocuous. Blood may occasionally be observed on the diapers of female infants. This *pseudomenstruation* is related to the withdrawal of maternal hormones. Males may have bloody spotting from a circumcision. In the absence of apparent causes for bleeding, the clinician should be notified. During early infancy, normal urine is straw colored and almost odorless, although odor occurs when there is a metabolic disorder or when infection is present. Table 29-5 summarizes urinalysis values of the normal newborn.

Immunologic Adaptations

The general purposes of the newborn immune system are those of defense (fighting microorganisms), homeostasis (disposition of worn out cells), and surveillance (recognition and destruction of foreign or aberrant cells). The newborn's immune system is not fully activated until sometime after birth. Because the womb is a relatively sterile environment, the limitations in the newborn's inflammatory response result in failure to recognize, localize, and destroy invasive bacteria. Thus the signs and symptoms of infection are often subtle and nonspecific in the newborn. The newborn also has a poor hypothalamic response to pyrogens; therefore, fever is not a reliable indicator of infection. In the neonatal period, hypothermia is a more reliable sign of infection.

Of the three major types of immunoglobulins primarily involved in immunity—IgG, IgA, and IgM—only IgG crosses the placenta. The pregnant woman forms antibodies in response to illness or immunization. This process is called **active acquired immunity**. When IgG antibodies are transferred to the fetus in utero, **passive acquired immunity** results because the fetus does not produce the antibodies himself or herself. IgG is very active against bacterial toxins.

Because the maternal immunoglobulin is transferred primarily during the third trimester, preterm newborns (especially those born before 34 weeks) may be more susceptible to infection. In addition, postmature infants often have low levels of IgG that suggest decreased transfer with placental damage and aging. In general, newborns have maternally induced immunity to tetanus, diphtheria, smallpox, measles, mumps, poliomyelitis, and a variety of other bacterial and viral diseases. The period of resistance varies: Immunity against common viral infections such as measles may last 4 to 8 months, whereas immunity to certain bacteria may disappear within 4 to 8 weeks.

Although newborn infants are more vulnerable to infection, the normal newborn does produce antibodies in response to an antigen but not as effectively as an older child does. It is customary to begin immunization at 2 months of age so the infant can develop active acquired immunity. Some immunizations for specific viruses (Hepatitis B) are even given in the first day after birth.

IgM immunoglobulins are produced in response to blood group antigens, gram-negative enteric organisms, and some viruses in the expectant mother. Because IgM does not normally cross the placenta, most or all is produced by the fetus beginning at 10 to 15 weeks' gestation. Elevated levels of IgM at birth may indicate placental leaks or, more commonly, fetal antigenic stimulation in utero. Consequently, elevations suggest that the infant was exposed to an intrauterine infection such as syphilis or TORCH syndrome (toxoplasmosis, rubella, cytomegalovirus, or herpes virus hominis type 2 infection). (For in-depth discussion of infection, see chapter 20 ∞ and Table 34-5 ∞ on page 976.) The lack of available maternal IgM in the newborn also accounts for the infant's susceptibility to gram-negative enteric organisms such as *Escherichia coli.*

The functions of IgA immunoglobulins are not fully understood. IgA appears to provide protection mainly on secreting surfaces such as the respiratory tract, gastrointestinal tract, and eyes. Serum IgA does not cross the placenta and is not normally produced by the fetus in utero. Unlike the other immunoglobulins, IgA is not affected by gastric action. Colostrum, the forerunner of breast milk, is very high in the secretory form of IgA. It may provide some passive immunity to the infant of a breastfeeding mother. Newborns begin to produce secretory IgA in their intestinal mucosa at about 4 weeks after birth.

Infant Abilities

Neurologic and Sensory/ Perceptual Functioning

The newborn's brain is about one quarter the size of an adult's, and myelination of nerve fibers is incomplete. Unlike the cardiovascular or respiratory systems, which undergo tremendous changes at birth, the nervous system is minimally influenced by the actual birth process. Because many biochemical and histologic changes have yet to occur in the newborn's brain, the postnatal period is considered a time of risk in regard to the development of the brain and nervous system. For neurologic development—including development of intellect—to proceed, the brain and other nervous system structures must mature in an orderly, unhampered fashion. For discussion of cranial nerves, see chapter 30 ∞.

Intrauterine Factors Influencing Newborn Behavior

Newborns respond to and interact with the environment in a predictable pattern of behavior that is shaped somewhat by their intrauterine experience. This intrauterine experience is affected by intrinsic factors such as maternal nutrition and drug exposure, and external factors such as the mother's physical environment. Depending on the newborn's intrauterine experience and individual temperament, newborn behavioral responses to different stresses vary. Some newborns react quietly to stimulation, others become overreactive and tense, and some may exhibit a combination of the two.

Factors such as exposure to intense auditory stimuli in utero can eventually be manifested in the behavior of the newborn. For example, the fetal heart rate (FHR) initially increases when the pregnant woman is exposed to auditory stimuli, but repetition of the stimuli leads to decreased FHR. Thus the newborn who was exposed to intense noise during fetal life is significantly less reactive to loud sounds postnatally.

Characteristics of Newborn Neurologic Function

Perinatal factors will affect how the infant interacts with the environment. Type of labor and delivery, drugs given to the mother during labor, overall infant health, and of course gestational age of the infant are all matters that affect infant behavior. The environment itself also plays into infant response. A quiet, dim, warm, calming environment will elicit different infant behavior than a noisy, bright, or cold surrounding will.

Normal newborns are usually in a position of partially flexed extremities with the legs near the abdomen. When awake, the newborn may exhibit purposeless, uncoordinated bilateral movements of the extremities. The organization and intensity of the newborn's motor activity are influenced by a number of factors, including the following (Brazelton, 1984):

- Sleep-wake states
- Presence of environmental stimuli, such as heat, light, cold, and noise
- Conditions causing a chemical imbalance, such as hypoglycemia
- Hydration status
- State of health
- Recovery from the stress of labor and birth

Eye movements are observable during the first few days of life. An alert newborn is able to fixate on faces and geometric objects or patterns such as black and white stripes. A bright light shining in the newborn's eyes elicits the optical blink reflex.

The cry of the newborn should be lusty and vigorous. High-pitched cries, weak cries, or no cries are all causes for concern.

The newborn's body grows in a cephalocaudal (head-to-toe), proximal-distal fashion. The newborn is somewhat hypertonic; that is, there is resistance to extending the elbow and knee joints. Muscle tone should be symmetric. Diminished muscle tone and flaccidity may indicate neurologic dysfunction.

Specific symmetric deep tendon reflexes can be elicited in the newborn. The knee jerk is brisk; a normal ankle clonus may

involve three or four beats. Plantar flexion is present. Other reflexes, including the Moro, grasping, rooting, Babinski, and sucking reflexes, are characteristics of neurologic integrity. (For further discussion, see chapter 30 ∞.)

Complex behavioral patterns reflect the newborn's neurologic maturation and integration. Newborns who can bring a hand to the mouth are demonstrating motor coordination as well as a self-quieting technique, thus increasing the complexity of the behavioral response. Newborns also possess complex organized defensive motor patterns as exhibited by the ability to remove an obstruction such as a cloth across the face.

Periods of Reactivity

The baby usually shows a predictable pattern of behavior during the first several hours after birth, characterized by two **periods of reactivity** separated by a sleep phase.

First Period of Reactivity

The first period of reactivity lasts from birth to approximately 30 minutes after birth. During this period the newborn is awake and active and may appear hungry and have a strong sucking reflex. This is an optimal period for parent-infant bonding as well as a natural opportunity to initiate breastfeeding if the mother has chosen it (Figure 29-14 ■). Bursts of random, diffuse movements alternating with relative immobility may occur. Respirations are rapid, as high as 80 breaths per minute, and there may be retraction of the chest, transient flaring of the nares, and grunting. The heart rate is rapid, and rhythm may be irregular. Bowel sounds are usually absent.

Period of Inactivity to Sleep Phase

After approximately half an hour, the newborn's activity gradually diminishes. The heart rate and respirations decrease as the newborn enters the sleep phase. The sleep phase may last from a few minutes to 2 to 4 hours. During this period the newborn will be difficult to awaken and will show no interest in sucking. Bowel sounds become audible, and cardiac and respiratory rates return to baseline values.

Figure 29-14 ■ Mother and baby gaze at each other. This quiet alert state is the optimal state for interaction.

Source: Superstock Royalty Free.

Second Period of Reactivity

Care Plan Activity: Physiologic Responses of the Newborn

During the second period of reactivity, the newborn is again awake and alert. This period lasts 4 to 6 hours in the normal newborn. Physiologic responses are variable during this stage. The heart and respiratory rates increase; however, the nurse must be alert for apneic periods, which may cause a drop in the heart rate and oxygen level (desaturation). The newborn is stimulated to continue breathing during such times. The newborn may develop rapid color changes and become mildly cyanotic or mottled during these fluctuations. Production of respiratory and gastric mucus increases, and the newborn responds by gagging, choking, and regurgitating.

Continued close observation and intervention may be required to maintain a clear airway during this period of reactivity. The gastrointestinal tract becomes more active. The newborn often passes the first meconium stool and may also have an initial voiding. The newborn shows he or she is ready to be fed by such behaviors as sucking, rooting, and swallowing. If feeding was not initiated in the first period of reactivity, it is done at this time. See Initial Feeding in chapter 32 ∞ for further discussion of the first feeding.

CLINICAL TIP

Because infants are often unable to handle oral secretions effectively enough to protect their airway, parents must be instructed in the proper use of the bulb syringe. The bulb syringe used correctly creates mild suction for removal of oral and nasal secretions. Overuse or vigorous use of the bulb syringe causes unnecessary trauma and inflammation of the small nasal airways resulting in swelling and partial airway obstruction.

Behavioral States of the Newborn

The behavior of the newborn can be divided into two categories: the sleep states and the alert states (Brazelton, 1984; Gardner & Goldson, 2011). These postnatal behavioral states are similar to those that have been identified during pregnancy. Subcategories are identified under each major category.

Sleep States

Newborn Sleep

The sleep states are as follows:

1. ***Deep or quiet sleep.*** The baby has closed eyes with no eye movements, regular even breathing, and jerky motion or startles at regular intervals. Behavioral responses to external stimuli are likely to be delayed. Startles are rapidly suppressed, and changes in state are not likely to occur. Heart rate may range from 100 to 120 beats/min.
2. ***Light sleep (rapid eye movement [REM] or active sleep).*** The baby has irregular respirations, eyes closed with REM, irregular sucking motions, minimal activity, and irregular but smooth movement of the extremities. Environmental and internal stimuli initiate a startle reaction and a change of state.

Newborn sleep cycles have been recognized and defined according to duration. The length of the cycle depends on the age of the newborn. At term, REM active sleep and quiet sleep occur in intervals of 50 to 60 minutes (Gardner & Goldson, 2011).

About 45% to 50% of the total sleep of the newborn is active sleep, 35% to 45% is quiet (deep) sleep, and 10% of sleep is transitional between these two periods. Growth hormone secretion depends on regular sleep patterns. Any disturbance of the sleep-wake cycle can result in irregular spikes of growth hormone. REM sleep stimulates the highest peaks of growth hormone and the growth of the neural system. Over time, the newborn's sleep-wake patterns become diurnal; that is, the newborn sleeps at night and stays awake during the day. (See "Newborn Behavioral Assessment" in chapter 30 ∞ for in-depth discussion of Brazelton's assessment of newborn states.)

Alert States

In the first 30 to 60 minutes after birth, many newborns display a quiet alert state, characteristic of the first period of reactivity. Nurses should use these alert states to encourage bonding and breastfeeding. These periods of alertness tend to be short the first 2 days after birth to allow the baby to recover from the birth process. Subsequent alert states are of choice or of necessity (Gardner & Goldson, 2011). The newborn's increasing choice of wakefulness indicates a maturing capacity to achieve and maintain consciousness. Heat, cold, and hunger are but a few of the stimuli that can cause wakefulness by necessity. Once the disturbing stimuli are removed, the baby tends to fall back asleep.

The following are subcategories of the alert state (Gardner & Goldson, 2011):

1. ***Drowsy or semidozing.*** The behaviors common to the drowsy state are open or closed eyes; fluttering eyelids; semidozing appearance; and slow, regular movements of the extremities. Mild startles may be noted from time to time. Although the reaction to a sensory stimulus is delayed, it often causes a change of state.
2. ***Quiet alert.*** In this state, the newborn is alert and follows and fixates on attractive objects, faces, or auditory stimuli. Motor activity is minimal, and the response to external stimuli is delayed.
3. ***Active alert.*** The eyes are open, and motor activity is quite intense, with thrusting movements of the extremities in the active awake state. Environmental stimuli increase startles or motor activity, but individual reactions are difficult to distinguish because of generalized high activity level.
4. ***Crying.*** Intense crying is accompanied by jerky motor movements. Crying serves several purposes for the newborn. It may be used as a distraction from disturbing stimuli such as hunger and pain. Fussiness often allows the newborn to discharge energy and reorganize behavior. Most important, crying elicits an appropriate response of help from the parents.

CLINICAL TIP

While the mother/infant couplet is in hospital, the nurse has a perfect opportunity to teach parents techniques to deal with infant crying and fussiness. Most importantly, it is necessary for parents and caregivers to know that for the first several months crying is the only means of communication available to the newborn and usually signifies unmet needs.

Behavioral and Sensory Capacities of the Newborn

Newborns have several behavioral capacities that assist in their adaptation to extrauterine life. For example, **self-quieting ability** is the ability of newborns to use their own resources to quiet and comfort themselves. Their repertoire includes hand-to-mouth movements, sucking on a fist or tongue, and attending to external stimuli.

Neurologically impaired newborns are unable to use self-quieting activities and require more frequent comforting from caregivers when stimulated. For example, drug-positive newborns often exhibit abnormal sleep and feeding patterns and irritability.

Swaddling newborns is a way to provide comfort and security. Swaddling also helps the newborn organize and control his body movements and behaviors. Blanket swaddling should be loose and should allow the infant easy hand to mouth access to promote self-soothing abilities. Tight swaddling, "straitjacket" techniques with arms at sides, is not comforting and may further agitate the infant.

Habituation is the newborn's ability to process and respond to complex stimulation, and to alter his response to a repeated stimulus. For example, when a bright light is flashed into the newborn's eyes, the initial response is blinking, constriction of the pupil, and perhaps a slight startle reaction. However, with repeated stimulation the newborn's response repertoire gradually diminishes and disappears. The capacity to ignore repetitious disturbing stimuli is a neonatal defense mechanism allowing him to shut out overwhelming and disturbing stimuli. Sensory abilities include visual, auditory, olfactory, taste, and tactile capacities.

Visual Capacity

Orientation is the newborn's ability to be alert to, to follow, and to fixate on complex visual stimuli that have a particular appeal and attraction. The newborn prefers the human face and eyes, and high contrast objects and patterns. The newborn is nearsighted and has best vision at a distance of 8 to 15 inches (Kyle & Kyle, 2008). As the face or object is brought into the line of vision, the newborn responds with bright, wide eyes; still limbs; and fixed staring. The newborn's eyes wander and occasionally can cross as this fixation occurs. This intense visual involvement may last several minutes, during which time the newborn is able to follow the stimulus from side to side. Figure 29-15 ■ illustrates this response. The newborn uses this sensory capacity to become familiar with family, friends, and surroundings.

Auditory Capacity

The newborn responds to auditory stimulation with a definite, organized behavior repertoire. The stimulus used to assess auditory response should be selected to match the state of the newborn. A rattle is appropriate for light sleep, a voice for an awake state, and a clap for deep sleep. As the newborn hears the sound, the cardiac rate rises, and a minimal startle reflex may be seen. If the sound is appealing, the newborn will become alert and search for the site of the auditory stimulus. Newborns prefer the sound of the human voice to nonhuman sounds and have very acute hearing immediately after birth (Cheffer & Rannalli, 2011).

Figure 29-15 ■ Head turning to follow an object.
Source: Photographer, Elena Dorfman.

Olfactory Capacity

Newborns develop the sense of smell rapidly, and can differentiate their mother by smell within the first week of life (Cheffer & Rannalli, 2011). Newborns are able to distinguish their mothers' breast pads from those of other mothers' at just 1 week postnatally, and will turn preferentially toward the mother's smell.

Taste and Sucking

The newborn responds differently to varying tastes. They can distinguish between sweet and sour at 3 days of age (Cheffer & Rannalli, 2011). Sugar, for example, increases sucking, and newborns tend to have a preference for sweet tastes. Newborns fed with a rubber nipple versus the breast also show sucking pattern variations. When breastfeeding, the newborn sucks in bursts with frequent regular pauses. The bottle-fed newborn tends to suck at a regular rate with infrequent pauses.

When awake and hungry, the newborn displays rapid searching motions in response to the rooting reflex. Once feeding begins, the newborn establishes a sucking pattern according to the method of feeding. Finger sucking happens not only postnatally, but also in utero. The newborn frequently uses nonnutritive sucking as a self-quieting activity, which assists in the development of self-regulation. For bottle-fed infants, there is no reason to discourage nonnutritive sucking with a pacifier. Pacifiers should be offered to breastfed infants only after breastfeeding is well established, or during prolonged times away from the mother, or when stressful or painful procedures are required. If the pacifier is offered too soon, a phenomenon called "nipple confusion" may occur in which the breastfed infant has difficulty learning to suck from the breast and may nurse less. (See Supplementary Bottle Feeding in chapter 32 ∞ for a more in-depth discussion.)

Tactile Capacity

The newborn is very sensitive to being touched, cuddled, and held; thus touch may be the most important of all of the senses for the newborn infant. Often a mother's first response to an upset or crying newborn is touching or holding. Swaddling, placing a hand on the abdomen, or holding the arms to prevent a startle reflex are other ways to soothe the newborn. The settled newborn is then able to attend to and interact with the environment. Touch is also used to rouse a drowsy infant making him or her more alert for feeding.

FOCUS YOUR STUDY

- Newborn respiration is initiated primarily by chemical and mechanical events in association with thermal and sensory stimulation.
- The production of surfactant is crucial to keeping the lungs expanded during expiration by reducing alveolar surface tension.
- The newborn is an obligatory nose breather. Respirations move from being primarily shallow, irregular, and diaphragmatic to synchronous abdominal and chest breathing.
- Normal respiratory rate is 30 to 60 breaths per minute.
- Periodic breathing is normal, and newborn sleep states affect breathing patterns.
- The status of the cardiopulmonary system may be measured by evaluating the heart rate, blood pressure, and presence or absence of murmurs. The normal heart rate is 110 to 160 beats/min.
- Oxygen transport in the newborn is significantly affected by the presence of greater amounts of HbF (fetal hemoglobin) than HbA (adult hemoglobin). HbF holds oxygen more efficiently but releases it to the body tissues only at low PO_2 levels.

- Blood values in the newborn are modified by several factors, such as site of the blood sample, gestational age, prenatal or perinatal hemorrhage, and the timing of the clamping of the umbilical cord.
- The newborn is considered to have established thermoregulation when oxygen consumption and metabolic activity are minimal.
- Evaporation is the primary heat loss mechanism in newborns who are wet from amniotic fluid or a bath. In addition, excessive heat loss occurs from radiation and convection because of the newborn's larger surface area compared with weight; and from thermal conduction because of the marked difference between core temperature and skin temperature.
- The primary source for heat production in the cold-stressed newborn is brown adipose tissue.
- Blood glucose levels should reach a steady state by 3 hours of age.
- The newborn's liver plays a crucial role in iron storage, carbohydrate metabolism, conjugation of bilirubin, and coagulation.
- Controversy continues about the relationship of breastfeeding and the development of prolonged jaundice.
- The normal newborn possesses the ability to digest and absorb nutrients necessary for newborn growth and development.
- The newborn's stools change from meconium (thick, tarry, black) to transitional stools (thinner, brown to green) and then to the distinct forms for either breastfed newborns (yellow-gold, soft, or mushy) or formula-fed newborns (pale yellow, formed, and pasty). Most newborns pass their first stool within 48 hours of birth.
- The newborn's kidneys are characterized by a decreased rate of glomerular flow, limited tubular reabsorption, limited excretion of solutes, and limited ability to concentrate urine. Most newborns void within 36 to 48 hours of birth.
- The immune system in the newborn is not fully activated until sometime after birth, but the newborn does possess some immunologic abilities.
- Neurologic and sensory perceptual functioning in the newborn is evident from the newborn's interaction with the environment, presence of synchronized motor activity, and well-developed sensory capacities.
- The first period of reactivity lasts for 30 minutes after birth. The newborn is alert and hungry at this time, making this a natural opportunity to promote attachment.
- The second period of reactivity requires close monitoring by the nurse because apnea, decreased heart rate, gagging, choking, and regurgitation are likely to occur and require nursing intervention.
- Behavioral states in the newborn can be divided into sleep states and alert states.
- Sensory development proceeds in a specific order: tactile/vestibular, olfactory/gustatory, and auditory/visual.

CRITICAL THINKING IN ACTION

Sandra Dee, a 21-year-old, G1, P0000, at 36 weeks' gestation, has been in labor for the last 12 hours and is fully dilated with caput visible on the perineum. The fetal heart rate is 148 to 152 with early deceleration down to 142 with contraction and pushing. Her contractions are 4 to 5 minutes apart of good quality. Sandra's mother and sister are present for the birth. Her prenatal record shows no significant pregnancy problems or complications, and her vital signs have been stable within normal limits. Sandra has received two doses of Stadol for a total of 2 mg IV for pain relief during her labor. The last dose was given 2 hours ago. You assist with the vaginal birth of a live baby without an episiotomy. You observe the sex and time as the midwife places the infant girl on the mother's abdomen, suctions out the baby's mouth and nose, and proceeds to clamp the cord. You dry and stimulate the infant to breathe, remove the wet blanket and replace it with a dry one, and place the infant skin to skin on the mother's chest. You assess the need for infant resuscitation. The baby has a lusty cry spontaneously less than 30 seconds after birth. You palpate the cord, obtaining a heart rate of 120, and observe that the baby's chest and face are pink, and the legs and arms are flexed with open fist.

1. Explain the changes that must occur in the infant's cardiopulmonary system at birth.
2. What criteria do you look for when you assess the newborn for adequate cardiopulmonary adaptation at birth?
3. What steps do you take to maintain a neutral thermal environment at birth?
4. Sandra plans to breastfeed. When would you initiate the first feeding?
5. Discuss nursing actions that can decrease the probability of high bilirubin levels in the newborn.

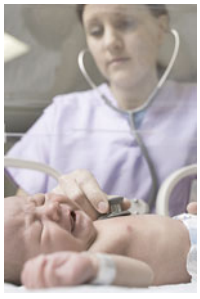
CHAPTER 30

Nursing Assessment of the Newborn



Something very special occurs within the first hour after birth. If the environment is quiet, the birthing without complications, the lights lowered, the handling diminished, newborn infants—aside from all the physiological adaptations they must make—begin in a uniquely human way to adapt to the new experience of being in the world.

—Marshall H. Klaus & Phyllis H. Klaus, *The Amazing Newborn*

LEARNING OUTCOMES

1. Describe the physical and neuromuscular maturity characteristics assessed to determine the gestational age of the newborn.
2. Delineate the normal physical and behavioral characteristics of the newborn.
3. Summarize the components of a systematic physical newborn assessment and the significance of normal variations and abnormal findings.
4. Describe the components of a newborn neurologic assessment.
5. Discuss the neurologic and neuromuscular characteristics of the newborn and the reflexes that may be present at birth.
6. Describe the components of the newborn behavioral assessment.
7. Compare the normal behavioral characteristics of the newborn with the normal variations that may be present.

Vernix caseosa *796*

Unlike adults, newborns communicate their needs primarily by their behavior. Because nurses are the most consistent professional observer of the newborn, they can translate this behavior into information about the newborn's condition and respond with appropriate nursing interventions. This chapter focuses on the assessment of the newborn and interpretation of findings. Assessment of the newborn is a continuous process used to evaluate development and adjustments to extrauterine life. In the birthing area, Apgar scoring and careful observation of the newborn form the basis of the assessment and are correlated with information such as the following:

- Maternal prenatal care history
- Birthing history
- Maternal analgesia and anesthesia
- Complications of labor or birth
- Treatment instituted immediately after birth, in conjunction with determination of clinical gestational age
- Consideration of the newborn's classification by weight and gestational age and by neonatal mortality risk
- Physical examination of the newborn

The nurse incorporates data from these sources with the assessment findings during the first 1 to 4 hours after birth to formulate a plan for nursing intervention.

The various newborn assessments and the data obtained from them are only valuable to the degree to which they are shared with the parents. The parents must be included in the assessment process from the moment of their child's birth. The *Apgar score* and its meaning should be explained immediately to the family (see further discussion in chapter 24 ∞). As soon as possible, the parents should take part in the physical and behavioral assessments as well.

The nurse encourages the parents to identify the unique behavioral characteristics of their newborn and to learn nurturing activities. Attachment is promoted when parents have the opportunity to explore their newborn in private, identifying individual physical and behavioral characteristics. The nurse's supportive responses to the parents' questions and observations are essential throughout the assessment process. The newborn physical examination is the beginning of newborn health surveillance and health education for the newborn's family that continues into the community setting.

Timing of Newborn Assessments

During the first 24 hours of life, the newborn makes the critical transition from intrauterine to extrauterine life. The risk of mortality and morbidity is statistically high during this period. Assessment of the newborn is essential to ensure that the transition is proceeding successfully

There are three major time frames for assessing newborns while they are in the birth facility.

TABLE 30-1 Timing and Types of Newborn Assessments

Assess immediately after birth:
Need for resuscitation
If newborn is stable and can be placed with parents to initiate early attachment/bonding
Assessments within 1 to 4 hours after birth:
Progress of newborn's adaptation to extrauterine life
Determination of gestational age
Ongoing assessment for high-risk problems
Assessment procedures within first 24 hours or before discharge:
Complete physical examination (Depending on agency protocol, the nurse may complete some components independently with the certified nurse-midwife/physician/nurse practitioner completing the exam before discharge.)
Nutritional status and ability to formula-feed or breastfeed satisfactorily
Behavioral state organization abilities

- The first assessment is done in the birthing area immediately after birth to determine the need for resuscitation or other interventions. The stable newborn can stay with the family after birth to initiate early attachment. The newborn with complications is usually taken to the nursery for further evaluation and intervention.
- A second assessment is done by the nursery nurse as part of the routine admission procedure. During this assessment, the nurse carries out a brief physical examination to estimate gestational age and evaluate the newborn's adaptation to extrauterine life. The accuracy of gestational age assessment decreases when performed more than 24 hours after birth. No later than 2 hours after birth, the admitting nursery nurse should evaluate the newborn's status and any problems that place the newborn at risk (American Academy of Pediatrics [AAP] & the American College of Obstetricians and Gynecologists [ACOG], 2007).
- Before discharge a certified nurse-midwife, physician, or nurse practitioner will carry out a behavioral assessment and a complete physical examination to detect any emerging or potential problems.

This chapter presents the procedures for estimating gestational age and performing the complete physical examination and behavioral assessment (Table 30-1). Chapter 24 ∞ discusses the immediate postbirth assessment. Chapter 31 ∞ describes the brief assessment performed during the first 4 hours of life.

Estimation of Gestational Age

It is essential to establish the newborn's gestational age in the first 4 hours after birth so that careful attention can be given to age-related problems. Traditionally, a newborn's gestational age was determined from the date of the pregnant woman's last menstrual period. This method was accurate only 75% to 85%

of the time. Because of the problems that develop with the newborn who is preterm or whose weight is inappropriate for gestational age, a more accurate system was developed to evaluate the newborn. Once learned, the procedure can be done in a few minutes. *It is essential that the nurse wear gloves when assessing the newborn in these early hours after birth and before the first bath until amniotic fluid, vaginal secretions, and blood on the skin are removed.*

Clinical **gestational age assessment tools** have two components: external physical characteristics and neurologic or neuromuscular development evaluations. Physical characteristics generally include sole creases, amount of breast tissue, amount of lanugo, cartilaginous development of the ear, testicular descent, and scrotal rugae or labial development. These objective clinical criteria are not influenced by labor and birth and do not change significantly within the first 12 hours after birth.

Neurologic examination facilitates assessment of functional or physiologic maturation in addition to physical development. However, the newborn's nervous system is unstable during the first 24 hours of life; neurologic evaluation findings based on reflexes or assessments dependent on the higher brain centers may not be reliable. If the neurologic findings drastically deviate from the gestational age derived by evaluation of the external characteristics, a second assessment is done in 24 hours.

The neurologic assessment components (excluding reflexes) are especially helpful in assessing the gestational age of newborns less than 34 weeks' gestation. Between 26 and 34 weeks, neurologic changes are significant, whereas significant physical changes are less evident. One significant neuromuscular change is that muscular tone develops from extension to having the ability to flex the extremity as neurologic maturity develops in a caudocephalad (tail-to-head) progression.

Ballard et al., (1991) developed the *estimation of gestational age by maturity rating*, a simplified version of the well-researched **Dubowitz tool**. The Ballard tool omits some of the neuromuscular tone assessments, such as head lag, ventral suspension (which is difficult to assess in very ill newborns or those on respirators), and leg recoil. In Ballard's tool, each physical and neuromuscular finding is given a point value, and the total score is matched to a gestational age (Figure 30-1 ■). The maximum score on the Ballard tool is 50, which corresponds to a gestational age of 44 weeks.

For example, on completing a gestational assessment of a 1-hour-old newborn, the nurse gives a score of 3 to all the physical characteristics, for a total of 18, and gives a score of 3 to all the neuromuscular assessments, for a total neurologic score of 18. The physical characteristics score of 18 is added to the neurologic score of 18 for a total score of 36, which correlates with 38 or more weeks' gestation. Because all newborns vary slightly in the development of physical characteristics and maturation of neurologic function, scores will usually vary instead of all being 3, as in this example.

Case Study: Newborn Maturity Assessment

Postnatal gestational age assessment tools can overestimate preterm gestational age and underestimate postterm gestational age. The tools have been shown to lose accuracy when newborns of less than 28 weeks' or more than 43 weeks' gestation are assessed. Ballard et al., (1991) in the **New Ballard Score (NBS)** added criteria for more accurate assessment of the gestational age of newborns between 20 and 28 weeks' gestation and less than 1500 g. They suggest that the assessment be made within 12 hours of birth to optimize accuracy, especially in infants of 22 to 28 weeks' gestational age. Also, the Ballard assessment may be overstimulating to infants of less than 27 weeks' gestation (Gardner & Hernandez, 2011).

Some maternal conditions such as preeclampsia, diabetes, and maternal analgesia and anesthesia may affect certain gestational assessment components and warrant further evaluation (see chapter 19 ∞, chapter 21 ∞, and chapter 25 ∞). Maternal diabetes, although it appears to accelerate fetal physical growth, seems to retard maturation. Maternal hypertension states, which retard fetal physical growth, seem to speed maturation.

Newborns of women with preeclampsia have a poor correlation with the criteria involving active muscle tone and edema. Maternal analgesia and anesthesia may cause the baby to have respiratory depression. Babies with respiratory distress syndrome (RDS) tend to be flaccid and edematous and to assume a "froglike" posture (see chapter 34 ∞). These characteristics affect the scoring of the neuromuscular components of the assessment tool used. The NBS gestational age assessment tool is used throughout this chapter to demonstrate the assessment of the physical and neuromuscular criteria associated with gestational age.

Assessment of Physical Maturity Characteristics

The nurse first evaluates observable characteristics without disturbing the baby. Selected physical characteristics common to the Dubowitz and Ballard gestational assessment tools are presented here in the order in which they might be most effectively evaluated:

1. *Resting posture,* although a neuromuscular component, should be assessed as the baby lies undisturbed on a flat surface (Figure 30-2 ■).
2. *Skin* in the preterm newborn appears thin and transparent, with veins prominent over the abdomen early in gestation. As the newborn approaches term, the skin appears opaque because of increased subcutaneous tissue. Disappearance of the protective vernix caseosa promotes skin desquamation, and this is commonly seen in postmature infants (infants greater than 42 weeks' gestational age and those showing signs of placental insufficiency; see chapter 33 ∞).
3. *Lanugo,* a fine hair covering, decreases as gestational age increases. The amount of **lanugo** is greatest at 28 to 30 weeks. It is most abundant over the back (particularly

between the scapulae), although it will be noted over the face, legs, and arms. Lanugo disappears first from the face, then from the trunk and extremities (Figure 30-3 ■).

4. *Sole (plantar) creases* are reliable indicators of gestational age in the first 12 hours of life. Later, the skin of the foot begins drying, and superficial creases appear. Development of sole creases begins at the top (anterior) portion of the sole and, as gestation progresses, proceeds to the heel (Figure 30-4 ■). Peeling may also occur. Plantar creases vary with race. In newborns of African descent, sole creases may be less developed at term.
5. The nurse inspects the *areola* and gently palpates the breast bud tissue by applying the forefinger and middle finger to the breast area and measuring the tissue between them in centimeters or millimeters (Figure 30-5 ■). At term gestation, the tissue will measure between 0.5 and 1 cm (5 to 10 mm). During the assessment, the nipple should not be grasped firmly because skin and subcutaneous tissue will prevent accurate estimation of size. The nurse must perform this procedure gently to avoid causing trauma to the breast tissue.

Figure 30-3 ■ Lanugo.

Source: Courtesy of Jo Engle, RN, MSN, NNP-BC and Vanessa Howell, RN, MSN.

As gestation progresses, the breast tissue mass and areola enlarge. However, a large breast tissue mass can occur as a result of conditions other than advanced gestational age or the effects of maternal hormones on the baby. In the large-for-gestational-age (LGA) infant of a diabetic mother, accelerated development of breast tissue is a reflection of subcutaneous fat deposits. Small-for-gestational-age (SGA) term or postterm newborns may have used subcutaneous fat (which would have been deposited as breast tissue) to survive in utero; as a result their lack of breast tissue may indicate a gestational age of 34 to 35 weeks, even though other factors indicate a term or postterm newborn.

6. *Ear form and cartilage distribution* develop with gestational age. The cartilage gives the ear its shape and substance (Figure 30-6 ■). In a newborn of less than 34 weeks' gestation, the ear is relatively shapeless and flat; it has little cartilage, so the ear folds over on itself and remains folded. By approximately 36 weeks' gestation, some cartilage and slight incurving of the upper pinna are present, and the pinna springs back slowly when folded. (The nurse tests this response by holding the top and bottom of the pinna together with the forefinger and thumb

and then releasing it, or by folding the pinna of the ear forward against the side of the head and releasing it, and observing the response.) By term, the newborn's pinna is firm, stands away from the head, and springs back quickly from the folding.

7. *Male genitals* are evaluated for size of the scrotal sac, the presence of rugae (wrinkles and ridges in the scrotum), and descent of the testes (Figure 30-7 ■). Before 36 weeks, the small scrotum has few rugae, and the testes are palpable in the inguinal canal. By 36 to 38 weeks, the testes are in the upper scrotum, and rugae have developed over the anterior portion of the scrotum. By term, the testes are generally in the lower scrotum, which is pendulous and covered with rugae.
8. The appearance of the *female genitals* depends in part on subcutaneous fat deposition and therefore relates to fetal

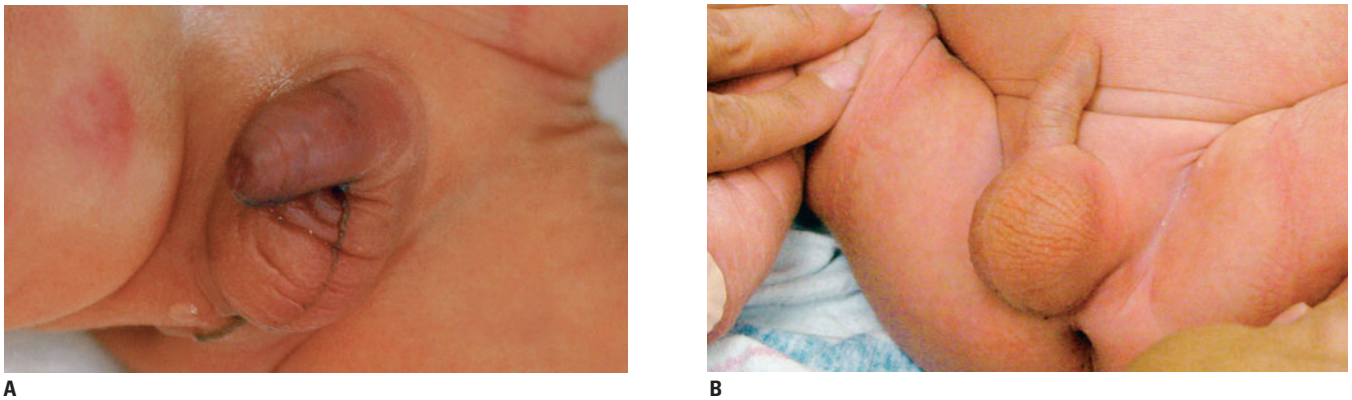
nutritional status (Figure 30-8 ■). The clitoris varies in size and occasionally is so large that it is difficult to identify the sex of the newborn. This swelling may be caused by adrenogenital syndrome, which causes the adrenals to secrete excessive amounts of androgen and other hormones. At 30 to 32 weeks' gestation, the clitoris is prominent, and the labia majora are small and widely separated. As gestational age increases, the labia majora increase in size. At 36 to 40 weeks, they nearly cover the clitoris. At 40 weeks and beyond, the labia majora cover the labia minora and clitoris.

Other physical characteristics assessed by some gestational age scoring tools include the following:

1. *Vernix* covers the preterm newborn. The postterm newborn has no vernix. After noting vernix distribution, the birthing area nurse (wearing gloves) dries the newborn to prevent evaporative heat loss, thus disturbing the vernix and potentially altering this gestational age criterion. The birthing area nurse must communicate to the neonatal nurse the amount of vernix and the areas of vernix coverage.
2. *Hair* of the preterm newborn has the consistency of matted wool or fur and lies in bunches rather than in the silky, single strands of the term newborn's hair.
3. *Skull firmness* increases as the fetus matures. In a term newborn, the bones are hard, and the sutures are not easily displaced. The nurse should not attempt to displace the sutures forcibly.
4. *Nails* appear and cover the nail bed at about 20 weeks' gestation. Nails extending beyond the fingertips may indicate a postterm newborn.



A B

Figure 30-7 ■ Male genitals. A. Preterm infant's testes are not within the scrotum. The scrotal surface has few rugae. Score 2. B. Term infant's testes are generally fully descended. The entire surface of the scrotum is covered by rugae. Score 3.

Assessment of Neuromuscular Maturity Characteristics

The central nervous system of the human fetus matures at a fairly constant rate. Tests have been designed to evaluate neurologic status as manifested by development of neuromuscular tone. As noted earlier, neuromuscular tone in the fetus develops in a caudocephalic direction, from the lower to the upper extremities.

The neuromuscular evaluation requires more manipulation and disturbances than the physical evaluation of the newborn. The neuromuscular evaluation (see Figure 30-1) is best performed when the infant has stabilized. The following characteristics are evaluated:

1. The *square window sign* is elicited by flexing the baby's hand toward the ventral forearm until resistance is felt. The angle formed at the wrist is measured (Figure 30-9 ■).
2. *Recoil* is a test of flexion development. Because flexion first develops in the lower extremities, recoil is first tested in the legs. The nurse places the newborn on his or her back on a flat surface. With a hand on the newborn's knees and while manipulating the hip joint, the nurse places the baby's legs in flexion, and then extends them parallel to each other and flat on the surface. The response to this maneuver is recoil of the newborn's legs. According to gestational age, they may not move, or they may return slowly or quickly to the flexed position. Preterm infants have less muscle tone than term infants so preterm infants have less recoil.

Arm recoil is tested by flexion at the elbow and extension of the arms at the newborn's side. While the baby is in the supine position, the nurse completely flexes both elbows, holds them in this position for 5 seconds, extends the arms at the baby's side, and releases them. Upon release, the elbows of a full-term newborn form an angle of less than 90 degrees and rapidly recoil back to a flexed position. The elbows of preterm newborns have slower recoil time and form a greater than 90-degree angle. Arm recoil is also slower in healthy but

A B C

Figure 30-9 ■ Square window sign. A. This angle is 90 degrees and suggests an immature newborn of 28 to 32 weeks' gestation. Score 0. B. A 30–40-degree angle is commonly found in newborns from 38 to 40 weeks' gestation. Score 2–3. C. A 0–15-degree angle occurs in newborns from 40 to 42 weeks' gestation. Score 4

Source: A-B. George Dodson/Lightworks Studio/Pearson Education. C. Courtesy of Jo Engle, RN, MSN, NNP-BC and Vanessa Howell, RN, MSN.

A B C

Figure 30-10 ■ Scarf sign. A. No resistance is noted until after 30 weeks' gestation. The elbow can be readily moved past the midline. Score 1. B. The elbow is at midline at 36 to 40 weeks' gestation. Score 2. C. Beyond 40 weeks' gestation, the elbow will not reach the midline. Score 4.

Source: A-B. George Dodson/Lightworks Studio/Pearson Education. C. Courtesy of Jo Engle, RN, MSN, NNP-BC and Vanessa Howell, RN, MSN.

fatigued newborns after birth; therefore, arm recoil is best elicited after the first hour of birth, when the baby has had time to recover from the stress of birth. The deep sleep state also decreases the arm recoil response. Assessment of arm recoil should be bilateral to rule out brachial palsy.

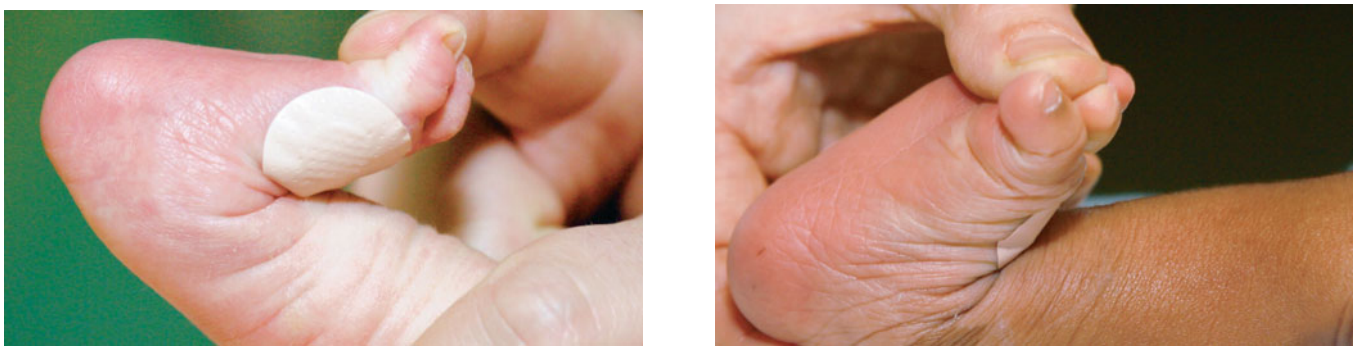
3. The *popliteal angle* (degree of knee flexion) is determined with the newborn flat on his or her back. The thigh is flexed on the abdomen and chest, and the nurse places the index finger of the other hand behind the newborn's ankle to extend the lower leg until resistance is met. The angle formed is then measured. Results vary from no resistance in the very immature newborn to an 80-degree angle in the term newborn.
4. The *scarf sign* is elicited by placing the newborn supine and drawing an arm across the chest toward the newborn's opposite shoulder until resistance is met. The location of the elbow is then noted in relation to the midline of the chest (Figure 30-10 ■). A preterm infant's elbow will cross the midline of the chest, whereas a full term infant's elbow will not cross midline.
5. The *heel-to-ear extension* is performed by placing the newborn in a supine position and then gently drawing the foot toward the ear on the same side until resistance is felt (Figure 30-11 ■). The nurse should allow the knee to bend during the test. It is important to hold the buttocks down to keep from rolling the baby. Both the proximity of foot to ear and degree of knee extension are assessed. The leg of a preterm, immature newborn remains straight and the foot goes to the ear or beyond. With advancing gestational age, the newborn demonstrates increasing resistance to this maneuver. Maneuvers involving the lower extremities of newborns who had frank breech presentation should be delayed to allow for resolution of leg positioning.
6. *Ankle dorsiflexion* is determined by flexing the ankle on the shin. The nurse uses a thumb to push on the sole of the newborn's foot while the fingers support the back of the leg. Then the angle formed by the foot and the interior leg is measured (Figure 30-12 ■). This sign can be influenced by intrauterine position and congenital deformities.

Figure 30-11 ■ Heel-to-ear. No resistance. Leg fully extended. Score 0.

Source: George Dodson/Lightworks Studio/Pearson Education.

7. *Head lag* (neck flexors) is measured by pulling the baby to a sitting position and noting the degree of head lag. Total lag is common in infants up to 34 weeks' gestation, whereas the postmature newborn (42 or more weeks) will hold the head in front of the body line. Full-term newborns are able to support their heads momentarily.
8. *Ventral suspension* (horizontal position) is evaluated by holding the newborn prone on the examiner's hand. The position of head and back and degree of flexion in the arms and legs are then noted. Some flexion of arms and legs indicates 36 to 38 weeks' gestation; fully flexed extremities, with head and back even, are characteristic of a term newborn.
9. Major reflexes such as sucking, rooting, grasping, Moro, tonic neck, Babinski, and others are also evaluated during the newborn exam. These reflexes are discussed later in the chapter.

A supplementary method for estimating gestational age (done by the physician or nurse practitioner) is to view the vascular network of the cornea with an ophthalmoscope. The nurse should delay administration of prophylactic eye ointment until after the eye exam. The amount of vascularity present over the surface of the lens has excellent correlation with infants of 27 through 34 weeks' gestational age. In babies less than 27 weeks' gestation,



A B

Figure 30-12 ■ Ankle dorsiflexion. A. A 45-degree angle indicates 32 to 36 weeks' gestation. A 20-degree angle indicates 36 to 40 weeks' gestation. Score 2–3. B. A 15- to 0-degree angle is common at 40 weeks' or more gestational age. Score 4.

Source: George Dodson/Lightworks Studio/Pearson Education.

the cornea is cloudy, and the vascular network is not visible; after 34 weeks' gestation the vascular network has generally disappeared completely.

When the gestational age determination and birth weight are considered together, the newborn can be identified as one whose *growth is below the 10th percentile,* or *small for gestational age (SGA); appropriate for gestational age (AGA);* or *above the 90th percentile,* or *large for gestational age (LGA)* (Figure 30-13 ■). This determination enables the nurse to anticipate possible physiologic problems. This information is

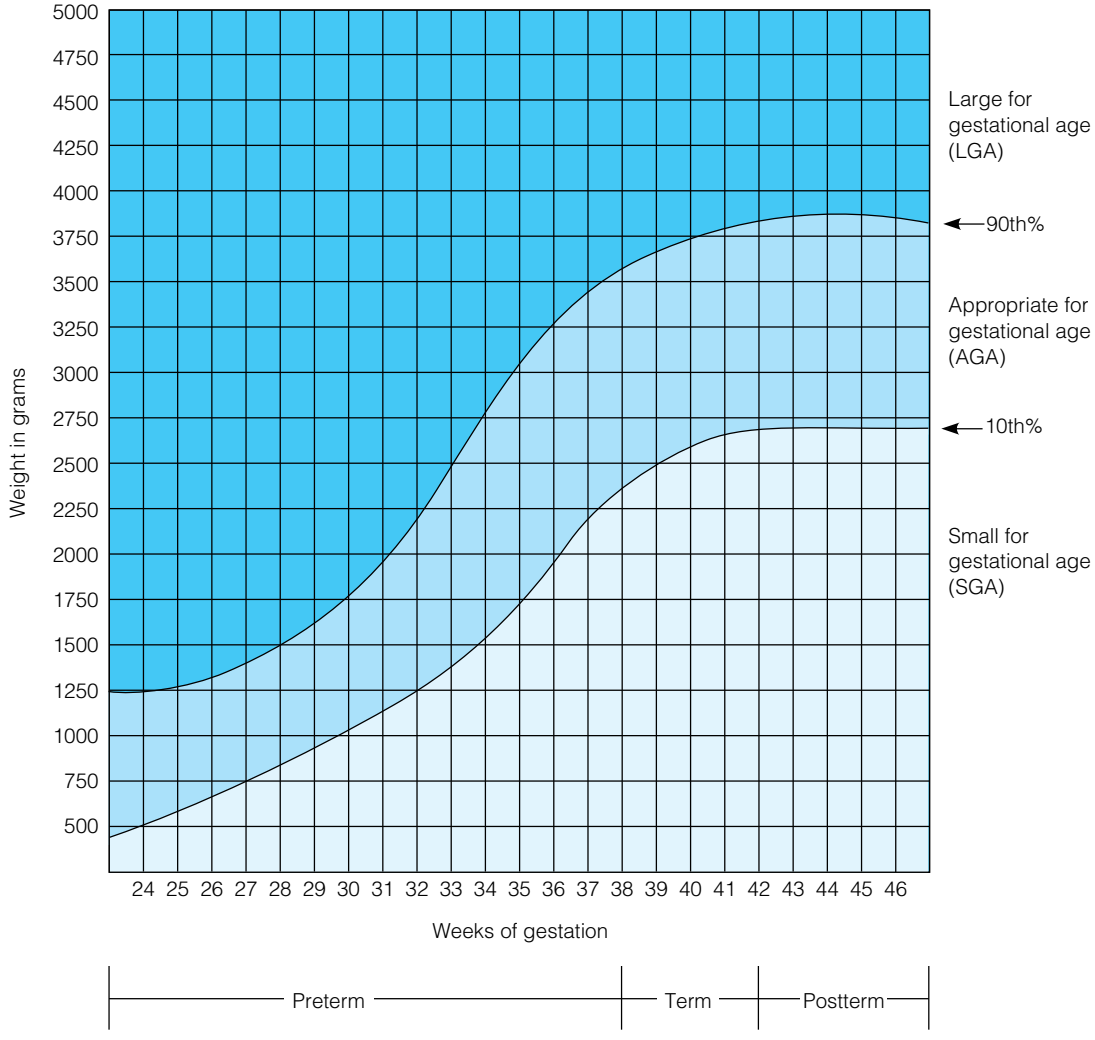


Figure 30-13 ■ Classification of newborns by birth weight and gestational age. The newborn's birth weight and gestational age are placed on the graph. The newborn is then classified as large for gestational age (LGA), appropriate for gestational age (AGA), or small for gestational age (SGA).

Source: Reprinted from Journal of Pediatrics, *71, 161, Battaglia, F. C., & Lubchenco, L. O. A practical classification of newborn infants by weight and gestational age. Copyright © 1967, with permission from Elsevier.*

used in conjunction with a complete physical examination to establish a plan of care appropriate for the individual newborn. For example, an SGA newborn often requires frequent glucose monitoring and early feedings. See chapter 33 ∞ for discussion of these categories and their potential problems.

The nurse also plots the gestational age against the newborn's length, head circumference, and weight on the appropriate growth chart to determine whether these measurements fall within the average range—the 10th to 90th percentile for the corresponding gestational age (Figure 30-14 ■). These correlations further document the level of maturity and appropriate category for the newborn. The comparison of the newborn's ratio of weight to length further facilitates identification of SGA newborns as being symmetrically or asymmetrically growth restricted. See chapter 33 ∞ for more detail.

CLINICAL JUDGMENT

Case Study: Travis Bell

A nurse has completed the gestational assessment on newborn Travis Bell who weighs 3000 g and is 48 cm long with a head circumference of 33 cm. His Apgar scores were 8 at 1 minute and 9 at 5 minutes. Other assessment data include skin dry and cracking with pale areas and rare veins; no lanugo; sole creases covering the entire sole; raised areola 3 mm; well-curved pinna soft with ready recoil; and testes descended with moderate rugae. Reflex data include square window at 0 degree; arm recoil 100 degree; popliteal angle 100 degree; scarf sign yield elbow will not reach midline; heel to ear 90 degree; and posture fully flexed. The parents express concerns over his small size.

Critical Thinking

What are the newborn's physical maturity score and neuromuscular maturity score?

Interpret the newborn's combined scores of neuromuscular and physical maturity.

Determine if the newborn is small for gestational age (SGA), appropriate for gestational age (AGA), or large for gestational age (LGA).

What should the nurse tell the parents regarding their concern over his small size?

See www.nursing.pearsonhighered.com for possible responses.

Physical Assessment

After the initial determination of gestational age and related potential problems, the nurse carries out a more extensive physical assessment in a warm, well-lighted area that is free of drafts. Completing the physical assessment in the presence of the parents provides an opportunity to acquaint them with their unique newborn. The examination is performed in a systematic, head-to-toe manner, and all findings are recorded. When assessing the physical and neurologic status of the newborn, the nurse should first consider general appearance and then proceed to specific areas.

The Assessment Guide: Newborn Physical Assessment on pages 811–819 outlines how to systematically assess the newborn. Normal findings, alterations, and related causes are presented and correlated with suggested nursing responses. The findings are typical for a full-term newborn.

General Appearance

The newborn's head is disproportionately large for the body. The neck looks short because the chin rests on the chest. Newborns have a prominent abdomen, sloping shoulders, narrow hips, and a rounded chest. The center of the baby's body is the umbilicus rather than the symphysis pubis, as in the adult. The body appears long and the extremities short.

Newborns tend to stay in a flexed position similar to the one maintained in utero and will offer resistance when the extremities are straightened. The flexed position that the newborn maintains contributes to the short appearance of the extremities. The hands are tightly clenched. After a breech birth, the feet are usually dorsiflexed, and it may take several weeks for the newborn to assume typical newborn posture.

Weight and Measurements

The normal full-term Caucasian newborn has an average birth weight of 3405 g (7 lb, 8 oz). In the United States, mothers of African descent have smaller newborns at birth at twice the rate of Caucasian mothers; newborns of mothers of Asian, Hispanic (mostly Mexican), and Native American descent have only a slightly higher rate of being smaller at term (Teitler, Reichman, Nepomnyaschy, et al., 2007). Other factors that influence weight are age and size of parents, health of mother (smoking and malnutrition decrease birth weight), and the interval between pregnancies (short intervals, such as every year, result in lower birth weight). After the first week and for the first 6 months, the newborn's weight will increase about 198 g (7 oz) weekly.

Approximately 70% to 75% of the newborn's body weight is water. During the initial newborn period (the first 3 or 4 days), term newborns have a physiologic weight loss of about 5% to 10% because fluid shifts. This weight loss may reach 15% for preterm newborns. Large babies tend to lose more weight because of greater fluid loss in proportion to birth weight. If weight loss is greater than 10%, clinical reappraisal is necessary. Factors contributing to weight loss include small fluid intake resulting from delayed breastfeeding or a slow adjustment to formula, increased volume of meconium excreted, and urination. Weight loss may be marked in the presence of temperature elevation (because of associated dehydration) or consistent chilling (because of nonshivering thermogenesis).

The length of the normal newborn is difficult to measure because the legs are flexed and tensed. To measure length, the nurse should place newborns flat on their backs with legs extended as much as possible (Figure 30-15 ■). The average length is 50 cm (20 in.), with the range being 48 to 52 cm (18 to 22 in.). The newborn will grow approximately 1 inch a month for the next 6 months. This is the period of most rapid growth.

At birth the newborn's head is one third the size of an adult's head. The circumference of the newborn's head is 32 to 37 cm (12.5 to 14.5 in.). For accurate measurement, the nurse places the tape over the most prominent part of the occiput and brings it to just above the eyebrows (Figure 30-16A ■). The circumference of the newborn's head is approximately 2 cm greater than the circumference of the newborn's chest at birth and will

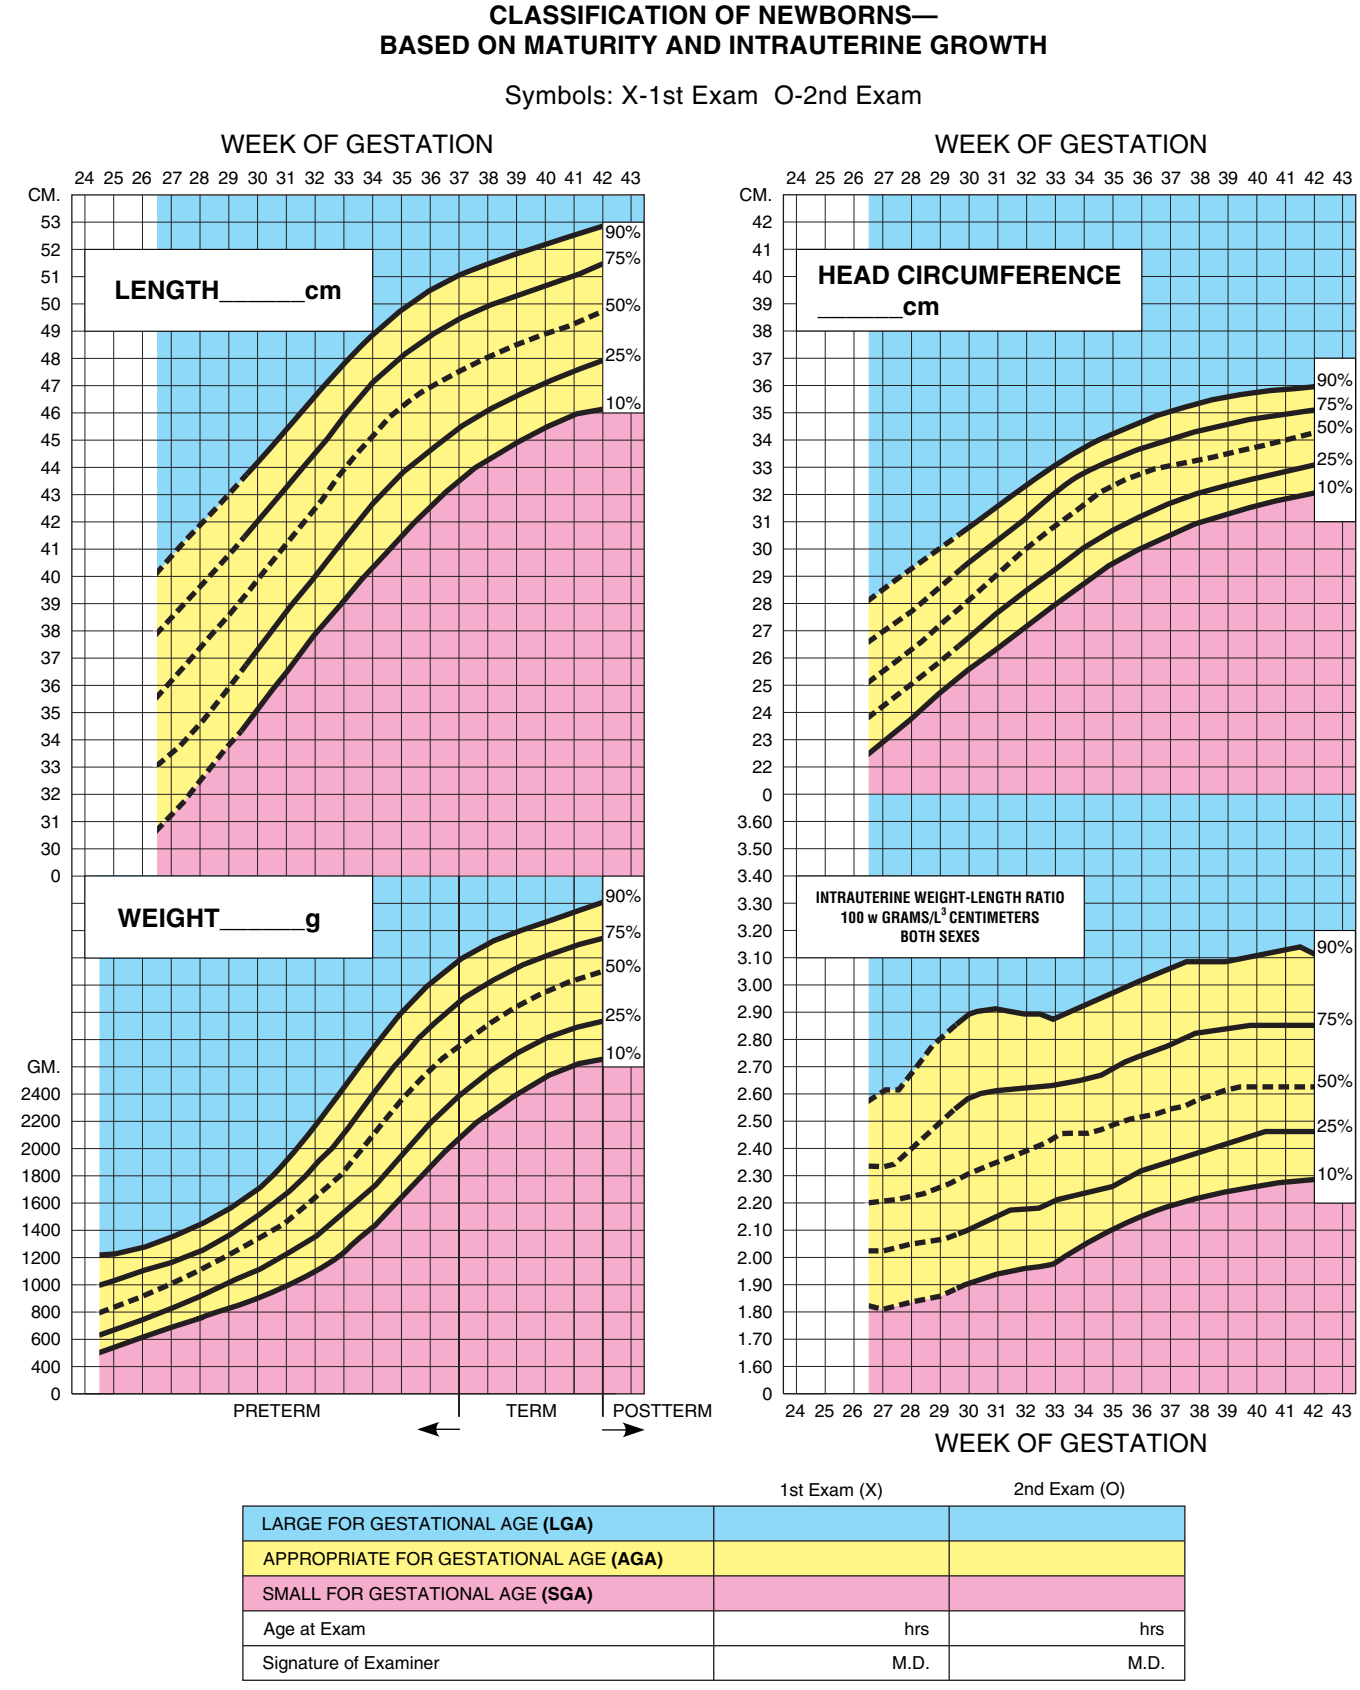

Figure 30-14 ■ Classification of newborns based on maturity and intrauterine growth.

TABLE 30-2 Newborn Measurements

Weight
Average: 3405 g (7 lb, 8 oz)
Range: 2500–4000 g (5 lb, 8 oz–8 lb, 13 oz)
Weight is influenced by racial origin and maternal age and size.
Physiologic weight loss: 5%–10% for term newborns, up to 15% for preterm newborns
Growth: 198 g (7 oz) per week for first 6 months

Length
Average: 50 cm (20 in.)
Range: 48–52 cm (18–22 in.)
Growth: 2.5 cm (1 in.) per month for first 6 months

Head Circumference
Average 33–35 cm (13–14 in.)
Range 32–37 cm (12.5–14.5 in.)
Approximately 2 cm larger than chest circumference

Chest Circumference
Average: 32 cm (12.5 in.)
Range: 30–35 cm (12–14 in.)

remain in this proportion for the next few months. (Factors that alter this measurement are discussed under the "Head" section.) It is best to take another head circumference on the second day if the newborn experienced significant head molding or caput from the birth process.

The average circumference of the chest at birth is 32 cm (12.5 in.) and ranges from 30 to 35 cm (12 to 14 in.). Chest measurements should be taken with the tape measure at the lower edge of the scapulas and brought around anteriorly directly over the nipple line (Figure 30-16B ■). The abdominal circumference or girth may also be measured at this time by placing the tape around the newborn's abdomen at the level of the umbilicus, with the bottom edge of the tape at the top edge of the umbilicus. Newborn measurements are summarized in Table 30-2.

Temperature

Initial assessment of the newborn's temperature is critical. In utero the temperature of the fetus is about the same as, or slightly higher than, the expectant mother's. When babies enter the outside world, their temperatures can suddenly drop as a result of exposure to cold drafts and the skin's heat loss mechanisms.

If no heat conservation measures are initiated, the normal term newborn's core temperature falls 0.1°C (0.2°F) per minute; skin temperature decreases 0.3°C (0.5°F) per minute. Skin temperature markedly decreases within 10 minutes after exposure to room air. The temperature should stabilize within 8 to 12 hours. Temperature should be monitored when the newborn is admitted to the nursery and at least every 30 minutes until the newborn's status has remained stable for 2 hours. Thereafter the nurse should assess temperature at least once every 8 hours or according to institutional policy (AAP & ACOG, 2007). In infants who have been exposed to group B hemolytic streptococcus, more frequent temperature monitor-

ing may be required. (See chapter 29 ∞ for a discussion of the physiology of temperature regulation.)

Temperature can be assessed by the axillary skin method, a continuous skin probe, or via the rectal route. Axillary temperature reflects body (core) temperature and the body's compensatory response to the thermal environment. Axillary temperatures are the preferred method and are considered to be a close estimation of the rectal temperature. In preterm and term newborns there is less than 0.1°C (0.2°F) difference between the two sites and the axillary method is preferred. If the axillary method is used, the thermometer must remain in place at least 3 minutes, unless an electronic thermometer is used (Figure 30-17 ■). Axillary temperature ranges from 36.4°C to 37.2°C (97.5°F to 99°F). Keep in mind that axillary temperatures can be misleading because the friction caused by apposition of the inner arm skin and upper chest wall and the nearness of brown fat to the probe may elevate the temperature.

Skin temperature is measured most accurately by continuous skin probe, especially for small newborns or newborns maintained in incubators or under radiant warmers. Normal skin temperature is 36°C to 36.5°C (96.8°F to 97.7°F). Assessing skin temperature allows time for interventions to be initiated before a more serious fall in core temperature occurs (Figure 30-18 ■).

Rectal temperature is assumed to be the closest approximation to core temperature, but the accuracy of this method depends on the depth to which the thermometer is inserted. Normal rectal temperature is 36.6°C to 37.2°C (97.8°F to 99°F). The rectal route is **not** recommended as a routine method because it may predispose to rectal mucosal irritation and increase chances of perforation (Blackburn, 2007).

Temperature instability, a deviation of more than 1°C (2°F) from one reading to the next, or a subnormal temperature may indicate an infection. In contrast with an elevated temperature in older children, an increased temperature in a newborn may

Figure 30-18 ■ Temperature monitoring for the newborn. A skin thermal sensor is placed on the newborn's abdomen, upper thigh, or arm and secured with porous tape or a foil-covered foam pad.

Source: Photographer, Elena Dorfman.

indicate a reaction to too many coverings, too hot a room, or dehydration. Dehydration, which tends to increase body temperature, occurs in newborns whose feedings have been delayed for any reason. Newborns respond to overheating (temperature greater than 37.5°C or 99.5°F) by increased restlessness and eventually by perspiration. The perspiration is initially seen on the head and face, then on the chest. Many newborns initially cannot perspire, so they increase their respiratory and heart rates, which increases oxygen consumption.

DEVELOPING CULTURAL COMPETENCE

Keeping Newborns Warm

In the Latino culture and others, parents may be overly concerned about keeping their newborn baby warm. Parents should be informed that overdressing babies while they are sleeping is related to a higher risk of Sudden Infant Death Syndrome (SIDS) and that bundling them excessively can be uncomfortable and lead to heat rash.

CLINICAL TIP

Measuring weight and height often aggravate newborns and may alter their vital signs. For better accuracy, take the newborn's vital signs before weighing and measuring.

Skin Characteristics

Although the newborn's skin color varies with genetic background, all healthy newborns have a pink tinge to their skin. The ruddy hue results from increased red blood cell concentration in the blood vessels and from limited subcutaneous fat deposits.

Skin pigmentation is slight in the newborn period, so color changes may be seen even in darker skinned babies. Caucasian newborns have a pinkish-red skin tone a few hours after birth, and African-American newborns can have a pale pink with yellow or red tinge to a reddish-brown skin color. Hispanic and Asian newborns can have a pink or rosy red with yellow tinge to an olive or yellow skin tone (Creehan, 2008). Skin pigmentation deepens over time; therefore, variations in skin color indicating illness are more difficult to evaluate in African-American and Asian newborns (Creehan, 2008). A newborn who is cyanotic at rest and pink only with crying may have choanal atresia (congenital

Figure 30-19 ■ Acrocyanosis.

blockage of the passageway between the nose and pharynx). If crying increases the cyanosis, heart or lung problems should be suspected. Very pale newborns may be anemic or have hypovolemia (low blood volume and blood pressure [BP]) and should be evaluated for these problems.

Acrocyanosis (bluish discoloration of the hands and feet) may be present in the first 2 to 6 hours after birth (Figure 30-19 ■). This condition is due to poor peripheral circulation, which results in vasomotor instability and capillary stasis, especially when the baby is exposed to cold. If the central circulation is adequate, the blood supply should return quickly (2 to 3 seconds) to the extremity after the skin is blanched with a finger. Blue hands and nails are a poor indicator of oxygenation in a newborn. The face and mucous membranes should be assessed for pinkness reflecting adequate oxygenation.

Mottling (lacy pattern of dilated blood vessels under the skin) occurs as a result of general circulation fluctuations. It may last several hours to several weeks or may come and go periodically. Mottling may be related to chilling, prolonged apnea, sepsis, or hypothyroidism.

Harlequin sign (clown) color change is occasionally noted. A deep color develops over one side of the newborn's body while the other side remains pale, so that the skin resembles a clown's suit. This color change results from a vasomotor disturbance in which blood vessels on one side dilate while the vessels on the other side constrict. It usually lasts from 1 to 20 minutes. Affected newborns may have single or multiple episodes, but they are transient and clinically insignificant. The nurse should document its occurrence.

Jaundice is first detectable on the face (where skin overlies cartilage) and the mucous membranes of the mouth (Creehan, 2008). Jaundice advances from head to toe and regresses in the opposite direction. It is evaluated by blanching the tip of the nose, the forehead, the sternum, or the gum line. This procedure must be carried out in appropriate lighting. If jaundice is present, the area will appear yellowish immediately after blanching. Another area to assess for jaundice is the sclera. Jaundice must be evaluated and its cause determined immediately to prevent possible serious sequelae. Jaundice may be related to breastfeeding (in some cases), hematomas, immature liver function, or bruises from forceps, or it may be caused by blood incompatibility, oxytocin (Pitocin) augmentation or induction, or a severe hemolytic process. Any jaundice noted before 24 hours of age should be reported to the physician or nurse practitioner. Breastfeeding is a possible cause of late onset jaundice. See Procedure 30-1: Assessing Jaundice in the Newborn. For a detailed discussion of the causes, assessment, and treatment of jaundice, see chapter 34 ∞.

Erythema toxicum is an eruption of lesions in the area surrounding a hair follicle that are firm, vary in size from 1 to 3 mm, and consist of a white or pale yellow papule or pustule with an erythematous base. It is often called "newborn rash" or "flea bite" dermatitis. The rash may appear suddenly, usually over the trunk and diaper area, and is frequently widespread (Figure 30-20 ■). The lesions do not appear on the palms of the hands or the soles of the feet. The peak incidence is at 24 to 48 hours of life. The condition rarely presents at birth or after 5 days of life. The cause is unknown and no treatment is necessary. Some clinicians feel it may be caused by irritation from clothing. The lesions disappear in a few hours or days. If a maculopapular rash (eruption consisting of both macules and papules) appears, a smear of the aspirated papule will show numerous eosinophils on staining; no bacteria will be cultured.

Milia, which are exposed sebaceous glands, appear as raised white spots on the face, especially across the nose (Figure 30-21 ■). No treatment is necessary, because they will clear up spontaneously within the first month. Infants of African heritage have a similar condition called *transient neonatal pustular melanosis*.

Skin turgor is assessed to determine hydration status, the need to initiate early feedings, and the presence of any infectious processes. The usual place to assess skin turgor is over the abdomen, forearm, or thigh. Skin should be elastic and should return rapidly to its original shape.

Vernix caseosa, a whitish cheeselike substance, covers the fetus while in utero and lubricates the skin of the newborn. The skin of the term or postterm newborn has less vernix and is frequently dry; peeling is common, especially on the hands and feet.

Forceps marks may be present after a difficult forceps birth. The newborn may have reddened areas over the cheeks and jaws. It is important to reassure the parents that these will dis-

Figure 30-20 ■ Erythema toxicum over cheek area.

PROCEDURE 30-1 Assessing Jaundice in the Newborn

NURSING ACTION

Preparation

- Wash hands
- Assemble equipment

Equipment and Supplies

- Transcutaneous bilimeter

Procedure

1. Observe infant in a well-lit room or near a window during daylight hours. Infant should be specifically checked for jaundice at least twice a shift or with every assessment.
2. Blanch skin on forehead and sternum with digital pressure for 1 second and release. Observe for underlying yellow tinge to skin. If jaundice is observed on the sternum, also check palms, soles, and blanch skin below the knee.

   Rationale: *Progression of jaundice is head to toe (caudal progression). Jaundice is first seen in the face and neck when levels reach 4–8 mg/dl. Jaundice can be seen on palmar and plantar surfaces at levels greater than 15 mg/dl. Visual assessment is often an inaccurate predictor of bilirubin levels.*
3. If infant appears jaundiced, a transcutaneous bilirubin (TcB) level should be checked. TcB levels are monitored with a transcutaneous bilimeter. The device should be used according to manufacturer directions and calibrated as directed. The TcB measurement is obtained from the forehead or sternum and plotted on a nomogram. A total serum bilirubin (TSB) level is still required when treatment with phototherapy or an exchange transfusion is being considered.

   Rationale: *A transcutaneous or total serum bilirubin level should be checked on all infants who appear jaundiced in the first 24 hours of life. A TcB is as reliable as a TSB in most instances and is less invasive. The hour specific nomogram recommended by the AAP provides guidelines for initiating phototherapy in hospitalized infants 35 weeks or greater gestational age. Full term infants receive phototherapy for bilirubin levels > 12 mg/dl. The recommended treatment levels for premature infants are dependent on postnatal age, weight, and contributing factors.*
4. Assessment of jaundice risk requires gathering information about hydration status to include how the infant is being fed, feeding tolerance, amount of urine and stool, and weight. Hemoglobin (Hgb) and hematocrit (Hct) levels are also helpful.

   Rationale: *Infants who are not eating well are more prone to hyperbilirubinemia. Infants born at high altitude develop higher levels of bilirubin than babies born at sea level related to elevated hematocrit and hypoxemia.*
5. The nurse assesses the infant for early signs of bilirubin encephalopathy, which include poor feeding, hypotonia, and lethargy.
6. Document any physical findings and TcB levels, and report jaundice to the primary care practitioner.

Figure 30-21 ■ Facial milia over bridge of nose.

appear, usually within 1 or 2 days. Transient facial paralysis resulting from the forceps pressure is a rare complication. Vacuum extractor suction marks on the vertex of the scalp are often seen when vacuum extractors are used to assist with the birth. These are benign and do not indicate any underlying brain lesions.

Sucking blisters (vesicles or bullae) may appear on the lips, fingers, or hands of newborns as a result of vigorous sucking, either in utero or after birth. These sucking blisters (Figure 30-22 ■) may be intact or ruptured and require no treatment.

Figure 30-22 ■ Sucking blister in middle of upper lip.

Birthmarks

Telangiectatic nevi (stork bites) appear as pale pink or red spots and are frequently found on the eyelids, nose, lower occipital bone, and nape of the neck (Figure 30-23 ■). The lesions are common in light-complexioned newborns and are more noticeable during periods of crying. These areas have no clinical significance and usually fade by the second birthday.

Mongolian blue spots are macular areas of bluish black or gray-blue pigmentation found on the dorsal area and the buttocks (Figure 30-24 ■). They are common in newborns of Asian, Hispanic, and African descent and other dark-skinned races and can be seen in 1% to 9% of Caucasians. They gradually fade during the first or second year of life. They may be mistaken for bruises and should be documented in the newborn's chart.

Nevus flammeus (port wine stain) is a capillary angioma directly below the epidermis. It is a nonelevated, sharply demarcated, red to purple area of dense capillaries (Figure 30-25 ■). In infants of African descent it may appear as a purple-black stain. The size and shape varies, but it commonly appears on the face. It does not grow in size, does not fade with time, and does not blanch as a rule. The birthmark may be concealed by using an opaque cosmetic cream. If convulsions and other neurologic problems accompany the nevus flammeus, the clinical picture is suggestive of *Sturge-Weber syndrome* with involvement of the fifth cranial nerve (the ophthalmic branch of the trigeminal nerve).

Nevus vasculosus (strawberry mark) is a capillary hemangioma. It consists of newly formed and enlarged capillaries in the dermal and subdermal layers. It is a raised, clearly delineated, dark red, rough-surfaced birthmark commonly found in the head region. Such marks usually begin to grow (often rapidly) during the second or third week of life and may not reach their full size until about 6 months of age (Tappero & Honeyfield, 2009). They begin to shrink and start to resolve spontaneously several weeks to months after they reach peak growth. A pale purple or gray spot on the surface of the hemangioma signals the start of resolution. The best cosmetic effect is achieved when the lesions are allowed to resolve spontaneously.

Birthmarks are frequently a cause of concern for the parents. The mother may be especially anxious, fearing that she is to blame ("Is my baby marked because of something I did?"). Guilt feelings are common in the presence of misconceptions about the cause. Birthmarks should be identified and explained to the parents. By providing appropriate information about the cause and course of birthmarks, the nurse frequently relieves the fears and anxieties of the family. The nurse should note any bruises, abrasions, or birthmarks seen on the newborn's admission to the nursery.

Head

General Appearance

The newborn's head is large (approximately one fourth of the body size), with soft, pliable skull bones. For most term infants,

Figure 30-26 ■ Overlapped cranial bones produce a visible ridge in a premature infant. Easily visible overlapping does not occur often in term infants.

Source: Courtesy of Jo Engle, RN, MSN, NNP-BC and Vanessa Howell, RN, MSN.

the occipital-frontal circumference (OFC) is 32 to 37 cm (12.6 to 14.6 in.). The head may appear asymmetric in the newborn of a vertex presentation. This asymmetry, called **molding**, is caused by the overriding of the cranial bones during labor and birth (Figure 30-26 ■). The degree of molding varies with the amount and length of pressure exerted on the head. Within a few days after birth, the overriding usually diminishes, and the suture lines become palpable. Because head measurements are affected by molding, a second measurement is indicated a few days after birth. The heads of breech-born newborns and those born by elective cesarean birth are characteristically round and well shaped because pressure was not exerted on them during birth. Any extreme differences in head size may indicate *microcephaly* (an abnormally small head) or *hydrocephalus* (an abnormal buildup of fluid in the brain). Variations in the shape, size, or appearance of the head may be due to *craniosynostosis* (premature closure of the cranial sutures), which needs to be corrected through surgery to allow brain growth, or *plagiocephaly* (asymmetry resulting in closure of sutures on one side caused by pressure on the fetal head during gestation) (Tappero & Honeyfield, 2009).

Two *fontanelles* ("soft spots") may be palpated on the newborn's head. Fontanelles, which are openings at the juncture of the cranial bones, can be measured with the fingers. Accurate measurement necessitates that the examiner's finger be measured in centimeters. The assessment should be carried out with the newborn in sitting position and not crying. The diamond-shaped *anterior fontanelle* is 3 to 4 cm long by 2 to 3 cm wide. It is located at the juncture of the frontal and parietal bones. The *posterior fontanelle,* smaller and triangular, is formed by the parietal bones and the occipital bone and is 0.5 cm by 1 cm. Because of molding, the fontanelles tend to be smaller immediately after birth than several days later. The anterior fontanelle closes within 18 months, whereas the posterior fontanelle closes within 8 to 12 weeks.

The fontanelles are a useful indicator of the newborn's condition. The anterior fontanelle may swell when the newborn cries or passes a stool or may pulsate with the heartbeat, which is normal. A bulging fontanelle usually signifies increased intracranial pressure, and a depressed fontanelle indicates dehydration (Creehan, 2008). The sutures between the cranial bones should be palpated for amount of overlap. In newborns whose growth has been restricted, the sutures may be wider than normal, and the fontanelle may also be larger because of impaired fetal growth of the cranial bones. In addition to being inspected for degree of molding and size, the head should be evaluated for soft-tissue edema and bruising.

Cephalhematoma

Cephalhematoma is a collection of blood resulting from ruptured blood vessels between the surface of a cranial bone (usually parietal) and the periosteal membrane (Figure 30-27 ■).

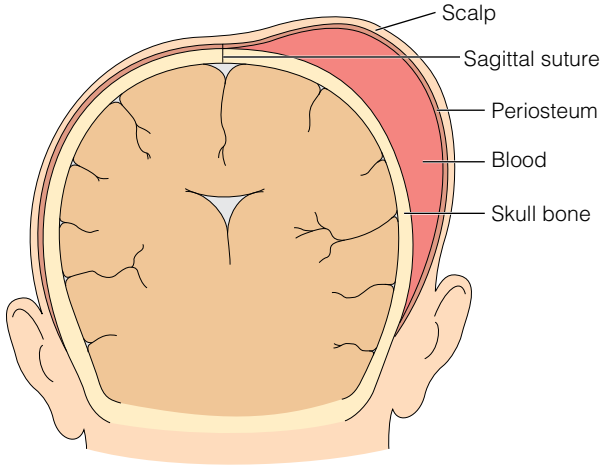

Figure 30-27 ■ Cephalhematoma is a collection of blood between the surface of a cranial bone and the periosteal membrane. This is a cephalhematoma over the right parietal bone.

Source: Courtesy of Jo Engle, RN, MSN, NNP-BC and Vanessa Howell, RN, MSN.

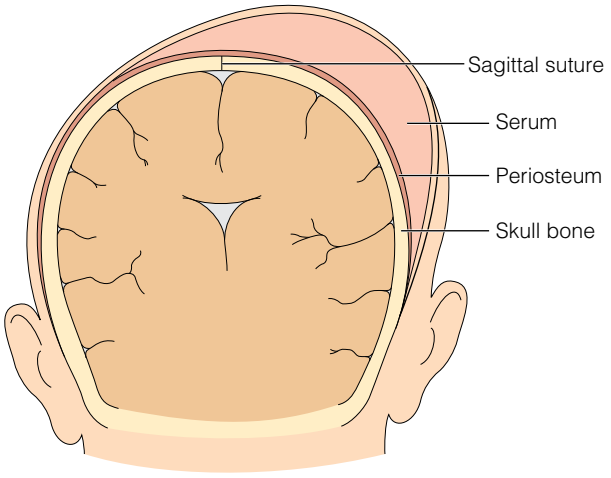

Figure 30-28 ■ Caput succedaneum is a collection of fluid (serum) under the scalp.

Source: B. George Dodson/Lightworks Studio/Pearson Education.

The scalp in these areas feels loose and slightly edematous. These areas emerge as defined hematomas between the first and second days. Although external pressure may cause the mass to fluctuate, it does not increase in size when the newborn cries. Cephalhematomas may be unilateral or bilateral and do not cross suture lines. They are relatively common in vertex births and disappear within 2 weeks to 3 months. They may be associated with physiologic jaundice, because there are extra red blood cells being destroyed within the cephalhematoma. A large cephalhematoma can lead to anemia and hypotension.

Caput Succedaneum

Caput succedaneum is a localized, easily identifiable soft area of the scalp, generally resulting from a long and difficult labor or vacuum extraction. The sustained pressure of the presenting part against the cervix results in compression of local blood vessels, and venous return is slowed. Slowed venous return causes an increase in tissue fluids, an edematous swelling, and occasional bleeding under the periosteum. The caput may vary from a small area to a large area covering a severely elongated head. The fluid in the caput is reabsorbed within 12 hours to a few days after birth. Caputs resulting from vacuum extractors are sharply outlined, circular areas up to 2 cm (0.8 in.) thick. They disappear more slowly than naturally occurring edema. It is possible to distinguish between a cephalhematoma and a caput because the caput overrides suture lines (Figure 30-28 ■), whereas the cephalhematoma, because of its location, never crosses a suture line (Table 30-3). Caput succedaneum is present at birth, whereas cephalhematoma generally is not.

TABLE 30-3 Comparison of Cephalhematoma and Caput Succedaneum

Cephalhematoma	Caput Succedaneum
• Collection of blood between cranial (usually parietal) bone and periosteal membrane	• Collection of fluid, edematous swelling of the scalp
• Does not cross suture lines	• Crosses suture lines
• Does not increase in size with crying	• Present at birth or shortly thereafter
• Appears on first and second days	• Reabsorbed within 12 hours or a few days after birth
• Disappears after 2 to 3 weeks or may take months	

Hair

The term newborn's hair is smooth with texture variations depending on ethnic background (Creehan, 2008). Scalp hair is usually high over the eyebrows. Assessment of the newborn's hair characteristics such as color, quantity, hairlines, direction of growth, and hair whorls can identify genetic, metabolic, and neurologic disorders. For example, coarse, brittle, and dry hair may indicate hypothyroidism.

Face

The newborn's face is well designed to help the newborn suckle. Sucking (fat) pads are located in the cheeks. The chin is recessed, and the nose is flattened. The lips are sensitive to touch, and the sucking reflex is easily initiated.

Symmetry of the eyes, nose, and ears is evaluated. See Assessment Guide: Newborn Physical Assessment on pages 811–819 for deviations in symmetry and variations in size, shape, and spacing of facial features.

Facial movement symmetry should be assessed to determine the presence of facial palsy. Facial paralysis appears when the newborn cries; the affected side is immobile, and the palpebral (eyelid) fissure widens (Figure 30-29 ■). Paralysis may result from forceps-assisted birth or pressure on the facial nerve from the maternal pelvis during birth. Facial paralysis usually disappears within a few days to 3 weeks, although in some cases it may be permanent.

Eyes

The eyes of newborns of northern European descent are a blue or slate blue-gray. Dark-skinned newborns tend to have dark eyes at birth. The scleral color tends to be white to bluish white because of its relative thinness. A blue sclera is associated with osteogenesis imperfecta. The infant's eye color is

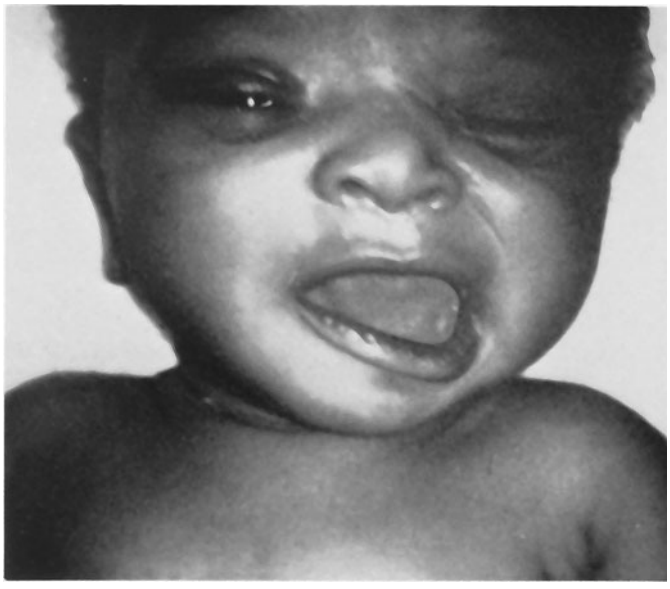

Figure 30-29 ■ Facial paralysis. Paralysis of the right side of the face from an injury to the right facial nerve.

Figure 30-30 ■ Transient strabismus in the newborn may be due to poor neuromuscular control.

Source: Used with permission from Mead Johnson Nutritionals, Evansville, IN.

usually established at approximately 3 months, but it may change any time up to 1 year.

The eyes should be checked for size, equality of pupil size, reaction of pupils to light, blink reflex to light, and edema and inflammation of the eyelids. The eyelids can be edematous during the first few days of life because of the pressure associated with birth.

Erythromycin and tetracycline (in some agencies) are used prophylactically and usually do not cause chemical irritation of the eye (see chapter 31 ∞). The instillation of silver nitrate drops in the newborn's eyes may cause edema and **chemical conjunctivitis**, which may appear a few hours after instillation and disappear in 1 to 2 days (AAP & ACOG, 2007). If infectious conjunctivitis exists, the newborn has the same purulent (greenish yellow) discharge as in chemical conjunctivitis, but it is caused by gonococcus, *Chlamydia,* staphylococci, or a variety of gram-negative bacteria and requires treatment with ophthalmic antibiotics. Onset is usually after the second day. Edema of the orbits or eyelids may persist for several days until the newborn's kidneys can evacuate the fluid.

Small **subconjunctival hemorrhages** appear in about 10% of newborns and are commonly found on the sclera. These hemorrhages are caused by the changes in vascular tension or ocular pressure during birth. They will remain for a few weeks and are of no pathologic significance. Parents need reassurance that the infant is not bleeding from within the eye and that vision will not be impaired.

The newborn may demonstrate transient strabismus (pseudostrabismus) or squinting caused by neuromuscular control of eye muscles (Figure 30-30 ■). It gradually regresses in 3 to 4 months. The "doll's eye" phenomenon is also present for about 10 days after birth. As the newborn's head position is changed to the left and then to the right, the eyes move to the opposite direction. "Doll's eye" results from underdeveloped integration of head-eye coordination.

The nurse should observe the newborn's pupils for opacities or whiteness and for the absence of a normal red retinal reflex. Red retinal reflex is a red-orange flash of color observed when an ophthalmoscope light reflects off the retina. In a newborn with dark skin color, the retina may appear paler or more grayish. The color of the red reflex can also be abnormal with retinoblastoma. Absence of red reflex occurs with cataracts. Congenital cataracts should be suspected in infants of mothers with a prenatal history of rubella, cytomegalic inclusion disease, or syphilis. Brushfield spots (black or white spots on the periphery of the iris) can be associated with Down syndrome (Creehan, 2008).

The cry of the newborn is commonly tearless because the lacrimal structures are immature at birth and are not usually fully functional until the second month of life. However, some babies may produce tears during the newborn period.

Poor oculomotor coordination and absence of accommodation limit visual abilities, but newborns do have peripheral vision and can fixate on near objects (20.3 to 25.4 cm [8 to 10 in.]) in front of their faces for short periods, can accommodate to large objects (7.6 cm [3 in.] tall by 7.6 cm [3 in.] wide), and can seek out high-contrast geometric shapes. Newborns can perceive faces, shapes, and colors and begin to show visual preferences early. Newborns generally blink in response to bright lights, to a tap on the bridge of the nose (glabellar reflex), or to a light touch on the eyelids. Pupillary light reflex is also present. The eye is best examined by rocking the newborn from an upright position to the horizontal a few times or by other methods, such as diminishing overhead lights, which will elicit an opened-eye response.

Nose

The newborn's nose is small and narrow. Infants are characteristically nose breathers for the first few months of life. The newborn generally removes obstructions by sneezing. The nose

is patent if the newborn breathes easily with the mouth closed. If respiratory difficulty occurs, the nurse checks for choanal atresia (congenital blockage of the passageway between the nose and pharynx). Historically, choanal atresia can be checked by attempting to gently pass a soft #5 French catheter into both nostrils. Because of possible trauma, a cold, flat metal object may also be held under the nose to observe for fogging (Tappero & Honeyfield, 2009).

The newborn has the ability to smell after the nasal passages are cleared of amniotic fluid and mucus. They will turn their heads toward the milk source, whether bottle or breast. Newborns react to strong odors, such as alcohol, by turning their heads away or blinking.

Mouth

The lips of the newborn should be pink, and a touch on the lips should produce sucking motions. Saliva is normally scant. The taste buds are developed before birth, and the newborn can easily discriminate between sweet and bitter flavors.

The easiest way to examine the mouth completely is to stimulate infants to cry by gently depressing their tongue, thereby causing them to open the mouth fully. It is extremely important to observe the entire mouth to look for a cleft palate, which can be present even in the absence of a cleft lip. The examiner moves a gloved index finger or pinky along the hard and soft palate to feel for any openings (Figure 30-31 ■).

Occasionally, an examination of the gums will reveal precocious teeth over the area where the lower central incisor will erupt. If they appear loose, they should be removed to prevent aspiration. Gray-white lesions (inclusion cysts) on the gums may be confused with teeth. On the hard palate and gum margins, **Epstein's pearls**, small glistening white specks (keratin-containing cysts) that feel hard to the touch, are often present. They usually disappear in a few weeks and are of no significance. **Thrush** may appear as white patches that look like milk curds adhering to the mucous membranes, and bleeding may occur when patches are removed. Thrush is caused by *Candida albicans,* often acquired from an infected vaginal tract during birth, antibiotic use, or poor hand washing when handling the newborn. Thrush is treated with a preparation of nystatin (Mycostatin).

A newborn who is tongue-tied has a ridge of frenulum tissue attached to the underside of the tongue at varying lengths from its base, causing a heart shape at the tip of the tongue. "Clipping the tongue," or cutting the ridge of tissue, is not recommended. This ridge usually does not affect speech or eating, but cutting does create an entry for infection. Transient nerve paralysis resulting from birth trauma may be manifested by asymmetric mouth movements when the newborn cries or by difficulty with sucking and feeding.

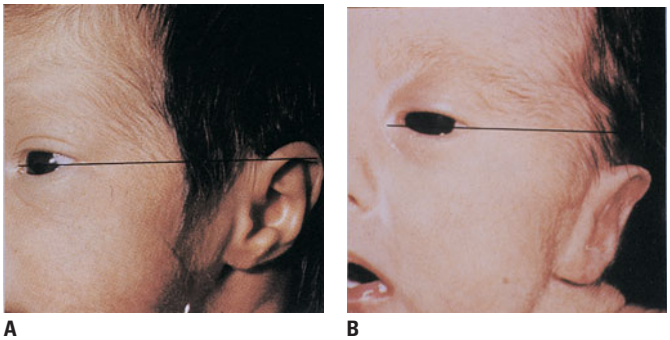
Figure 30-31 ■ The nurse inserts the index finger (or "pinky") into the newborn's mouth and feels for any openings along the hard and soft palates. *Note:* Gloves or a finger cot are always worn to examine the palate.

Source: Courtesy of Vanessa Howell, RNC, BSN.

Ears

The ears of the newborn are soft and pliable and should recoil readily when folded and released. In the normal newborn, the top of the ear (pinna) should be parallel to the outer and inner canthus of the eye. The ears should be inspected for shape, size, position, and firmness of ear cartilage. *Low-set ears* are characteristic of many syndromes and may indicate chromosomal abnormalities (especially trisomies 13 and 18), intellectual disability (mental retardation), or internal organ abnormalities, especially bilateral renal agenesis as a result of embryologic developmental deviations (Figure 30-32 ■). A *preauricular skin tag* may be present just in front of the ear. Visualization of the tympanic membranes is not usually done soon after birth because blood and vernix block the ear canal.

Following the first cry, the newborn's hearing becomes acute as mucus from the middle ear is absorbed, the eustachian tube is aerated, and the tympanic membrane becomes visible. The newborn's hearing initially can be evaluated by response to loud or moderately loud noises unaccompanied by vibrations. The sleeping newborn should stir or awaken in response to the nearby sounds. (This is not a very accurate test, but it may help to alert the examiner to possible problems.) The newborn can discriminate the individual characteristics of the human voice and is especially sensitive to sound levels within the normal conversation range. The newborn in a noisy nursery may be able



A B

Figure 30-32 ■ The position of the external ear may be assessed by drawing a line across the inner and outer canthus of the eye to the insertion of the ear. A. Normal position. B. True low-set position.

to habituate to the sounds and not stir unless the sound is sudden or much louder.

AAP has endorsed universal newborn hearing screening (UNHS) in birthing units as the standard of care (Creehan, 2008) (see chapter 31 ∞ for further discussion). Risk factors (AAP & ACOG, 2007) associated with potential hearing loss include the following:

- The presence of familial hearing loss.
- Serum bilirubin level greater than 20 mg/dl for the full-term newborn or hyperbilirubinemia with a level exceeding indications for exchange transfusion because of toxic drugs.
- Prolonged mechanical ventilation of more than 5 days.
- Congenital infection with rubella, herpes, cytomegalovirus, toxoplasmosis, or syphilis.
- Bacterial meningitis or sepsis.
- Congenital defects of the ear, nose, or throat.
- Small preterm newborns, particularly less than 1500 g at birth.
- Perinatal asphyxia.
- Ototoxic medications.

If congenital hearing loss risk factors exist, two types of tests are commonly used: otoacoustic emissions (OAEs) and auditory brainstem response (ABR).

CLINICAL TIP
