Creating a Floor-Ready Nurse

Instructor Resources—Redefined!

INTRODUCING
Pearson Nursing myClassPrep!

- **New and Unique!** **Correlation to Today's Nursing Standards!**
  - Correlation guides link book and supplement content to nursing standards such as the *2010 ANA Scope and Standards of Practice, QSEN, National Patient Safety Goals, AACN Essentials of Baccalaureate Education* and more

- **New and Unique!** **Pearson Nursing Lecture Series**
  - Highly visual, fully narrated and animated, these short lectures focus on topics that are traditionally difficult to teach and difficult for students to grasp
  - All lectures accompanied by case studies and classroom response questions for greater interactivity within even the largest classroom
  - Useful as lecture tools, remediation material, homework assignments and more

- **Additional instructor resources!**
  - Find assets such as **videos, animations, lecture starters, classroom and clinical activities** and more!
  - **Add selected resources** to presentations that can be shown online or exported to PowerPoint™ or HTML pages
  - Organized by topic and **fully searchable** by type and keyword
  - **Upload your own resources** to keep everything in one place
  - **Rate resources** and view other instructor ratings

- **New and Unique!** **Pearson Nursing Q-Bank**
  - Even **more** accessible with both pencil and paper and online delivery options
  - Expanded question bank for each chapter
  - **All New!** Approximately 30% of questions now in alternate-item format
  - **Complete rationales** for both correct and incorrect answers mapped to learning outcomes

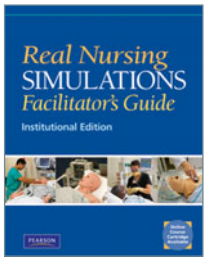
Book-specific resources also available to instructors including:

- Online Instructor's Manual with detailed lecture outlines and activities
- Comprehensive PowerPoint™ presentations integrating lecture notes and images
- Image library
- Classroom Response Questions
- Online course management systems complete with instructor tools and student activities

mynursinglab™

- Saves instructor time by providing quality feedback, ongoing formative assessments, and customized remediation for students
- **New!** Track student progress against nursing standards and competencies such as ANA, QSEN, Joint Commission, and more
- **New!** Select *Real Nursing Simulation* scenarios
- Includes select set of *Real Nursing Skill 2.0* videos
- Available with *Pearson's Interactive e-Text*
  - Integrated media and website links
  - Full search capability and note-taking functionality
  - Customizable organization

REAL NURSING SIMULATIONS



- 25 simulation scenarios that span the nursing curriculum
- Consistent format includes learning objectives, case flow, set-up instructions, debriefing questions and more!
- Companion online course cartridge with student pre- and post-simulation activities, videos, skill checklists and reflective discussion questions

Brief Contents

UNIT 1 Contemporary Maternal-Newborn Nursing 1

1 Current Issues in Maternal-Newborn Nursing 2
2 Care of the Family in a Culturally Diverse Society 24
3 Complementary and Alternative Therapies 44

Notice: Care has been taken to confirm the accuracy of information presented in this book. The authors, editors, and the publisher, however, cannot accept any responsibility for errors or omissions or for consequences from application of the information in this book and make no warranty, express or implied, with respect to its contents.

The authors and publisher have exerted every effort to ensure that drug selections and dosages set forth in this text are in accord with current recommendations and practice at time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and reactions, the reader is urged to check the package inserts of all drugs for any change in indications or dosage and for added warning and precautions. This is particularly important when the recommended agent is a new and/or infrequently employed drug.

Sally B. Olds is the quintessential nurse and teacher—
She sees possibilities where others see problems, abilities where others see limitations.
She cares passionately about childbearing families and has a clear vision of what excellent nursing means.
She stresses the importance of clinical skill and acumen but never loses sight of the human side of caregiving.
She is committed to students, to helping them to learn and grow, to develop their own sense of the difference a nurse can make.

She is the best of the best of nursing. . .
And so, with the deepest affection and respect we dedicate this book to Sally, our dear friend and colleague.
Thank you for the inspiration you provided, the warmth you brought, and the expertise you shared.
We hope you enjoy many days of sunshine, blessings, and joy.

And, as always, to our beloved families
To Nathan Davidson, Hayden, Chloe, Caroline, and Grant
To David London, Craig and his fiancé Jennifer, and Matthew
To Tim Ladewig, Ryan, Amanda, Reed, and Addison, and Erik, Kedri, Emma, and Camden

About the Authors

Michele Davidson

Michele Davidson received an ADN degree from Marymount University in 1990 and upon graduation began working in postpartum and the newborn nursery in Washington, DC. Because of her interest in educating expectant and new families, she began an education and consulting service providing childbirth education classes, lactation consulting services, and newborn care courses. During this time she also worked as a reproductive endocrinology/infertility nurse while she obtained a BSN from George Mason University. Dr. Davidson then attended Case Western Reserve University where she earned her MSN and a nurse-midwifery certificate. She worked as a nurse-midwife at Columbia Hospital for Women in Washington, DC, while completing her PhD in nursing administration and healthcare policy from George Mason University (GMU). Dr. Davidson began teaching at GMU in 1999. Dr. Davidson has developed an immersion clinical experience for GMU students on a remote island in the Chesapeake Bay, where she teaches community health nursing to students who reside in the community. In 2003, she founded the Smith Island Foundation, a nonprofit organization in which she serves as executive director. In her free time, Michele enjoys spending time with her mother, gardening, reading, and spending time at their home on Smith Island with her nurse practitioner husband, Nathan, and their four young children, Hayden, Chloe, Caroline, and Grant. Dr. Davidson recently received certification as a Certified Forensic Nurse. Her research interests include maternal-newborn and women's mental health issues.

Marcia L. London

Marcia L. London has been able to combine her two greatest passions by being both a nurse caring for children and families and a teacher for almost 40 years. She received her BSN and school nurse certificate from Plattsburgh State University in Plattsburgh, New York. After graduation, she began her nursing career as a pediatric nurse at St. Luke's Hospital in New York City, then moved to Pittsburgh, where she began her teaching career. Mrs. London accepted a faculty position at Pittsburgh's Children's Hospital Affiliate Program and received her MSN in pediatrics as a clinical nurse specialist from the University of Pittsburgh. Mrs. London began teaching at Beth-El School of Nursing and Health Science in 1974 after opening the first intensive care nursery at Memorial Hospital of Colorado Springs. She has served in many administrative and faculty positions at Beth-El, including coordinator for nursing care of children for 32 years. Mrs. London maintained her clinical skills working in an urgent care and after-hours clinic, doing undergraduate pediatric clinical supervision, and teaching class. She obtained her postmaster's neonatal nurse practitioner certificate in 1983 and subsequently developed the neonatal nurse practitioner (NNP) program and the master's NNP program at Beth-El. She is active nationally in neonatal nursing and was involved in the development of the Neonatal Nurse Practitioner Educational Program Guidelines. She has contributed five chapters to various neonatal nursing texts. Mrs. London is active in nurse practitioner education in general. She was involved in the revision of the Core Competency for Nurse Practitioners and Curriculum Guidelines for Nurse Practitioner Education, as a member of the Education Committee of the National Organization of Nurse Practitioner Faculties, and participated as part of the Core Competency Validation Expert Panel. Mrs. London has also pursued her interest in college student learning by taking doctoral classes in higher education administration and adult learning at the University of Denver in Colorado. She feels fortunate to be involved in the education of her future colleagues. Her teaching philosophy is that, with support, students can achieve more than they may initially believe they are capable of achieving. She believes in lifelong learning and applying it to her nursing care of patients as part of her faculty practice. Mrs. London and her husband have two sons and one dog (Reilly, daughter by proxy). Her son, Craig is involved in computer informatics and his fiancé Jennifer a future nurse. Matthew studied media arts and animation, and both sons are more than willing to give Mom and Dad helpful hints.

Patricia A. Wieland Ladewig

Patricia A. Wieland Ladewig received her BS from the College of Saint Teresa in Winona, Minnesota. After graduation, she worked as a pediatric nurse before joining the U.S. Air Force. After completing her tour of duty, Dr. Ladewig relocated in Florida, where she accepted a faculty position at Florida State University. There she embraced teaching as her calling. Over the years, she taught at several schools of nursing while earning her MSN in maternal-newborn nursing from Catholic University of America in Washington, DC, and her PhD in higher education administration from the University of Denver in Colorado. In addition, she became a women's health nurse practitioner and maintained a part-time clinical practice for many years. In 1988 Dr. Ladewig became the first director of the nursing program at Regis College in Denver and, in 1991, when the college became Regis University, she became dean of the Rueckert-Hartman College for Health Professions (RHCHP). Under her guidance, the Department of Nursing, now the Loretto Heights School of Nursing, added a graduate program and RHCHP added two new schools: the School of Physical Therapy and the School of Pharmacy as well as two departments: the Department of Health Services Administration and the Department of Health Care Ethics. Dr. Ladewig has now taken on a new role as Vice President for Academic Affairs at Regis University. She is excited by the opportunity this position gives her to help ensure the quality of academic programs across the entire university. When not at work or writing textbooks, Pat and her husband, Tim, enjoy skiing, Colorado Rockies baseball games, and traveling. However, their greatest pleasure comes from their family: son Ryan, his wife, Amanda, and grandchildren Reed and Addison; and son, Erik, his wife Kedri, and grandchildren Emma and Camden.

Thank You

Contributors

Reviewers

We are grateful to all the nurses, both clinicians and educators, who reviewed the manuscript of this textbook. Their insights, suggestions, and eye for detail helped us prepare a more relevant and useful textbook, one that will prepare caring and competent nurses in the field of maternal-newborn and women's health nursing.

Acknowledgments

Our goal with every revision is to incorporate the latest research and information from the literature of nursing and related fields to make our text as relevant and useful as possible. This would not be possible without the support and encouragement of our colleagues in nursing. The comments and suggestions we have received from nurse educators and practitioners around the country have helped us keep this text accurate and up to date. Whenever a nurse takes the time to write or to speak to one of us at a professional gathering, we recognize again the intense commitment of nurses to excellence in practice. And so we thank our colleagues.

We are grateful, too, to our students, past, present, and future. They stimulate us with their interest; they reinvigorate us with their enthusiasm; they challenge us with their questions to make each edition of this text clear and understandable. We learn so much from them.

In publishing, as in health care, quality assurance is an essential part of the process. That is the dimension our reviewers have added. Some reviewers assist us by validating the accuracy of the content, some by their attention to detail, and some by challenging us to examine our ways of thinking and to develop a new awareness about a given topic. Thus, we extend our sincere thanks to all those who reviewed the manuscript for this book. Their names and affiliations are listed on the preceding pages.

We are also grateful to the contributors to the ninth edition of ***Olds' Maternal-Newborn Nursing & Women's Health Across the Lifespan***. Their knowledge of clinical practice and current literature in their areas of expertise helps make the chapters relevant and accurate. They, too, are listed on the preceding pages.

The success of a project of this scope requires the skills and dedication of many people. We would personally like to thank the following people:

Thanks to Kim Mortimer, our new editor. Kim has been supportive and helpful throughout the project. She brings a wealth of publishing experience to challenge us, a fresh eye to refocus us, and a warmth and responsiveness that has already enabled us to bond as a team.

Julie Alexander, our publisher, has played an important role in the development of our text. Her leadership of Prentice Hall Health has resulted in the growth of a company committed to excellence, to technology, and to student support. She is a visionary in publishing.

We cannot say enough good things about our developmental editor Elena Mauceri, and her colleague and partner on this project, Lynda Hatch. We have worked with Elena on other books and deeply appreciate her creativity, organizational skill, and ability to stay calm and unflappable. Things simply go more smoothly because of all she brings to a project. Having Lynda join her has been an added benefit. Lynda, too, has a wonderful eye for detail and brings a new perspective to our work. We have enjoyed getting to know her and deeply appreciate all she has done to keep us on track. We thank you both. Our thanks to Marion Gottlieb, who managed the myriad details required in the administration of this project; Mary Siener, Maria Guglielmo, and Christopher Weigand for the stunning interior and cover design; to Anne Garcia for the production support; to Patty Gutierrez, who skillfully managed our photographs and illustrations; and to Heather Willison of S4Carlisle Publishing Services. Without support in these crucial areas, our work would not be as visually appealing and accurate as it is.

We are especially grateful to Kim Mohler, RN, and to Kaitlyn and Kyle Kersey—and their beautiful baby, Braeden—for their participation in the "Through the Eyes of a Nurse" features and videos. This edition benefits immensely because they were willing to share with nursing students this special time of their lives.

During these times of uncertainty in the healthcare environment, we are sustained by our passion for nursing and our vision of what childbirth means. Time and again, we have seen the difference a skilled nurse can make in the lives of people in need. We, like you, are committed to helping all nurses recognize and take pride in that fact. Thank you for your letters, your comments, and your suggestions. We are renewed by your support.

Michele R. Davidson
Marcia L. London
Patricia W. Ladewig

Preface

Most often, pregnancy and childbirth are times of great joy, a celebration of life, and a promise of the future. But they may also be times of deepest sorrow as families deal with illness, complications, and loss. Nurses play a central role in all aspects of the childbearing experience, from the earliest days of pregnancy, through the moments of birth, and during the early days of parenthood. Often the quality of the nursing care that a family receives profoundly influences their perceptions of the entire experience—for better or for worse. However, the changes occurring in the healthcare delivery system are altering the way we practice nursing and have staggering implications for nurses everywhere, even nurses caring for childbearing women and their families.

Now, more than ever, nurses must be flexible, creative, and open to change. They must be able to think critically and problem solve effectively. They must be able to meet the teaching needs of their patients so that their patients can, in turn, better meet their own healthcare needs. They must be open to an increasingly multicultural population. They must understand and use the healthcare technology available in their chosen area of practice. Most crucially, they must never lose sight of the importance of excellent nursing care to promote patient safety and in improving the quality of people's lives.

Important Themes in This Edition

The underlying philosophy of ***Olds' Maternal-Newborn Nursing & Women's Health Across the Lifespan*** remains unchanged. We believe that pregnancy and birth are normal life processes and that family members are partners in care. We believe that women's health care is an important aspect of nursing. We remain committed to providing a text that is accurate and readable—a text that helps students develop the skills and abilities they need now and in the future in an ever-changing healthcare environment.

Partnering with Families Through Health Promotion Education

Developing a partnership with women and their families is a pivotal aspect of maternal-newborn nursing, and one key element of that partnership is patient and family health promotion teaching. It is a crucial responsibility of the maternal-newborn nurse to find opportunities to educate patients and their families, and we continue to emphasize and highlight this in the ninth edition. Again, the focus is on the teaching that nurses do at all stages of pregnancy and the childbearing process, including the important postpartum teaching that is done before and immediately after families are discharged.

In this textbook, we also subscribe to the paradigm that women and childbearing families need health promotion and health maintenance interventions, no matter where they seek health care or what health conditions they may be experiencing. Nurses integrate health promotion and health maintenance into the care for women and childbearing families in a variety of birthing and community settings where they go to obtain health supervision care. This textbook integrates health promotion and health maintenance content throughout, most visibly in Unit 2, *Women's Health* and Chapter 37, "Home Care of the Postpartum Family." In addition, a new heading, **Health Promotion Education**, has been added that emphasizes the health promotion education that women and childbearing families need.

Because we believe that nursing excellence must include partnering with women and their families for all outcomes, we have included Chapter 38, "Grief and Loss in the Childbearing Family." It is designed to assist nurses to support families as they deal with the painful losses—maternal, fetal, and neonatal—that sometimes turn moments of great joy into times of deep sorrow. We know that it often takes time for nurses to find authentic ways to support grieving families. Our aim in having this chapter is to help you understand the dynamics of loss and to offer concrete guidance about effective nursing approaches.

We further the concept of partnering with childbearing families with a special feature called **Through the Eyes of a Nurse**. This feature helps you prepare for clinical experiences, with this unfolding story of an expecting couple and their nurse. **Through the Eyes of a Nurse** vignettes show the interaction between the nurse and the couple surrounding a typical topic of concern for expecting women and their partners. Viewing the partnership that develops will prepare you for success in clinical encounters and in practice.

The book's companion Web site features the interaction between Kaitlyn and Kyle and their nurse during four examinations at various stages throughout their childbirth experience. Author Michele Davidson introduces each segment to help you notice the important communication and patient education that takes place. View the partnership that develops and use it to help you prepare for clinical by answering the questions about what you have seen.

The companion Web site includes videos of four examinations to model nurse-patient interaction:

- ***Through the Eyes of a Nurse:*** The First Trimester
- ***Through the Eyes of a Nurse:*** The Second Trimester
- ***Through the Eyes of a Nurse:*** The Third Trimester
- ***Through the Eyes of a Nurse:*** The Postpartum Visit: *Welcoming the New Arrival*

Another special feature that focuses on the nurse's partnership with the woman and family is the full-color foldout, **A Day in the Life of a Nurse-Midwife**. This pictorially depicts the many opportunities that a nurse-midwife has throughout the course of a day to partner with women and families to optimize the nurse-patient relationship.

Women's Health Care

This edition continues to provide expanded coverage of women's health care with updated information on contraception, commonly occurring infections, health maintenance recommendations, menopause, and a variety of gynecologic conditions such as polycystic ovarian syndrome and pelvic relaxation. Special attention is given to violence against women, which is the focus of a separate chapter. Other pressing societal issues are also covered in a separate chapter, as well as throughout the women's health unit. Moreover, because of the text's focus on community-based care, gynecologic cancers are covered briefly in the text.

Nursing Excellence in Maternal-Newborn and Women's Health

Truly effective nurses have both a solid understanding of underlying nursing theory and excellent clinical skills. Perhaps equally important, they have a deep appreciation of the essential need to partner with childbearing women and their families to ensure optimum outcomes for all. But how do we help students develop this level of expertise? We believe that nursing excellence as it relates to women's health and to childbearing families starts here, in the pages of this text. This book provides essential theoretical content within a contemporary, holistic, family-centered context. Our goal is to lay a foundation that you can build on with each clinical experience you have.

You may notice a change in terminology from "postpartal" and "intrapartal" to "postpartum" and "intrapartum." The latter terms reflect the official style of the American College of Obstetricians and Gynecologists. Because the former versions are still commonly recognized and used, we have left some as-is within the text, but you'll see the change to the official –um endings in chapter titles and headings.

Evidence-Based Practice

Nursing professionals are increasingly aware of the importance of using evidence-based approaches as the foundation for planning and providing effective care and to foster patient safety and quality improvement. The approach of evidence-based practice draws on information from a variety of sources, including nursing research. To help nurses become more comfortable integrating new knowledge into their nursing practice, a brief discussion of evidence-based practice is included in Chapter 1, "Current Issues in Maternal-Newborn Nursing."

A new feature entitled **Research Evidence in Practice** further enhances the approach of using research to determine nursing actions. It describes a particular problem or clinical question and investigates the research evidence from a variety of sources including systematic reviews of research literature, recent research findings, and national organization policy that have direct application to nursing practice. The feature asks the student to use critical thinking (clinical reasoning and clinical judgment) to determine what additional information is needed, what the evidence showed best practice at this time, and invite the student to apply critical thinking skills to further identify nursing approaches to meet women's health and maternal-newborn nursing care issues.

Commitment to Diversity

As nurses and as educators, we recognize the importance of honoring diversity and of providing culturally competent care. Thus, we continually strive to make our text ever more inclusive. Chapter 1, "Current Issues in Maternal-Newborn Nursing," briefly introduces cultural issues relevant to maternity and newborn nursing care. Chapter 2, "Care of the Family in a Culturally Diverse Society," provides the theoretical basis for the consideration of cultural factors that influence a family's expectations of their healthcare providers and their experience with the healthcare system. We elaborate upon this information throughout the text in a boxed feature entitled **Developing Cultural Competence**. In addition, we have worked hard to ensure that our photos, illustrations, charts, and case scenarios are inclusive in their appearance and in the information they provide. As our society becomes more global in nature, nurses need to cultivate their awareness of these issues because they ultimately do affect how we deliver health care in this country.

Critical Thinking

The abilities needed to think critically and problem solve effectively are learned skills that you can cultivate and develop. To help students hone their critical-thinking skills, **Clinical Judgment** case studies present a brief scenario and **Critical Thinking** questions ask students to determine the appropriate response in that situation. Suggested answers to the questions are provided on the book's companion Web site so that students will have immediate feedback on their decision-making skills.

Another feature that emphasizes these skills is **Critical Thinking in Action**, found at the end of each chapter. This case study introduces a patient situation at the end of each chapter with questions to enable the student to decide which nursing actions are appropriate. Suggested answers appear on the book's companion Web site.

Nursing Professionalism

Professionalism requires that the astute professional nurse demonstrate professional standards of moral, ethical, and legal conduct and model the values of the nursing profession as he or she cares for women and childbearing families. With these expectations, a new feature called **Professionalism in Practice** has been added. This feature focuses on topics such as legal and ethical considerations, contemporary nursing practice issues, professional accountability, patient advocacy, and home and community care considerations.

Patient Education

Patient education remains a critical element of effective nursing care, one that we emphasize in this text. Nurses teach their patients during the care of women, all stages of pregnancy, the childbearing process, and while providing care for specific conditions. Throughout the book, we include **Patient Education** features that present a special healthcare issue or problem and the related key teaching points for care by the patient and family.

The tear-out **Patient/Family Teaching Cards** are also handy tools for you to use while studying or for quick pocket-size reference in the clinical setting. Furthermore, a foldout, full-color **Maternal-Fetal Growth and Development Chart** depicts maternal/fetal development month by month and provides specific teaching guidelines for each stage of pregnancy. You can use this chart as another tool for study or as a quick clinical reference.

Complementary and Alternative Therapies

Nurses and other healthcare professionals recognize that today, more than ever, complementary and alternative therapies have become a credible component of holistic care. To help nurses become more familiar with these therapies, Chapter 3, "Complementary and Alternative Therapies," provides basic information on some of the more commonly used therapies. Then throughout the text, we expanded the topic by providing a heading and an icon that highlight specific therapies your patients might be using or therapies you might suggest, keeping patient safety upmost in our thoughts. In all cases, research is cited for safe practice of these therapies.

Community-Based Nursing Care

By its very nature, maternal-newborn nursing is community-based nursing. Only a brief portion of the entire pregnancy and birth is spent in a birthing center or hospital. Moreover, because of changes in practice, even women with high-risk pregnancies are receiving more care in their homes and in the community and spending less time in hospital settings. Similarly, most aspects of women's health care are addressed in ambulatory settings.

The provision of nursing care in community-based settings is a driving force in health care today and, consequently, is a dominant theme throughout this edition. Four chapters provide a theoretical perspective and important tools in caring for childbearing families in the community setting: Chapter 15, "Antepartum Nursing Assessment;" Chapter 16, "The Expectant Family: Needs and Care;" Chapter 36, "The Postpartum Family: Needs and Care;" and Chapter 37, "Home Care of the Postpartum Family." We have addressed this topic in a variety of ways. **Community-Based Nursing Care** is a heading used throughout the text to assist you in identifying specific aspects of this content. Because we consider **Home Care** to be one form of community-based care, it is often a separate heading under Community-Based Nursing Care.

Other New or Expanded Concepts in This Edition

Nursing is a dynamic profession, which requires textbooks to reflect current practice. As such, we have added several important areas of content in the ninth edition.

- Ensuring appropriate **nutrition** during pregnancy and infancy is important to promote growth, development, and health. A growing national focus on healthy nutrition patterns underscores the importance of this information. Chapter 18, "Maternal Nutrition" and

Chapter 32, "Newborn Nutrition" address nutrition for pregnant women and newborns.

- **Pain management** is a priority in healthcare settings. All of the chapters in Unit 5, *Birth* address pain assessment and management, and it is the primary focus in Chapter 25, "Pain Management During Labor." We discuss applicable pain assessment and management when appropriate in other chapters in Unit 6, *The Newborn* and Unit 7, *Postpartum.*
- Content related to caring for **women with intellectual disabilities** has been added to Chapter 8, "Women's Care: Social Issues." Such women are more commonly choosing to live independently and even become mothers. Therefore, we have added coverage of caring for mothers with intellectual disabilities in Chapter 36, "The Postpartum Family: Needs and Care."

Organization: A Nursing Care Management Framework

Nurses today must be able to think critically and to solve problems effectively. For these reasons, we begin with an introductory unit to set the stage by providing information about maternal-newborn nursing and important related concepts. Subsequent units progress in a way that closely reflects the steps of the nursing process. We clearly delineate the nurse's role within this framework. Thus, the units related to pregnancy, labor and birth, the newborn period, and postpartum care begin with a discussion of basic theory followed by chapters on nursing assessment and nursing care for essentially healthy women or infants. Within the nursing care chapters and content areas, we use the heading **Nursing Care Management** and the subheadings **Nursing Assessment and Diagnosis, Planning and Implementation**, and **Evaluation**.

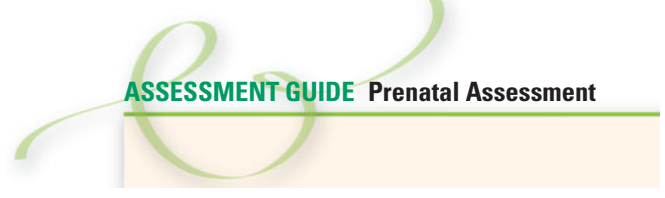
Complications of a specific period appear in the last chapter or chapters of each unit. The chapters also use the nursing process as an organizational framework. We believe that students can more clearly grasp the complicated content of the high-risk conditions once they have a good understanding of the normal processes of pregnancy, birth, and postpartum and newborn care. However, to avoid overemphasizing the prevalence of complications in such a wonderfully normal process as pregnancy and birth, we avoid including an entire unit that focuses only on complications. To aid student study, we have developed a new chapter, Chapter 26, "Childbirth at Risk: Prelabor Complications," which focuses on content that impacts both pregnancy and labor and birth. This new chapter allows more discussion of the impact of pregestational physiologic and pathophysiologic conditions so that students can apply the principles they have learned to changes experienced in pregnancy.

NURSING CARE MANAGEMENT

The ***Nursing Care Management*** head delineates the important care management role of the nurse within the organizing framework of the nursing process to help you understand what nursing actions are needed. Numerous special features reinforce the nursing care management role.

Nursing Care Plans address nursing care for patients who have complications, such as a woman with preeclampsia. We designed this feature to help you approach care from the nursing process perspective. These care plans use a nursing diagnosis approach in planning and providing care when pregnancy-related and newborn complications arise. We have added four care plans to this edition: Epidural Anesthesia, Hemorrhage in the Third Trimester and at Birth, A Woman with Engorgement, and Induction of Labor.

Clinical Pathways describe nursing actions as women are integrated into care of other health professionals. They help you organize care for healthy women and evaluate its effectiveness.

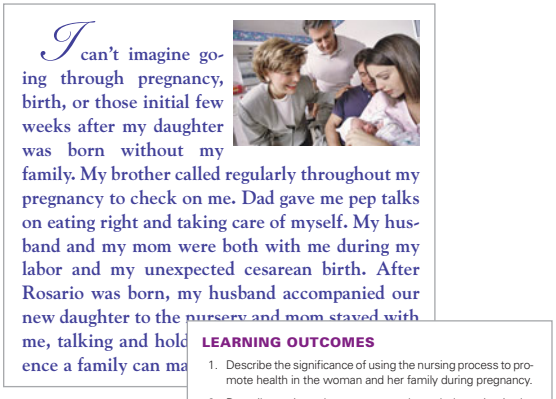


Assessment Guides help you organize your questions and steps during a physical assessment, and provide normal findings, alterations, and possible causes, as well as guidelines for nursing interventions.

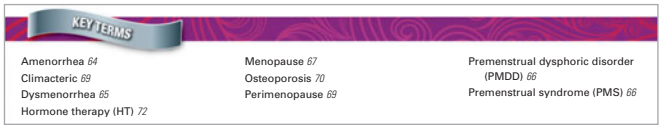
Features That Help You Use This Text Successfully

Instructors and students alike value the in-text learning aids that we include in our textbooks. The following guide will help you use the features and resources from ***Olds' Maternal-Newborn Nursing & Women's Health Across the Lifespan***, Ninth Edition, to be successful in the classroom, in the clinical setting, on the NCLEX-RN® examination, and in nursing practice.

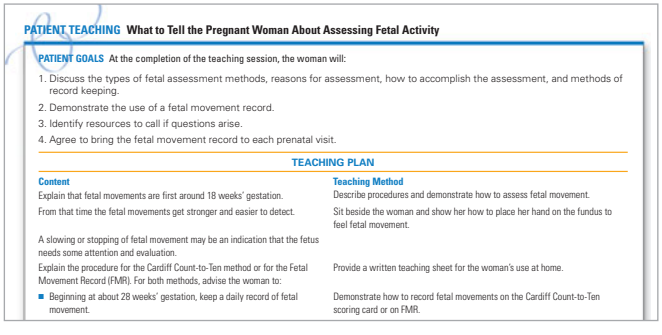
Each chapter begins with a personal **vignette** and photo that sets the tone for the chapter.



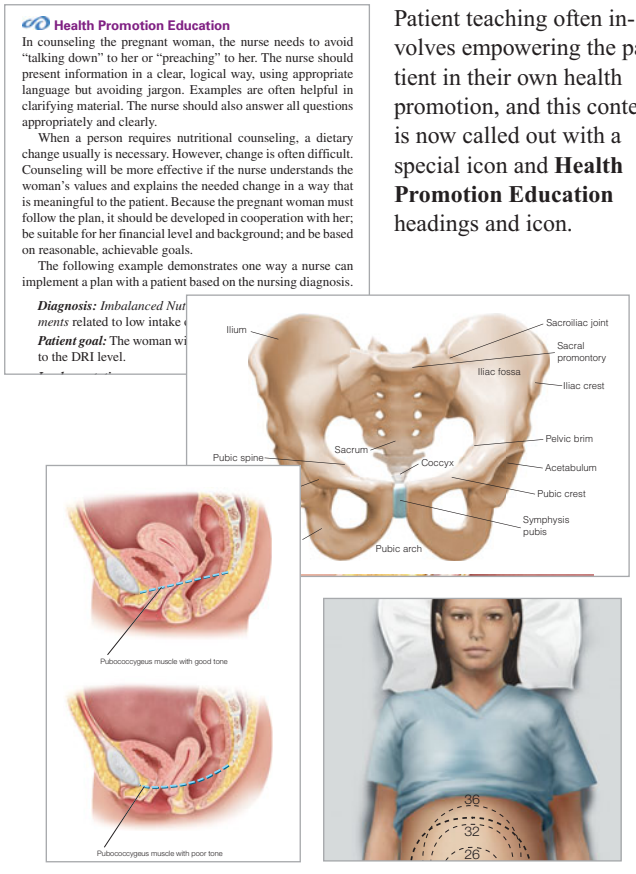
Learning Outcomes introduce you to the topics covered in each chapter. The terminology in the new Bloom's taxonomy is reflected in these learning outcomes.



Key Terms introduce each chapter, with page numbers showing where each term first appears in the chapter, in bold type.

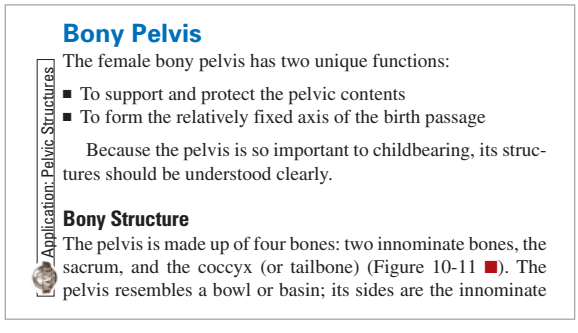


The teaching that nurses do at all stages of pregnancy and childbearing and throughout the life of a woman is one of the most important aspects of their work. The **Patient Teaching** boxes in the textbook help you plan and organize your patient teaching.



Patient teaching often involves empowering the patient in their own health promotion, and this content is now called out with a special icon and **Health Promotion Education** headings and icon.

We have continued our tradition of providing top-notch visuals to enhance students' learning by including nearly **100 new lifelike obstetric illustrations**. The 9th edition continues to provide a large amount of tabular material that provides students with quick reference to high-priority information.



The companion Web site thumbtabs in each chapter remind you to use the accompanying supplemental materials found on the text's companion Web site. These thumbtabs cross-reference additional information or specific activities related to the concepts introduced on that page in the textbook. These resources enhance learning and provide an application beyond the textbook experience.

Features

To help you understand the use of reliable information to plan and provide effective nursing care, **Research Evidence in Practice** boxes relate research evidence to women's health and maternal-newborn nursing. Each feature asks the student to use critical thinking skills to analyze the data to best meet women's health and maternal-newborn nursing care issues.

RESEARCH EVIDENCE IN PRACTICE

Passive Descent Versus Immediate Pushing in Women with Epidural Analgesia

CLINICAL QUESTION
Which method of pushing—passive descent or active pushing upon full cervical dilatation—most benefits women with epidural analgesia?

RESEARCH EVIDENCE
Epidural analgesia has become a common method of pain management for laboring women, yet one of its side effects is a decrease in a woman's lower body sensations. This may inhibit the natural urge to push upon full cervical dilatation. Traditionally, active management of labor meant that women were directed to push immediately upon full cervical dilatation, whether they felt the urge or not. The chief concern leading to this practice was that an extended second stage of labor was deleterious for both mother and baby, leading to acidosis, maternal exhaustion, and neonatal morbidity.

The natural second stage of labor includes a period of rest and descent, often described as passive descent. This practice involves allowing the woman to delay pushing until she feels the urge to push, or the head is visible vaginally.

A group of obstetric and gynecologic nurse experts conducted a meta-analysis of studies comparing the effects and outcomes of immediate pushing versus passive descent in women with epidural analgesia. The results demonstrated that immediate pushing did not reduce the incidence of acidosis or shorten the second stage of labor. Indeed, prolonged active pushing was shown to increase the incidence of fetal and maternal acidosis, increased the risk of having an instrument-assisted spontaneous vaginal birth. Pushing time was lengthened with immediate pushing as compared to passive descent.

Furthermore, passive descent had additional benefits in that it allowed for further fetal descent and rotation, better situating the fetus in the woman's pelvis. It also caused further release of oxytocin that augmented the progress of labor. These findings suggest that the duration of active pushing should be limited, not the duration of the second stage of labor.

No differences were found between immediate pushing and passive descent in terms of the rate of cesarean birth, lacerations, or episiotomies.

WHAT QUESTIONS REMAIN UNANSWERED?
Are there any conditions under which active pushing should be used? Are there differences in these findings when women do not use epidural analgesia?

WHAT IS BEST PRACTICE?
Passive descent should be used during birth to safely and effectively increase spontaneous vaginal births, decrease instrument-assisted birth, and shorten pushing time.

CRITICAL THINKING
How can the nurse help the mother recognize the urge to push at an effective time when epidural analgesia is in place?

Brancato, R., Church, S., & Stone, P. (2008). A meta-analysis of passive descent versus immediate pushing in nulliparous women with epidural analgesia in the second stage of labor. *Journal of Gynecological and Neonatal Nursing, 37*, 4–12. doi:10.1111/J.1552-6909.2007.00205.x

COMPLEMENTARY AND ALTERNATIVE THERAPIES

According to the National Center for Complementary & Alternative Medicine (NCCAM) (2008), the use of complementary and alternative medicine (CAM) is more common in women and in those with higher levels of education and higher incomes. Many women are electing to use CAM therapies, such as homeopathy, herbal medicine (phytomedicine), acupressure, acupuncture, biofeedback, Therapeutic Touch, massage, and chiropractic, as part of a holistic approach to their healthcare regimens. Nurses are in a unique position to bridge the gap between conventional therapies and CAM therapies. As patient advocates, nurses are able to provide patients with information needed to make informed decisions about their health and health

Complementary and Alternative Therapies have become a credible component of holistic care. To help you become familiar with this content, we have integrated this content into the chapter content to inform you about therapies your patients might be using or therapies you might safely suggest. In all cases, research is cited for safe practice of these therapies. Special icons denote the location of this content.

PROFESSIONALISM IN PRACTICE

2008 Prenatally and Postnatally Diagnosed Conditions Act

The Prenatally and Postnatally Diagnosed Conditions Act was signed into law in 2008. This law requires that medical providers give parents accurate, updated, and scientific information regarding their child's diagnosis, prognosis, treatment, and life expectancy. Nurses are often an important source of information and support when a prenatal or postnatal diagnosis of a genetic condition or birth defect is made.

Nursing professionalism is fostered in new features called Professionalism in Practice, which focuses on topics such as legal and ethical considerations, contemporary nursing practice issues, professional accountability, patient advocacy, and home and community care considerations.

CLINICAL JUDGMENT

Case Study: Jillian Rundus

Jillian Rundus is a 31-year-old G1P0 who is 35 weeks' pregnant. She presents for a routine office visit with complaints of nausea and abdominal pain rating 7/10. She has had a headache and general malaise for 2 days. She denies visual changes. Upon examination, you find her to be alert and oriented and her physical exam is unremarkable with the exception of abdominal tenderness and a blood pressure of 170/110. She has had no previous history of hypertension. Fetal heart rate ranges from 140–150 beats per minute.

Critical Thinking

What should the nurse do at this time?

See www.nursing.pearsonhighered.com for possible responses.

Clinical Judgment case studies help students hone their critical thinking and clinical reasoning skills by presenting a brief scenario and **Critical Thinking** questions to determine the appropriate response in that situation.

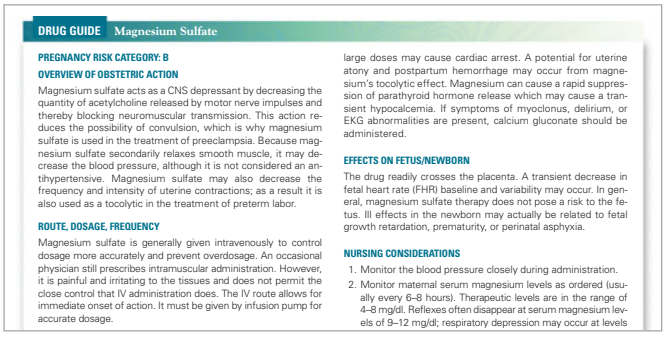
DEVELOPING CULTURAL COMPETENCE

Culture and Response to Fetal Loss

Remember that individual responses to fetal loss following miscarriage may vary greatly and may be influenced by ethnic or cultural norms.

- Miscarriage may be viewed in many ways. For example, it may be seen as a punishment from God, as the result of the evil eye or of a hex or curse by an enemy, or as a natural part of life.
- When grieving over a pregnancy loss, women from some cultures and ethnic groups may show their emotions freely, crying and wailing, whereas other women may hide their feelings behind a mask of stoicism.
- In some cultures the woman's partner is her primary source of support and comfort. In others, the woman turns to her mother or close female relatives for comfort.
- Avoid stereotyping women according to culture. Individual responses are influenced by many factors, including the degree of assimilation into the dominant culture.

The **Developing Cultural Competence** boxes foster your awareness of cultural factors that influence a family's expectations of and responses to their healthcare provider and their experiences with the healthcare system.



DRUG GUIDE Magnesium Sulfate

PREGNANCY RISK CATEGORY: B

OVERVIEW OF OBSTETRIC ACTION

Magnesium sulfate acts as a CNS depressant by decreasing the quantity of acetylcholine released by motor nerve impulses and thereby blocking neuromuscular transmission. This action reduces the possibility of convulsion, which is why magnesium sulfate is used in the treatment of preeclampsia. Because magnesium sulfate secondarily relaxes smooth muscle, it may decrease the blood pressure, although it is not considered an antihypertensive. Magnesium sulfate may also decrease the frequency and intensity of uterine contractions; as a result it is also used as a tocolytic in the treatment of preterm labor.

ROUTE, DOSAGE, FREQUENCY

Magnesium sulfate is generally given intravenously to control dosage more accurately and prevent overdosage. An occasional physician still prescribes intramuscular administration. However, it is painful and irritating to the tissues and does not permit the close control that IV administration does. The IV route allows for immediate onset of action. It must be given by infusion pump for accurate dosage.

large doses may cause cardiac arrest. A potential for uterine atony and postpartum hemorrhage may occur from magnesium's tocolytic effect. Magnesium can cause a rapid suppression of parathyroid hormone release which may cause a transient hypocalcemia. If symptoms of myoclonus, delirium, or EKG abnormalities are present, calcium gluconate should be administered.

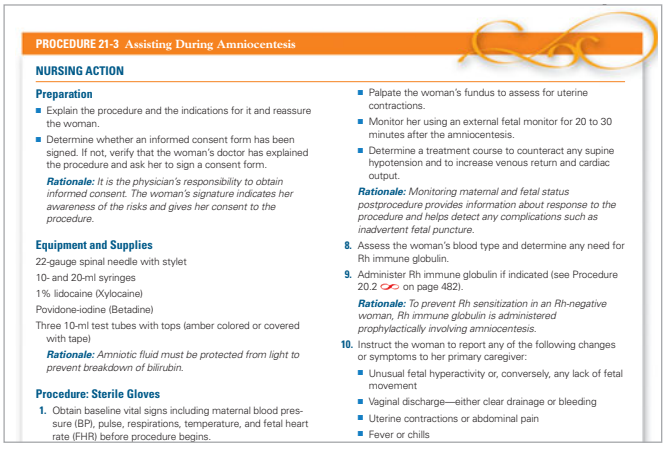
EFFECTS ON FETUS/NEWBORN

The drug readily crosses the placenta. A transient decrease in fetal heart rate (FHR) baseline and variability may occur. In general, magnesium sulfate therapy does not pose a risk to the fetus. Ill effects in the newborn may actually be related to fetal growth retardation, prematurity, or perinatal asphyxia.

NURSING CONSIDERATIONS

1. Monitor the blood pressure closely during administration.
2. Monitor maternal serum magnesium levels as ordered (usually every 6–8 hours). Therapeutic levels are in the range of 4–8 mg/dl. Reflexes often disappear at serum magnesium levels of 9–12 mg/dl; respiratory depression may occur at levels

Drug Guide boxes for selected medications commonly used in maternal-newborn nursing guide you in correctly administering the medications and evaluating your actions.



PROCEDURE 21-3 Assisting During Amniocentesis

NURSING ACTION

Preparation

- Explain the procedure and the indications for it and reassure the woman.
- Determine whether an informed consent form has been signed. If not, verify that the woman's doctor has explained the procedure and ask her to sign a consent form.

Rationale: *It is the physician's responsibility to obtain informed consent. The woman's signature indicates her awareness of the risks and gives her consent to the procedure.*

Equipment and Supplies

22-gauge spinal needle with stylet

10- and 20-ml syringes

1% lidocaine (Xylocaine)

Povidone-iodine (Betadine)

Three 10-ml test tubes with tops (amber colored or covered with tape)

Rationale: *Amniotic fluid must be protected from light to prevent breakdown of bilirubin.*

Procedure: Sterile Gloves

1. Obtain baseline vital signs including maternal blood pressure (BP), pulse, respirations, temperature, and fetal heart rate (FHR) before procedure begins.
- Palpate the woman's fundus to assess for uterine contractions.
- Monitor her using an external fetal monitor for 20 to 30 minutes after the amniocentesis.
- Determine a treatment course to counteract any supine hypotension and to increase venous return and cardiac output.

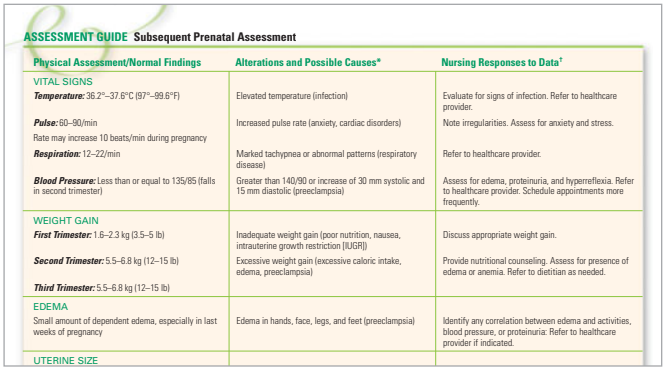
Rationale: *Monitoring maternal and fetal status postprocedure provides information about response to the procedure and helps detect any complications such as inadvertent fetal puncture.*

8. Assess the woman's blood type and determine any need for Rh immune globulin.
9. Administer Rh immune globulin if indicated (see Procedure 20.2 ↩ on page 482).

Rationale: *To prevent Rh sensitization in an Rh-negative woman, Rh immune globulin is administered prophylactically involving amniocentesis.*

10. Instruct the woman to report any of the following changes or symptoms to her primary caregiver:
    - Unusual fetal hyperactivity or, conversely, any lack of fetal movement
    - Vaginal discharge—either clear drainage or bleeding
    - Uterine contractions or abdominal pain
    - Fever or chills

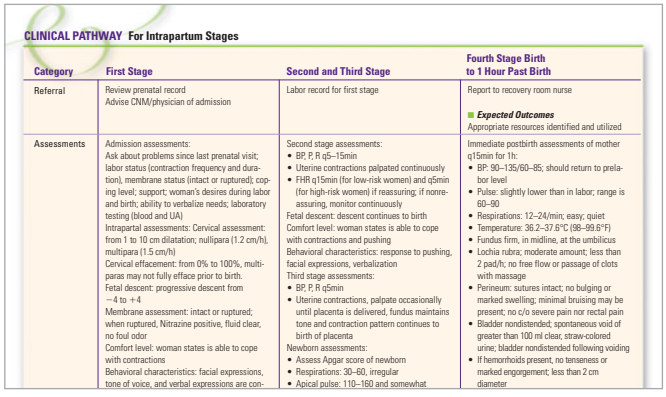
Procedure boxes offer step-by-step techniques that show you the tasks expected of a nurse in clinical situations, preparing you for your clinical experiences. Included in each box are the preparation steps with rationales, equipment and supplies needed, and steps for the procedure itself, with rationales for the nurse's actions.



ASSESSMENT GUIDE Subsequent Prenatal Assessment

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
VITAL SIGNS		
Temperature: 36.2°–37.6°C (97°–99.6°F)	Elevated temperature (infection)	Evaluate for signs of infection. Refer to healthcare provider.
Pulse: 60–90/min Rate may increase 10 beats/min during pregnancy	Increased pulse rate (anxiety, cardiac disorders)	Note irregularities. Assess for anxiety and stress.
Respiration: 12–22/min	Marked tachypnea or abnormal patterns (respiratory disease)	Refer to healthcare provider.
Blood Pressure: Less than or equal to 135/85 (falls in second trimester)	Greater than 140/90 or increase of 30 mm systolic and 15 mm diastolic (preeclampsia)	Assess for edema, proteinuria, and hyperreflexia. Refer to healthcare provider. Schedule appointments more frequently.
WEIGHT GAIN		
First Trimester: 1.6–2.3 kg (3.5–5 lb)	Inadequate weight gain (poor nutrition, nausea, intrauterine growth restriction [IUGR])	Discuss appropriate weight gain.
Second Trimester: 5.5–6.8 kg (12–15 lb)	Excessive weight gain (excessive caloric intake, edema, preeclampsia)	Provide nutritional counseling. Assess for presence of edema or anemia. Refer to dietitian as needed.
Third Trimester: 5.5–6.8 kg (12–15 lb)		
EDEMA		
Small amount of dependent edema, especially in last weeks of pregnancy	Edema in hands, face, legs, and feet (preeclampsia)	Identify any correlation between edema and activities, blood pressure, or proteinuria: Refer to healthcare provider if indicated.
UTERINE SIZE		

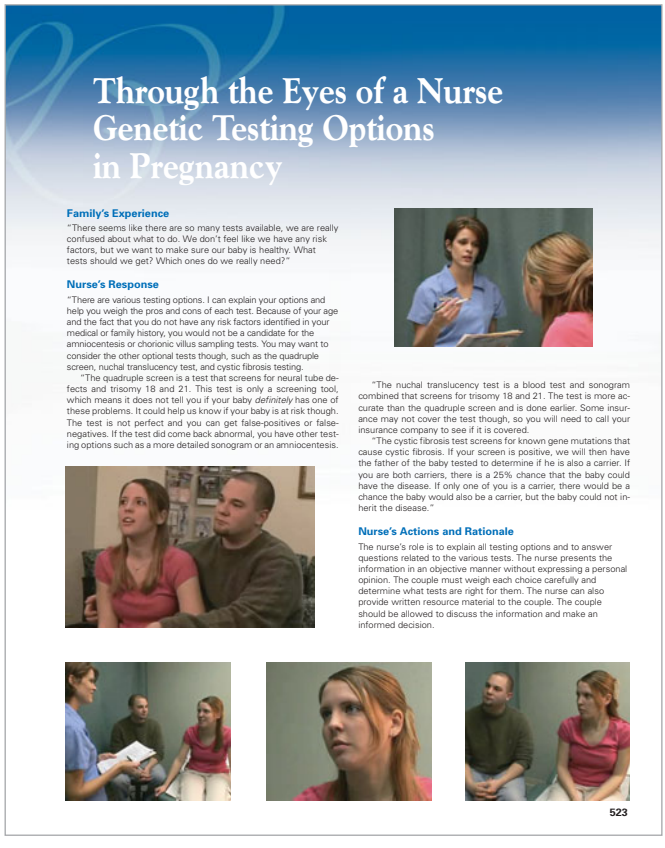
Assessment Guides assist you with diagnoses by incorporating physical assessment and normal findings, alterations and possible causes, and guidelines for nursing interventions.



CLINICAL PATHWAY For Intrapartum Stages

Category	First Stage	Second and Third Stage	Fourth Stage Birth to 1 Hour Past Birth
Referral	Review prenatal record Advise CNM/physician of admission	Labor record for first stage	Report to recovery room nurse ■ ***Expected Outcomes*** Appropriate resources identified and utilized
Assessments	Admission assessments: Ask about problems since last prenatal visit; labor status (contraction frequency and duration), membrane status (intact or ruptured); coping level; support; woman's desires during labor and birth; ability to verbalize needs; laboratory testing (blood and UA) Intrapartal assessments: Cervical assessment: from 1 to 10 cm dilatation; nullipara (1.2 cm/h), multipara (1.5 cm/h) Cervical effacement: from 0% to 100%, multiparas may not fully efface prior to birth. Fetal descent: progressive descent from −4 to +4 Membrane assessment: intact or ruptured; when ruptured, Nitrazine positive, fluid clear, no foul odor Comfort level: woman states is able to cope with contractions Behavioral characteristics: facial expressions, tone of voice, and verbal expressions are con-	Second stage assessments: • BP, P, R q5–15min • Uterine contractions palpated continuously • FHR q15min (for low-risk women) and q5min (for high-risk women) if reassuring; if nonreassuring, monitor continuously Fetal descent: descent continues to birth Comfort level: woman states is able to cope with contractions and pushing Behavioral characteristics: response to pushing, facial expressions, verbalization Third stage assessments: • BP, P, R q5min • Uterine contractions, palpate occasionally until placenta is delivered, fundus maintains tone and contraction pattern continues to birth of placenta Newborn assessments: • Assess Apgar score of newborn • Respirations: 30–60, irregular • Apical pulse: 110–160 and somewhat	Immediate postbirth assessments of mother q15min for 1h: • BP: 90–135/60–85; should return to prelabor level • Pulse: slightly lower than in labor; range is 60–90 • Respirations: 12–24/min; easy; quiet • Temperature: 36.2–37.6°C (98–99.6°F) • Fundus firm, in midline, at the umbilicus • Lochia rubra; moderate amount; less than 2 pad/h; no free flow or passage of clots with massage • Perineum: sutures intact; no bulging or marked swelling; minimal bruising may be present; no c/o severe pain nor rectal pain • Bladder nondistended; spontaneous void of greater than 100 ml clear, straw-colored urine; bladder nondistended following voiding • If hemorrhoids present, no tenseness or marked engorgement; less than 2 cm diameter

In keeping with the changing approaches to nursing care management, **Clinical Pathways** are designed to help you plan and manage care within normally anticipated time frames.



Through the Eyes of a Nurse
Genetic Testing Options in Pregnancy

Family's Experience

"There seems like there are so many tests available, we are really confused about what to do. We don't feel like we have any risk factors, but we want to make sure our baby is healthy. What tests should we get? Which ones do we really need?"

Nurse's Response

"There are various testing options. I can explain your options and help you weigh the pros and cons of each test. Because of your age and the fact that you do not have any risk factors identified in your medical or family history, you would not be a candidate for the amniocentesis or chorionic villus sampling tests. You may want to consider the other optional tests though, such as the quadruple screen, nuchal translucency test, and cystic fibrosis testing.

"The quadruple screen is a test that screens for neural tube defects and trisomy 18 and 21. This test is only a screening tool, which means it does not tell you if your baby *definitely* has one of these problems. It could help us know if your baby is at risk though. The test is not perfect and you can get false-positives or false-negatives. If the test did come back abnormal, you have other testing options such as a more detailed sonogram or an amniocentesis.

"The nuchal translucency test is a blood test and sonogram combined that screens for trisomy 18 and 21. The test is more accurate than the quadruple screen and is done earlier. Some insurance may not cover the test though, so you will need to call your insurance company to see if it is covered.

"The cystic fibrosis test screens for known gene mutations that cause cystic fibrosis. If your screen is positive, we will then have the father of the baby tested to determine if he is also a carrier. If you are both carriers, there is a 25% chance that the baby could have the disease. If only one of you is a carrier, there would be a chance the baby would also be a carrier, but the baby could not inherit the disease."

Nurse's Actions and Rationale

The nurse's role is to explain all testing options and to answer questions related to the various tests. The nurse presents the information in an objective manner without expressing a personal opinion. The couple must weigh each choice carefully and determine what tests are right for them. The nurse can also provide written resource material to the couple. The couple should be allowed to discuss the information and make an informed decision.

523

The relationship you create with your patients and their families is the most essential and rewarding part of your nursing career. You will enjoy your job and be more effective in it when you develop these bonds. **Through the Eyes of a Nurse** shows you how one nurse establishes a connection with a couple throughout the pregnancy and after the birth of their baby. We believe that seeing this partnership develop—in your textbook and on the videos on the companion Web site—will help you understand how this wonderful process works.

Features

Nursing Care Plans address nursing care for women who have complications such as preeclampsia or diabetes mellitus, as well as for high-risk newborns. We designed this information to enhance your preparation for the clinical setting.

NURSING CARE PLAN The Woman with Diabetes Mellitus

INTERVENTION	RATIONALE
1. Nursing Diagnosis: Imbalanced Nutrition: Less than body requirements related to poor carbohydrate metabolism **Goal:** Patient will maintain adequate nutrition throughout pregnancy.	
▪ Emphasize importance of regular prenatal visits for assessment of *weight gain, controlled blood sugar,* heart tones, urine ketones, and fundal height measurement.	▪ Regular follow-up and assessment of weight, blood sugar levels, fetal heart tones, urine ketones, and fundal height will promote a healthy pregnancy and outcome as well as allow for modifications in the treatment regimen if necessary.
▪ Coordinate care with a dietitian to assist patient in meal planning and educate patient on the daily caloric needs of pregnancy.	▪ A daily intake of high-quality foods promotes fetal growth and controls maternal glucose levels.
▪ Instruct patient on signs and symptoms of hyperglycemia: polyphagia, nausea, hot flushes, polydipsia, polyuria, fruity breath, abdominal cramps, rapid deep breathing, headache, weakness, drowsiness, and general malaise. Instruct patient on signs and symptoms of hypoglycemia: hunger; clammy skin; irritability; slurred speech; seizures; tachycardia; headache; pallor; sweating; disorientation; shakiness; blurred vision; and, if untreated, coma or convulsions.	▪ Maintaining a euglycemic state throughout pregnancy aids in preventing diabetic complications and promotes a positive pregnancy outcome.
▪ Instruct patient on management of hyperglycemia and hypoglycemia.	
▪ Include family members in meal.	▪ Gives the family member a sense of involvement and an understanding of the importance of adequate nutrition in pregnancy.
EXPECTED OUTCOME: The patient will maintain adequate nutrition as evidenced by adequate weight gain, normal blood sugar levels, fetal heart rate, verbalization of understanding of personal treatment regimen, and appropriate fetal growth and development during pregnancy.	
2. Nursing Diagnosis: Risk for Injury to the fetus related to possible complications associated with altered tissue perfusion secondary to maternal diagnosis of diabetes mellitus **Goal:** Uncomplicated birth of a healthy newborn.	
▪ Assess fetal heart tones for reassuring variability and accelerations.	▪ Reassuring fetal heart rate variability and accelerations are interpreted as adequate placental oxygenation.
▪ Instruct mother on how to lie in a left recumbent position after eating and record how many fetal movements she feels in an hour.	▪ More than five fetal kicks in an hour are indicative of fetal well-being.
▪ Collaborative: Perform oxytocin challenge test (OCT)/contraction stress test (CST) and nonstress tests as determined by physician.	▪ Fetal surveillance testing assesses fetal well-being and adequate placental perfusion.
▪ Prepare patient for frequent ultrasound assessments.	▪ Ultrasonography is indicated at 7–9 weeks to confirm gestational age and then every 4–6 weeks to evaluate fetal well-being per physician's orders.
▪ Prepare patient for possible amniocentesis procedure.	▪ A sample of amniotic fluid that can be used to detect fetal lung maturity and enables medical personnel to prepare for a potential preterm birth.
▪ Assist physician with biophysical profile assessment.	▪ Helps ensure fetal well-being and a positive fetal outcome.
EXPECTED OUTCOME: The fetus will not exhibit signs and symptoms of altered tissue perfusion as evidenced by positive fetal activity, reassuring fetal heart rate patterns, a biophysical profile score between 8 and 10, negative CST, L/S ratio indicating fetal lung maturity, and a reactive nonstress test.	
3. Nursing Diagnosis: Readiness for Enhanced Knowledge about the effects of blood sugar on pregnancy related to an expressed desire to maintain stable blood glucose levels **Goal:** The patient and her family will verbalize the importance of maintaining blood sugar within prescribed ranges during	

CLINICAL TIP

In most cases, Rh immune globulin is administered in the deltoid muscle. However, in an extremely thin woman, or in the cases of a larger-than-normal dose, consider administering the medication in the ventrogluteal or posterior gluteal site. You may also divide the dose into multiple injections. Both Rhophlac and WinRho-SFD may be administered intravenously.

Clinical Tip features offer hands-on suggestions for specific procedures and interventions. The authors' wealth of clinical knowledge—reflecting many decades of experience—are reflected in these pearls of wisdom.

Tests to evaluate fetal status are done more frequently as a pregnant woman's preeclampsia progresses. These tests are described in detail in chapter 21 ∞. Monitoring fetal well-being is essential to achieving a safe outcome for the fetus. The following tests are used:

Cross-reference icons (∞) help the student to easily locate related information in other chapters.

78 UNIT 2 / Women's Health

FOCUS YOUR STUDY

- Nurses should provide girls and women with clear information about menstrual issues, such as the use of pads and tampons (including warnings regarding deodorant and absorbency); vaginal spray and douching practices; and self-care comfort measures during menstruation, such as maintaining good nutrition, exercising, and applying heat and massage.
- Dysmenorrhea usually begins at, or a day before, the onset of menses and disappears by the end. Hormone therapy (e.g., combined oral contraceptives), nonsteroidal anti-inflammatory drugs, or prostaglandin inhibitors can alleviate dysmenorrhea. Self-care measures include improving nutrition, exercising, applying heat, and getting extra rest.
- Premenstrual syndrome occurs most often in women over 30. The most pronounced symptoms occur 2 to 3 days before onset of menstruation and subside as menstruation starts, with or without treatment. Medical management usually includes prostaglandin inhibitors and calcium supplementation. Self-care measures include improving nutrition (taking vitamin B complex and E supplements and avoiding methylxanthines, which are found, for example, in chocolate and caffeine), undertaking a program of aerobic exercise, and participating in self-care support groups. In some cases, pharmacologic agents such as selective serotonin reuptake inhibitors may be indicated.
- During her adult years, a healthy woman should make healthful lifestyle choices such as avoiding smoking and exercising regularly. She should also participate in regular health screenings, following a recommended schedule.
- Menopause is a physiologic, maturational change in a woman's life. Physiologic changes include the cessation of menses and a decrease in circulating hormones. Hormonal changes sometimes bring unsettling emotional responses. The more common physiologic symptoms are "hot flashes," palpitations, dizziness, and increased perspiration at night. The woman's anatomy also undergoes changes, such as atrophy of the vagina, reduction in size and pigmentation of the labia, and myometrial atrophy. Osteoporosis becomes an increasing concern.
- Osteoporosis is becoming a significant health problem in the United States. Prevention is the preferred approach to addressing the issue. This includes adequate calcium intake, regular weight-bearing exercise, and HT. For women who have already developed osteoporosis, medications are available as a treatment option.
- Coronary heart disease is the number one killer of women in the United States. Prevention is the goal of therapy.
- Current management of menopause centers on hormone replacement therapy, complementary therapies, and patient healthcare education. Decisions regarding the use of HT should be made individually, based on each woman's symptoms and risks, and women should be advised of the known risks.

CRITICAL THINKING IN ACTION

You are working at a local clinic when Joy Lang, age 20, presents for her first pelvic exam. You obtain the following GYN history; menarche age 12 menstrual cycle 28–30 days lasting 4–5 days, heavy one day, then lighter. She tells you that she needs to u... her period an... tampon for th... the tampon e... She denies pr... problems and... regular schedule. She tells you that she recently got married, but would like to wait before getting pregnant. She'd like to discuss birth control methods. Joy tells you that doctors make her nervous and she admits to being anxious about her first pelvic exam.

1. What steps would you take to reduce Joy's anxiety relating to the pelvic exam?
2. What position is best to relax Joy's abdominal muscles for the pelvic exam?
3. What precaution should be taken when obtaining a Pap smear?

CRITICAL THINKING IN ACTION

Ann Nelson, a 28-year-old, G2, P0010 at 41 weeks' gestation, is admitted to the birthing unit where you are working. She is here for cervical ripening and induction of labor due to postdate pregnancy and decreased amniotic fluid volume. A review of her prenatal chart reveals a pertinent history of infertility (Clomid-induced pregnancy) and asthma (treated with... dilatation in th... Each chapter ends with **Focus Your Study**, which outlines the main points of the chapter, and **Critical Thinking in Action** exercises, which present brief patient scenarios with questions that help you apply concepts learned in the chapter. Not only can you review chapter content in an easy, quick-view format, but you can also apply the concepts used in preparation for clinical work, ensuring success in partnering with your patients.

Each chapter wraps up with a list of **References**, and directions to **the companion Web site** for additional resources.

Resources for Student Success

Companion Web site This Web site offers study tools to enrich your learning. Included are NCLEX-RN®-style questions with rationales, case studies, care plans, an audio glossary, animations, Through the Eyes of a Nurse videos, Newborn Reflex videos, interactive activities, and other material to prepare you for success in the classroom, in clinicals, and on the NCLEX-RN® exam.

MyNursingLab This Web site gives you an opportunity to test yourself on key concepts and skills and track your progress throughout the course. The personalized study plan is designed to help you achieve success. MyNursingLab features NCLEX-RN® practice questions and activities of all types with image- and media-based questions, and other interactive exercises. MyNursingLab also comes with an option to use Pearson's Interactive E-Text. The E-Text includes integrated, rich media; links to Web sites; organization that can be customized; search capability; and note-taking functionality.

Clinical Handbook for Olds' Maternal-Newborn Nursing & Women's Health Across the Lifespan (ISBN: 0-13-211849-1)—This pocket guide serves as a portable, quick-reference to maternal-newborn nursing care. Encompassing pregnancy through the postpartum and newborn stages, this handbook allows you to take the information you learn in class into any clinical setting.

Student Workbook (ISBN: 0-13-255778-9)—This popular study tool incorporates strategies for you to focus your study and increase comprehension of concepts of nursing care.

Resources for Faculty Success

C**ompanion Web site**—This site provides the tools faculty need for ease in classroom preparation and evaluation. Included are the testbank with peer-reviewed NCLEX-RN®-style questions, integrated PowerPoint presentations, an image library, and animations and videos.

MyNursingLab—This Web site saves instructors time by providing quality feedback, ongoing formative assessments, and customized remediation for students. It provides easy, one-stop access to a wealth of teaching resources, such as a testbank with 35 questions per chapter, PowerPoint slides, and video suggestions.

MyNursingLab is also available with Pearson Interactive E-Text, which includes integrated, rich media; links to Web sites; organization that can be customized; search capability; and note-taking functionality.

Instructor's Resource Manual—This online manual contains detailed, chapter-by-chapter lecture outlines to be used with the Lecture Summary PowerPoint slides and includes individual, small group, and large group activities.

UNIT 1 Contemporary Maternal-Newborn Nursing 1

CHAPTER 1 Current Issues in Maternal-Newborn Nursing 2

Contemporary Childbirth 3
The Self-Care Movement and Health Promotion Education 5
The Healthcare Environment 6
Culturally Competent Care 8
Professional Options in Maternal-Newborn Nursing Practice 8
Collaborative Practice 9
Community-Based Nursing Care 10
Legal and Ethical Considerations 10
Scope of Practice 10
Nursing Negligence 11
Standards of Nursing Care 11
Patients' Rights 12
Special Ethical Situations in Maternity Care 13
Maternal-Fetal Conflict 13
Abortion 14
Fetal Research 14
Reproductive Assistance 15
Embryonic Stem Cell Research 16
Cord Blood Banking 16
Implications for Nursing Practice 16
Statistical Data and Maternal-Infant Care 16
Birth Rate 17
Infant Mortality 18
Maternal Mortality 19
Implications for Nursing Practice 20
Evidence-Based Practice in Maternal-Child Nursing 20
Nursing Research 21
Clinical Pathways and Nursing Care Plans 21

CHAPTER 2 Care of the Family in a Culturally Diverse Society 24

Defining Family 25
Family Values 25
Family Power and Decision Making 25
Family Roles 25
Changes Affecting the Contemporary Family 26
Types of Families 27
Traditional Nuclear Family 27
Dual-Career/Dual-Earner Family 27
Childless or Childfree Family 27
Extended Family 27
Extended Kin Network Family 28
Single-Parent Family 28
Stepparent Family 28
Binuclear Family 28
Nonmarital Heterosexual Cohabitating Family 29
Gay and Lesbian Families 29
Contemporary Family Development Frameworks 29
Model of the Childbearing Family 29
Model Incorporating the Unattached Young Adult 31
Model Incorporating Divorce and Remarriage 31
Model of the Lesbian or Gay Family 31
Family Assessment 32
Health History 32
Environmental Considerations 32
Family Assessment Tool 33
Cultural Influences Affecting the Family 33
Cultural Concepts 33
Acculturation 33
Impact of Culture on Family Structure 33
Cultural Influences on Childbearing and Childrearing 35
Cultural Diversity in Family Nursing Care 37
Culturally Influenced Responses 37
Impact of Religion and Spirituality 41
Diverse Meanings of Religion and Spirituality 41
Range of Religious Beliefs 41
Provision of Spiritually Sensitive Nursing Care 41

CHAPTER 3 Complementary and Alternative Therapies 44

Evolution of Complementary and Alternative Therapies 45
Historic Perspective 45
Resurgence of Complementary and Alternative Therapies 46
Growing Integration with Conventional Western Medicine 46
Benefits and Risks of Complementary and Alternative Therapies 47
Benefits 47
Risks 48
Types of Complementary and Alternative Therapies 49
Complementary Therapeutic Systems 49
Mind-Body Therapies 50
Manipulative and Body-Based Therapies 51
Nutritional and Herbal Therapies 53
Sense Therapies 54
Energy Therapies 54
Nursing Care of the Childbearing Family Using Complementary Therapies 55
Assessing a Patient's Use of Complementary Therapies 55
Incorporating Complementary Therapies into Maternal-Newborn Nursing Care 56

UNIT 2 Women's Health 59

CHAPTER 4 Health Promotion of Women Across the Lifespan 60

Community-Based Nursing Care 61
The Nurse's Role in Addressing Issues of Women's Wellness and Sexuality 61
Taking a Sexual History 62

Menstruation 62
Counseling the Premenstrual Girl About Menarche 62
Educational Topics 63
Associated Menstrual Conditions 64
Nursing Care Management 66
Health Promotion Education for Well Women 66
Body Piercing and Tattoos 67
Menopause 67
Perimenopause 69
Psychologic Aspects of Menopause 70
Physical Aspects of Menopause 70
Premature Menopause 72
Medical Therapy 72
Complementary and Alternative Therapies 76
Nursing Care Management 77

CHAPTER 5 Women's Health: Family Planning 80
Overview of Family Planning 81
Demographics 81
Choosing a Method of Contraception 81
Fertility Awareness-Based Methods 82
Basal Body Temperature Method 82
Ovulation Method 82
Calendar Rhythm Method 83
Symptothermal Method 83
Other Options 83
Situational Contraceptives 84
Abstinence 84
Coitus Interruptus 84
Douching 84
Spermicide 84
Barrier Methods of Contraception 84
Male Condom 85
Female Condom 86
Diaphragm 87
Cervical Caps 87
Vaginal Sponge 87
Intrauterine Devices 88
Hormonal Contraceptives 89
Combination Estrogen-Progestin Approaches 90
Progestin Contraceptives 91
Postcoital Emergency Contraception 92
Operative Sterilization 93
Vasectomy 93
Tubal Ligation 93
Nonoperative Sterilization 94
Male Contraception 94
Nursing Care Management 94
Clinical Interruption of Pregnancy 94
Medical Interruption of Pregnancy 95
Surgical Interruption of Pregnancy 95
Nursing Care Management 96

CHAPTER 6 Women's Health: Commonly Occurring Infections 99
Care of the Woman with a Lower Genital Tract Infection (Vaginitis) 100
Bacterial Vaginosis 100
Vulvovaginal Candidiasis 101
Nursing Care Management 102
Care of the Woman with a Sexually Transmitted Infection 103
Prevention of Sexually Transmitted Infections 103
Trichomoniasis 103
Chlamydial Infection 104
Gonorrhea 105

Ovarian (Adnexal) Masses 133
Uterine Masses 134
Nursing Care Management 135
Care of the Woman with Toxic Shock Syndrome 135
Nursing Care Management 136
Care of the Woman with Endometriosis 136
Nursing Care Management 137
Care of the Woman with Polycystic Ovarian Syndrome 137
Signs and Symptoms of PCOS 137
Diagnosis of PCOS 138

Clinical Therapy 138
Long-Term Implications 138
Nursing Care Management 139
Care of the Woman with Pelvic Relaxation 139
Cystocele 139
Rectocele 139
Uterine Prolapse 139
Care of the Woman Requiring Gynecologic Surgery 139
Hysterectomy 140
Dilation and Curettage 141
Uterine Ablation 141
Salpingectomy 141
Oophorectomy 141
Vulvectomy 141
Pelvic Exenteration 141
Nursing Care Management 141

CHAPTER 8 Women's Care: Social Issues 145
Social Issues Affecting Women Living in Poverty 146
The Feminization of Poverty 146
Economic Effects of Divorce 147
Factors Contributing to Poverty in Working Women 147
Public Assistance 148
Homelessness 148
Effects of Poverty on Women's Health Care 149
Social Issues Affecting Women in the Workplace 150
Wage Discrepancy 150
Maternal and Paternal Leave Issues 151
Discrimination Against Pregnant Women 151
Child Care 152
Advocacy for Working Women 153
Environmental Hazards in the Workplace and at Home 153
Social Issues Affecting Older Women 155
Economic Vulnerability of Older Women 155
Elder Abuse 156
Implications of Aging for Women's Health and Health Care 157
Social Issues Affecting Women with Disabilities 157
Definitions of Disability 158
Types of Disabilities 158
Economic Vulnerability of Women with Disabilities 158
Violence Against People with Disabilities 159
Effects of Disability on Women's Health Care 159
Social Issues Affecting Lesbian and Bisexual Women 159
Employment Discrimination 159
Housing Discrimination 160
Parenting Issues 160
Social Barriers 160
Effects of Discrimination on Lesbian and Bisexual Women's Health Care 161
Female Genital Mutilation (FGM) 161
Origin and Demographics of FGM 161
Nature of the Procedure(s) 162
Health Implications 162
Efforts to Eradicate FGM 162
Responding Appropriately to Circumcised Women 162

CHAPTER 9 Violence Against Women 165
Historic Factors Contributing to Violence Against Women 166
Domestic Violence 166
Contributing Factors 167
Common Myths About Battering and Women with Abusive Partners 168
Cycle of Violence 169
Characteristics of Batterers 169
Nursing Care Management 169
Sexual Assault 176
Common Myths About Rape 176
Characteristics of Perpetrators 177
Types of Rape 177
Role of Substances in Sexual Assault 178
Rape Trauma Syndrome 178
Sexual Assault as a Cause of Post-Traumatic Stress Disorder 179
Physical Care of the Sexual Assault Survivor 179
Nursing Care Management 181
Prosecution of the Assailant 183
Responding to Violence Against Women: Vicarious Trauma 183

UNIT 3 Human Reproduction 186

CHAPTER 10 The Reproductive System 187
Embryonic Development of Reproductive Structures and Processes 188
Ovaries and Testes 188
Other Internal Structures 188
External Structures 188
Puberty 188
Major Physical Changes 188

Iron Deficiency Anemia 432
Nursing Care Management 433
Folic Acid Deficiency Anemia 433
Nursing Care Management 433
Sickle Cell Disease 434
Nursing Care Management 434
Thalassemia 435
Nursing Care Management 436
Care of the Woman with AIDS 436
Pathophysiology of HIV/AIDS 436
Maternal Risks 437
Fetal-Neonatal Risks 437
Clinical Therapy 437
Nursing Care Management 438
Care of the Woman with Heart Disease 441
Congenital Heart Defects 441
Rheumatic Heart Disease 442
Marfan Syndrome 442
Peripartum Cardiomyopathy 442
Eisenmenger Syndrome 442
Mitral Valve Prolapse 442
Clinical Therapy 442
Nursing Care Management 443
Other Medical Conditions and Pregnancy 445

CHAPTER 20 Pregnancy at Risk: Gestational Onset 450
Care of the Woman at Risk Because of Bleeding During Pregnancy 451
General Principles of Nursing Intervention 451
Spontaneous Abortion (Miscarriage) 451
Nursing Care Management 453
Ectopic Pregnancy 454
Nursing Care Management 455
Gestational Trophoblastic Disease 456
Nursing Care Management 458
Care of the Woman with Hyperemesis Gravidarum 459
Clinical Therapy 459
Nursing Care Management 460
Care of the Woman with a Hypertensive Disorder 460
Preeclampsia and Eclampsia 460
Nursing Care Management 470
Chronic Hypertension 475
Chronic Hypertension with Superimposed Preeclampsia 476
Gestational Hypertension 476
Care of the Woman at Risk for Rh Alloimmunization 476
Pathophysiology of RhD Alloimmunization 477
Fetal-Neonatal Risks 478
Clinical Therapy 479
Nursing Care Management 480
Care of the Woman at Risk Due to ABO Incompatibility 481
Care of the Woman Requiring Surgery During Pregnancy 481
Nursing Care Management 483
Care of the Woman Suffering Trauma from an Accident 483
Clinical Therapy 484
Nursing Care Management 485
Care of the Battered Pregnant Woman 485
Care of the Woman with a Perinatal Infection Affecting the Fetus 486
Toxoplasmosis 486
Nursing Care Management 487
Rubella 487
Nursing Care Management 487
Cytomegalovirus 488
Herpes Simplex Virus 488
Nursing Care Management 489
Group B Streptococcus Infection 489
Human B19 Parvovirus 491
Other Infections in Pregnancy 491

CHAPTER 21 Assessment of Fetal Well-Being 496
Psychologic Reactions to Antenatal Testing 497
Nursing Care Management 497
Ultrasound 498
Extent of Ultrasound Exams 499
Methods of Ultrasound Scanning 499
Safety of Ultrasound 500
Who Should Perform Ultrasound Examinations? 500
Nursing Care Management 501
Assessment of Fetal Well-Being in the First Trimester 501
Viability 501
Gestational Age 502
Nuchal Translucency Testing 503
Assessment of Fetal Well-Being in the Second Trimester 503
Fetal Life 504
Fetal Number 504
Fetal Presentation 504
Fetal Anatomy Survey 504
Gestational Age and Growth 504
Amniotic Fluid Volume 504
Placenta Location 505
Survey of Uterine Anatomy 506
Assessment of Fetal Well-Being in the Third Trimester 507
Conditions Warranting Fetal Surveillance 507
Fetal Movement Assessment 507
Nonstress Test 508
Nursing Care Management 510
Vibroacoustic Stimulation 510
Contraction Stress Test 511
Nursing Care Management 514
Amniotic Fluid Index 514
Biophysical Profile 514
Modified Biophysical Profile 515
Doppler Flow Studies 516
Evaluation of Placental Maturity 516
Estimation of Fetal Weight 517
Other Diagnostic Tests 518
Maternal Serum Alpha-Fetoprotein (MSAFP) 518
Amniocentesis 519
Nursing Care Management 521
Chorionic Villus Sampling 522
Nursing Care Management 524
Cordocentesis 524
Nursing Care Management 524
Fetal Fibronectin 524
Evaluation of Fetal Lung Maturity 524
Nursing Care Management 525

UNIT 5 Birth 528

CHAPTER 22 Processes and Stages of Labor and Birth 529
Critical Factors in Labor 530
Birth Passageway 530
Birth Passenger (Fetus) 530
Relationship of Maternal Pelvis and Presenting Part 533
Physiologic Forces of Labor 535
Psychosocial Considerations 537
Physiology of Labor 538
Possible Causes of Labor Onset 538
Myometrial Activity 538
Musculature Changes in the Pelvic Floor 539
Premonitory Signs of Labor 540
Differences Between True Labor and False Labor 541
Stages of Labor and Birth 541
First Stage 541
Second Stage 542

Third Stage 545
Fourth Stage 545
Maternal Systemic Response to Labor 546
Cardiovascular System 546
Blood Pressure 547
Fluid and Electrolyte Balance 547
Respiratory System 547
Renal System 547
Gastrointestinal System 547
Immune System and Other Blood Values 547
Pain 548
Fetal Response to Labor 550
Heart Rate Changes 550
Acid–Base Status in Labor 550
Hemodynamic Changes 550
Behavioral States 550
Fetal Sensation 551

CHAPTER 23 Intrapartum Nursing Assessment 554
Maternal Assessment 555
Prenatal Record 555
Historical Data 555
Intrapartum High-Risk Screening 558
Intrapartum Physical and Psychosociocultural Assessment 558
Evaluating Labor Progress 563
Fetal Assessment 569
Determination of Fetal Position and Presentation 569
Auscultation of Fetal Heart Rate 572
Electronic Fetal Monitoring 574
Indications for Electronic Fetal Monitoring 576
External Monitoring 576
Internal Monitoring 576
Telemetry 577
Fetal Heart Rate Patterns 578
Baseline Fetal Heart Rate 578
Baseline Variability 581
Fetal Heart Rate Changes 582
Interpretation of Fetal Heart Rate Patterns 588
Indirect Methods of Fetal Assessment 591
Cord Blood Analysis at Birth 591

CHAPTER 24 The Family in Childbirth: Needs and Care 594
Nursing Diagnosis During Labor and Birth 595
Nursing Care During Admission 595
Establishing a Positive Relationship 595
Labor Assessment 600
Collecting Laboratory Data 600
Social Assessment 601
Documentation of Admission 602
Nursing Care During the First Stage of Labor 602
Integration of Family Expectations 602
Integration of Cultural Beliefs 603
Provision of Care in the First Stage 605
Promotion of Comfort in the First Stage 607
Nursing Care During the Second Stage of Labor 612
Provision of Care in the Second Stage 612
Promotion of Comfort in the Second Stage 614
Assisting the Couple and Physician or CNM During Birth 614
Nursing Care During the Third Stage of Labor 620
Provision of Initial Newborn Care 620
Delivery of the Placenta 624
Use of Oxytocics 625
Nursing Care During the Fourth Stage of Labor 625
Provision of Care in the Fourth Stage 626
Promotion of Comfort in the Fourth Stage 628
Nursing Care of the Adolescent 628
Age-Related Responses to Labor and Birth 629
The Adolescent Father 629
Other Members of the Support Team 629
Teaching the Adolescent Mother 630
Nursing Care During Precipitous Birth 630
Birth of the Infant 630
Record Keeping 631
Postbirth Interventions 632
Evaluation 632

CHAPTER 25 Pain Management During Labor 634
Systemic Analgesia 635
Administration of Analgesic Agents 636
Sedatives 637
Nursing Care Management 638
Narcotic Analgesics 638
Nursing Care Management 639
Nursing Care Management 640
Nursing Care Management 640
Nursing Care Management 641
Regional Analgesia and Anesthesia 641
Action and Absorption of Anesthetic Agents 644
Types of Local Anesthetic Agents 644
Adverse Maternal Reactions to Anesthetic Agents 644
Lumbar Epidural Block 645
Nursing Care Management 650
Epidural Analgesia After Birth 652
Spinal Block 652
Nursing Care Management 654
Combined Spinal-Epidural Block 655
Pudendal Block 655
Nursing Care Management 655
Local Infiltration Anesthesia 655
Nursing Care Management 656
General Anesthesia 656
Intravenous Anesthetics 656
Inhaled Anesthesia Agents 656
Complications of General Anesthesia 657
Care During General Anesthesia 657
Neonatal Neurobehavioral Effects of Anesthesia and Analgesia 657
Analgesic and Anesthetic Considerations for the High-Risk Mother and Fetus 657
Preterm Labor 658
Preeclampsia 658
Diabetes Mellitus 659
Cardiac Disease 659
Bleeding Complications 659

CHAPTER 26 Childbirth at Risk: Prelabor Complications 662
Care of the Woman with Cervical Insufficiency 663
Cerclage Procedures 663

Care of the Woman with Premature Rupture of Membranes 664
Maternal Risks 665
Fetal-Neonatal Risks 665
Nursing Care Management 667
Care of the Woman at Risk Due to Preterm Labor 668
Maternal Risks 668
Fetal-Neonatal Risks 669
Nursing Care Management 672
Care of the Woman and Fetus at Risk Because of Placental Problems 675
Abruptio Placentae 675
Nursing Care Management 678
Placenta Previa 680
Nursing Care Management 682
Care of the Woman with a Multiple Gestation 683
Embryology of Multiple Gestation 683
Pregnancy Loss in Multiple Gestation 683
Nursing Care Management 685
Care of the Woman and Fetus at Risk Because of Amniotic Fluid–Related Complications 687
Hydramnios 688
Nursing Care Management 688
Oligohydramnios 688
Nursing Care Management 689

CHAPTER 27 Childbirth at Risk: Labor-Related Complications 692

Care of the Woman at Risk Because of Psychologic Disorders 693
Maternal Implications 693
Nursing Care Management 695
Care of the Woman Experiencing Dystocia Related to Dysfunctional Uterine Contractions 696
Tachysystole Labor Patterns 696
Nursing Care Management 697
Hypotonic Labor Patterns 697
Nursing Care Management 698
Care of the Woman and Fetus at Risk for Precipitous Labor and Birth 699
Risks of Precipitous Labor and Birth 699
Nursing Care Management 700
Care of the Woman with Postterm Pregnancy 700
Maternal Risks 701
Fetal-Neonatal Risks 701
Nursing Care Management 701
Care of the Woman and Fetus at Risk Because of Fetal Malposition 702
Maternal-Fetal-Neonatal Risks 702
Nursing Care Management 704
Care of the Woman and Fetus at Risk Because of Fetal Malpresentation 705
Brow Presentation 705
Nursing Care Management 706
Face Presentation 706
Nursing Care Management 707
Breech Presentation 708
Nursing Care Management 709
Shoulder Presentation (Transverse Lie) of a Single Fetus 710
Nursing Care Management 711
Compound Presentation 711
Care of the Woman and Fetus at Risk Because of Macrosomia 711
Nursing Care Management 712
Care of the Woman and Fetus in the Presence of Nonreassuring Fetal Status 713
Nursing Care Management 713
Care of the Woman Experiencing Placental and Umbilical Cord Problems 714
Placenta Problems 714
Umbilical Cord Abnormalities 716
Nursing Care Management 716
Care of the Woman and Fetus with a Prolapsed Umbilical Cord 717
Maternal-Fetal-Neonatal Risks 717
Nursing Care Management 717
Care of the Woman and Fetus at Risk Because of Anaphylactoid Syndrome of Pregnancy (Amniotic Fluid Embolism) 718
Nursing Care Management 718
Care of the Woman with a Uterine Rupture 719
Nursing Care Management 719
Care of the Woman with Cephalopelvic Disproportion 719
Types of Contractures 720
Implications of Pelvic Contractures 720
Nursing Care Management 720
Care of the Woman at Risk Because of Complications of Third and Fourth Stages of Labor 721
Retained Placenta 721
Lacerations 721
Placenta Accreta 721

CHAPTER 28 Birth-Related Procedures 724

Care of the Woman During Version 725
External Cephalic Version 725
Criteria for External Version 727
Contraindications for External Version 727
External Version Procedure 727
Nursing Care Management 728
Care of the Woman During Cervical Ripening 728
Use of Misoprostol (Cytotec) 728
Use of Prostaglandin Agents (Cervadil, Prepidil) 729
Advantages and Disadvantages of Prostaglandin Administration 729
Prostaglandin Agent Insertion Procedure 730
Mechanical Methods of Cervical Ripening and Labor Induction 730
Nursing Care Management 731
Care of the Woman During Induction or Augmentation of Labor 731
Contraindications to Labor Induction or Augmentation 731
Methods of Inducing or Augmenting Labor 732
Nursing Care Management 736
Care of the Woman During an Amniotomy 736
Advantages and Disadvantages of Amniotomy 738
Amniotomy Procedure 738

Nursing Care Management 740
Care of the Woman During Amnioinfusion 740
Nursing Care Management 740
Care of the Woman During an Episiotomy 741
Risk Factors That Predispose Women to Episiotomy 741
Episiotomy Procedure 741
Nursing Care Management 742
Care of the Woman During Forceps-Assisted Birth 743
Criteria for Forceps Application 743
Indications for Use of Forceps 743
Neonatal and Maternal Risks 744
Prerequisites for Forceps Application and Birth 745
Trial or Failed Forceps Procedure 745
Nursing Care Management 745
Care of the Woman During Vacuum Extraction 745
Nursing Care Management 747
Care of the Family During Cesarean Birth 748
Indications 748
Maternal Mortality and Morbidity 748
Surgical Techniques 748
Analgesia and Anesthesia 750
Nursing Care Management 750
Care of the Woman Undergoing Vaginal Birth After Cesarean 752
Nursing Care Management 752

UNIT 6 The Newborn 755

CHAPTER 29 Physiologic Responses of the Newborn to Birth 756
Respiratory Adaptations 757
Intrauterine Factors Supporting Respiratory Function 757
Initiation of Breathing 757
Factors Opposing the First Breath 759
Cardiopulmonary Physiology 760
Oxygen Transport 760
Maintaining Respiratory Function 761
Characteristics of Newborn Respiration 761
Cardiovascular Adaptations 761
Fetal-Newborn Transitional Physiology 761
Characteristics of Cardiac Function 764
Hematopoietic Adaptations 764
Temperature Regulation 766
Heat Loss 766
Heat Production (Thermogenesis) 768
Response to Heat 768
Hepatic Adaptations 769
Iron Storage and Red Blood Cell Production 769
Carbohydrate Metabolism 769
Conjugation of Bilirubin 769
Physiologic Jaundice 770
Breastfeeding Jaundice and Breast Milk Jaundice 772
Coagulation 773
Gastrointestinal Adaptations 773
Digestion and Absorption 773
Elimination 774
Urinary Adaptations 775
Kidney Development and Function 775
Characteristics of Newborn Urinary Function 775
Immunologic Adaptations 775
Neurologic and Sensory/Perceptual Functioning 776
Intrauterine Factors Influencing Newborn Behavior 776
Characteristics of Newborn Neurologic Function 776
Periods of Reactivity 777
Behavioral States of the Newborn 777
Behavioral and Sensory Capacities of the Newborn 778

CHAPTER 30 Nursing Assessment of the Newborn 782
Timing of Newborn Assessments 783
Estimation of Gestational Age 783
Assessment of Physical Maturity Characteristics 784
Assessment of Neuromuscular Maturity Characteristics 789
Physical Assessment 792
General Appearance 792
Weight and Measurements 792
Temperature 794
Skin Characteristics 795
Birthmarks 798
Head 798
Hair 800
Face 800
Eyes 800
Nose 801
Mouth 802
Ears 802
Neck 803
Chest 803
Cry 803
Respiration 803
Heart 804
Abdomen 805
Umbilical Cord 805
Genitals 806
Anus 806
Extremities 806
Back 808
Assessment of Neurologic Status 808
Newborn Physical Assessment Guide 810
Newborn Behavioral Assessment 820

CHAPTER 31 The Normal Newborn: Needs and Care 823
Nursing Care During Admission and the First Four Hours of Life 824
Nursing Assessment and Diagnosis 824
Nursing Plan and Implementation 824
Evaluation 832
Nursing Management of the Newborn Following Transition 832
Nursing Diagnosis 832
Nursing Plan and Implementation 833
Evaluation 839

Nursing Management in Preparation for Discharge 839
Nursing Assessment and Diagnosis 839
Planning and Implementation 840
Evaluation 846

CHAPTER 32 Newborn Nutrition 849

Nutritional Needs and Breast Milk/Formula Composition 850
Dietary Reference Intakes 850
Growth 850
Fluid 851
Energy 852
Fats 852
Carbohydrates 852
Protein 852
Vitamins, Minerals, and Trace Elements 853
The Evolution of Formula 855
Specialty Formulas 856
Feeding Intolerances 857
Breastfeeding 858
Breast Milk Production 858
Physiologic and Endocrine Control of Lactogenesis 858
Stages of Human Milk 859
Advantages of Human Milk 860
Potential Disadvantages and Contraindications to Breastfeeding 861
Timing of Newborn Feedings 865
Initial Feeding 865
Establishing a Feeding Pattern 866
Cultural Considerations in Infant Feeding 867
Bottle-Feeding Human Milk (Expression, Pumps, Storage) 876
Formula Feeding 879
Involving Fathers 882
Community-Based Nursing Care 882
Promotion of Successful Infant Feeding 882
WIC 883
Nutritional Assessment 884

CHAPTER 33 The Newborn at Risk: Conditions Present at Birth 889

Identification of At-Risk Newborns 890
Care of the Small-for-Gestational-Age/Intrauterine Growth Restricted Newborn 891
Factors Contributing to Intrauterine Growth Restriction 892
Patterns of IUGR 893
Common Complications of the SGA Newborn 893
Clinical Therapy 894
Nursing Care Management 894
Care of the Large-for-Gestational-Age Newborn 897
Common Complications of the LGA Newborn 898
Nursing Care Management 898
Care of the Infant of a Diabetic Mother 898
Common Complications of the IDM 898
Clinical Therapy 899
Nursing Care Management 900
Care of the Postterm Newborn 900
Common Complications of the Newborn with Postmaturity Syndrome 900
Clinical Therapy 900
Nursing Care Management 901
Care of the Preterm (Premature) Newborn 901
Alteration in Respiratory and Cardiovascular Physiology 902
Alteration in Thermoregulation 902
Alteration in Gastrointestinal Physiology 903
Alteration in Renal Physiology 903
Alteration in Hepatic and Hematologic Physiology 904
Alteration in Immunologic Physiology 904
Alteration in Neurologic Physiology 904
Alteration in Reactivity Periods and Behavioral States 905
Management of Nutrition and Fluid Requirements 905
Common Complications of Preterm Newborns and Their Clinical Management 907
Long-Term Complications 911
Nursing Care Management 912
Care of the Newborn with Congenital Anomalies 918
Care of the Infant of a Substance-Abusing Mother 921
Alcohol Dependence 921
Nursing Care Management 922
Drug Dependence 923
Common Complications of the Drug-Exposed Newborn 923
Nursing Care Management 924
Infants of Mothers Who Are Tobacco Dependent 926
Nursing Care Management 928
Care of the Newborn Exposed to HIV/AIDS 928
Nursing Care Management 929
Care of the Newborn with Congenital Heart Defect 931
Overview of Congenital Heart Defects 931
Nursing Care Management 931
Care of the Newborn with Inborn Errors of Metabolism 931
Types of Inborn Errors of Metabolism 931
Clinical Therapy 934
Nursing Care Management 934

CHAPTER 34 The Newborn at Risk: Birth-Related Stressors 938

Care of the Newborn at Risk Due to Asphyxia 939
Risk Factors Predisposing to Asphyxia 939
Clinical Therapy 939
Resuscitation Management 940
Nursing Care Management 942
Care of the Newborn with Respiratory Distress 944
Respiratory Distress Syndrome 944
Nursing Care Management 947
Transient Tachypnea of the Newborn 949
Nursing Care Management 952
Care of the Newborn with Meconium Aspiration Syndrome 953
Nursing Care Management 954
Persistent Pulmonary Hypertension of the Newborn 955
Nursing Care Management 955

Care of the Newborn with Complications Due to Respiratory Therapy 956
Pulmonary Interstitial Emphysema 956
Pneumothorax 956
Bronchopulmonary Dysplasia/Chronic Lung Disease 957
Nursing Care Management 957
Care of the Newborn with Cold Stress 958
Nursing Care Management 958
Care of the Newborn with Hypoglycemia 959
Clinical Therapy 960
Care of the Newborn with Jaundice 963
Physiologic Jaundice 963
Pathophysiology of Hyperbilirubinemia 963
Causes of Hyperbilirubinemia 963
Clinical Therapy 965
Clinical Therapy 966
Nursing Care Management 967
Care of the Newborn with Anemia 973
Clinical Therapy 973
Nursing Care Management 974
Care of the Newborn with Polycythemia 974
Clinical Therapy 974
Nursing Care Management 974
Care of the Newborn with Infection 975
Clinical Therapy 975
Nursing Care Management 977
Care of the Family with Birth of an At-Risk Newborn 979
Parental Responses 979
Developmental Consequences 980
Nursing Care Management 980
Considerations for the Nurse Who Works with At-Risk Newborns 986

UNIT 7 Postpartum 990

CHAPTER 35 Postpartum Family Adaptation and Nursing Assessment 991

Postpartum Physical Adaptations 992
Reproductive System 992
Abdomen 996
Lactation 996
Gastrointestinal System 996
Urinary Tract 997
Vital Signs 997
Blood Values 997
Cardiovascular Changes 998
Neurologic Changes and Conditions 998
Weight Loss 998
Postpartum Chill 998
Postpartum Diaphoresis 998
Afterpains 998
Postpartum Psychologic Adaptations 999
Taking In and Taking Hold Periods 999
Becoming a Mother 999
Postpartum Blues 999
Importance of Social Support 1000
Development of Family Attachment 1000
Initial Attachment Behavior 1000
Cultural Influences in the Postpartum Period 1002
Postpartum Nursing Assessment 1003
Risk Factors 1003
Physical Assessment 1003
Psychologic Assessment 1015
Assessment of Early Attachment 1015
Discharge Assessment and Follow-Up 1016

CHAPTER 36 The Postpartum Family: Needs and Care 1019

Nursing Care During the Early Postpartum Period 1020
Nursing Diagnosis 1020
Nursing Plan and Implementation 1020
Community-Based Nursing Care 1023
Health Promotion Education 1023
Timing and Methods of Teaching 1024
Content of Teaching 1024
Evaluating Learning 1024
Promotion of Maternal Comfort and Well-Being 1027
Monitoring Uterine Status 1027
Relief of Perineal Discomfort 1028
Relief of Hemorrhoidal Discomfort 1032
Relief of Afterpains 1032
Relief of Discomfort from Immobility and Muscle Strain 1033
Postpartum Diaphoresis 1033
Suppression of Lactation in the Nonbreastfeeding Mother 1033
Pharmacologic Interventions 1033
Support of Maternal Psychosocial Well-Being 1035
Promotion of Maternal Nutrition, Rest, and Activity 1036
Promotion of Nutrition 1036
Relief of Fatigue 1036
Resumption of Activity 1037
Postpartum Exercises 1037
Promotion of Family Wellness and Shared Parenting 1039
Reactions of Siblings 1040
Resumption of Sexual Activity 1040
Contraception 1042
Parent-Infant Attachment 1042
Nursing Care Following Cesarean Birth 1043
Promotion of Maternal Physical Well-Being After Cesarean Birth 1043
Promotion of Parent-Infant Interaction After Cesarean Birth 1044
Newborn Safety Following Cesarean Birth 1045
Nursing Care of the Obese Postpartum Patient 1046
Nursing Care of the Postpartum Adolescent 1046
Nursing Care of the Woman Who Relinquishes Her Infant 1048
Nursing Care of the Lesbian Mother 1049
Nursing Care of the Developmentally Disabled Postpartum Mother 1049
Nursing Care of the Mother with a History of Sexual Abuse 1049
Discharge Information 1049
Evaluation of the Postpartum Family 1051

CHAPTER 37 Home Care of the Postpartum Family 1054
Role of Length of Stay and Professional Guidelines and Recommendations in Postpartum Home Care 1055
Considerations for the Home Visit 1055
Purpose and Timing of the Home Visit 1055
Fostering a Caring Relationship with the Family 1056
Planning the Home Visit 1056
Maintaining Safety 1056
Carrying Out the Home Visit 1058
Home Care: The Newborn 1058
Physical Assessment of the Newborn at Home 1059
Positioning and Handling of the Newborn 1059
Skin Care and Bathing 1060
Cord Care 1062
Nail Care 1063
Dressing the Newborn 1063
Temperature Assessment, Fever, and Illness 1063
Stools and Urine 1064
Sleeping 1065
Sleep-Wake States 1068
Injury Prevention 1069
Newborn Screening and Immunization Program 1071
Home Care: The Mother and Family 1071
Assessment of the Mother and Family at Home 1071
Breastfeeding Concerns Following Discharge 1074
Other Types of Follow-Up Care 1082
Return Visits 1082
Telephone Follow-Up 1082
Postpartum Classes and Support Groups 1082

CHAPTER 38 Grief and Loss in the Childbearing Family 1086
Common Causes of Perinatal Loss 1087
Maternal Physiologic Implications 1088
Clinical Therapy 1088
Postbirth Evaluation 1089
The Experience of Loss 1089
Frameworks for Understanding Perinatal Loss 1090
Special Issues for Consideration 1091
Individual and Family Issues 1092
Societal Issues 1093
Specific Circumstance 1094
Nursing Care Management 1098

CHAPTER 39 The Postpartum Family at Risk 1114
Care of the Woman with Postpartum Hemorrhage 1115
Early (Primary) Postpartum Hemorrhage 1115
Late (Secondary) Postpartum Hemorrhage 1120
Nursing Care Management 1120
Care of the Woman with a Reproductive Tract Infection or Wound Infection 1124
Postpartum Uterine Infection 1125
Postpartum Wound Infections 1126
Clinical Therapy 1126
Nursing Care Management 1127
Care of the Woman with a Urinary Tract Infection 1129
Overdistention of the Bladder 1129
Nursing Care Management 1130
Cystitis (Lower Urinary Tract Infection) 1130
Nursing Care Management 1131
Care of the Woman with Postpartum Mastitis 1131
Clinical Therapy 1132
Nursing Care Management 1133
Care of the Woman with Postpartum Thromboembolic Disease 1134
Superficial Vein Disease 1135
Deep Vein Thrombosis 1135
Pulmonary Embolism 1136
Clinical Therapy 1136
Nursing Care Management 1136
Care of the Woman with a Postpartum Psychiatric Disorder 1141
Types of Postpartum Psychiatric Disorders 1141
Nursing Care Management 1144

APPENDICES 1151
A Common Abbreviations in Maternal-Newborn and Women's Health Nursing 1151
B Conversions and Equivalents 1154
C Spanish Translations of English Phrases 1155
D Guidelines for Working with Deaf Patients and Interpreters 1158
E Sign Language for Healthcare Professionals 1159
F Actions and Effects of Selected Drugs During Breastfeeding 1162

GLOSSARY 1164

INDEX 1179

Special Features

Assessment Guide

Initial Prenatal Assessment 324
Intrapartum—First Stage of Labor 560
Newborn Physical Assessment 811
Postpartum—First 24 Hours After Birth 1005
Postpartum—First Home Visit and Anticipated Progress at Six Weeks 1072

Current Issues in Maternal-Newborn Nursing 2

CHAPTER 2
Care of the Family in a Culturally Diverse Society 24

CHAPTER 3
Complementary and Alternative Therapies 44

CHAPTER 1

Current Issues in Maternal-Newborn Nursing

Our daughter just told us that she is 3 months pregnant with our first grandchild. As a labor and delivery nurse for 30 years, I've helped with hundreds of births, but it still seems magical to me, especially now. I'm excited for her and a little worried because I know all the risks as well as the joys. She is so happy; when I am with her I just want to laugh out loud. I already know I love being a grandmother!

LEARNING OUTCOMES

1. Discuss the impact of the self-care movement on contemporary childbirth.
2. Compare the nursing roles available to the maternal-newborn nurse.
3. Describe the use of community-based nursing care in meeting the needs of childbearing families.
4. Identify specific factors that contribute to a family's value system.
5. Delineate significant legal and ethical issues that influence the practice of nursing for childbearing families.
6. Evaluate the potential impact of some of the special situations in contemporary maternity care.
7. Contrast descriptive and inferential statistics.
8. Relate the availability of statistical data to the formulation of further research questions.
9. Identify the impact of evidence-based practice in improving the quality of nursing care for childbearing families.

KEY TERMS

Professional nurse *9*
Therapeutic insemination (TI) *15*

The practice of most nurses is filled with special moments, shared experiences, times in which they know they have practiced the essence of nursing and, in doing so, have touched a life. What is the essence of nursing? Simply stated, nurses care for people, care about people, and use their expertise to help people help themselves.

> "I like working with students. I enjoy the enthusiasm they bring, the questions they ask, the ways they cause me to examine my practice. I love being a nurse. I am passionate about the importance of what I do, and I feel the need to seize every chance to influence those who will be practicing beside me someday. Last week was a perfect example. I had a nursing student working with me in one of our birthing rooms. It was her first day caring for a laboring woman, and she was scared and excited at the same time. We were taking care of a healthy woman who had two boys at home and really wanted a girl.
>
> As labor progressed, the student and I worked closely together monitoring contractions, teaching the woman and her husband, doing what we could to ease her discomfort. Sometimes the student would ask how I knew when to do something, a vaginal exam, for example, and I'd have to think beyond "I just do" to give her some clues. At the birth the student stayed close to the mother, coaching and helping with breathing. The student was excited but felt she had an important role to play, and she handled it beautifully. At the moment of birth the student and the dad were leaning forward watching as the baby just slipped into the world. There wasn't a sound until the student said in a voice filled with awe, "Oh, it's a girl!" Then we all laughed and hugged each other. What a day—using my expertise to help others and helping a future nurse recognize the importance of what we do!"

All nurses who provide care and support to childbearing women and their families can make a difference. Expert nurses, like the nurse in the preceding situation, have a clear vision of what is possible in a given situation. This holistic perspective that expert nurses develop is based on a wealth of knowledge bred of experience and enables them to act "intuitively" to provide effective care. In reality nurses' intuition reflects their internalization of information. When faced with a clinical situation, expert nurses draw almost subconsciously on their stored knowledge and judgment. New nurses need time to develop this level of skill and can benefit greatly from mentoring and coaching by their more seasoned colleagues.

This intuitive perception is integral to the "art of nursing," especially in areas such as maternal-newborn nursing, where change occurs quickly and families look to the nurse for help and guidance. Labor nurses become attuned to a woman's progress or lack of progress; nursery nurses detect subtle changes in the infants under their care; antepartal and postpartal nurses become adept at assessing and teaching. Similarly, nurses who are cross-trained as labor, delivery, recovery, and postpartum (LDRP) nurses become skilled at caring for childbearing families during all phases of childbirth. Thus skilled nursing practice depends on a solid base of knowledge and clinical expertise delivered in a caring, holistic manner.

> "My first pregnancy ended in spontaneous abortion at 8 weeks, so this time I decided not to tell anyone I was pregnant until I was 3 months along. We had just told both families the news the preceding day when it happened again. I began bleeding heavily, and we rushed to the ED. Here I was, a maternal-newborn nursing instructor, and I couldn't seem to handle a pregnancy. I was in the bathroom when I passed the fetus into the Johnny cap. My poor baby—so small, maybe 3 or 4 inches long. I began to sob uncontrollably as I rang for the nurse. I told her what happened, and she helped me to bed. My husband sat with his arm around me as I cried while the nurse took our baby out. A few minutes later, she came back and said, "I saw on your record that you are Catholic. Would you like me to baptize your baby?" I said, "Oh, yes, please," and she left. I've never forgotten how that made me feel. She saw me as a total person. I'm still teaching, and now I have two children. Whenever I teach high-risk pregnancy, I tell that story to the students. I want them to know what a difference a nurse can make."

Many nurses who work with childbearing families are sensitive, intuitive, knowledgeable, critical thinkers. They are technically skilled, empowered professionals who can collaborate effectively with others and advocate for those individuals and families who need their support. Such nurses do make a difference in the quality of care that childbearing families receive.

Contemporary Childbirth

The scope of practice of maternal and newborn nurses has changed dramatically in the past 30 years. Today's maternal-newborn nurses have far broader responsibilities and focus more on the specific goals of the individual childbearing woman and her family (Figure 1-1 ■).

Contemporary childbirth is characterized by an emphasis on the family, and family-centered childbirth is accepted and encouraged. Fathers are active participants in the birth experience. Families and friends are also often included. Siblings are encouraged to visit and meet their newest family member and may even attend the birth. In addition, new definitions of family are evolving as discussed in chapter 2 ∞. For example, the family of the single mother may include her mother, sister, another relative, a close friend, or the father of the child. Many

Figure 1-1 ■ Individualized education for childbearing couples is one of the prime responsibilities of the maternal-newborn nurse.

cultures also recognize the importance of extended families, where several family members often provide care and support.

Contemporary childbirth is also characterized by an increasing number of choices about many aspects of the childbirth experience, including the place of birth (hospital, free-standing birthing center, or home birth); the primary caregiver (physician, certified nurse-midwife, or certified midwife); and birth-related experiences (methods of childbirth preparation, use of analgesia and anesthesia, and position for labor and birth, for example).

In many areas of the United States there is a movement from a natural, family-focused, low-tech form of childbirth—sometimes called normal childbirth—to high-tech birthing. This movement is influenced in part by childbearing families, sometimes called generation Y or the iGeneration, who have grown up with technology and know no other way. They may view elective induction and mother-requested cesarean birth as accepted options, for example. This movement is often reinforced by caregivers who, aware of legal liability issues, practice defensive medicine. Furthermore, many hospitals now support a high-tech model of maternity care because it is "easier" to manage more patients if their pain is controlled by epidurals and their contractions are monitored by electronic fetal monitors (Zwelling, 2008). This high-tech approach can potentially interfere with family-focused care. Zwelling (2008) has identified several actions that nurses can take to promote family-focused, low-tech childbirth, including:

- Advocating vigorously within the community for normal childbirth.
- Working to ensure that childbirth preparation classes are readily available.
- Increasing personal labor support skills as well as technical skills.
- Accepting doulas as part of the labor team.
- Promoting changes in the birth environment where they work.
- Participating in interdisciplinary committees to develop and implement standardized practices for care.

It seems likely that home follow-up nursing care will continue to gain acceptance because it is a cost-effective approach with favorable long-term family outcomes. In addition, families can access a variety of community resources, from local programs focusing on specific topics such as parenting or postpartal exercise to the widely recognized support provided by national organizations such as La Leche League.

For families with access to the Internet, a wealth of information and advice is available. For example, the Department of Health and Human Services' Office on Women's Health offers a wide variety of educational resources designed to help promote women's health and well-being. Web links to a variety of other organizations and consumer publications also exist.

Interest in complementary and alternative medicine (CAM) practices is growing nationwide and is having an impact on the care of childbearing families. In response to this trend, the National Institutes of Health now has an Office of Alternative Medicine. Nurses caring for childbearing families need to recognize that a significant percentage of Americans are using some form of unconventional or alternative practice, although they may not share this information with their healthcare provider. Thus it is important for nurses to communicate a willingness to work with the women and their families to recognize and respect these alternative approaches. To assist nurses caring for these childbearing families, we have devoted chapter 3 ∞ to complementary and alternative therapies.

Many women elect to have their pregnancy and birth managed by a certified nurse-midwife (CNM), a registered nurse who is also prepared as a midwife. In 2006, for example, CNMs and CMs attended 7.4% of all births in the United States and 10.8% of all vaginal births (American College of Nurse-Midwives (ACNM), 2009a). The preparation and role of the CNM is described on page 9.

Some women choose to receive care from a direct-entry certified midwife or even a lay midwife, who is an unlicensed or uncertified midwife trained through an informal route such as apprenticeship or self-study rather than a formal educational program (Midwives Alliance of North America [MANA], 2009). Midwives who complete a direct-entry midwifery education program that meets the standards established by the American College of Nurse-Midwives (ACNM) may take a certification exam to become a *certified midwife (CM).* ACNM has mandated that, as of 2010, a graduate degree is required for entry into clinical practice as either a CNM or CM. The ACNM Position Statement does support the continued recognition of CNMs and CMs without graduate degrees who completed their education prior to 2010 so that they can retain their licenses and become licensed in additional states (ACNM, 2009b).

The North American Registry of Midwives (NARM) is also a certification agency. Midwives certified through NARM may

RESEARCH EVIDENCE IN PRACTICE

Factors Influencing Planned Home Birth and Outcomes

CLINICAL QUESTIONS

What are the factors that influence the choice to give birth at home? What are the comparable outcomes of home versus hospital births for low-risk pregnancy?

RESEARCH EVIDENCE

Home birth remains controversial, even though it is commonplace in many cultures. Healthcare providers' attitudes about maternity care options influence the advice they give to expectant mothers as to where to give birth. The mother's desire to influence the conditions under which she gives birth also has a powerful impact on the choice of birth site. Evidence integrating qualitative inquiry, surveys of provider attitudes, and quantitative research comparing birth outcomes can help determine the factors that influence the choice to give birth at home and describe the comparable outcomes of planned home birth.

In a large, multisite study of certified nurse-midwives and their attitudes toward home birth, the provider's comfort and amount of experience with planned home birth was the primary predictor of willingness to advise mothers to give birth at home. In a qualitative study of mothers who gave birth at home, women felt strongly positive about the experience. They reported feeling more relaxed during the perinatal period, felt more informed about the process, and believed they were more fully engaged in the planning of their care. These mothers had a great deal of trust in their midwives' skills and knowledge and felt a genuine sense of support throughout the process.

In a large (n = 6692) Canadian study, women with expected low-risk pregnancies who gave birth at home were compared with similar women who gave birth in the hospital. There was no difference in maternal or neonatal mortality or morbidity; both groups had low mortality rates. All measures of serious maternal morbidity were lower in the planned home birth group as were rates for all interventions, including cesarean birth.

Still, more than 12% of planned home births end up with the mother transported to the hospital to complete the birth. Nulliparas were more likely to require transport than multiparas, most commonly due to failure to progress. Women who planned a home birth also ended up giving birth in the hospital when their selected provider was unavailable to them. A pregnancy exceeding 42 weeks increased the risk of transfer for both primiparas and multiparas.

WHAT QUESTIONS REMAIN UNANSWERED?

Even though these studies were large, the women who gave birth at home were self-selected and not randomly assigned to groups. Are there characteristics of women who choose home birth that influence outcomes, such as nutritional choices or exercise? What are the mortality and morbidity rates for women who plan a home birth but are transported to the hospital to complete the birth?

WHAT IS BEST PRACTICE?

When the provider is experienced and establishes a trusting relationship with the mother, planned home birth can be a viable alternative for the mother with a low-risk pregnancy. Women who have had previous births may be able to complete a home birth more easily than those who are having their first baby. The rate of serious outcomes for low-risk birth is the same for mothers who give birth at home and in the hospital and, in some cases, may result in fewer interventions.

CRITICAL THINKING

What characteristics of a mother might make her a good candidate for a planned home birth? How can these characteristics be assessed in the prenatal period?

become midwives through a formal educational program at a college, university, or midwifery school, or through apprenticeship or self-study. They are eligible to use the credential *certified professional midwife (CPM)* (MANA, 2009).

Some women choose to give birth at home although healthcare professionals do not generally recommend this approach. The concern of the healthcare professional is that, in the event of an unanticipated complication that threatens the well-being of the mother or her infant, delay in obtaining emergency assistance might result. Some CNMs do attend home births; however, the majority of home births are attended by CMs, CPMs, or lay midwives. In fact, in 2006, just over half of 1 percent (0.59%) of births occurred at home. Of these, about 61% were attended by midwives. Of midwife-attended home births, one fourth (27%) were done by CNMs; 73%, however, were done by other midwives (MacDorman & Menacker, 2010).

The Self-Care Movement and Health Promotion Education

The *self-care* movement began to emerge in the late 1960s as consumers sought to understand technology and take an interest in their own health and basic self-care skills. More and more people have begun to exercise, control their diet, and monitor their psychologic and physiologic status. They thus assume many primary care functions. Furthermore, today's healthcare consumers are requiring greater information and accountability from their healthcare providers. These consumers recognize that knowledge, indeed, is power.

Practicing self-care—assuming responsibility for one's own health—often requires assertiveness and taking an active role in seeking necessary information. Healthcare providers can help foster self-care by focusing on *health promotion education* during every patient encounter. This may be as simple as

discussing actions that foster a healthy lifestyle, such as exercising regularly or wearing a helmet when biking, skiing, or snowboarding, or it may be more involved for a person with a chronic health condition. Health promotion education can be especially effective when it is related to a specific health concern. For example, discussion about the importance of a healthy diet, weight control, and regular exercise may be particularly impactful for a woman who learns she has high cholesterol or who is diagnosed with gestational diabetes mellitus. Nurses can foster self-care by providing information readily and by acknowledging people's right to ask questions and become actively involved in their own care.

Gradually, as more and more people have come to recognize that promoting health can help decrease healthcare costs, health promotion education activities have increased significantly. Literature and handouts are available in offices, pharmacies, stores, and other public places. Television, radio, newspapers, and magazines regularly address health-related topics. Community organizations have become more active in promoting health through events such as bicycle safety camps for youngsters and by providing car seats to low-income families so that newborns are protected from the moment they leave their place of birth.

Maternal-newborn care offers a special opportunity to promote health-related activities and to foster active participation in health care because it is essentially health focused; in most cases, patients are well when they enter the system. The consumer movement that has already influenced childbirth encourages people to speak up for preferences in dealing with healthcare providers.

We believe that health promotion education and its corollary, self-care, will be vital parts of health care for years to come. Obviously, self-care is not always realistic or appropriate, especially in acute emergencies, but in many situations it is appropriate. With this in mind, throughout this book we have attempted to suggest ways in which nurses might offer health promotion education that would enable the childbearing family to meet its own healthcare needs. We see this as one of nursing's most important functions and one that nurses are especially well qualified to perform.

The nursing profession has been at the forefront in recognizing that people who are able to do so should take an active role in their own health care, and we agree. Because of that, in previous editions we used the term *client* as more descriptive of this relationship. Many of the students and faculty who use our book have expressed a preference for the term *patient*, however, because it is the norm in most clinical areas. We have returned to this more traditional language because we feel sure that the practice of nursing has evolved sufficiently so that both nurses and the people they serve understand that it is the nurse's professional expertise and skill that is sought in an equal partnership.

The Healthcare Environment

Healthcare issues are at the top of policy and legislative agendas. Cost, access, and quality of health care have become the "bywords" of the times. In 2007, healthcare expenditures in the United States were $2.2 trillion, a 6% increase over the previous year. The healthcare share of the gross domestic product (GDP) was 16%, up from 14% in 2000. This share of the GDP is greater than that of any other developed country. Switzerland is the next closest country, spending 11.3% of its GDP on health care (National Center for Health Statistics [NCHS], 2010).

Despite this increase in spending, however, not all adults and children in the United States have access to health care. In 2007, 16.6% of the population (43.3 million people) were without health insurance. For people living in poverty, Medicaid is the most prevalent form of insurance, covering almost 14% of people (36.2 million), including pregnant women who fall into specified income categories (NCHS, 2010).

Almost all adults over age 65 are covered by Medicare, so the vast majority of uninsured are under age 65. The percentage of people covered by private insurance declined from 73% in 1999 to 67% in 2007. This decrease has been offset, however, by increases in the percentage of people with Medicaid or coverage through the Children's Health Insurance Program (CHIP) (NCHS, 2010). As a result, the percentage of uninsured people under age 65 has not changed significantly. See Figure 1-2 ■.

Taken together, Medicare, Medicaid, and other federal, state, and local programs account for 45% of healthcare spending as shown in Figure 1-3A ■. Of those dollars, almost two thirds are spent on hospitalizations and physician and clinical services (Figure 1-3B ■ [NCHS, 2010]).

For women who become pregnant, early prenatal care is one of the most important approaches available to reduce adverse pregnancy outcomes. In 2006, 83.2% of pregnant women in the United States began prenatal care in the first trimester. However, these percentages vary significantly among groups, with black or African American, Hispanic or Latina, and Native American women less likely to receive early and adequate prenatal care than white and Asian women (NCHS, 2010). As mentioned previously, the United States spends more per capita than any other country in the world on health care; nevertheless, compared with other industrialized nations, the United

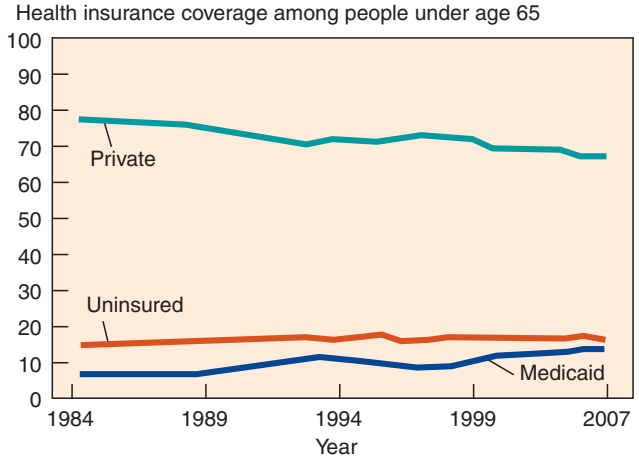

Figure 1-2 ■ Health insurance coverage among people under age 65 in the United States, 2009.

States has higher infant mortality rates, similar life expectancy, and less access to care. Many people who have insurance fear changing or losing jobs because they may lose healthcare benefits and access to insurance. They may be denied insurance in the future because of preexisting conditions. The increase in serious, debilitating illnesses, such as AIDS and tuberculosis, and in chronic illnesses, such as diabetes and hypertension, makes this problem of "job lock" and lack of transferability of insurance benefits even more significant. For some uninsured people, the only access to the healthcare system is an emergency department. This inappropriate use of expensive services for basic primary care is both an access and a cost problem.

Among the insured, many people are enrolled in some type of managed care organization because, in an effort to curtail costs, many employers have moved from fee-for-service coverage to some form of managed care. Thus managed care is now the dominant form of healthcare delivery in the United States. The move toward managed care has sparked concerns about the quality of health care. Because a fee-for-service model allows the consumer to register dissatisfaction by choosing to seek care elsewhere, quality is a high priority among fee-for-service providers. A managed care model, in contrast, limits consumer choice and, in turn, potentially affects quality. Establishing managed care's effects on quality poses a problem because in the U.S. system, quality indicators such as outcomes of care usually have not been well determined. An outcome-based system is essential if there is to be comprehensive healthcare reform.

Changing the current system requires a new way of thinking and providing services. Primary healthcare services should be the base on which all other secondary and tertiary services are built. Today in the United States the opposite is still the case. The system emphasizes high-technology care rather than prevention. However, morbidity and mortality from disease are reduced significantly when people use preventive health services. The *Health Insurance Portability and Accountability Act (HIPAA)* of 1996, which was fully implemented in 2002, has also had an impact on health care. HIPAA has two areas of focus: It protects the health insurance coverage of employees and their family if they lose a job or change jobs. It also addresses the privacy and security of health information and requires that national standards be established for the electronic transmission of healthcare data. The *privacy rule* is the federal regulation developed to meet HIPAA requirements. It defines the policies and procedures to be followed to safeguard an individual's protected health information. It also guarantees people access to their medical records and provides recourse for them if their medical privacy is violated. HIPAA regulations have caused healthcare facilities to take a wide variety of actions to ensure client/patient privacy. It has also empowered individuals by giving them access to information about their health care. Academic programs that prepare nurses, physicians, and other healthcare professionals have had to develop tools and resources to ensure that their students understand privacy requirements and comply with them.

Providing all segments of the population with access to primary health care should be the chief criterion for meaningful reform of the U.S. healthcare system. This includes a focus on health promotion, prevention, and individual responsibility for one's own health. In this model, secondary healthcare services would use a smaller proportion of the healthcare dollar.

The current emphasis on healthcare reform has yielded an unexpected benefit: Many healthcare providers and consumers

have become more aware of the vitally important role nurses play in providing excellent care to patients and families. The emerging shift in the U.S. healthcare system presents a significant opportunity for the nursing profession. However, this opportunity for responding to and creating change in nursing and healthcare delivery requires a new way of thinking. Nurses must clearly articulate their role in the changing environment. They need to define and differentiate practice roles and the educational preparation required for those new roles, especially in community-based nursing practice and advanced practice roles such as nurse practitioners (NPs) and certified nurse-midwives (CNMs). Nurses must delineate the roles of caregiver and care manager. Nurses also need to assume greater roles in promoting health and preventing disease. In reality, in many settings nurses assume the primary responsibility for preventive healthcare services and screening programs.

Healthcare reform is influencing women's health and maternal-newborn nursing. Several factors, including demographic changes, the nationally recognized need to improve access to care, public demand for more effective healthcare options, new research findings, and women's preferences for health care, are contributing to changes in the field. Changes are predicted in clinical procedures, provider roles, care settings, and financing of care. As access to health care and the need to control costs increase, so will the need for, and utilization of, nurses in advanced practice roles.

Culturally Competent Care

The U.S. population has a varied mix of cultural groups with ever-increasing diversity. Approximately 44% of all children less than 18 years of age are from families of minority populations (Forum on Child and Family Statistics, 2009). Culture develops from socially learned beliefs, lifestyles, values, and integrated patterns of behavior that are characteristic of the family, cultural group, and community. The cultural background and values of childbearing families are often quite different from those of the nurse.

Specific elements that contribute to a family's value system include the following:

- Religion and social beliefs
- Presence and influence of the extended family as well as socialization within the ethnic group
- Communication patterns
- Beliefs and understanding about the concepts of health and illness
- Permissible physical contact with strangers
- Education

Specific differences in beliefs between families and healthcare providers are common in the following areas:

- Help-seeking behaviors
- Pregnancy and childbirth practices
- Causes of diseases or illnesses
- Death and dying
- Caretaking and caregiving
- Childrearing practices

These elements in differing degrees influence the cultural beliefs and values of an ethnic group, making the group unique. Misunderstandings may occur when the healthcare professional and the family come from different cultural groups. In addition, past experiences with care may have made the family angry or suspicious of providers. Nurses need to be able to recognize, respect, and respond to ethnic diversity in a way that leads to an outcome that is satisfactory to both the patient and the healthcare provider. The nurse needs to identify culturally relevant facts about the patient to provide culturally appropriate and competent care.

DEVELOPING CULTURAL COMPETENCE

Values Conflicts

Conflicts can occur with a childbearing woman and her family when traditional rituals and practices of the family's elders do not conform to current healthcare practices. Nurses need to be sensitive to the potential implications for the woman's health and that of her newborn, especially after they are discharged home. When cultural values are not part of the nursing care plan, a woman and her family may be forced to decide whether the family's beliefs should take priority over the healthcare professional's guidance.

When the family's cultural values are incorporated into the care plan, the family is more likely to accept and comply with the needed care, especially in the home care setting. It is important for nurses to avoid imposing personal cultural values on the women and families in their care. By learning about the values of the different ethnic groups in the community—their religious beliefs that have an impact on healthcare practices, their beliefs about common illnesses, and their specific healing practices—nurses can develop an individualized nursing care plan for each childbearing woman and her family.

Because of the importance of culturally competent care, this topic is discussed in more depth in chapter 2 ∞ and throughout the book as well.

Professional Options in Maternal-Newborn Nursing Practice

"As a man, I don't always find it easy to be a labor and delivery nurse. I have three children of my own and attended all their births. It meant a lot to me to be there, and I like helping others to have good childbirth experiences, too. I don't fit some people's image of a nurse; so they refer to me as a "male nurse" as opposed to a real nurse, and they ask why I didn't go into medicine instead. Why can't they understand that I'm a nurse because it's what I really want to be—and I'm darned good at it, too. More men are choosing nursing now, and I think that will help. I hope to see the day when we don't have "female doctors" and "male nurses," but doctors and nurses, period!"

Maternal-newborn nurses are found in the maternity departments of acute care facilities, in physicians' offices, in clinics, in college health services, in school-based programs dealing with sex education or adolescent pregnancies, in community health services, and in any other setting where a patient has a need for maternity care. The depth of nursing involvement in various settings is determined by the qualifications and the role or function of the nurse employed. Many different titles have evolved to describe the professional requirements of the nurse in various maternity care roles. These titles include the following:

- A **professional nurse** is a graduate of an accredited basic program in nursing who has successfully completed the nursing examination (NCLEX-RN) and is currently licensed as a registered nurse (RN). Professional nurses are typically educated as generalists.
- A **certified registered nurse (RNC)** has shown expertise in a particular field of nursing such as labor and delivery by taking a national certification examination.
- A **nurse practitioner (NP)** is a professional nurse who has received specialized education in either a Doctor of Nursing Practice (DNP) or master's degree program and thus can function in an expanded role. (Note: Early nurse practitioner programs were sometimes certificate programs.) The area of specialization determines the NP's title, so that there are family nurse practitioners, neonatal nurse practitioners, pediatric nurse practitioners, women's health nurse practitioners, and so forth. Nurse practitioners often provide ambulatory care services to the expectant family (women's health nurse practitioner, family nurse practitioner); some NPs also function in acute care settings (neonatal nurse practitioner, perinatal nurse practitioner). NPs focus on physical and psychosocial assessment, including health history, physical examination, and certain diagnostic tests and procedures. The nurse practitioner makes clinical judgments and begins appropriate treatments, seeking physician consultation when necessary. The emerging emphasis on community-based care has greatly increased opportunities for NPs.
- A **clinical nurse specialist (CNS)** is a professional nurse with a master's degree who has additional specialized knowledge and competence in a specific clinical area. CNSs assume a leadership role within their specialty and work to improve patient care both directly and indirectly.
- A **certified nurse-midwife (CNM)** is educated in the two disciplines of nursing and midwifery and is certified by the American College of Nurse-Midwives (ACNM). The certified nurse-midwife is prepared to manage independently the care of women at low risk for complications during pregnancy and birth and the care of normal newborns (Figure 1-4 ■).

The term *advanced practice nurse* is used to describe nurses who, by education and practice, function in an expanded nursing role. The term, often used in a legal sense in state nurse practice acts, most frequently applies to NPs, CNSs, certified registered nurse anesthetists (CRNAs), and CNMs. As NPs assume a more prominent role in providing care, the distinctions between the roles of the nurse practitioner and the clinical nurse specialist are beginning to blur and these roles may ultimately merge.

Figure 1-4 ■ A certified nurse-midwife confers with her patient.
Source: Photographer, Jenny Thomas.

The **nurse researcher** has an advanced doctoral degree, typically a Doctor of Philosophy (PhD) and assumes a leadership role in generating new research. Nurse researchers are typically found in university settings although more and more hospitals are employing them to conduct research relevant to patient care, administrative issues, and the like.

Collaborative Practice

Managed care has led to a rethinking of care delivery. One approach that is becoming increasingly popular is collaborative practice. Collaborative practice is a comprehensive model of health care that uses a multidisciplinary team of health professionals to provide cost-effective, high-quality care. In maternal-newborn settings, the team generally includes CNMs and NPs in practice with physicians (often obstetricians or family practice physicians) and may include other health professionals, such as lactation consultants, social workers, or CNSs (Figure 1-5 ■).

In a successful team, each individual has autonomy but functions within a clearly defined scope of practice. In such a

Figure 1-5 ■ A collaborative relationship between nurse and physician contributes to excellent patient care.
Source: Photographer, Elena Dorfman.

collaborative approach, no single profession "owns the patient." Rather, the team seeks to empower patients and families and include them as partners in their care and in decision making.

Community-Based Nursing Care

Many advocates of a new direction for health care support the increasing emphasis on primary care. Primary care includes a focus on health promotion, illness prevention, and individual responsibility for one's own health. These services are best provided in community-based settings. Third-party payers are beginning to recognize the importance of primary care in containing costs and maintaining health. Community-based health services providing primary care and some secondary care will be available in schools, workplaces, homes, churches, clinics, transitional care programs, and other ambulatory settings.

The growth and diversity of third-party payer plans offer both opportunities and challenges for women's health care. The potential exists for third-party payers to work with consumers to provide a model for coordinated and comprehensive well-woman care that includes improved screening and preventive services. One challenge payers will face is how to relate to essential community providers of care—organizations such as family planning clinics or women's health centers—that offer a unique service or serve groups of women with special needs (adolescents, disabled women, ethnic or racial minorities). Community-based care remains an essential element of health care for uninsured and underinsured individuals as well as for those individuals who benefit from programs such as Medicare or state-sponsored health-related programs. Some of these programs, such as those offered through public health departments, are broad based; others, such as parenting classes for adolescents, are geared to the needs of a specific population.

Community-based care is also part of a trend initiated by consumers, who are asking for a "seamless" system of family-centered, comprehensive, coordinated health care, health education, and social services. This seamless system requires coordination as patients move from primary care services to acute care facilities and then back into the community. The shortened length of hospital stays further mandates the need for coordination of services. Nurses can assume this care management role and perform an important service for individuals and families.

Application: Scope of Practice

Maternal-newborn nurses are especially sensitive to these changes in healthcare delivery because the vast majority of health care provided to childbearing families takes place outside hospitals in clinics, offices, and community-based organizations. In addition, maternal-newborn nurses offer specialized services such as childbirth preparation classes or postpartal exercise classes. In essence, we are already experts at providing community-based nursing care. However, it is important that we remain knowledgeable about current practices and trends and open to new approaches to meet the needs of women and children.

Home Care

The provision of health care in the home is emerging as an especially important dimension of community-based nursing care. The shortened length of hospital stays has resulted in the discharge of individuals who still require support, assistance, and teaching. Home care can help fill this gap. Conversely, home care also enables individuals to remain at home with conditions that formerly would have required hospitalization.

Nurses are the major providers of home care services. Home care nurses perform direct nursing care and also supervise unlicensed assistive personnel who provide less skilled levels of service. In a home setting, nurses can use their skills in assessment, therapeutics, communication, teaching, problem solving, and organization to meet the needs of childbearing families. They also play a major role in coordinating services from other providers, such as physical therapists or lactation consultants.

Postpartum and newborn home visits are becoming a recognized way of ensuring that childbearing families make a satisfactory transition from the hospital or birthing center to the home. We see this trend as positive and hope that this method of meeting the needs of childbearing families becomes standard practice. Chapter 36 ∞ discusses home care in more detail and provides guidance about making a home visit. In addition, throughout the text we have provided information on how home care can meet the needs of women with health problems such as diabetes or preterm labor, which put them at risk during pregnancy. We believe that home care offers nurses the opportunity to function in an autonomous role and make a significant difference for individuals and families.

Legal and Ethical Considerations

Professional nursing practice requires full understanding of practice standards; institutional or agency policies; and local, state, and federal laws. Professional practice also requires an understanding of the ethical implications of those standards; policies; and laws that impact care, care providers, and care recipients. Every professional nurse is responsible for obtaining and maintaining current information regarding ethics and laws related to nursing practice and health care.

Scope of Practice

State nurse practice acts protect the public by broadly defining the legal *scope of practice* within which every nurse must function and by excluding untrained or unlicensed individuals from practicing nursing. Although some state practice acts continue to limit nursing practice to the traditional responsibilities of providing patient care related to health maintenance and disease prevention, most state practice acts cover expanded practice roles that include collaboration with other professionals in planning and providing care, diagnostic and prescriptive privilege, and the delegation of patient care tasks to other specified licensed and unlicensed personnel. Specified care activities for certified nurse-midwives (CNMs) and women's health, perinatal, or neonatal nurse practitioners may include diagnosis and prenatal management of uncomplicated pregnancies (CNMs may also manage births) and prescribing and dispensing medications using protocols in specified circumstances. A nurse must function within the scope of practice or risk being accused of practicing medicine without a license.

Correctly interpreting and understanding state practice acts enables the nurse to provide safe care within the limits of nursing practice. State boards of nursing may provide official interpretation of practice acts when the limits are not clear. On occasion hospital policy may conflict with a state's nurse practice act. It is important to recognize that hospital or agency policy may restrict the scope of practice specified in a state practice act, but such policy cannot legally expand the scope of practice beyond the limits stated in the practice act.

Nurse practice acts are subject to change. One component of professional nursing practice is the responsibility of each nurse to remain up to date regarding scope of practice and even to participate actively in promoting appropriate changes.

Nursing Negligence

Negligence is defined as omitting or committing an act that a reasonably prudent person would not omit or commit under the same or similar circumstances. Negligence consists of four elements:

1. There was a duty to provide care.
2. The duty was breached.
3. Injury occurred.
4. The breach of duty caused the injury (proximate cause).

Duty may be breached by omission—failing to give a medication, failing to assess properly, failing to notify a physician of a change in a laboring woman's condition, and so on. Duty may also be breached by commission—giving the wrong medication, placing an infant in the wrong crib, and so on. The injury that results may be physical or mental (pain and suffering). In determining whether nursing negligence occurred, the care that was given is compared with the standard of care. If the standard was not met, negligence occurred.

Standards of Nursing Care

Standards of care establish minimum criteria for competent, proficient delivery of nursing care. Such standards are designed to protect the public and are used to judge the quality of care provided. Legal interpretation of actions within standards of care is based on what a reasonably prudent nurse with similar education and experience would do in similar circumstances.

Sources of Care Standards

Written standards of care are provided by a number of different sources. The American Nurses Association (ANA) has published standards of professional practice since 1950. In 1973, the ANA Congress for Nursing Practice began to write generic standards for all nurses in all settings. In addition, the ANA Divisions of Practice have published standards that include nursing practice for maternal-child health. The Council of Perinatal Nurses has published standards for perinatal nursing. Other specialty organizations, such as the Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN), the Association of Operating Room Nurses (AORN), and the National Association of Neonatal Nurses (NANN), have developed standards of specialty practice. Agency policies, procedures, and protocols also provide appropriate guidelines for care standards. The Joint Commission on Accreditation of Healthcare Organizations, referred to simply as The Joint Commission, a private, nongovernmental agency that audits the operation of hospitals and healthcare facilities, has also contributed to the development of nursing standards.

Agency policies, procedures, and protocols also provide appropriate guidelines for care standards. For example, *clinical practice guidelines* and clinical pathways are comprehensive interdisciplinary care plans for a specific condition that describe the sequence and timing of interventions that should result in expected patient outcomes. Clinical practice guidelines or clinical pathways are adopted within a healthcare setting to reduce variation in care management, to limit costs of care, and to evaluate the effectiveness of care.

Although standards do not carry the force of law, they carry important legal significance. Any nurse who fails to meet appropriate standards of care invites allegations of negligence or malpractice. (*Malpractice* is negligent action of a professional person.) However, any nurse who practices within the guidelines established by agency, local, or national standards is assured that patients are provided with competent nursing care, which, in turn, diminishes the potential for litigation.

Ethical Components of Care Standards

Standards of care are based on a legal model rather than on ethics. However, they incorporate important ethical components that extend the narrow legal interpretation of the term *standard.* Although there is a great deal of interplay between the two disciplines, each has a different perspective.

Law is based primarily on a rights model that establishes rules of conduct to define relationships among individuals. Law may also define relationships to impersonal entities like formal organizations, agencies, or hospitals.

Ethics, in contrast, is based on a responsibility or duty model that considers a wider range of factors than the rights model of law. Ethics incorporates factors such as risks, benefits, other relationships, concerns, and the needs and abilities of persons affected by and affecting decisions.

Law and ethics are interrelated; they share a similar decision process and standards. Both disciplines incorporate fact-finding, conflict negotiation, prioritization of related issues and values, and the application of resolutions of particular cases in decision making. Professional nurses must consider the ethical implications of legal decisions and the legal implications of ethical decisions.

Understanding the distinctions among medical or healthcare decisions, legal decisions, and ethical decisions is important. Consider the case in which parents from a culture unfamiliar to the nurse refuse surgery for their newborn based on a deeply held spiritual belief that intentional cutting of a body will result in spiritual death. Such a decision to forgo surgery may be viewed as negligent in the eyes of the law, unwise and inappropriate from a medical perspective, yet fully justifiable ethically. Similarly, legally sanctioned maintenance of life support for a severely damaged newborn with little hope for meaningful existence may remain a medically viable alternative, but to

many it is not ethically justifiable. Recognizing the type of decision to be made often helps measure the worth and outcome of a decision more appropriately.

Patients' Rights

Law and ethics impact all of nursing practice, and several topics have specific implications for maternal-child nursing practice. Patients' rights encompass such topics as informed consent, privacy, and confidentiality.

Patient Safety

The Joint Commission has identified patient safety as an important responsibility of healthcare providers. Patient safety goals, which are evaluated and updated regularly, are requirements for accreditation. The Joint Commission has also developed recommendations related to newborn identification and prevention of kidnapping. These goals and recommendations can be found on The Joint Commission Web site. (Infant identification and security are discussed in chapter 24 ∞.)

Informed Consent

Informed consent is a legal concept designed to allow patients to make intelligent decisions regarding their own health care. Informed consent means that a patient, or a legally designated decision maker, has granted permission for a specific treatment or procedure based on full information about that specific treatment or procedure as it relates to that patient under the specific circumstances of the permission. Although this policy is usually enforced for such major procedures as surgery or regional anesthesia, it pertains to any nursing, medical, or surgical intervention. To touch a person without consent (except in an emergency) constitutes battery.

Several elements must be addressed to ensure that the patient has given informed consent. The information must be clearly and concisely presented in a manner understandable to the patient and must include risks and benefits, the probability of success, and significant treatment alternatives. The patient also needs to be told the consequences of receiving no treatment or procedure. Finally, the patient must be told of the right to refuse a specific treatment or procedure. Each patient should be told that refusing the specified treatment or procedure does not result in the withdrawal of all support or care.

The individual who is ultimately responsible for the treatment or procedure should provide the information necessary to obtain informed consent. In most instances, this is a physician. In such cases, the nurse's role may be to witness the patient's signature giving consent. A nurse who knows the patient and the procedure may certainly help the physician obtain the patient's consent by clarifying the information the physician provides. It is also part of the nurse's role to determine that the patient understands the information before making a decision. Anxiety, fear, pain, and medications that alter consciousness may influence an individual's ability to give informed consent. An oral consent is legal but written consent is easier to defend in a court of law.

Society grants parents the authority and responsibility to give consent for their minor children. Parents are presumed to possess what a child lacks in maturity, experience, and capacity for judgment in life's difficult decisions. Although the age of majority is 18 years in most states, variations in certain states require that nurses be aware of the law in the state where they practice. Children under 18 or 21 years of age, depending on state law, can legally give informed consent in the following circumstances:

- When they are minor parents of the infant or child patient
- When they are *emancipated minors* (self-supporting adolescents under 18 years of age, not subject to parental control)
- When they are adolescents between 16 and 18 years of age seeking birth control, mental health counseling, or substance abuse treatment (Anderson, Schaechter, & Brosco, 2005)

Mature minors (14- and 15-year-old adolescents who are able to understand treatment risks) can give consent for treatment or refuse treatment in some states.

Special problems can occur in maternity nursing when a minor gives birth. It is possible, depending on state law, that a minor may be able to consent to treatment for her infant but not for herself. In some states, however, a pregnant teenager is considered an emancipated minor and may, therefore, give consent for herself as well.

Additionally, some states require a married woman to obtain the consent of her spouse when a procedure involves sterilization or threatens the life of a fetus. Although childbearing women sign a general consent form on admission to an agency, separate informed consent is often required for surgery, cesarean birth, the administration of anesthesia, tubal ligation, or participation in research.

Refusal of a treatment, medication, or procedure after appropriate information also requires that a patient sign a form to release the physician and agency from liability. Jehovah's Witnesses' refusal of blood transfusion or Rh immune globulin is an example of such refusal.

Nurses are responsible for educating patients about any nursing care provided. Before each nursing intervention, the maternal-child nurse lets the individual and/or family know what to expect, thus ensuring cooperation and obtaining consent. Afterward, the nurse documents the teaching and the learning outcomes in the person's record. The importance of clear, concise, and complete nursing records cannot be overemphasized. These records are evidence that the nurse obtained consent, performed prescribed treatments, reported important observations to the appropriate staff, and adhered to acceptable standards of care.

Right to Privacy

The *right to privacy* is the right of a person to keep his or her person and property free from public scrutiny. Maternity nurses need to remember that this includes avoiding unnecessary exposure of the childbearing woman's body. In the context of health care, the right to privacy dictates that only those responsible for a person's care should examine the person or discuss his or her case.

Most states have recognized the right to privacy through statutory or common law, and some states have written that right into their constitution. The ANA, the National League for Nursing (NLN), and The Joint Commission have adopted pro-

fessional standards protecting patients' privacy. Healthcare agencies should also have written policies dealing with patient privacy. The Health Insurance Portability and Accountability Act (HIPAA), discussed previously, also has a provision to guarantee the security and privacy of health information.

Laws, standards, and policies about privacy specify that information about an individual's treatment, condition, and prognosis can be shared only by the health professionals responsible for his or her care. Authorization for the release of any patient information should be obtained from competent individuals or their surrogate decision makers. Although it may be legal to reveal vital statistics such as name, age, occupation, and prognosis, such information is often withheld because of ethical considerations. The patient should be consulted regarding what information may be released and to whom. When a patient is a celebrity or is considered newsworthy, inquiries may be best handled by the public relations department of the agency.

Confidentiality

Given the highly personal and intimate information requested of patients, the need for maintaining confidentiality is crucial for the development of trust in the relationship between the individual and the provider. Privileged communications exist between patient and physician, patient and attorney, husband and wife, and clergy and those who seek their counsel. In some states, laws of privilege also protect nurses. Nurses should become well informed about privileged communication laws in their state.

A patient may waive the right to confidentiality of medical records by action or words. For example, if a childbearing woman sues a physician, hospital, or other care provider, she waives the right to confidentiality of the medical record because the record becomes a source of evidence. Patients commonly consent to disclose information to insurance companies or to their employers. Computerization of medical records has created a greater concern for the integrity of records and the potential invasion of privacy.

In some instances, the public good takes precedence over an individual's right to privacy. For example, state laws require that care providers report gunshot wounds, child abuse, elder abuse, and some communicable diseases.

The Federal Patient Self-Determination Act requires all healthcare institutions that are reimbursed by Medicare or Medicaid to provide all hospitalized individuals with written information about their rights, which include expressing a preference for treatment options and making *advance directives* (writing a living will or authorizing a durable power of attorney for healthcare decisions on the individual's behalf). This often comes as a surprise to young women and couples of childbearing age who may have no experience of hospitals. However, with an advance directive in place, a childbearing woman can be certain that, even if she becomes incompetent, she can retain her autonomy about healthcare decisions. Nurses often discuss these issues with patients and their families and can help them explore their beliefs and values about treatment options and dying.

PROFESSIONALISM IN PRACTICE

Confidentiality and the Pregnant Adolescent

Breaching confidentiality is a potential problem for pregnant adolescents, who are just learning whom they can trust in the healthcare system. Make sure you openly discuss the limits of confidentiality for such things as mandatory reporting requirements with the patient and family. Inadvertent disclosure of personal information may lead to psychologic, social, or physical harm for some patients.

Special Ethical Situations in Maternity Care

Maternity care is fraught with unique circumstances in which an ethical dilemma may arise. These include situations of maternal-fetal conflict, issues related to termination of pregnancy, embryonic and fetal research, reproductive assistance, and cord blood banking.

Maternal-Fetal Conflict

Until fairly recently, the fetus was viewed legally as a nonperson. Mother and fetus were viewed as one complex patient—the pregnant woman—of which the fetus was an essential part. However, advances in technology have permitted the physician to treat the fetus and monitor fetal development. The fetus is increasingly viewed as a patient separate from the mother, although treatment of the fetus necessarily involves the mother. This type of approach, by nature adversarial, tends to emphasize the divergent interests of the mother and her fetus rather than focus on their shared interests. This focus on the fetus intensified in 2002 when President George W. Bush announced that "unborn children" would qualify for government healthcare benefits. The move was designed to promote prenatal care, but it represented the first time that any U.S. federal policy had defined childhood as starting at conception.

Most women are strongly motivated to protect the health and well-being of their fetuses. In some instances, however, women have refused interventions on behalf of the fetus, and forced interventions have occurred. These include forced cesarean birth, coercion of mothers who practice high-risk behaviors such as substance abuse to enter treatment, and, perhaps most controversial, mandating experimental in utero therapy or surgery in an attempt to correct a specific birth defect. These interventions infringe on the autonomy of the mother. They may also be detrimental to the baby if, as a result, maternal bonding is hindered, the mother is afraid to seek prenatal care, or the mother is herself harmed by the actions taken. Attempts have also been made to criminalize the behavior of women who fail to follow a physician's advice or who engage in behaviors that are considered harmful to the fetus. These forced interventions raise two thorny questions: (1) What practices should be monitored? and (2) Who will determine when the behaviors pose such a risk to the fetus that the courts should intervene?

The American College of Obstetricians and Gynecologists (ACOG) Committee on Ethics (2004) has affirmed the fundamental right of pregnant women to make informed, uncoerced

decisions about medical interventions and has taken a direct stand against coercive and punitive approaches to the maternal-fetal relationship, citing the following "overwhelming rationale" for avoiding such approaches.

1. Coercive and punitive legal approaches to pregnant women who refuse medical advice fail to recognize that all competent adults are entitled to informed consent and bodily integrity. . . .
2. Court-ordered interventions in cases of informed refusal, as well as punishment of pregnant women for their behavior that may put a fetus at risk, neglect the fact that medical knowledge and predictions of outcomes in obstetrics have limitations. . . .
3. Coercive and punitive policies treat medical problems such as addiction and psychiatric illness as if they were moral failings. . . .
4. Coercive and punitive policies are potentially counterproductive in that they are likely to discourage prenatal care and successful treatment, adversely affect infant mortality rates, and undermine the physician-patient relationship. . . .
5. Coercive and punitive policies directed toward pregnant women unjustly single out the most vulnerable women. . . .
6. Coercive and punitive policies create the potential for criminalization of many types of otherwise legal maternal behavior" (ACOG, 2005, pp. 6–9).

ACOG and the American Academy of Pediatrics (AAP) recognize that cases of maternal-fetal conflict involve two patients, both of whom deserve respect and treatment. Such cases are best resolved by using internal hospital mechanisms including counseling, the intervention of specialists, and consultation with an institutional ethics committee. Court intervention should be considered a last resort, appropriate only in extraordinary circumstances.

Abortion

Since the 1973 Supreme Court decision in *Roe v. Wade,* abortion has been legal in the United States. It can be performed until the period of viability, that is, the point at which the fetus can survive independently of the mother. After viability, abortion is permissible only when the life or health of the mother is threatened. Before viability, the mother's rights are paramount; after viability, the rights of the fetus take precedence. Abortion is often defined as a pregnancy that is terminated before 20 weeks' gestation or, if the gestation is not certain, a fetus that weighs less than 500 g. In truth, although opinion varies somewhat, it is generally accepted that "births before 26 weeks, especially those weighing less than 750 g, are at the current threshold of viability and that those preterm infants pose a variety of complex medical, social, and ethical considerations" (Cunningham et al., 2010, p. 807).

Personal beliefs, cultural norms, life experiences, and religious convictions shape people's attitudes about abortion. Ethicists have thoughtfully and thoroughly argued positions supporting both sides of the question. Nevertheless, few issues spark the intensity of response seen when the issue of abortion is raised.

At present, decisions about abortion are made by a woman and her physician. Nurses (and other caregivers) have the right to refuse to assist with the procedure if abortion is contrary to their moral and ethical beliefs. However, if a nurse works in an institution where abortions may be performed, the nurse may be dismissed for refusing. To avoid being placed in a situation contrary to their values and beliefs, nurses should determine the philosophy and practices of an institution before going to work there. A nurse who refuses to participate in an abortion because of moral or ethical beliefs does have a responsibility to ensure that someone with similar qualifications is able to provide appropriate care for the patient. Patients may never be abandoned, regardless of the nurse's beliefs.

Fetal Research

Research with fetal tissue has been responsible for remarkable advances in the care and treatment of fetuses with health problems and advances in the treatment of progressive, debilitating adult diseases such as Parkinson disease, Alzheimer disease, and DiGeorge syndrome. Therapeutic research with living fetuses has been instrumental in the treatment of infants who are Rh sensitized, the evaluation of lung maturity using the lecithin/sphingomyelin ratio, and the treatment of pulmonary immaturity in the newborn. Because it is aimed at treating a fetal condition, therapeutic fetal research raises fewer ethical questions than does nontherapeutic fetal research. To be approved, nontherapeutic research requires that the risk to the fetus be minimal, that the knowledge to be gained be important, and that the information be unobtainable by any other means. Control over research standards and attention to state and federal regulations remain foci of debate regarding fetal research.

Intrauterine fetal surgery, which began in 1981 and developed through therapeutic research, is a therapy for anatomic lesions that can be corrected surgically and are incompatible with life if not treated. Intrauterine fetal surgery involves opening the uterus during the second trimester (before viability), treating the fetal lesion, and replacing the fetus in the uterus. The risks to the fetus are substantial, and the mother is committed to cesarean births for this and subsequent pregnancies because the upper, active segment of the uterus is incised during the surgery. The parents must be informed of the experimental nature of the treatment, the risks of the surgery, the commitment to cesarean birth, and alternatives to the treatment.

As with other aspects of maternity care, caregivers must respect the pregnant woman's autonomy. The procedure does involve health risks to the woman, and she retains the right to refuse any surgical procedure.

Healthcare professionals are generally encouraged to provide a clear summary of the risks and benefits of a given approach and to follow the principle of nondirectiveness, in which only the patient's values are discussed during the decision-making process. However, it is likely that some "slippage" in approach occurs, which can result in a blurring of the boundaries between choice and coercion. This may be

Care Plan Activity: Request for Second Trimester Abortion

complicated by the reality that many women are influenced by their views about what it means to be a "good" mother, to behave responsibly. As a result some women may feel that they must opt for a risky procedure to avoid a sense of blame for failing to do their "duty" (Williams, 2006). The dilemmas associated with the consideration of fetal surgery are challenging and complex. Healthcare providers must be careful that their zeal for new technology does not lead them to focus unilaterally on the fetus at the expense of the mother.

Reproductive Assistance

The number and sophistication of reproductive assistance techniques continue to grow. Infertile couples now have available a wide range of reproductive options, from therapeutic insemination to in vitro fertilization and beyond. The ethical dimensions of such techniques are discussed here. The techniques themselves are identified and described in detail in chapter 12 ∞.

Therapeutic insemination (TI) is accomplished by depositing into a woman sperm obtained from her husband, partner, or other donor. Some women who are single are choosing TI as a childbearing option. No states prohibit therapeutic insemination using a husband's sperm because there is no question of the child's legitimacy. Legal problems may occur with TI using donor sperm, however. Because the child is the biologic child of the mother, legal concerns center on the donor. A donor must sign a form waiving all parental rights. The donor must also furnish accurate health information, particularly regarding genetic traits or diseases. Donor sperm must be tested for HIV. Husbands often are requested to sign a form to agree to the insemination and to assume parental responsibility for the child. Some men legally adopt the child so there is no question of parental rights and responsibilities. Several states have enacted legislation regarding paternity of the child conceived by insemination with donor sperm.

Assisted reproductive technology (ART) is the term used to describe any fertility treatment in which both the egg and sperm are handled. Treatments in which only the sperm are handled (e.g., therapeutic insemination) or in which a woman takes medication to stimulate egg production without subsequent egg retrieval are not included in the definition of ART. In vitro fertilization and embryo transfer (IVF-ET), a therapy offered to selected infertile couples, is perhaps the best known ART technique. Some effort has been made legislatively to address consumer concerns about ART. In the United States, the Federal Fertility Clinic Success Rate and Certification Act (FCSRCA) of 1992 addresses issues related to laboratory quality and the standardized reporting of pregnancy success rates associated with ART programs. To help ensure data accuracy, a validation process, which includes site visits to a portion of reporting clinics, is completed.

The use of ART has significantly increased multifetal pregnancies. Multifetal pregnancy occurs because the use of ovulation-inducing medications typically triggers the release of multiple eggs, which, when fertilized, produce multiple embryos, which are then implanted. Multifetal pregnancy increases the risk of miscarriage, preterm birth, and neonatal morbidity and mortality. It also increases the mother's risk of complications, including cesarean birth. To help prevent a high-level multifetal pregnancy, the American Society for Reproductive Medicine (ASRM) and the Society for Assisted Reproductive Technology (SART) have jointly issued guidelines to limit the number of embryos transferred. These guidelines are designed to decrease risk while allowing for individualized care (ASRM & SART, 2009). This practice raises ethical considerations about the handling of the unused embryos. However, when a multifetal pregnancy does occur, the physician may suggest that the woman consider fetal reduction, in which some of the embryos are aborted to give the remaining ones a better chance for survival. Clearly this procedure raises ethical concerns about the sacrifice of some so that the remainder can survive.

Prevention should be the first approach to the problem of multifetal pregnancy. It begins with careful counseling about the risks of multiple gestation and the ethical issues that relate to fetal reduction. No physician who is morally opposed to fetal reduction should be expected to perform the procedure; however, physicians should be aware of the ethical and medical issues involved and be prepared to respond to families in a professional and ethical manner (ACOG, 2007).

Surrogate childbearing is another approach to addressing the issue of infertility. Surrogate childbearing occurs when a woman agrees to become pregnant for another woman or for a couple who are usually childless. Depending on the infertile woman's or couple's needs, the surrogate may be therapeutically inseminated with the male partner's sperm or a donor's sperm, or she may receive a gamete transfer. If fertilization occurs, the woman carries the fetus to term and then releases the infant to the couple after birth.

These methods of resolving infertility raise many ethical questions, including the problem of religious objections to artificial conception, the question of who will assume financial and moral responsibility for a child born with a congenital defect, the issue of candidate selection, and the threat of genetic engineering. Other ethical questions include the following:

- What should be done with surplus fertilized oocytes?
- To whom do frozen embryos belong—parents together or separately? The hospital or infertility clinic?
- Who is liable if a woman or her offspring contracts HIV disease from donated sperm?
- Should children be told the method of their conception?

> "Our son was born after artificial insemination. Nick, my husband, was sterile because of radiation therapy, so his cousin was the donor for us. I thought that might be awkward but the whole family was so excited that there was a way to help us after Nick's battle with cancer that it has been OK. Every time we look at Vincent Joseph (he is named for his grandfathers) and see him smile, we know that we would do it again in an instant."

Embryonic Stem Cell Research

Human stem cells can be found in embryonic tissue and in the primordial germ cells of a fetus. Research has demonstrated that in tissue cultures these cells can be made to differentiate into other types of cells such as blood, nerve, or heart cells, which might then be used to treat problems such as diabetes, Parkinson and Alzheimer diseases, spinal cord injury, or metabolic disorders. The availability of specialized tissue or even organs grown from stem cells might also decrease society's dependence on donated organs for organ transplants.

Positions about embryonic stem cell research vary dramatically, from the view that any use of human embryos for research is wrong to the view that any form of embryonic stem cell research is acceptable, with a variety of other positions that fall somewhere in between these extremes. Other questions also arise: What sources of embryonic tissue are acceptable for research? Is it ever ethical to clone embryos solely for stem cell research? Is there justification for using embryos remaining after fertility treatments?

The question of how an embryo should be viewed—with status in some way as a person or in some sense as property (and, if property, whose?)—is a key question in the debate. Ethicists recognize that it is not necessary to advocate full moral status or personhood for an embryo to have significant moral qualms about the instrumental use of a human embryo in the "interests" of society. The issue of consent, which links directly to an embryo's status, also merits consideration. In truth, the ethical questions and dilemmas associated with embryonic stem cell research are staggeringly complex and require careful analysis and thoughtful dialogue.

Case Study: Cord Blood Banking

Cord Blood Banking

Cord blood, which is taken from a newborn's umbilical cord by the physician or nurse-midwife assisting with the birth, may play a role in combating leukemia, certain other cancers, metabolic disorders, and other immune and blood system disorders such as sickle cell anemia, thalassemia, and severe aplastic anemia. This is possible because cord blood, like bone marrow and embryonic tissue, contains hematopoietic stem cells, which can replace diseased cells in the affected individual. The value of bone marrow transplants has long been recognized, and a national registry of potential bone marrow donors has been established. The process of collecting bone marrow is expensive and uncomfortable, however, and the National Marrow Donor Registry often has difficulty finding a matching bone marrow donor.

Cord blood banks that store cord blood have been established in the United States. Public banks receive cord blood given on a volunteer basis and are designed to support unrelated-donor transplant programs. Private banks are for-profit entities designed primarily for families who plan to use the cord blood for the infant who provided the blood or for another family member who might need transplantation therapy in the future because of a genetic blood condition, cancer, bone marrow failure, or inborn error of metabolism, for example (ACOG, 2008).

Ethical concerns focus on the issue of confidentiality for the mother and family throughout the process; the question of ownership of the blood (donor, parents, the blood bank, or society); the concern about fair distribution of the harvested blood; and the obligations to the family that may arise if testing of the blood reveals genetic disorders or infectious diseases.

Both ACOG and the American Academy of Pediatrics (AAP) have issued statements about umbilical cord blood banking. ACOG (2008) stresses the importance of providing balanced information about the advantages and disadvantages of public vs. private banking and the need for healthcare professionals to disclose any financial interests they have in private cord blood banks.

The AAP (Lubin & Shearer, 2007) recommendations support the ACOG opinion and address other clinical considerations too. Key recommendations include:

- Parents are encouraged to bank their newborn's cord blood privately if they have an older child who has a condition that could benefit from a cord blood transfusion.
- In general, parents are encouraged to donate their newborn's cord blood to a public bank because it might help treat someone in need.
- Private cord blood banking as "insurance" against possible future personal or family need is discouraged because often the genetic traits associated with the condition that develops are present in the cord blood.
- Collection centers should test all donated cord blood for infectious and genetic disorders and should have a protocol developed for notifying families of abnormal results.
- Written consent for cord blood donation should be obtained before labor begins.

Implications for Nursing Practice

The complex ethical issues facing maternal-newborn nurses have many social, cultural, legal, and professional ramifications. Nurses, like all healthcare professionals, need to learn to anticipate ethical dilemmas, clarify their own positions and values related to the issues, understand the legal implications of the issues, and develop appropriate strategies for ethical decision making. To accomplish these tasks, they may read about bioethical issues, participate in discussion groups, or attend courses and workshops on ethical topics pertinent to their areas of practice. Most nurses develop solid skills in logical thinking and critical analysis. These skills, coupled with theoretic knowledge about ethical decision making, can serve nurses well in dealing with the many ethical dilemmas found in health care.

Statistical Data and Maternal-Infant Care

Increasingly nurses are recognizing the value and usefulness of statistics. Health-related statistics provide an objective basis for projecting patient needs, planning use of resources, and determining the effectiveness of treatment.

There are two major types of statistics: *descriptive* and *inferential. Descriptive statistics* describe or summarize a set of data. They report the facts—what is—in a concise and easily retrievable way. How the data are compiled and presented is determined by the question being asked. An example of a descriptive

statistic is the birth rate in the United States. Although no conclusion may be drawn from these statistics about why some phenomenon has occurred, they can identify certain trends and high-risk "target groups" and generate possible research questions.

Inferential statistics allow the investigator to draw conclusions or inferences about what is happening between two or more variables in a population and to suggest or refute causal relationships between them. For example, descriptive statistics reveal that the infant mortality rate in the United States has declined over the past decade. Exactly why that trend has occurred cannot be answered by simply looking at these data, however. More data and inferential statistics using smaller samples of the population of pregnant women are needed to determine whether this finding is because of earlier prenatal care, improved maternal nutrition, use of electronic fetal monitoring during labor, and/or any number of factors potentially associated with maternal-fetal survival.

Descriptive statistics are the starting point for the formation of research questions. Inferential statistics answer specific questions and generate theories to explain relationships between variables. Theory applied in nursing practice can help change the specific variables that may cause or contribute to certain health problems.

TABLE 1-1 Live Births and Birth Rates by Age, Race, and Origin of Mother: United States, 2007 (Estimated)

	2007	
AGE AND RACE AND HISPANIC ORIGIN OF MOTHER	**NUMBER**	**RATE**
All races and origins[1]		
Total[2]	4,317,119	14.3
10–14 years	6218	0.6
15–19 years	445,015	42.5
15–17 years	140,640	22.2
18–19 years	304,405	73.9
20–24 years	1,082,837	106.4
25–29 years	1,208,504	117.5
30–34 years	962,179	99.9
35–39 years	499,916	47.5
40–44 years	105,071	9.5
45–54 years[3]	7349	0.6
Non-Hispanic white[2]	2,312,473	11.5
Non-Hispanic black[2]	627,230	16.4
American Indian or Alaska Native total[4,5]	49,284	15.2
Asian or Pacific Islander total[2,5]	254,734	17.2
Hispanic[6]	1,061,970	23.3

[1]Includes origin not stated.
[2]The total number includes births to women of all ages, 10–54 years.
[3]The number of births shown is the total for women aged 45–54 years. The birth rate is computed by relating the number of births to women aged 45–54 years to women aged 45–49 years, because most of the births in this group are to women aged 45–49.
[4]Includes births to Aleuts and Eskimos.
[5]Data for persons of Hispanic origin are included in the data for each race group according to the mother's reported race.
[6]Includes all persons of Hispanic origin of any race.

This section discusses descriptive statistics that are particularly important to maternal-newborn health care. Inferences that may be drawn from these descriptive statistics are addressed as possible research questions that may help identify relevant variables.

Birth Rate

Birth rate refers to the number of live births per 1000 people. In 2007, the U.S. birth rate was 14.3 per 1000, a slight increase from the 2006 rate of 14.2. The actual number of live births rose by 1% to 4,317,119. In 2007, births rose for every race and Hispanic origin group, and the birth rate for teenagers rose 1% to 42.5 births per 1000, up from 40.5 in 2005 (Hamilton, Ventura, & Martin, 2009). Table 1-1 provides valuable information about births in the United States in 2007 by age and race of the mother.

Childbearing by unmarrried women continued to increase in 2007, reaching record highs—over 1.7 million births—an increase of 5% over 2006. In fact, 39.7% of all births were to unmarried women. Moreover, these increases occurred in all ages, races, and Hispanic-origin subgroups (Hamilton et al., 2009). The cesarean birth rate reached record levels, increasing by 2% to 31.8% of all births in 2007 (Hamilton et al., 2009). Birth rates also vary dramatically from country to country. Table 1-2 identifies the birth rates for selected countries.

- Is there an association between birth rates and changing societal values?
- Do the differences in birth rates between various age groups reflect education? Changed attitudes toward motherhood?

TABLE 1-2 Live Birth Rates and Infant Mortality Rates for Selected Countries*

COUNTRY	BIRTH RATE	INFANT MORTALITY RATE
Afghanistan	38.4	153.1
Argentina	17.9	11.4
Australia	12.8	4.8
Cambodia	25.7	54.8
Canada	10.3	5.0
China	14	20.3
Egypt	25.4	27.3
Germany	8.2	4.0
Ghana	28.7	51.2
India	21.7	50.8
Iraq	30.1	44.7
Japan	7.6	2.8
Mexico	19.7	18.4
Russia	11.1	10.6
United Kingdom	10.7	4.9
United States	14.2**	6.69**

* Based on 2009 estimates.
** Based on final data for 2006.

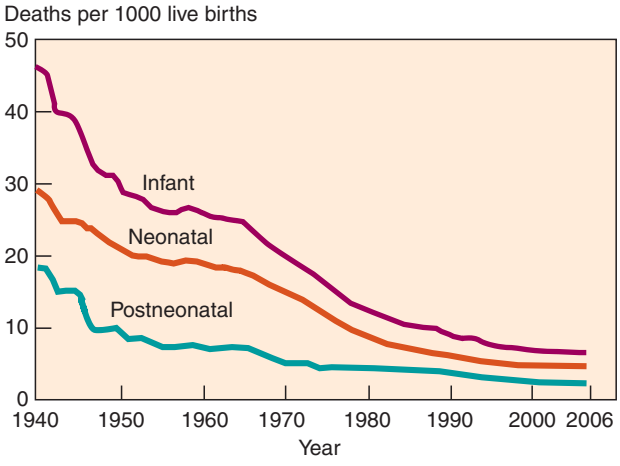
- Do the differences in birth rates among various countries reflect cultural differences? Do they represent availability of contraceptive information? Are there other factors at work?

Infant Mortality

The **infant mortality rate** is the number of deaths of infants under 1 year of age per 1000 live births in a given population. In 2003 the U.S. infant mortality rate was 6.85, a decrease over 2002. The infant mortality rate in 2006 was 6.68, a decrease of 3% from the 2005 rate of 6.87 (Mathews & McDorman, 2010). However, the infant mortality rate varied widely by race of the mother, from 5.57 for infants of white mothers to 12.9 for infants of black mothers (Mathews & McDormand, 2010). *Neonatal mortality* is the number of deaths of infants less than 28 days of age per 1000 live births. *Postneonatal mortality* refers to the number of deaths of infants between 28 days and 1 year of age. *Perinatal mortality* includes both neonatal deaths and fetal deaths per 1000 live births. (*Fetal death* is death in utero at 20 weeks' or more gestation.) Figure 1-6 ■ shows the changes in infant, neonatal, and postneonatal mortality since 1940. Figure 1-7 ■ shows the 10 leading causes of deaths of infants in the United States.

The U.S. infant mortality rate has continued to be of concern in the United States. In 2005, the United States ranked 30th in infant mortality among industrialized nations (Figure 1-8 ■). The very high percentage of preterm births in the United States



NOTE: Rates are infant (under 1 year), neonatal (under 28 days), and postneonatal (28 days–11 months) deaths per 1000 live births in specified group.

Figure 1-6 ■ Infant, neonatal, and postneonatal mortality rates in the United States from 1940 to 2006. In 2006, the infant mortality rate was 6.69, the neonatal mortality rate was 4.45, and the postneonatal mortality rate was 2.24 per 1000 live births.

Source: Heron, M., Hoyert, D. L., Murphy, S. L., Xu, J., Kochanek, K. D., & Tejada-Vera, B. (2009). Deaths: Final data for 2006. National Vital Statistic Reports, 57*(14), 13.*

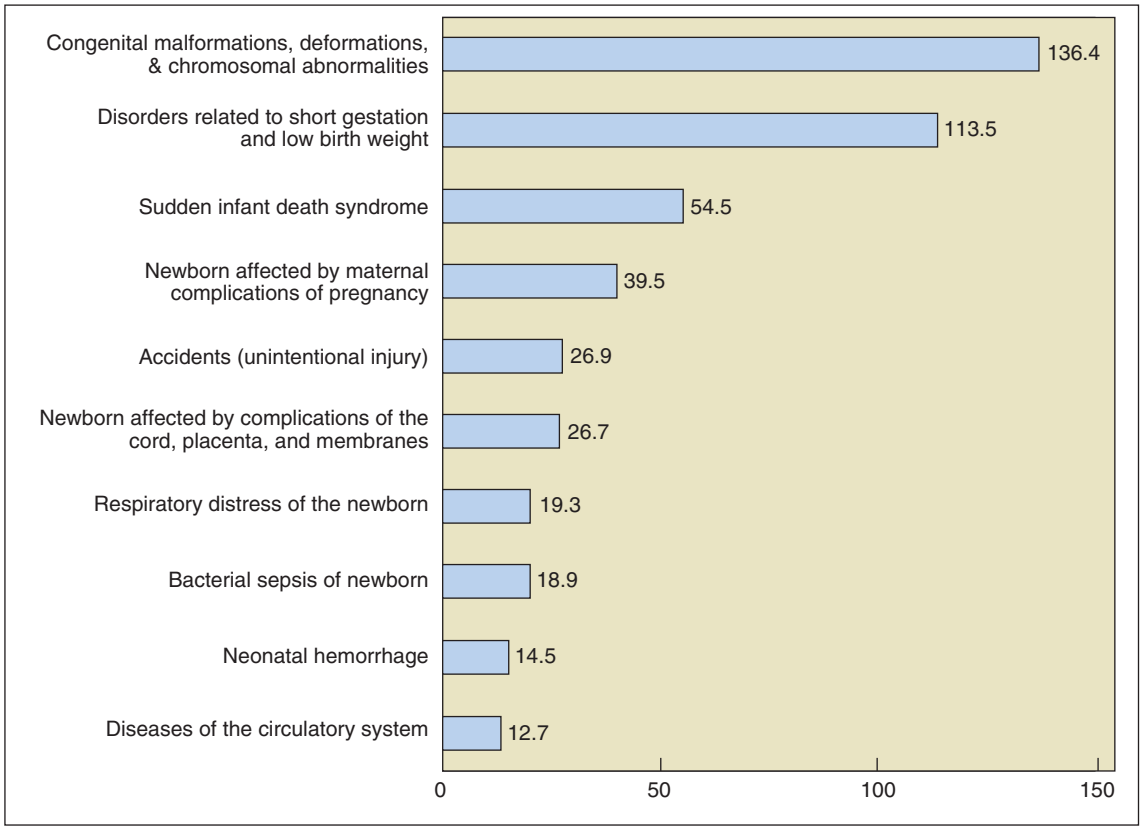


Figure 1-7 ■ Leading causes of death by mortality rate for infants in the United States, 2006.

Source: Adapted from Heron, M., Hoyert, D. L., Murphy, S. L., Xu, J., Kochanek, K. D., & Tejada-Vera, B. (2009). Deaths: Final data for 2006. National Vital Statistic Reports, 57*(14), 13.*

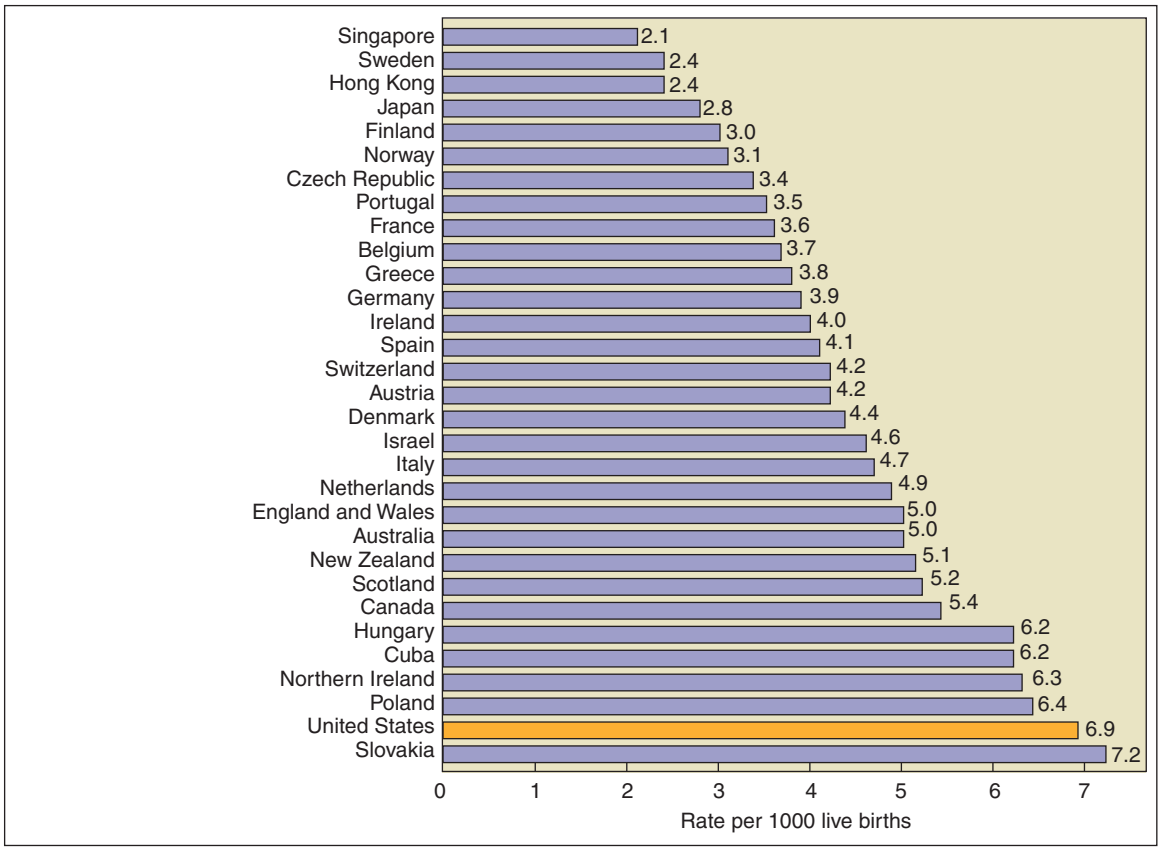

Figure 1-8 ■ Infant mortality rates for selected countries, 2005.

Source: Health, United States 2008 *in MacDorman, M. F., & Mathews, T. J. (2009). Behind international rankings of infant mortality: How the United States compares with Europe.* NCHS Data Brief, No. 23.

is the main cause of this high rate when compared to other countries (MacDorman & Mathews, 2009). While differences in reporting processes do exist, it is unlikely that these differences are the primary cause of the United States's low ranking, especially considering the fact that in 2005, 22 countries had infant mortality rates of 5.0 or less (MacDorman & Mathews, 2009). Healthcare professionals, policy makers, and the public have continued to stress the need in the United States for better prenatal care, coordination of health services, and the provision of comprehensive maternal-child services.

Table 1-2 identifies infant mortality rates for selected countries. As the data indicate, the range is dramatic among the countries listed. Unfortunately, information about birth rates and mortality rates is limited for some countries because of a lack of organized reporting mechanisms.

The information prompts questions about access to health care during pregnancy and following birth, standards of living, nutrition, sociocultural factors, and more. Additional factors affecting the infant mortality rate may be identified by considering the following research questions:

- Does infant mortality correlate with a specific maternal age?
- What are the leading causes of infant mortality in each country?
- Is there a difference in mortality rates among racial groups? If so, is it associated with the availability of prenatal care? With the educational level of the mother or father?

Maternal Mortality

The **maternal mortality rate** is the number of deaths from any cause related to or aggravated by pregnancy or its management during the pregnancy cycle (including the 42-day postpartum period) per 100,000 live births. It does not include accidental or unrelated causes. In 2006, 569 women were reported to have died from maternal cause, resulting in a maternal mortality rate of 13.3 per 100,000 live births (Heron et al., 2009).

Table 1-3 identifies the number of maternal deaths and maternal mortality rates by cause for 2006. In general, maternal mortality rates are significantly lower than they were 25 years ago. Nevertheless, worldwide, an estimated 350,000 to 500,000 women die in childbirth each year (Brooks, 2010). Six countries—India, Nigeria, Pakistan, Afghanistan, Ethiopia, and the Democratic Republic of the Congo—account for over half of these deaths (Barclay, 2010). Encouragingly, significant decreases in maternal mortality have occurred in China, Egypt, Ecuador, and Bolivia. However, in a recent study, maternal mortality rates appear to have increased in the United States, Canada, and Norway. These increases may be explained by improved determination of maternal deaths and by changes in the way late maternal deaths are included in the data (Hogan et al., 2010). Nevertheless, the U.S. maternal mortality rate of 17 per 100,000 live births in 2008 is more than double the rate in the United Kingdom, 3 times the rate in Australia, and 4 times the rate in Italy (Barclay, 2010).

TABLE 1-3 Number of Maternal Deaths and Maternal Mortality Rates for Selected Causes by Race: United States, 2006

	NUMBER				RATE			
			ALL OTHER				ALL OTHER	
	ALL RACES	WHITE	TOTAL	BLACK	ALL RACES	WHITE	TOTAL	BLACK
Maternal causes	569	313	256	218	13.31	9.5	26.8	32.7
Pregnancy with abortive outcome	26	10	16	12	0.6	*	*	*
Ectopic pregnancy	15	5	10	10	*	*	*	*
Spontaneous abortion	5	3	2	1	*	*	*	*
Medical abortion	-	-	-	-	*	*	*	*
Other and unspecified pregnancy with abortive outcome	6	2	4	1	*	*	*	*
Other direct obstetric causes	394	207	187	160	9.2	6.3	19.6	24
Eclampsia and pre-eclampsia	54	30	24	22	1.3	0.9	4.1	3.3
Hemorrhage of pregnancy and childbirth and placenta previa	39	21	18	12	0.9	0.6	*	*
Complications predominately related to the puerperium	109	54	55	47	2.6	1.6	5.8	7.1
Obstetric embolism	41	21	20	15	1.0	0.6	2.1	*
Other complications predominately related to the puerperium	68	33	35	32	1.6	1.0	3.7	4.6
All other direct obstetric causes	192	102	90	79	4.5	3.1	9.4	11.9
Obstetric death of unspecified cause	22	17	6	5	0.5	*	*	*
Indirect obstetric causes	126	79	47	41	3.0	2.4	4.9	6.2

*Figure does not meet standards of reliability followed by the National Center for Health Statistics.
Source: Heron, M., Hoyert, D. L., Murphy, S. L., Xu, J., Kochanek, K. D., & Tejada-Vera, B. (2009). Deaths: Final data for 2006. National Vital Statistics Reports, 57*(14), 1–135.*

Factors influencing the decrease in maternal mortality include the increased use of hospitals and specialized healthcare personnel by antepartum, intrapartum, and postpartum maternity patients; the establishment of care centers for high-risk mothers and infants; the prevention and control of infection with antibiotics and improved techniques; the availability of blood and blood products for transfusions; and the lowered rates of anesthesia-related deaths.

Additional factors to consider may be identified by asking the following research questions:

- Is there a correlation between maternal mortality and age?
- Is there a correlation with availability of health care? Economic status?

Implications for Nursing Practice

Nurses can use statistics in a number of ways. For example, statistical data may be used to:

- Determine populations at risk.
- Assess the relationship between specific factors.
- Help establish databases for specific patient populations.
- Determine the levels of care needed by particular patient populations.
- Evaluate the success of specific nursing interventions.
- Determine priorities in caseloads.
- Estimate staffing and equipment needs of hospital units and clinics.

Statistical information is available through many sources, including professional literature; state and city health departments; vital statistics sections of private, county, state, and federal agencies; special programs or agencies (family-planning and similar agencies); and demographic profiles of specific geographic areas. Most of these sources are accessible via the Internet. Nurses who use this information will be better prepared to promote the health needs of maternal-newborn patients and their families.

Evidence-Based Practice in Maternal-Child Nursing

Evidence-based practice—that is, nursing care in which all interventions are supported by current, valid research or other forms of evidence such as committee opinions or task force recommendations—is emerging as a force in health care. It provides a useful approach to problem solving/decision making and to self-directed, patient-centered, lifelong learning. Evidence-based practice builds on the actions necessary to transform research findings into clinical practice by also considering other forms of evidence that can be useful in making clinical practice decisions. These other forms of evidence may include, for example, statistical data, quality improvement measurements, risk management measures, and information from support services such as infection control.

As clinicians, nurses need to meet three basic competencies related to evidence-based practice:

1. To recognize which clinical practices are supported by sound evidence, which practices have conflicting findings as to their effect on patient outcomes, and which practices have no evidence to support their use

2. To use data in their clinical work to evaluate outcomes of care
3. To appraise and integrate scientific bases into practice

Unfortunately, some agencies and clinical units where nurses practice still operate in the old style, which often generates conflict for nurses who recognize the need for more responsible clinical practice. In truth, market pressures are forcing nurses and other healthcare providers to evaluate routines to improve efficiencies and provide better outcomes for patients.

Nurses need to know what data are being tracked where they work and how care practices and outcomes are improved as a result of quality improvement initiatives. However, there is more to evidence-based practice than simply knowing what is being tracked and how the results are being used. Competent, effective nurses learn to question the very basis of their clinical work.

Throughout this text we have provided *snapshots* of evidence-based practice related to childbearing women, children, and families in the Research Evidence in Practice features, such as the one on page 5. We believe that these snapshots will help you understand the concept more clearly. We also expect that these examples may challenge you to question the usefulness of some of the routine care you observe in clinical practice. That is the impact of evidence-based practice—it moves clinicians beyond practices of habit and opinion to practices based on reliable, valid, current science.

Nursing Research

Research is vital to expanding the science of nursing, fostering evidence-based practice, and improving patient care. Research also plays an important role in advancing the profession of nursing. For example, nursing research can help determine the psychosocial and physical risks and benefits of both nursing and medical interventions.

The gap between research and practice is being narrowed by the publication of research findings in popular nursing journals, the establishment of departments of nursing research in hospitals, and collaborative research efforts by nurse researchers and clinical practitioners. Interdisciplinary research between nurses and other healthcare professionals is also becoming more common. This ever-increasing recognition of the value of nursing research is important because well-done research supports the goals of evidence-based practice. To make this link clear, most chapters of this text include Research Evidence in Practice.

Clinical Pathways and Nursing Care Plans

One result of nursing research into the nursing process has been the creation of clinical pathways. *Clinical pathways* specify essential nursing activities and provide basic guidelines about expected outcomes at specified time intervals. These guidelines are research based and enable the nurse to determine whether a patient's responses meet expected norms at any given time. In the text, we have provided sample clinical pathways for a woman experiencing a normal vaginal birth, for the normal newborn, and for a woman in the postpartal period.

Nursing care plans, which use the nursing process as an organizing framework, are also invaluable in planning and organizing care. Care plans are especially valuable for nursing students and novice nurses. To help organize care, this text also provides several examples of nursing care plans such as those found in chapter 19 ∞.

FOCUS YOUR STUDY

- Many nurses working with childbearing families are expert practitioners who are able to serve as role models for nurses who have not yet attained the same level of competence.
- Contemporary childbirth is family centered, offers choices about birth, and recognizes the needs of siblings and other family members.
- The self-care movement, which emerged in the late 1960s, emphasizes personal health goals, a holistic approach, and preventive care.
- The U.S. healthcare system is facing a variety of challenges including the high cost of health care and the need for cost containment while retaining quality; the large numbers of uninsured and underinsured people; high infant mortality rates as compared with other industrialized nations; and a high incidence of poverty, especially among children and women-headed households.
- The nurse who provides culturally competent care recognizes the importance of the childbearing family's

value system, acknowledges that differences occur among people, and seeks to respect and respond to ethnic diversity in a way that leads to mutually desirable outcomes.

- A nurse must practice within the scope of practice or be open to the accusation of practicing medicine without a license. The standard of care against which individual nursing practice is compared is that of a reasonably prudent nurse.
- Nursing standards provide information and guidelines for nurses in their own practice, in developing policies and protocols in healthcare settings, and in directing the development of quality nursing care.
- Informed consent—based on knowledge of a procedure and its benefits, risks, and alternatives—must be secured before providing treatment.
- State constitutions, statutes, and common law protect the right to privacy.
- Maternal-fetal conflict may arise when the fetus is viewed as a person of equal rights to those of the mother's and external agents' attempt to force the mother to accept a therapy she wishes to refuse, or similarly attempt to restrict a mother's actions to support the well-being of the fetus.
- Abortion can be performed until the age of viability. Caregivers have the right to refuse to perform an abortion or assist with the procedure.
- A variety of procedures are available to help infertile couples achieve a pregnancy. However, some of these procedures provoke serious ethical dilemmas.
- Embryonic stem cell research using human stem cells obtained from a human embryo is marked by controversy. On the one hand, it raises the possibility of treatment for a variety of major diseases such as diabetes, Parkinson disease, and Alzheimer disease. On the other hand, ethicists question the ethical implications of using embryonic tissue—especially tissue obtained specifically for stem cell research.
- Cord blood banking provides the opportunity to make stem cells available to treat a variety of cancers and blood system disorders. Its growing popularity has revealed several ethical issues, such as: Who owns the blood? How will informed consent be obtained and by whom? How will confidentiality be ensured? How can the harvested blood be distributed fairly, so that it is available to individuals from all races, ethnic groups, income levels, and so forth?
- Descriptive statistics describe or summarize a set of data. Inferential statistics allow the investigator to draw conclusions about what is happening between two or more variables in a population.
- Evidence-based practice—that is, nursing care in which all interventions are supported by current, valid research evidence—is emerging as a positive force in health care.
- Nursing research plays a vital role in adding to the nursing knowledge base, expanding clinical practice, and expanding nursing theory.

CRITICAL THINKING IN ACTION

You are working as a prenatal nurse in a local clinic. Before entering a patient's room, you review the chart for pertinent information such as cultural background, significant family members, weeks of gestation, test results, birth plan, and her education for health promotion. You greet each patient and her family members by name and ask how they are coping with the pregnancy. Depending on the trimester of the pregnancy, you review the discomforts or concerns of the mother/family and what they may expect. You examine the mother, including fundal height, fetal heart rate and fetal position if appropriate, maternal blood pressure, weight gain, and urine analysis. With each patient, you discuss the community resources available such as prenatal classes, lactation consultants, and prenatal exercise/yoga classes. Based upon the information you obtain, you might refer the mother to social services or the WIC program as appropriate. At the end of the clinic session, you review the patients with the collaborating physician.

1. How would you define the terms *family* and *family-centered care?*
2. Describe how the nursing process provides the framework for the delivery of direct nursing care.
3. How would you describe the concept of community-based care?
4. How would you describe culturally competent care?

CHAPTER 2

Care of the Family in a Culturally Diverse Society

I can't imagine going through pregnancy, birth, or those initial few weeks after my daughter was born without my family. My brother called regularly throughout my pregnancy to check on me. Dad gave me pep talks on eating right and taking care of myself. My husband and my mom were both with me during my labor and my unexpected cesarean birth. After Rosario was born, my husband accompanied our new daughter to the nursery and mom stayed with me, talking and holding my hand. What a difference a family can make.

LEARNING OUTCOMES

1. Explore factors that influence the values, decision making, and roles within the family unit.
2. Discuss employment, marital, and economic trends affecting the contemporary family.
3. Distinguish among different types of families.
4. Explain major developmental tasks to be completed by the childbearing family.
5. Examine the advantages of using a family assessment tool.
6. Discuss the impact of culture in caring for the childbearing family.
7. Analyze prevalent cultural norms related to childbearing and childrearing.
8. Explain the importance of cultural competency in providing nursing care.
9. Discuss the use of a cultural assessment tool as a means of providing culturally sensitive nursing care.
10. Examine the key considerations in providing spiritually sensitive nursing care.

KEY TERMS

Acculturation *33*
Assimilation *33*
Cultural competence *37*
Culture *33*
Ethnicity *33*
Ethnocentrism *37*
Family *25*
Family assessment *32*
Family development *29*
Family power *25*
Family roles *25*
Family values *25*
Religion *41*
Spirituality *41*
Taboos *35*

Although a woman may arrive for her healthcare appointment physically alone, in another sense, she is always accompanied by her family. Her parents, partner, spouse, or in-laws may accompany her in the form of internalized messages about her body, contraception, sex, or childbearing or in the form of their expectations for her behavior. In addition, her family's culture and religious beliefs will influence her healthcare practices, decisions, and needs. Thus, a nurse may provide expert teaching about condom use to an adolescent, but the teaching may not be put into practice because the patient's partner or family objects. Or a nurse may encourage a pregnant woman to increase her consumption of cow's milk, but a religious proscription against consuming animal products may prohibit this behavior. The goal of effective, holistic nursing care requires nurses to recognize that their patients' values, behaviors, decisions, and needs do not exist in a vacuum; instead, nurses must actively seek to learn about and care for the entire childbearing family.

In this chapter, we provide a perspective on the childbearing family in a culturally diverse society. We begin by discussing family values, power, and roles as well as key social changes affecting the contemporary family. We then identify a variety of different family types the nurse is likely to encounter, and explore the developmental tasks of these varied families. Because families cannot be considered in isolation from their culture, we introduce several concepts essential to culturally competent nursing care. We close the chapter with a brief look at the influence of a family's religious beliefs on health outcomes, and identify key considerations in providing spiritually sensitive nursing care.

Defining Family

There are multiple definitions of family found in the literature. For example, according to McGrath and Edwards (2009), geneticists or clinicians would base their definition of family on biology, whereas individuals might include those linked socially in their definition. The U.S. Census Bureau (2008a) defines **family** in more traditional terms as "a group of two people or more (one of whom is the householder) related by birth, marriage, adoption and residing together: all such people (including related subfamily members) are considered as members of one family."

Family Values

Family values are values that guide behavior and interactions within society and their own family units. These values are greatly influenced by external factors including cultural background, social norms, education, environmental influences, socioeconomic status, and beliefs held by peers, coworkers, political and community leaders, and other individuals outside of the family unit. Because of the influence of these external factors, a family's values may change significantly over the years.

Family Power and Decision Making

Individuals act in accordance with a set of internalized norms and values that are learned primarily through socialization (Kaakinen, Gedaly-Duff, Coehlo, et al., 2010). Within each family, there is an individual or group who possesses **family power**; that is, the potential or actual ability to change the behavior of other family members. This individual or group may affect how a patient responds to a healthcare provider, a diagnosis, treatments, or health teaching. Research has shown that many families make health-related decisions only with the aid of other family members. For example, in the Korean culture, in which elders are highly respected and play a key role in family matters, family power may rest with the grandfather. If the son wanted to make a health-related change in the family's diet, for example, he would first seek the advice and approval of his grandfather. Similarly, many Chinese identify themselves in relation to other members of the family and believe that personal independence is not as important. Thus, a Chinese patient may avoid taking action regarding a health matter unless a family leader gives permission (Galanti, 2008).

In many traditional families, the father figure is the decision maker. In traditional Cuban culture, for example, the father may be assertive and dominant and is critical to all family decisions (Galanti, 2008). In contrast, the mother typically remains at home, passive and dependent. However, Cubans in the United States have become much more egalitarian because women are usually the first ones able to find jobs and contribute to their families. Thus, among Cubans who have assimilated, one may find equal decision-making power.

In many immigrant families, the child is first to learn the new language. In families in which the father is considered the power holder, this situation can cause problems if the family perceives that the healthcare provider is relating only to the child. They may feel that their child is being placed in a superior position, which may be unacceptable to them. In most cases, children acculturate more rapidly than their parents, which can lead to stress within the family unit (Wagner et al., 2008).

Family Roles

Family roles are homogeneous sets of behaviors that are normatively defined and expected of an occupant of a given social position. Roles vary depending on age, position within the family, conflict within the family, stressors, cultural backgrounds, health status of family members, and demographic trends. However, within each family, roles commonly encountered include breadwinner, homemaker, nurturer, social planner, and peacemaker. Although roles are sometimes perceived to be gender specific, they are more accurately assigned to the family member who performs that specific function. In the majority of U.S. households in the 1950s, a male was the sole breadwinner and a female performed all homemaker functions. In contemporary society, these roles are often shared. For example, both parents may be employed and may participate equally in the care of the children. Segregated roles are more evident in certain cultures where roles are defined more sharply based on gender.

Any one individual within a family may have two or more roles. In nuclear families, roles are typically paired and consist of father-husband, wife-mother, son-brother, and so forth. In extended families the number of paired roles increases, whereas in single-parent families the numbers are less.

Increasingly important in the contemporary U.S. family is the role of the grandparent. High adolescent pregnancy rates have created a sizable population of young grandparents (as young as the 30s), and increased life expectancy rates have created a sizable population of great-grandparents. Grandparents vary in how they express their role. Role functions may include: (1) witness who is simply present for the grandchildren, (2) protector who provides care and ensures safety when needed, (3) peacemaker who helps resolve conflicts between parents and children, and (4) active participant who maintains involvement in family life in the past, present, and future.

Grandparents can offer a great deal to children and provide substantial support and advice to parents (Figure 2-1 ■). Often grandparents are able to spend more quality time with grandchildren than they did with their own children. Many grandparents are retired and use this opportunity to build lasting bonds with grandchildren. Although extended families are often geographically separated, many grandparents have identified alternative means to stay connected with grandchildren when frequent visits are not possible. These alternatives include phone calls; emails; and letters as well as sharing journals, photos, and videotapes.

> "Computers, emails, and cell phones were not the kinds of communication I grew up using; however, I decided to learn so that I could communicate with my grandchildren who don't live close by. My grandchildren send me jokes and digital photos, and it has helped me to feel like I am more a part of their lives. They think I am "cool" because I have learned to use their technology. We exchange cards electronically now for many special occasions, and we communicate much more often than we did before I knew how to use my computer. It sure doesn't replace being together face-to-face, but it does help me feel like I know them better!"

Figure 2-1 ■ Grandparents can offer nurturing and guidance to their grandchildren, not to mention lots of fun.

Changes Affecting the Contemporary Family

The contemporary family has changed dramatically from the family unit of the 1950s, which typically consisted of a working father and a stay-at-home mother who cared for the children and ran the family home (Figure 2-2 ■). Affecting the contemporary family are employment trends, changes in marriage rates, and economic trends.

Changes in the number and types of households are influenced by patterns of population growth, shifts in the age composition of the population, and the decisions individuals make about their living arrangements. Demographic trends in marriage, cohabitation, divorce, fertility, and mortality also affect family and household composition. Moreover, shifts in social norms, values, laws, and the economy and improvements in health care also influence how people organize their lives. Individual decisions produce aggregate societal changes in household and family composition (U.S. Census Bureau, 2009).

Today, the mother may be working outside the home and the father may be the stay-at-home parent. In 2007, the United States had an estimated 5.5 million "stay-at-home" parents: 5.3 million mothers and 140,000 fathers (U.S. Census Bureau News, 2009).

Employment Trends

Employment trends have changed with the shift from a male-dominated workforce to a mixed male-female workforce. Today, the majority of households consist of dual-earner families in which both parents have employment outside of the home. Dual-earner families may have different needs than traditional families. For example, when a child becomes ill in a dual-earner family, the parents must decide who will take off work to care for the child. In traditional families, the mother would care for the child and work stresses from illness-related absences would not be a concern.

Figure 2-2 ■ The traditional family of the mid-20th century consisted of a father who worked outside of the home, a mother who performed all homemaking and childrearing functions, and one or more children.

Changes in Marriage Rates

Since World War II, there has been a consistent decline in marriage rates. According to the U.S. Census Bureau News (2008b), 68% of households in 2007 were family households, compared with 81% in 1970. The area with the highest percentage of single-parent households was the District of Columbia (54%), while the state with the lowest percentage of single-parent households was Utah (15%). The proportion of one-person households increased by 10%—from 17% to 27%—between 1970 and 2007. Households with children make up only one third of all U.S. households. It is interesting to note the decline in the proportion of married-couple households with their own children—from 40% of all households in 1970 to 23% in 2007. In contrast, the proportion of households that were made up of married couples without children dropped only slightly over the same time period—from 30% in 1970 to 28% in 2007. From 1950 to 2007, the proportion of family households with children that were maintained by a married couple decreased from 93% to 71%. There was a corresponding increase in the percentage of family households with children that were maintained by a mother who was a single parent (6% to 23%) and by a father who was a single parent (1% to 5%).

These changes reflect changing societal norms including a delay in the median age at first marriage. The median age for a man's first marriage was 27.7 years in 2007, up from 26.1 in 1990. The median age for a woman's first marriage was 26.0 years in 2007, up from 23.9 in 1990. According to the Centers for Disease Control and Prevention (CDC) (National Center for Health Statistics, Division of Vital Statistics, 2009), additional societal changes include an increase in the rate of nonmarital births, up 26% from 2002 to 2007, and a higher percentage of marriages that result in divorce.

Along with the high proportion of single-parent families, there is also a higher proportion of never-married individuals in the United States than ever before, and those who do marry tend to do so at a later age than in the past. A combination of factors has led to delayed childbearing (see chapter 8 ∞). There is also a growing trend for women to remain childless. The U.S. Census Bureau News report on fertility (2008) shows that 20% of women ages 40 to 44 were childless in 2006, twice as high as the level in 1980. American women spend fewer childbearing years in marriage, which increases the likelihood of nonmarital childbearing.

Other trends in the United States include increasing acceptance of single women giving birth. In 1950, 3% of births were to unmarried women. Today, the National Center for Health Statistics (2009) reported almost 30% of all births are to unmarried women. While this trend is increasing in the United States, in some cultures an unmarried woman giving birth is viewed negatively. We discuss cultural views on birth outside of marriage later in this chapter.

Economic Trends

Changes in income levels have directly affected families. Families who experienced the most economic growth had two wage earners and higher educational preparation. Although family median income levels fell slightly, between 2007 and 2008, income levels have continued to rise since 2001; unemployment statistics, however, have been on the rise since 2009.

Types of Families

Various types of families—both traditional and nontraditional—exist in contemporary society.

Traditional Nuclear Family

The *traditional nuclear family* consists of a husband provider, a wife who stays home, and children. Although the traditional nuclear family was once the norm in the United States, it is no longer the most common type of family. It has become a demographic minority as those in the United States and many cultures around the world redefine what family is.

Dual-Career/Dual-Earner Family

The *dual-career/dual-earner family* is now considered the norm in modern U.S. society. Today, two thirds of all two-parent families have both parents working. Although many women work outside the home because of financial necessity, other women work either full or part time out of personal choice. Dual-career/dual-earner families have specific challenges. Because both parents are working, child care, household chores, and spending time with other family members are priorities that need to be addressed.

Childless or Childfree Family

A growing trend exists for couples to remain childless or childfree (Figure 2-3 ■). As many as 10% of couples experience infertility problems and are considered to be childless, while another 6.5% of married couples are voluntarily without children and consider themselves to be childfree. This trend is continuing to grow with the increased opportunities available to women in the workplace, delayed marriage, availability of contraceptives to prevent unwanted pregnancy, and wider acceptance of women choosing not to become mothers.

Extended Family

Extended families consist of a couple who shares household responsibilities, chores, and expenses with parents, siblings, or other relatives. Multigenerational family living arrangements

Figure 2-3 ■ Today, 5% of married couples voluntarily choose to remain childless.

Source: Michael Keller/CORBIS.

Figure 2-4 ■ In an extended kin network family, two nuclear families live in close proximity to each other and share responsibilities and resources.

Source: Zigy Kaluzny/Getty Images, Inc.—Hulton Archive photos.

are most common in non-U.S. cultures and in working-class families. Children are reared by their parents and other relatives. Extended families are also common when an elderly or ill relative requires care by the younger family members.

Extended Kin Network Family

An *extended kin network family* is a specific form of an extended family in which two nuclear families of primary or unmarried kin live in close proximity to each other. The family shares a social support network, chores, goods, and services. This type of family model is common in the Latino community (Figure 2-4 ■).

Single-Parent Family

Single-parent families are headed by only one parent (Figure 2-5 ■). While rare in the past, in the year 2006, there were 13 million one-parent families in the United States, about one third of all families. These consisted of 10.4 million single-mother families and 2.5 million single-father families (Pan, 2008).

In the traditional single-parent family the head of the household is widowed, divorced, abandoned, or separated. In the nontraditional single-parent family the head of the household, most often the mother, was never married. Single-parent families often face difficulties because the sole parent may lack social and emotional support, need assistance with childrearing issues, and face financial strain. Mothers who have not married tend to have more financial difficulties, less educational achievement, and are younger in age than those who are divorced.

Stepparent Family

Stepfamilies include a biologic parent with children and a new spouse who may or may not have children. These families are also known as *remarried families, reconstituted families,* or *blended families.* It is estimated that 75% of all divorced individuals eventually remarry. Sixty-five percent of these remarriages involve children from a prior marriage (Stewart, 2007).

Stepfamily models have both strengths and weaknesses. Although marriage is often a new opportunity for success in a marital relationship for the parents, the relationship between stepparents and stepchildren can be strained. Stresses can include discipline issues, adjustment problems, role ambiguity, strain with the other biologic parent, and communication issues. Although stepfamilies may have fewer financial issues and may actually offer the child a new support person and role model, open communication is imperative to ensure a smooth transition.

Figure 2-5 ■ Single-parent families account for nearly one third of all U.S. families.

Source: © Joyce Choo/CORBIS. All Rights Reserved.

Binuclear Family

A *binuclear family* is a post-divorced family in which the biologic children are members of two nuclear households, both that of the father and that of the mother. The children alternate between the two homes, typically spending a week with the father and a week with the mother. This is also called *coparenting* and involves joint custody. Legally, *joint custody* refers to situations in which both parents have equal responsibility and legal rights, regardless of where the children live. Although this type of family represents a small number as yet, there has been an increase in this type of household as fathers assume a more active role in parenting. The increased recognition of the importance of having both a maternal and paternal presence has encouraged more parents to actively raise their children together, regardless of their relationship with each other. The benefits of a binuclear family include the ability to have both the mother and father involved in the child's upbringing, a model for effective communication (in a successful family model), and additional support and role models from extended family members.

Nonmarital Heterosexual Cohabitating Family

A *nonmarital heterosexual cohabitating family* is a heterosexual couple who may or may not have children and live together outside of marriage. This may include never-married individuals as well as divorced or widowed persons. Some individuals prefer this family model for personal reasons, whereas others do so for financial reasons or to seek companionship. For example, a widow may fear losing her pension if she remarries, or an individual who owns significant assets may fear losing these assets to a spouse, especially if residing in a community-property state.

CLINICAL TIP

It is important to establish which parent has legal custody, current visitation policies, and other legal variables (restraining orders, supervised visitation, etc.) when communicating information to parents about their children. Certain legal issues may prohibit the nurse from sharing some information with the noncustodial parent.

Gay and Lesbian Families

Gay and *lesbian families* include those in which two or more people who share a same-sex orientation live together (with or without children) as well as families consisting of a gay or lesbian single parent rearing a child (Figure 2-6 ■). The number of gay and lesbian families is underreported. The 2000 census was the first census to record unmarried same sex partners living together. There were a recorded 601,209 lesbian and gay families, but it is unknown how many of those households had minor children living with them. These numbers are said to be underreported also (Smith & Gates, 2009).

Small studies have evaluated children raised by gay and lesbian couples and have found that they show no significant differences from children raised in other types of families. These children get along with their parents and peers the same as children raised in heterosexual households. Children raised in gay or lesbian families may face unique issues in interacting with peers and in revealing their parents' sexual orientation.

Figure 2-6 ■ Some gay and lesbian couples choose to adopt children in need of loving homes.

Contemporary Family Development Frameworks

Family development refers to the dynamics or changes that families experience over time. It includes relationships, communication patterns, roles, and changes in interactions. Although each family is unique, the members must go through a set of fairly predictable changes. The amount of time in each stage and the duration between stages vary within each family unit.

Multiple family models and frameworks have been proposed over the years to facilitate an understanding of the complexities of family development. These developmental frameworks observe a family's progression over time by identifying specific stages in family life. Models, primarily based on the classic traditional work of Duvall (1977) and Duvall and Miller (1985), have embraced the trends and changes of contemporary society and family life. Duvall developed an eight-stage family life cycle that describes the developmental process that each family encounters. This model is based on a nuclear family (Table 2-1). The oldest child serves as a marker for the family's developmental stage except in the last two stages when the children are no longer present. Couples with more than one child may be in overlapping stages with developmental advances occurring simultaneously.

Model of the Childbearing Family

Multiple tasks exist for the childbearing family. The couple must first arrange the home to meet the needs of the newborn. This entails preparing for the infant by providing a safe environment; a safe, clean place to sleep; and appropriate clothing and supplies.

At the time of birth of the first child, the childbearing family will engage in behaviors aimed at identifying responsibility and accountability for the newborn. Couples are rapidly faced with the realization that infants require 24-hour care. Although fathers are taking a more active role in childrearing, the mother is frequently the primary care provider, especially if she is breastfeeding. Although a breast pump can be used and milk can be given by bottle, the breastfeeding mother still assumes the majority of the feeding responsibilities. The father may assume other household tasks or other baby care activities, such as changing, bathing, and putting the infant down to sleep. Many facilities are now offering special classes just for fathers that help them learn to care for their infants. During the early stages, new roles will be identified as couples strive to establish a daily routine that includes the new family member.

Another task of the couple in a childbearing family is reestablishing a satisfying sexual relationship. Nurses can play an active role in teaching couples about normal changes during this period of family life. For example, in the postpartum period, sexual activity typically declines or ceases. The parents are transitioning to new roles, especially the mother. Fatigue is common. Women may also feel discomfort because of the birth and may fear pain with resumption of sexual intercourse. Reduced desire and vaginal

TABLE 2-1 The Traditional Family Life-Cycle Stages and Developmental Tasks

Stage I	Married couple	Establishing relationship as a married couple: blending of individual needs, developing conflict-and-resolution approaches, communication patterns, and intimacy patterns.
Stage II	Childbearing families with infants	Adjusting to pregnancy and then infant; adjusting to new roles as mother and father; maintaining couple bond and intimacy.
Stage III	Families with preschool children	Understanding normal growth and development; adjusting to different temperaments and styles of children if more than one child in family; coping with energy depletion; maintaining couple bond and intimacy.
Stage IV	Families with school-age children	Working out authority and socialization roles with school; supporting children in outside interests and needs; determining disciplinary actions and family rules and roles.
Stage V	Families with adolescents	Allowing adolescents to establish their own identities and still be part of family; thinking about the future, education, jobs, working; increasing roles of adolescents in family, cooking, repairs, and power base.
Stage VI	Families launching young adults	After member moves out, reallocating roles, space, power, and communication; maintaining supportive home base; maintaining parental couple intimacy and relationship.
Stage VII	Middle-aged parents	Refocusing on marriage relationship; ensuring security after retirement; maintaining kinship ties.
Stage VIII	Aging families	Adjusting to retirement, grandparent roles, death of spouse, and living alone.

Source: Duvall, Marriage & Family Development, *Table "The Traditional Family Life-Cycle Stages and Development Tasks," © 1984 Harper & Row Publishing, Inc. Reproduced by permission of Pearson Education, Inc.*

dryness due to low estrogen levels are especially common in breastfeeding women. Counseling can provide the couple with reassurance that these changes are a common part of this developmental stage.

Couples need to communicate effectively and share thoughts and feelings as they adjust to their new roles. Fathers may feel isolated or "left out" as the mother embraces her new role. New mothers may feel overwhelmed with the responsibility of caring for an infant when alone. Even dual-career families typically have a transition period in which the mother is at home caring for the newborn and the father is working. For some women who previously worked full-time, being at home may cause feelings of isolation.

> "I thought I would love being at home with my beautiful new son. It wasn't that I didn't love him and want to be with him, I just felt like I was losing part of myself. I wasn't me anymore, and I missed talking with other adults and working. I felt tremendously guilty when I returned to work at 3 months; however, it made my time with him so much more special, and I regained my self-confidence and felt like a real person again."

As the new family adapts to changing roles and responsibilities, the roles of other family members also emerge. Some extended families take an active role, whereas others may be more passive. Family members frequently provide guidance, advice, and assistance with child care. Both sets of grandparents may have strong beliefs about childrearing and may attempt to promote their own beliefs and rituals. Couples must effectively communicate with each other and other family members to avoid conflict. Although both families may want their traditions followed in terms of childrearing, the couple may wish to develop new traditions and rituals within their own family unit.

Along with changes in family relationships, the childbearing family may also experience changes in personal relationships and outside activities. After the birth of an infant, couples are typically more involved with their home life, may stay home more often, and may engage in different activities. Many women, especially women who formerly worked outside of the home, may feel like they have less in common with previous coworkers or friends who do not have children. This may lead to new friendships with other families who have more in common with the new family unit.

> "Allie and I met in high school, and from then on, we were inseparable. Even after I got married, we stayed close, going out to lunch or shopping together every couple of weeks, and talking on the phone every few days. When she found out I was pregnant, she threw a surprise shower for me, but as my due date approached, we started to drift apart. Since my daughter's birth, we've gotten together just once. Allie says she feels excluded and that all I ever talk about is the baby. I guess she's right—my daughter is the center of my world now, so it's hard to talk about anything else. I haven't seen Allie for several months now. It makes me sad when I think about it."

Childbearing families face multiple changes and challenges as they embark into new parenthood. The nurse can assist the childbearing family by providing teaching about family-planning issues, infant care and appropriate development, and safety concerns. The nurse can also offer guidance to the couple as they transition into parenthood by identifying interventions that can assist in meeting the emotional and physical needs of caring for a newborn. The nurse can provide support by actively listening as the couple expresses feelings related to current role transitions and changes in personal and family relationships.

Resources can be provided to the new parents that will enable them to establish new relationships within their community.

Model Incorporating the Unattached Young Adult

Other models have been created to encompass the changes in contemporary families. For instance, Carter and McGoldrick (2005) modified the Duvall (1977) model to include the unattached young adult (Carter, 2010). This stage begins when the young adult leaves the family home and becomes financially independent, and lasts throughout young adulthood as long as the individual remains unmarried. Developmental tasks in this stage include differentiating self from the family unit, developing intimate peer relationships, and establishing a career and financial independence.

Because the median age at first marriage continues to rise (27.6 years for men and 26 years for women in 2007), it is important to include the unattached young adult in family models. Due to this increased age at first marriage, it is less common for adolescents to go directly from their parental home to a marital relationship. However, there is also a trend, perhaps due to economic factors, for young adults to reside with their parents well into their 20s. This is especially true for young men.

TABLE 2-2 Stages in Divorce and Postdivorce

STAGE	ISSUES
Divorce	
I. Decision to divorce	Accepting responsibility/part of responsibility for failed marriage.
II. Planning the breakup	Collaboratively working to resolve marital issues: financial, child care/custody; communicating dissolution of marriage to relatives and friends.
III. Separation	Adapting to loss of previously established family unit; reorganizing relationships with spouse and children; restructuring finances; adapting to living apart; addressing issues related to attachment to spouse; maintaining bonds with extended family and spouse's extended family.
IV. Divorce	Grieving related to loss of prior family unit; accepting that the marriage is over; retrieving positive aspects of marriage (hopes, memories, dreams, expectations); overcoming negative feelings (anger, guilt, hurt, disappointment); maintaining relationships with extended family members.
Postdivorce	
I. Single parent (custodial)	Dealing with issues related to visitation and custody; rebuilding social relationships; ensuring financial stability.
II. Single parent (noncustodial)	Continuing parenting role; identifying new means to relate to children; facilitating relationship between ex-spouse and children; providing support with childrearing decisions; providing financial support to ex-spouse for children; establishing new social relationships.

Model Incorporating Divorce and Remarriage

Carter and McGoldrick (2005) devised another developmental model to describe issues encountered in undergoing divorce and in postdivorce (Carter, 2010). See Table 2-2. Both emotional and developmental issues are encountered as families dissolve during the divorce process. Family members not only mourn the loss of a two-parent family, they also must adjust to a single-parent family model. Child visitation, financial issues, guilt, and attachment difficulties all play a major role in the changing family dynamics. Remarriage, which is becoming increasingly common, is another transitional stage in which family members must adjust to new roles and expectations (Table 2-3).

Model of the Lesbian or Gay Family

Lesbian or gay families face unique challenges in completing their developmental tasks. For example, they are frequently faced with discrimination and disapproval from mainstream society. In the past, many gay or lesbian families opt to keep their sexual orientation a secret. In most states, they do not have the option of legal marriage and, therefore, do not have many of the benefits of marriage that heterosexual couples have, such as insurance benefits, rights to property, custody issues, and family leave benefits associated with family illness or childbirth. Some states now recognize same-sex marriage and civil unions, which provide protection of rights for same-sex partners (Giger & Davidhizar, 2007). Chapter 8 ∞ provides an overview of some of the obstacles faced by lesbian families.

TABLE 2-3 Stages in Remarriage

STAGE	ISSUES
I. Establishing a new relationship	Resolve feelings from divorce; determine new marriage is desired; evaluate emotional readiness for new family; commit to new family.
II. Planning new marriage and family	Deal with personal fears and fears of new spouse and children; establish openness and open communication; determine financial obligations and coparenting roles with former spouses; plan for adjustment to new roles for parents and children: set new boundaries, resolve loyalty conflicts, maintain relationships with extended family members of ex-spouses, foster relationships between extended family and new spouse.
III. Remarriage and reconstitution of family	Include new spouse into family unit; dissolve previous attachment to former spouse and image of the "ideal family;" restructure family system to include stepparent role; incorporate both families into a system to support children; foster all family relationships with extended family (including ex-spouses); share special memories to enhance family bonding and integration.

TABLE 2-4 Lesbian and Gay Family Stages

STAGE	ISSUES
I. Formation of couple	Establish themselves as a couple versus individuals: combine two lives together, develop trust, reveal details about self, respond empathetically to partner to encourage further risk taking in relationship, tell others about their relationship.
II. Ongoing couplehood	Move from a passionate physical relationship to a stable relationship that includes passion and dailiness; manage differences between partners and handle conflict; increase sense of security and belonging as a couple.
III. Middle years	Progress into a long-term relationship with commitment and a continued sense of security; make efforts to keep relationship fresh and new; rework rewards and disappointments.
IV. Generativity	Create a legacy beyond each partner's own self-identity that will endure.

Slater (1995) developed a model specific to the stages of family life for lesbian and gay families (Table 2-4). The model identifies five stages in the development of the gay or lesbian family and addresses different issues and tasks in each stage.

Family Assessment

Case Study: Family Assessment

The nurse's understanding of the family structure helps provide insight into the family's support systems and needs. A **family assessment** is a collection of data regarding the family's current level of functioning, support systems, sociocultural information, environmental information, type of family, family structure, and needs.

To obtain an accurate and concise family assessment, the nurse needs to establish a trusting relationship with the woman and her family. Data are best collected in a comfortable, private environment, free from interruptions. The nurse can use therapeutic communication skills, such as active listening, reflection, and silence, to encourage the woman and family to verbalize information. Basic information should include:

- Name, age, sex, and family relationship of all family members residing in the household
- Cultural associations, including cultural norms and customs related to childbearing, childrearing, and infant feeding (discussed later in the chapter)
- Religious affiliations, including specific religious beliefs and practices related to childbearing
- Support network, including extended family, friends, and religious and community associations
- Family type, structure, roles, and values
- Communication patterns, including verbal and written language barriers

Health History

The health of individual family members can have a great impact on the health, well-being, and functioning of the family as a whole. The nurse should gather data about acute and chronic illnesses, genetic conditions, history of family violence, and mental health. A personal history beginning with pregnancies, pregnancy losses, infant health concerns, or deaths is also obtained. The nurse completes a comprehensive review of current health practices and health promotion behaviors to assess the family's ability to prevent accidents and chronic health conditions and performs a brief nutritional assessment. Families with nutritional excesses or deficits are provided with nutritional education to reduce the risk of nutrition-related illnesses.

The health history should also assess current exercise and activity patterns, sleep patterns, occupational exposures, use of prescription and nonprescription drugs, herbal remedies, alcohol consumption, smoking, and use of illegal drugs.

Environmental Considerations

A family's home environment can be assessed through home visits. Although not always possible, multiple home visits will yield more information than a single visit. A home visit enables the nurse to observe the family directly in their own environment and personal space. It also provides a more realistic view of family relationships, roles, parenting styles, and family needs. Often, the first visit serves as an introduction for the nurse to lay the foundation for a therapeutic relationship.

Observations should include the availability of personal space for all family members, including a place to sleep. The home should have basic necessities for daily living such as safe drinking water, a working waste-disposal system, electricity, and heat. The nurse can ensure that adequate cooking facilities, including a stove and refrigerator, are available for safe meal preparation. The availability of a phone is important so family members have access to healthcare providers and emergency services as needed.

The childbearing family should have resources available for the new baby, including a safe place to sleep, appropriate clothing, blankets, hygienic equipment, and age-appropriate resources for other children.

The home should also be inspected for potential hazards. Childproofing the home is a topic generally covered during the home visit. A safe place to bathe the infant should be identified. Parents should be taught never to leave the infant unattended during bathing and never to leave the infant in a location where a fall can occur. Environmental hazards such as open stairs, uncovered electrical outlets, fragile items that could harm the infant or other children if the items were broken, and unattended electrical appliances need to be discussed. Many new childbearing families may not recognize the potential environmental dangers and will benefit from a brief review.

During the home visit, the nurse can also assess the neighborhood in which the family lives. Observations should include availability of resources (drug store, grocery store, closest medical facility, child care resources, and schools), characteristics of the neighborhood (safety issues, proximity of public transportation), and community resources (new mothers'

groups, breastfeeding support groups, and availability of infant development/first aid classes).

Upon completion of the home visit(s), the nurse can make recommendations and identify community resources and sources of support for the new family. Families can also be counseled on the availability of social services, such as the Special Supplemental Food Program for Women, Infants, and Children (WIC), and financial support programs. Parents without health insurance coverage should be encouraged to apply for Medicaid coverage for their infant. Community health programs, such as local health department immunization clinics, should also be discussed.

Family Assessment Tool

Multiple tools are available to assist the nurse in collecting data regarding the family. The Friedman Family Assessment tool is a comprehensive assessment of family functioning and other essential family data (Figure 2-7 ■). It can be used during the home visit to obtain pertinent information and provide a framework for the nurse when planning and implementing interventions for the family.

Cultural Influences Affecting the Family

When caring for families, it is critical to consider the influence of culture, which may affect how a family reacts and responds to health-related issues. Cultural beliefs that may seem strange to a person born and raised in Ohio might have significant meaning for an immigrant from West Africa. Developing knowledge about cultural beliefs and traditions can increase the nurse's appreciation of diversity; prevent violation of cultural norms; and, most important, improve the family's healthcare experience.

Within the United States there is tremendous cultural diversity. In 2008 the Census Bureau reported that 15.4% of Americans are Hispanic or Latino, 12.8% are of African descent, 4.5% are of Asian descent, 10% are American Indian or Alaska Native, 0.18% are of non-Hispanic Pacific Islander descent, and 1.7% are of two or more races. Thus it is important for nurses to have an understanding of how culture can influence family care.

Cultural Concepts

Culture can be defined as the beliefs, values, attitudes, and practices that are accepted by a population, a community, or an individual. Culture is learned and not ingrained in our genetic material, yet it can be passed on from generation to generation by means of *enculturation.* When a group is isolated, whether geographically or economically, culture is often reinforced.

Ethnicity is a social identity that is associated with shared behaviors and patterns. These include family structure, religious affiliation, language, dress, eating habits, and health behaviors. Many Americans define ethnicity by physical characteristics such as skin color. However, many individuals consider themselves to be "biracial" or identify with a specific ethnic group not because of skin color but because of a shared ideology or attitude. Many Americans are blends of ethnic backgrounds, and it is often difficult to assign a specific ethnic identity to someone. Although some beliefs and cultural practices are common among certain ethnic groups, one must be careful to avoid stereotyping individuals. It is important not to assume that because individuals identify themselves as a specific ethnicity, they must practice a certain custom.

Within the United States, cultures have in the past been forced to blend. When people from one culture are transported to another place with new cultural norms, many adapt to these new behaviors. This process by which people adapt to a new cultural norm is called **acculturation**. Moreover, when a group completely changes their cultural identity to become part of the majority culture, **assimilation** occurs.

Acculturation

Many immigrants acculturate, and sometimes the acculturation process has an effect on the family's health. Acculturation is frequently associated with improved health status and health behaviors; however, this does not suggest that the American lifestyle is somehow more healthful than others. Instead, it seems that many factors contribute to the improved health status of acculturated immigrants. Primary among these are socioeconomic factors. Many immigrants are financially better off in the United States than they were in their country of origin, particularly those who have emigrated from developing nations.

Despite economic resources, acculturation plays a major role in immigrants' use of preventive care services. It appears that the length of time spent in the United States is a predictor for utilization of health services. A study by the Kaiser Commission (Cunningham & Artiga, 2009) showed that the uninsured rate for recent immigrants is almost 3 times that of immigrants who have been in the United States for more than 20 years (63% vs. 22%). Cunningham and Artiga point out that among immigrants, recent immigrants are the most likely to lack a usual source of care and experience language barriers with a physician, and they have lower levels of physician visits than longer-term immigrants.

Often overlooked in debates and discussions related to immigrant issues is the great diversity among the immigrant population, and, in particular, the fact that their circumstances and situations change over time as they assimilate socially and economically within American society. "New immigrants should be recognized as a vulnerable group with regard to the impact of work on their well-being" (De Castro, Gilbert, & Takeuchi, 2008). In a study that investigated how immigrants' duration of time in the United States impacts the relationship between job-related stress and health conditions, researchers concluded that job-related stressors are associated with adverse health outcomes, and this relationship is strongest for newer immigrants.

Sometimes health declines with acculturation. A study examining patterns of substance abuse by Hispanics in the United States found acculturation to result in increased rather than decreased drug use (Akins, Mosher, Smith, et al., 2007). Obesity is another problem that is growing rapidly within the United States, particularly among immigrant populations.

Impact of Culture on Family Structure

Traditional family structure within the United States usually consists of a nuclear family with an extended family living separately.

Meeting of Physical, Emotional, and Spiritual Needs of Members

- Ability to provide food and shelter
  - Space management as regards living, sleeping, recreation, privacy
  - Crowding if over 1.5 persons per room
  - Territoriality or control of each member over lifespace
  - Access to laundry, grocery, recreation facilities
  - Sanitation including disposal methods, source of water supply, control of rodents and insects
  - Storage and refrigeration
  - Available food supply
  - Food preparation, including preserving and cooking methods (stove, hotplate, oven)
  - Use of food stamps and donated foods as well as eligibility for food stamps
  - Education of each member as to food composition, balanced menus, special preparations or diets if required for a specific member
- Access to health care
  - Regularity of health care
  - Continuity of caregivers
  - Closeness of facility and means of access such as car, bus, cab
  - Access to helpful neighbors
  - Access to phone
- Family health
  - Longevity
  - Major or chronic illnesses
  - Familial or hereditary illnesses such as rheumatic fever, gout, allergy, tuberculosis, renal disease, diabetes mellitus, cancer, emotional illness, epilepsy, migraine, other nervous disorders, hypertension, blood diseases, obesity, frequent accidents, drug intake, pica
  - Emotional or stress-related illnesses
  - Pollutants that members are chronically exposed to such as air, water, soil, noise, or chemicals that are unsafe
- Neighborhood pride and loyalty
- Job access, energy output, shift changes
- Sensitivity, warmth, understanding between family members
  - Demonstration of emotion
  - Enjoyment of sexual relations
    - Male: Impotence, premature or retarded ejaculation, hypersexuality
    - Female: Frigidity (inability to achieve orgasm), enjoyment of sexual relations, feelings of disgust, shame, self-devaluation; fear of injury, painful coitus
    - Menstrual history, including onset, duration, flow, missed periods and life situation at the time, pain, euphoria, depression, other difficulties
- Sharing of religious beliefs, values, doubts
  - Formal membership in church and organizations
  - Ethical framework and honesty
  - Adaptability, response to reality
  - Satisfaction with life
  - Self-esteem

Childrearing Practices and Discipline

- Mutual responsibility
  - Joint parenting
  - Mutual respect for decision making
  - Means of discipline and consistency
- Respect for individuality
- Fostering of self-discipline
- Attitudes toward education, reading, scholarly pursuit
- Attitudes toward imaginative play
- Attitudes toward involvement in sports
- Promotion of gender stereotypes

Communication

- Expression of a wide range of emotion and feeling
- Expression of ideas, concepts, beliefs, values, interests
- Openness
- Verbal expression and sensitive listening
- Consensual decision making

Support, Security, Encouragement

- Balance in activity
- Humor
- Dependency and dominance patterns
- Life support groups of each member
- Social relationship of couple: go out together or separately; change since marriage mutually satisfying; effect of sociability patterns on children

Growth-Producing Relationships and Experiences Within and Without the Family

- Creative play activities
- Planned growth experiences
- Focus of life and activity of each member
- Friendships

Responsible Community Relationships

- Organizations, including involvement, membership, active participation
- Knowledge of and friendship with neighbors

Growing with and Through Children

- Hope and plans for children
- Emulation of own parents and its influence on relationship with children
- Relationship patterns: authoritarian, patriarchal, matriarchal
- Necessity to relive (make up for) own childhood through children

Unity, Loyalty, and Cooperation

Positive interacting of members toward each other

Self-Help and Acceptance of Outside Help in Family Crisis

Figure 2-7 ■ Family Assessment Tool.

Source: Murray, R. B., & Zentner, J. P. (2001). Health promotion strategies through the lifespan *(7th ed., p. 200, Figure 4–2 Family Assessment Tool). Printed and electronically reproduced by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.*

However, many immigrants to the United States live together with and rely on a network of grandparents and even aunts, uncles, and cousins. For example, Cuban families are often multigenerational and consider grandmothers to be part of the nuclear family. Further, godparents (or *compadrazgos*) are often considered part of the family even if they are not related by blood (Giger & Davidhizar, 2007).

Many Islamic families from West Africa practice polygamy. Although they do not often freely admit this when in the United States, sometimes women live in households with their co-

wives. Sometimes the co-wives work well together and get along, and in some cases they do not. Often children view each co-wife as their own mother.

CLINICAL TIP

When caring for a family in which grandparents play a key role in family decision making, the nurse should include the grandparents in the decision-making and teaching sessions because their views are highly respected within the family unit.

Cultural Influences on Childbearing and Childrearing

A family's culture may influence its beliefs about and practices surrounding many aspects of childbearing and childrearing, including beliefs about the importance of children, beliefs and attitudes about pregnancy, health practices, and infant feeding behaviors.

Beliefs Regarding the Importance of Children

Children are generally valued all over the world, not only for the joy they bring, but also because they ensure continuation of the family and cultural values. This valuing of children may manifest in different ways, however. Families in the United States and many Western countries commonly have only one or two children, often out of a desire to provide the children with the best home and education they can afford, and to spend as much free time with them as possible. Many fear that additional children would too greatly dilute their financial and emotional resources. In contrast, in many cultures throughout the world, it is common to have as many children as possible. In Mali, West Africa, for example, the average woman has about seven children in her lifetime.

An understanding of the meaning of children in a culture may explain reactions of joy or shame to pregnancy. In the western United States, people of the Mormon faith view motherhood as the most important aspect of a woman's life, comparable with the male role of priesthood. In Mexican American society and among many other Hispanic groups, having children is evidence of the male's virility and is a sign of manliness, or *machismo,* a desired trait.

In cultures that value children only when they are born to a legally married couple, however, pregnancy is a shameful event if it occurs outside of marriage. In some Middle Eastern countries, for example, a woman who conceives outside of marriage would be permanently banned from her family. Pregnancy outside of marriage may even be dangerous. In many Muslim countries, an unmarried pregnant woman may seek a clandestine abortion because the consequences of carrying an illegitimate child can be social ostracism or even death—in some cases, even when the pregnancy has resulted from rape. It is not unheard of for women to be killed if the family discovers she engaged in sexual intercourse outside of marriage and became pregnant.

There are also many culturally influenced beliefs related to contraception. Many Muslims from the Middle East may use birth control but do not believe in sterilization because it is a permanent method. Other Muslims may not practice contraception because children are highly valued and it is believed that the traditional role of the woman is to bear children.

Beliefs and Attitudes About Pregnancy

Beliefs and attitudes about pregnancy may also be culturally influenced and may influence a woman's health behaviors. Thus certain health behaviors can be expected if a culture views pregnancy as a sickness, whereas other behaviors can be expected if pregnancy is viewed as a natural occurrence. Prenatal care may not be a priority for women who view pregnancy as a natural occurrence. Americans of African descent, for example, usually consider pregnancy as a state of wellness. Mexican Americans generally view pregnancy as a natural and desirable condition, and most Native American groups consider pregnancy a normal process. Although pregnancy is perceived as a natural occurrence in many cultures, it may also be viewed as a time of increased vulnerability. Individuals with European/Western ideas might expect the woman to be away from work before and right after childbirth. In Orthodox Judaism, it is a man's responsibility to procreate, but it is a woman's right, not her obligation, to do so.

Individuals of many cultures take certain protective precautions based on their beliefs. For example, many women of Malawi, Africa, avoid preparing clothes for the infant during the prenatal period because they believe that this action will lead to the birth of a stillborn infant. Similarly, many Southeast Asian women fear that they will have a complicated labor and birth if they sit in a doorway or on a step. Thus they tend to avoid areas near doors in waiting rooms and examining rooms. For many Vietnamese women, lifting the arms above the head is believed to increase the risk of preterm birth. Vietnamese women are also discouraged from sitting or lying down for lengthy periods because doing so might allow the baby to become too large.

In the Mexican American culture, the concept of *mal aire,* or bad air, is sometimes related to evil spirits. It is thought that air, especially night air, may enter the body and cause illness. Preventive measures, such as keeping the windows closed or covering the head, are used. Some Latinos may place a raisin on the cord stump of a newborn to prevent drafts from entering the baby's body.

For many Southeast Asians, the wind (or *vata*) is a potentially negative force that can disturb the body's internal harmony when a person is in a vulnerable state, such as during and after childbirth or during surgery. The natural forces thought to be more desirable during pregnancy include the earth, for groundedness, and water, for fluidity. Thus, in addition to avoiding wind and drafts, the pregnant woman is encouraged to eat creamy, oily, and other heavy foods; retire early and sleep until dawn; avoid stimulants and stress; and drink plenty of water.

Taboos refer to behaviors or things that are avoided. Many cultures, including those found in the United States, have taboos centered on the unborn baby that are meant to ensure that the baby will survive. Many of these beliefs stem from the fear of injuring an unborn child or the worry that a baby might die. In developing countries, mortality rates among infants and young children are extremely high; thus, certain traditions have centered on preventing early death. For example, it is common among Muslims to avoid naming babies until after birth and to ensure that the first words a baby hears are from God. In the

western part of Mali, babies' faces are covered in mud and they are called ugly names to ward off evil spirits. Taboos also emanate from the fear that a pregnant woman has evil powers. For this reason, pregnant women are sometimes prohibited from taking part in certain activities with other people.

Many cultures ascribe to the *equilibrium model of health,* which is based on the concept of balance between light and dark, heat and cold. As described in chapter 3 ∞, Far Eastern philosophic belief systems focus on the notion of yin and yang. Yin represents the female, passive principle—darkness, cold, and wetness. Yang is the masculine, active principle—light, heat, and dryness. When the two are combined, they are all that can be.

The hot-cold classification is also seen in cultures in Latin America, the Near East, and Southeast Asia. The dimensions and meanings of this classification vary, however, and require further investigation. Spanish priests brought the concept of "hot" and "cold" to Mexico, where it was combined with ancient Aztec beliefs. Consequently, some Mexican Americans may consider illness to be an excess of either hot or cold (Galanti, 2008). To restore health, imbalances are often corrected by the proper use of foods, medications, or herbs. These substances are also classified as hot or cold. For example, an illness attributed to an excess of coldness will be treated only with hot foods or medications. The classification of foods is not always consistent, but it does conform to a general structure of traditional knowledge. Certain foods, spices, herbs, and medications are perceived to cool or heat the body. These perceptions do not necessarily correspond to the actual temperature; some hot dishes are said to have a cooling quality.

Southeast Asians believe it is important to keep the woman "warm" after the birth because blood, which is considered "hot," has been lost, and the woman is at risk of becoming "cold." Therefore, they avoid cold drinks and foods following birth. In addition, many women in India consider pregnancy a hot period and eat cool foods to counterbalance the hot state (Galanti, 2008). The concepts of hot and cold are not as important in Native American or African American beliefs. There are some similarities, however, in all of these groups because of the emphasis on a balance in nature.

Care Plan Activity: Effects of Hispanic Culture on Infant Feeding Practices

CLINICAL TIP

When caring for a woman of Asian descent, ask her if she would prefer hot water or ice water at her bedside. This can help ensure that proper oral hydration is maintained and cultural beliefs are supported.

Health Promotion Practices During Pregnancy

Health practices during pregnancy are influenced by numerous factors, such as the prevalence of traditional home remedies and folk beliefs, the importance of indigenous healers, and the influence of professional healthcare workers. In an urban setting the age of the family members, length of time in the city, marital status, and strength of the family may affect these patterns. Socioeconomic status is also important because modern medical services are more accessible to those who can afford them.

An awareness of alternative health sources is crucial for health professionals because these practices affect health outcomes. For example, many members of the Mexican American community utilize the *partera,* a lay midwife, as a healer who gives advice and treats illnesses during pregnancy as well as being in attendance during labor and birth.

Indigenous healers are also important in some cultures. In the Mexican American culture the healer is called a *curandero* or *curandera.* In some Native American tribes the medicine man may fulfill the healing role. Herbalists are often found in Asian cultures; and faith healers, root doctors, and spiritualists are sometimes consulted in the African American culture.

Cultural Norms Regarding Infant Feeding Practices

Culture can greatly affect new mothers' as well as experienced mothers' choices in feeding decisions. For example, in the Hispanic culture, women often believe that newborns need to be supplemented with infant formula before the milk comes in. Although colostrum provides vital antibodies for the infant, many Hispanic women refuse to nurse until their milk supply is established. It is important for the nurse to understand cultural norms and make recommendations that complement these norms, rather than conflict with them. In the preceding example, the nurse may advise the woman to first nurse her newborn at the breast and then offer the infant formula.

The majority of research on formula-feeding behavior has been conducted among Hispanic mothers and African American mothers. One common practice in these cultural groups is the addition of foods to the formula bottle, usually after 2 to 3 months, but for some, as early as 2 weeks into a baby's life. The kinds of food added vary from nonnutritive, high-calorie substances like sugar to adult foods like rice, beans, cereal, potatoes, yams, and eggs. Once the food is added, the nipple is often enlarged so that the baby can consume the food, creating a potential choking hazard.

Such supplementation may be done for a variety of reasons. Hispanic mothers report that it is important to add these foods to the formula to help the baby grow to be large. In Latin American culture, many people believe that "the bigger the baby, the better," so parents supplement the breast or formula, hoping for a big and healthy baby. Unfortunately, the parents are usually unaware of the fact that the addition of these foods can hurt the growth and health of the infant. Indeed, if a mother does not feed her child in the culturally accepted way, she may appear to be unfit or irresponsible within the community.

A second reason why foods are added to formulas lies in the belief that the addition of traditional foods at a very young age will prepare children to accept and enjoy their traditional foods when they are older. Food is an extremely important component of many Hispanic cultures; it ties people together and is usually the centerpiece of religious events and holidays. This relates to the third reason why foods are added to formula. During the holidays, it is considered important that everyone eat the same thing and participate equally; thus, infants are often included by being given the same foods the adults are eating.

African American mothers have also reported adding foods like cereal, potatoes, evaporated milk, or even extra scoops of

powdered formula to thicken the formula. As with Hispanic families, the addition of these foods is thought to be necessary to help the child grow to be big and healthy, but more immediately, it is thought that this thickened formula will better satisfy a baby, so that he or she will sleep better through the night and allow the mother to do so as well. Thin formulas are associated with making a baby cry at night.

Overfeeding is a common cultural behavior as well. Hispanic mothers are reported to often overfeed their infants. Some mothers have reported to feed a child until he or she spits up. That is the indication that a child is eating in a healthful manner. Puerto Rican mothers believe overfeeding to be a protective care behavior that keeps a child healthy, well fed, and safe from illness or harm.

Many immigrants choose formula-feeding over breastfeeding. Although this choice may be partly due to their busy lives, it also can be due to cultural beliefs, particularly among immigrants from developing countries, where the ability to formula-feed is a status symbol because it is so expensive. In Mali, for example, a can of formula can cost the equivalent of $2, although the average individual only earns $200 per year. In the United States, formulas are more affordable and available to the poor; however, when additional cultural practices come into play, such as overfeeding and adding extra formula, the subsidized formulas can run out quickly, and mothers may choose to substitute cow's milk, use canned evaporated or condensed milk, dilute the formula, or purchase unsafe formulas on the "black market." Obviously, these choices have dangerous health implications for the infant.

A nurse may educate a mother in her native language about appropriate infant feeding practices, but the influences from her family and their cultural beliefs may have a greater impact than the health teaching on her feeding behavior. Understanding parents' beliefs and traditions can help nurses to educate families more effectively about healthful feeding behaviors.

Cultural Diversity in Family Nursing Care

Cultural attitudes, behaviors, and beliefs that are related to health can greatly affect how a patient will respond to and comply with health advice. Thus it is critical that nurses develop a holistic understanding of their patients' needs. (See www.nursing.pearsonhighered.com for a list of cultural resources.) Healthcare providers are often unaware of the cultural characteristics they themselves demonstrate. Without cultural awareness, caregivers tend to project their own cultural responses onto foreign-born patients; patients from different socioeconomic, religious, or educational groups; or patients from different regions of the country. This leads caregivers to assume that patients are demonstrating a specific behavior for the same reason that they themselves would. Moreover, healthcare providers frequently fail to recognize that medicine has its own culture, which has been dominated historically by traditional, middle-class values and beliefs.

Ethnocentrism is the conviction that the values and beliefs of one's own cultural group are the best ones or the only acceptable ones. It is characterized by an inability or unwillingness to understand the beliefs or worldview of another group or culture. To a certain extent, most people are guilty of ethnocentrism, at least some of the time. Thus the nurse who values stoicism during labor may be uncomfortable with the more vocal response of a Latin American woman. Another nurse may be disconcerted by the Southeast Asian woman who believes that pain is something to be endured rather than alleviated and is very intent on maintaining self-control in labor (Andrews & Boyle, 2008).

Healthcare providers sometimes believe that if members of other cultures do not share Western values, they should adopt them. This is especially difficult for a nurse caring for childbearing families if the nurse is a firm believer in the equality of the sexes and feminism. The nurse may find it difficult to remain silent if a woman from a Middle Eastern culture defers to her husband in decision making. It is important to remember that pressure to defy cultural values and beliefs can be stressful and anxiety provoking for these women.

To address issues of cultural diversity in the provision of health care, emphasis is being placed on developing **cultural competence**—that is, the skills and knowledge necessary to appreciate, understand, and work with individuals from different cultures. It requires self-awareness, awareness and understanding of cultural differences, and the ability to adapt clinical skills and practices as necessary.

The nurse can begin developing cultural competence by becoming knowledgeable about the cultural practices of local groups. For example, is it considered courteous to avoid eye contact? Should last names be used in conversation as a sign of respect? Is a female rather than male healthcare provider necessary? Do communication and language barriers exist? If so, how can they be addressed?

Giger and Davidhizar (2007) have suggested that care providers conduct a "cultural assessment" to glean information about health practices based on the patient's beliefs, values, and customs. This kind of assessment might include questions such as:

1. Who in the family must be consulted before decisions are made about a person's care?
2. Does the patient see primarily in the present or does he or she have a futuristic time orientation?
3. What type of health provider is most appropriate for the patient?
4. Does the patient have beliefs or traditions that may impact the care plan?

Several cultural assessment tools are in use to assist the nurse in obtaining cultural information. Giger and Davidhizar (2007) developed a transcultural assessment tool that identifies the cultural background, communication patterns, issues related to personal space, social organization, time, roles within the environment, biologic variations, and a nursing assessment (Figure 2-8 ■).

Culturally Influenced Responses

It is imperative when caring for families that nurses provide culturally sensitive care that supports cultural differences. The nurse who respects cultural diversity is an asset to the childbearing family as they adjust to their new role. Establishing a trusting relationship enables the nurse to assist the family in

Application: Examine Your Cultural Influences

meeting educational needs. The nurse who considers the woman's personal values, beliefs, and customs will be a far more effective caregiver than the nurse who does not.

Biologic Differences

Genetic and physical differences occur among cultural groups and can lead to disparities in needs and care. African Americans are more likely to experience hypertension, strokes, obesity, diabetes, and sickle cell anemia. Thalassemia, another type of anemia, occurs primarily in individuals of Mediterranean descent. African Americans and Native Americans tend to have higher rates of tuberculosis than the general population. On the other hand, African Americans have higher bone mass than Caucasians and lower rates of osteoporosis. Caucasians have higher rates of heart disease. Caucasians from certain geographic regions have higher rates of cystic fibrosis, celiac disease, and Crohn's disease. Hispanics have higher rates of diabetes and lactose intolerance. Asians and Native Americans often do not metabolize alcohol readily and are more prone to either injury after alcohol ingestion or to alcohol abuse. Otitis media, or infection of the middle ear, is common in Native American and Alaskan Native children. Diabetes, liver disease, and injuries are common in Native American groups. Metabolism of certain drugs is also linked to genetics in certain groups.

Nurses must understand other genetic characteristics in order to provide culturally competent nursing assessments and interventions. Differences in skin color may make cyanosis, pallor, and jaundice difficult to recognize and describe. Mongolian spots are darkened skin spots on the lower back and buttocks of some babies with dark skin. Variations in texture of hair require different approaches to hygiene among various racial groups.

Communication Patterns

Communication is a method by which members of culture groups share information and preserve their beliefs, values, norms, and practices. To ensure effective nursing care, it is

A Transcultural Assessment Model

CULTURALLY UNIQUE INDIVIDUAL

1. Place of birth
2. Cultural definition
   What is . . .
3. Race
   What is . . .
4. Length of time in country

COMMUNICATION

1. Voice quality
   A. Strong, resonant
   B. Soft
   C. Average
   D. Shrill
2. Pronunciation and enunciation
   A. Clear
   B. Slurred
   C. Dialect
3. Use of silence
   A. Infrequent
   B. Often
   C. Length
      (1) Brief
      (2) Moderate
      (3) Long
      (4) Not observed
4. Use of nonverbal
   A. Hand movement
   B. Eye movement
   C. Moves entire body
   D. Kinesics (gestures, expressions, or stances)
5. Touch
   A. Startles or withdraws when touched
   B. Accepts touch without difficulty
   C. Touches others without difficulty
6. Ask these and similar questions:
   A. How do you get your point across to others?
   B. Do you like communicating with friends, family, and acquaintances?
   C. When asked a question, do you usually respond (in words or body movements, or both)?
   D. If you have something important to discuss with your family, how would you approach them?

SPACE

1. Degree of comfort
   A. Moves when space invaded
   B. Does not move when invaded
2. Distance in conversations
   A. 0 to 18 inches
   B. 18 inches to 3 feet
   C. 3 feet or more
3. Definition of space
   A. Describe degree of comfort with closeness when talking with or standing near others
   B. How do objects (e.g., furniture) in the environment affect your sense of space?
4. Ask these and similar questions:
   A. When you talk with family members, how close do you stand?
   B. When you communicate with coworkers and other acquaintances, how close do you stand?
   C. If a stranger touches you, how do you react or feel?
   D. If a loved one touches you, how do you react or feel?
   E. Are you comfortable with the distance between us now?

SOCIAL ORGANIZATION

1. Normal state of health
   A. Poor
   B. Fair
   C. Good
   D. Excellent

Figure 2-8 ■ Cultural assessment tool.

2. Ask these and similar questions:
   A. How do you define social activities?
   B. What are some activities that you enjoy?
   C. What are your hobbies, or what do you do when you have free time?
   D. Do you believe in a Supreme Being?
   E. How do you worship that Supreme Being?
   F. What is your function (what do you do) in your family unit/system?
   G. What is your role in your family unit/system (father, mother, child, advisor)?
   H. When you were a child, what or who influenced you most?
   I. What is/was your relationship with your siblings and parents?
   J. What does work mean to you?
   K. Describe your past, present, and future jobs.
   L. What are your political views?
   M. How have your political views influenced your attitude toward health and illness?

TIME

1. Orientation to time
   A. Past-oriented
   B. Present-oriented
   C. Future-oriented
2. View of time
   A. Social time
   B. Clock-oriented
3. Physiochemical reaction to time
   A. Sleeps at least 8 hours a night
   B. Goes to sleep and wakes on a consistent schedule
   C. Understands the importance of taking medication and other treatments on schedule
4. Ask these and similar questions:
   A. What kind of timepiece do you wear daily?
   B. If you have an appointment at 2 PM, what time is acceptable to arrive?
   C. If a nurse tells you that you will receive a medication in "about a half hour," realistically, how much time will you allow before calling the nurses' station?

ENVIRONMENTAL CONTROL

1. Locus-of-control
   A. Internal locus-of-control (believes that the power to affect change lies within)
   B. External locus-of-control (believes that fate, luck, and chance have a great deal to do with how things turn out)
2. Value orientation
   A. Believes in supernatural forces
   B. Relies on magic, witchcraft, and prayer to affect change
   C. Does not believe in supernatural forces
   D. Does not rely on magic, witchcraft, or prayer to affect change
3. Ask these and similar questions:
   A. How often do you have visitors at your home?
   B. Is it acceptable to you for visitors to drop in unexpectedly?
   C. Name some ways your parents or other persons treated your illnesses when you were a child.
   D. Have you or someone else in your immediate surroundings ever used a home remedy that made you sick?
   E. What home remedies have you used that worked? Will you use them in the future?
   F. What is your definition of "good health"?
   G. What is your definition of illness or "poor health"?

BIOLOGIC VARIATIONS

1. Conduct a complete physical assessment noting:
   A. Body structure
   B. Skin color
   C. Unusual skin discolorations
   D. Hair color and distribution
   E. Other visible physical characteristics (e.g., keloids, chloasma)
2. Ask these and similar questions:
   A. What diseases or illnesses are common in your family?
   B. Describe your family's typical behavior when a family member is ill.
   C. How do you respond when you are angry?
   D. Who (or what) usually helps you to cope during a difficult time?
   E. What foods do you and your family like to eat?
   F. Have you ever had any unusual cravings for:
      (1) White or red clay dirt?
      (2) Laundry starch?
   G. When you were a child what types of foods did you eat?
   H. What foods are family favorites or are considered traditional?

NURSING ASSESSMENT

1. Note whether the client has become culturally assimilated or observes own cultural practices.
2. Incorporate data into plan of nursing care:
   A. Encourage the client to discuss cultural differences; people from diverse cultures who hold different worldviews can enlighten nurses.
   B. Make efforts to accept and understand methods of communication.
   C. Respect the individual's personal need for space.
   D. Respect the rights of clients to honor and worship the Supreme Being of their choice.
   E. Identify a clerical or spiritual person to contact.
   F. Determine whether spiritual practices have implications for health, life, and well-being (e.g., Jehovah's Witnesses may refuse blood and blood derivatives; an Orthodox Jew may eat only Kosher food high in sodium and may not drink milk when meat is served).
   G. Identify hobbies, especially when devising interventions for short or extended convalescence or for rehabilitation.
   H. Honor time and value orientations and differences in these areas. Allay anxiety and apprehension if adherence to time is necessary.
   I. Provide privacy according to personal need and health status of the client (Note: the perception and reaction to pain may be culturally related).
   J. Note cultural health practices
      (1) Identify and encourage efficacious practices.
      (2) Identify and discourage dysfunctional practices.
      (3) Identify and determine whether neutral practices will have a long-term ill effect.
   K. Note food preferences
      (1) Make as many adjustments in diet as health status and long-term benefits will allow and that dietary department can provide.
      (2) Note dietary practices that may have serious implications for the client.

Figure 2-8 ■ Cultural assessment tool. continued

essential for nurses to be able to communicate with the family. This becomes an issue when the family and nurse do not speak the same language. In such cases, translators should be provided. The Joint Commission of Accreditation of Hospital Organizations (JCAHO) requires that hospitals provide a mechanism for patients to communicate in their own language. This reduces medical errors and increases effective communication. The use of children and other family members to act in the role of translator is not recommended because of confidentiality issues. Written instructions, signs, and brochures should be offered in the individuals' native language.

Language can also affect health literacy skills. A large number of instructions are given in writing. Examples include prescriptions and directions on medication bottles, signs hanging in health facilities, consent forms for procedures and surgery, insurance forms, directions for techniques or procedures, future appointment dates, and health promotion materials. Nurses need to verify that the patient and family can read and whether alternate methods are needed. Nurses can verbally give the information and provide paper and pencil so that the family can write it down in their own language. Translation services should be available in all healthcare settings.

Variations in communication among cultures are reflected in their word meaning, voice inflection and quality, and verbal styles. Culture not only influences the manner in which feelings are expressed, but also which verbal and nonverbal expressions of communication are considered appropriate. An individual's willingness to discuss certain topics or to express or conceal certain thoughts and feelings are also influenced by the cultural norms. For example, Native Americans and people of Asian descent may feel it is appropriate to remain quiet when experiencing pain, whereas people of Italian, Jewish, and Latino descent may feel that it is best to express pain more vocally.

Use of names varies among cultural groups. Assuming that each person wishes to be called by a first name can be disrespectful. Address family members respectfully, usually using terms such as Mr., Mrs., and Ms. If the person has a title such as doctor, judge, or senator, it should be used. Ask what the person prefers to be called and record this in the health record for future reference. In some cultures such as Korean, Cambodian, and Filipino, the first name used is actually the family name. Asking for the "family name" rather than the "last name" may clarify this practice.

NONVERBAL COMMUNICATION Nonverbal communication patterns may hinder or help communication. For example, gestures and body language may be misunderstood or misinterpreted. Similarly, eye contact has different meanings among cultures. European Americans, for example, value eye contact with communication and interpret this as a sign of sincerity and interest. In other cultures, such as Asian and Native American, sustained eye contact may be considered rude or disrespectful.

Silence may also be considered a sign of respect in some cultures. Among those groups, offering an immediate response to a question may be viewed as being disrespectful because an instant reply could indicate that no thought was given to the matter. Nurses should watch for patterns in various cultures and alter their own approach to be more congruent. For example, many nurses commonly nod and say "yes" or "oh, I see" when a healthcare patient is speaking. This may seem disruptive to some cultures. Noting that the listener is silent and does not use such patterns of agreement alerts the nurse to alter his or her own response to match more closely the acceptable method of communication for the family. Nurses need to learn that silence and quiet listening can be perceived as positive approaches.

TOUCH The appropriateness of touch varies with each culture. For example, an Asian may consider touching an unfamiliar person of the opposite gender to be inappropriate, whereas touch between men and women may be viewed as appropriate by another culture. Adults commonly feel that it is acceptable to touch children of all ages but this may not be accurate. Nurses should look for responses from family to touch and progress accordingly.

SPACE Depending on an individual's specific culture, the use of space has different meanings. "Space," as defined in this context, refers to the relationship between the individual and other persons and objects in the environment. Cultures may have specific spatial preferences, such as personal distance and social distance. Some cultures tend to prefer close contact with less space because they use touch as a form of communication. Nurses should be alert for how close a childbearing woman or a child comes to them and other individuals and try to maintain this space in their interactions. Nursing procedures often cause the space barrier to be broken. Nurses need to touch patients to take vital signs, administer injections, change dressings, and the like. This does not mean that close touch is appropriate at all times. Telling all patients before touching them for procedures will help them understand what is happening.

Time Orientation

Time orientation can vary significantly among cultures. Cultural groups may place emphasis on the events of the past, those events that occur in the present, or those events that will occur in the future. Time is also influenced by development so that young children sometimes do not understand the use of clocks, the importance ascribed to being "on time," or other time orientations.

Cultures that are oriented predominantly to the past may want to begin healthcare encounters with lengthy descriptions of past healthcare treatments, family history of diseases, or individual past experiences with health. There may be little interest in learning methods of adapting to or maintaining a new plan of care.

For cultures that are oriented predominantly to the present, little consideration may be given to either the past or the future. For example, adolescents commonly focus on the present and may not engage in preventive health practices for long-term health. Short-term goals often provide more incentive to adolescents.

Cultures that are oriented predominantly to the future, such as European Americans, may not focus on what is important at the present time. For example, the family focusing on the future

may focus on the dreams they had for a child's education or sports performance and have trouble setting present goals for treatment of a disease such as juvenile rheumatoid arthritis. One commonly hears that it was a big adjustment to learn to "take one day at a time." Not living up to the family's expectation for their future success may be difficult for a child who has developed an illness that has a chronic course.

Time also refers to punctuality about schedules and appointments. In the United States and Canada, the predominant culture respects promptness and considers time valuable and not to be wasted. Other cultures may not reflect this same concern for time. This may be manifested by a family's inability to follow timed medication schedules or treatments, or to show up as scheduled for an appointment. In these cases, it is not intended as a sign of disrespect.

Impact of Religion and Spirituality

The goal of truly holistic care of the childbearing family requires that the nurse understand the influence that religion and spirituality may have on the childbearing experience.

Diverse Meanings of Religion and Spirituality

The terms *religion* and *spirituality* mean very different things to different people. Although many people think of **religion** as an institutionalized system that shares a common set of beliefs and practices, others define it more simply as a belief in a transcendent power. The latter definition approaches most people's understanding of **spirituality** as a concern with the spirit or soul.

Philosophers and mystics have debated the meaning of religion for millennia, but within the last 200 years, technologic advances and the ascendance of rationalism and postmodernism have led many influential thinkers to condemn religion as mere wishful thinking. For example, in 1844, philosopher Karl Marx famously decried religion as "the opium of the people" (Marx, 1971), and in 1932, in his *New Introductory Lectures on Psychoanalysis,* psychologist Sigmund Freud stated: "Religion is an illusion . . . an attempt to get control over the sensory world, in which we are placed, by means of the wish-world . . . " (Freud, 1965). More recently, however, religious teachers have offered new visions of a religious life grounded in day-to-day experience.

Range of Religious Beliefs

The diverse meanings and approaches to religion and spirituality are reflected in the diversity of religious beliefs encountered in contemporary childbearing families. Some may belong to large institutionalized religious organizations; others may feel deeply religious yet have no formal affiliation or practice. Many patients are *agnostic,* or doubtful about the existence of a transcendent being, or truly *atheist,* meaning that they believe there is no higher power.

A childbearing family's religious beliefs, affiliation, and practices can influence deeply their experience and attitudes toward health care, childbearing, and childrearing. Members of certain religious groups such as Christian Scientists may attempt to avoid all medical interventions, whereas others such as Jehovah's Witnesses may refuse specific interventions, such as blood transfusions. Roman Catholics may refuse contraception. Many religions promote childbearing as a sacred right and responsibility, and some prescribe childrearing practices as well. In most cases, the woman and her family gain comfort from acknowledgment of and respect for their religious beliefs and practices in the healthcare setting. However, the agnostic or atheist family may be offended if care providers assume that references to God or a higher power will be comforting.

Provision of Spiritually Sensitive Nursing Care

For all these reasons, nurses are increasingly committed to providing spiritually sensitive nursing care to childbearing families. On admission to the clinic or labor setting, a religious or spiritual history is now included when assessing the childbearing family. Many patients specify a religious affiliation on admission to an acute care facility, but more specific information is also needed. The assessment can include questions about current spiritual beliefs and practices that will affect the mother and baby during the hospital stay or preferences for religious rituals during labor and birth.

Whenever possible, the nurse and other healthcare providers should attempt to accommodate religious rituals and practices requested by the childbearing family. Most such requests, such as for certain music, foods, or keeping a statue or picture by the bed, can be accommodated without causing danger; however, some, such as lighting candles, could present a risk in an acute care setting. In these circumstances, the family should be given a clear explanation of why the particular action cannot safely be carried out. In addition, nurses can provide patients with resources to meet their religious needs, such as consultation with on-staff chaplains. In settings where chaplains are not readily available, the nurse should be familiar with community resources in the area and offer referral as needed. In circumstances of spiritual distress, such as with severe fetal deformity or loss of a newborn, the family may prefer to meet with their personal religious adviser and the nurse can arrange for that visit.

Considering the diversity of religious beliefs, it is not unusual for nurses to encounter childbearing families whose beliefs conflict with their own. This is not problematic as long as the nurse avoids attempts to influence the patient's decision making. For example, a nurse who does not believe in baptism should avoid revealing this belief to a Catholic patient seeking baptism for her stillborn infant. Nurses should also examine their religious beliefs related to genetic screening procedures; use of assisted reproductive technology to achieve pregnancy; use of technology to support life in a severely compromised newborn; abortion; and even less dramatic issues such as methods of contraception, circumcision, and infant feeding. In many institutions, nurses can ask to be reassigned to a different patient if their religious beliefs are in conflict; however, if other personnel are not available, it is the nurse's responsibility to provide sensitive, appropriate, and nonjudgmental care to that patient.

FOCUS YOUR STUDY

- Family values, power, and roles are important to consider when attempting to provide holistic health care to contemporary families.
- Multiple trends have influenced changes in the traditional family, including employment trends, changes in marital status patterns, and economic trends.
- Nuclear families consist of a mother, father, and children.
- Dual-career/dual-earner families make up the majority of contemporary families in the United States.
- Childless families are a growing trend in American culture.
- Extended family members can play an active role in family life, decision making, and family roles.
- Single-parent families account for almost a third of all U.S. families, and stepparent and binuclear families are increasingly common.
- The developmental framework looks at a family over time as it progresses through predictable stages within the life cycle.
- A family assessment provides an in-depth tool to collect pertinent family life information that can assist the nurse in planning care.
- Culture plays a significant part in a family's development; roles; and observance of traditions, customs, and taboos.
- Cultural norms influence a family's beliefs about the importance of children, pregnancy, health practices, and infant feeding.
- A cultural assessment can assist the nurse in identifying cultural norms and providing culturally appropriate nursing care.
- A religious history is included when assessing contemporary families. Whenever possible, the nurse accommodates the family's religious-based preferences for care.

CRITICAL THINKING IN ACTION

While working in an inner-city clinic for adolescents, you meet a new patient, a 14-year-old Latina girl named Juanita. She is accompanied by her parents. None of them speak English. Through an interpreter, Juanita tells you that she recently moved here with her parents. They have brought her here today because she has a sore throat. The curandero they took her to see prescribed the herbal remedy *Echinacea*, but her throat is still sore. The rapid test you perform for strep throat is positive and the nurse practitioner prescribes an antibiotic.

1. According to the national standards for culturally and linguistically appropriate services in health care set by the government, what are examples of important standards of care that you, as the nurse, can provide in the care of this adolescent?
2. How can you, as the nurse, take steps to achieve cultural competence?
3. How would you, as the nurse, be able to address some of the disparities that can exist when this patient comes to the clinic?
4. What are some examples of common food preferences in the Latino American culture?

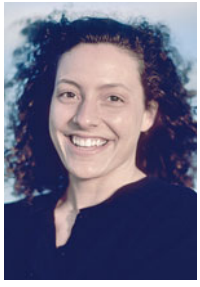
CHAPTER 3

Complementary and Alternative Therapies



As part of a continuing education course on body-based therapies for nurses, I was giving a back massage to one of my classmates. At one point, I felt a buzz of energy shoot up my hands and arms. At that exact moment, the other student said, "Wow!" Our instructor just laughed and said, "Oh, you're just exchanging friendly energy." That experience changed forever my views as a nurse and educator. I like the fact that nursing is based in science, but I remain open to the mysteries of the human body, mind, and spirit.

LEARNING OUTCOMES

1. Distinguish between *complementary* and *alternative therapies.*
2. Identify several factors that have contributed to the rise in popularity of complementary and alternative therapies in the United States and Canada.
3. Describe the role of the National Center for Complementary and Alternative Medicine.
4. Explain the role of complementary and alternative therapies in promoting wellness, disease prevention, and holistic healing.
5. Delineate the risks of using complementary and alternative therapies.
6. Compare the basic principles and components of homeopathy, naturopathy, traditional Chinese medicine, and ayurvedic medicine.
7. Describe the use of mind-body therapies in promoting the well-being of childbearing families.
8. Contrast the different manipulative and body-based therapies.
9. Explain the advantages and disadvantages to childbearing women of therapies involving ingestion of substances such as foods, dietary supplements, herbs, and homeopathic remedies.
10. Distinguish between acupressure and acupuncture.
11. Distinguish between Reiki and Therapeutic Touch.
12. Discuss complementary therapies appropriate for the nurse to use with childbearing families.

Until the latter part of the 20th century in the United States, it was rare for European American childbearing families to consult anyone except their obstetrician for advice about their pregnancy, birth, and postpartum. Though such patients are still encountered today, perinatal nurses are more likely to care for childbearing families who integrate other types of practitioners and therapies with traditional Western medicine. Families choosing complementary and alternative therapies may include those whose health practices are rooted in their cultural heritage, as well as European Americans who have explored one or more of the vast number of non-Western healing approaches available today. The nurse may even encounter families who consider alternative approaches superior to the diagnostics and treatments that conventional Western medicine offers, and who enter a clinic or hospital environment only reluctantly.

Because the use of complementary and alternative therapies has become so widespread, all nurses need to have at least a fundamental understanding of their benefits and risks and guidelines for their safe use. The chapter begins with an overview of the evolution of complementary and alternative therapies. A brief description of the most common therapies currently used by childbearing families is also provided.

Evolution of Complementary and Alternative Therapies

Complementary and alternative medicine (CAM) is a group of diverse medical and healthcare systems, practices, and products that are not generally considered part of conventional medicine (National Center for Complementary and Alternative Medicine [NCCAM], 2008). A **complementary therapy** may be defined as any procedure or product that is used together with conventional medical treatment. For example, a childbearing woman might request aromatherapy to help her cope with the discomfort she anticipates following a scheduled cesarean birth. Although complementary therapies were entirely absent from clinics and hospitals until the last few decades, they are now often used in conjunction with surgery, pharmaceuticals, and other conventional treatments for a variety of injuries and illnesses. They are also being more and more frequently integrated with conventional perinatal care.

In contrast, an **alternative therapy** is used in place of conventional medicine (NCCAM, 2008). For example, a woman with a postterm pregnancy may refuse medication to induce labor, and instead ingest an herb she believes will stimulate contractions. Because alternative therapies are used in place of medically prescribed treatments, people may be reluctant to discuss them with a conventional physician or registered nurse.

The very terms *complementary* and *alternative* suggest the contemporary view that herbs, homeopathy, chiropractic, and other such healing techniques are peripheral to conventional Western medicine, which is the "primary" treatment. How did we come to hold this view? And what has contributed to the resurgence in complementary and alternative therapies in the last few decades?

Historic Perspective

Five hundred years ago, a Native American woman drinking hot water steeped with chamomile to settle her stomach would never have described her beverage as a complementary or alternative therapy. She was merely following a custom handed down to her by her ancestors and practiced widely in her tribe. If her symptoms continued, she would likely have consulted a medicine woman or medicine man, who might have performed a healing ritual using other herbs, stones, chanting, and/or communion with the "animal spirits" or ancestors who had passed on. Such forms of self- and community-based treatment, though varying somewhat from one culture to another, are thought to have been the norm around the world for thousands of years.

Many therapies that are today considered complementary or alternative grew out of indigenous cultures' use of the herbs, spices, flowers, fruits, and other plants and natural materials available in the region, and reflected their health concerns. For example, it has been proposed that one rationale for the highly spiced cuisine of India is that the spices used, in addition to being widely available, have an antimicrobial effect. This would have been important for a hot region of the world where food could not be preserved without fear of spoilage. In contrast, people in colder regions of the world, such as northern Europe, developed techniques such as salting, drying, and freezing foods during long winters to preserve them from microbial decay.

Many other complementary and alternative therapies developed from cultures' spiritual beliefs. Thousands of years ago, most cultures held the belief that illnesses and injuries—as well as therapies to heal them—were spiritually based. For example, peoples from ancient China, India, and the Americas shared the belief that all animals, plants, and even minerals contain a spiritual "essence," a vibrational life force that could be employed in healing. European peoples once believed that disease was caused by supernatural forces either to punish human beings or to teach them spiritual lessons. Others, such as the people of ancient India, believed that illness demonstrated a lack of alignment of the mind and body with God. For Patanjali, who wrote the *Yoga Sutras* in the third century BCE, a healthy body was a precondition for spiritual wholeness. In some cultures, spiritual healers performed rituals to exorcise the evil spirit from the diseased body.

Around 400 BCE, Hippocrates became the first practitioner in the West known to challenge the idea that illnesses and injuries have spiritual causes and remedies. His school of medicine investigated impurities in the individual's food, water, and environment as causes of disease and attempted to base healing practices in the known laws of nature. Students began to investigate systematically the healing properties of local plants and other substances and to develop standards of practice.

Over the next millennium, indigenous peoples worldwide continued to hand down the knowledge of healing plants and practices. Shamans, alchemists, and midwives were highly respected members of their communities and were relied on for their cures. However, between the 13th and 17th centuries in Europe, church-led inquisitions sought out and killed indigenous healers, typically burning them as "witches." At the same time, the new philosophy of rationalism became popular, and community leaders began to demand empiric evidence for

healing practices. During the 17th century, the scientific method gained ascendancy, single-celled organisms were discovered, and the first experiments challenging the idea of spontaneous generation of life were conducted.

From the 18th to the 19th centuries, several scientific achievements further advanced the supremacy of empirically based medical techniques. High-powered microscopes were developed that could allow detection of microorganisms such as bacteria. In 1796, the English physician Edward Jenner developed the first effective vaccine, which used material from cowpox lesions to stimulate immunity to smallpox. In the mid-1800s, the French scientist Louis Pasteur conducted experiments that led to the formulation of the *germ theory of disease,* that is, the theory that microbes can cause human disease. In the 1860s, the English surgeon Joseph Lister introduced aseptic techniques using phenol and dramatically reduced the mortality rate following surgery. His techniques were widely adopted by other surgeons and led to increased acceptance of surgery as a viable treatment. By 1875, the German scientist Robert Koch had established postulates to prove whether a certain organism was pathogenic and what disease it caused. Thus, people learned that infectious disease, which was the leading cause of death at that time, was not due to spiritual flaws.

At the same time, European colonization of countries in Asia, Africa, Australia, and the Americas brought European medical practices as well. Indigenous healers and their therapies, such as the ayurvedic system of India and the nature-based therapies of Africa, were prohibited by the colonial powers and replaced with Western procedures and pharmaceuticals. In the United States, the American Medical Association (AMA) grew in prominence, replacing female midwives with male obstetricians, and homeopathic physicians (estimated to comprise about 50% of U.S. physicians in the mid-19th century) with medical doctors who had graduated from AMA-approved schools of medicine.

In the early 20th century, several factors combined to ensure a virtual monopoly of conventional medicine in the United States. First, antimicrobial drugs and vaccines were developed that dramatically reduced morbidity and mortality due to infectious disease. Second, pharmaceutical companies began dominating medicine by heavily subsidizing U.S. medical schools, giving rewards and subsidies to physicians who used their drugs, and lobbying U.S. legislators for statutes and regulations favorable to their industry. Third, two world wars led to advances in both pharmaceuticals and surgical techniques that helped convince legislators of the superiority of the AMA's approach to health care.

National Center for Complementary and Alternative Medicine

Resurgence of Complementary and Alternative Therapies

Complementary and alternative therapies never entirely died out in the United States. Even in the 1950s, some people were able to eke out a living as chiropractors or herbalists. The social upheavals and "back to the land" movements of the 1960s and 1970s led to a renewed study of the healing therapies of indigenous cultures. Moreover, as Americans began to engage more widely in international work, study, and travel, their exposure to other healing systems and practices increased. Indeed, several American physicians, disillusioned by the limitations of conventional Western medicine, traveled to Asia and other regions to study alternative therapies.

By the final years of the 20th century, America's love affair with conventional Western medicine had begun to cool even more significantly as costs increased, health care began to be seen as more technologic and less "human," and access to healthcare professionals' time became strictly limited. Childbearing families in particular began to seek more "natural" birth experiences, without anesthesia, in homelike settings attended by female certified nurse-midwives. Americans began to recognize that many health problems, such as back pain, headaches, cancer, diabetes, heart disease, autoimmune diseases, and others, could not be cured simply by swallowing a pill or "going under the knife." Such disorders came to be seen as complex, involving lifestyle factors, cultural factors, emotional elements, and—many people believed—spiritual aspects that were ignored by conventional approaches. Increasingly, people with such diseases turned to the complementary and alternative healing community.

But perhaps the most explosive element in the resurgence of complementary and alternative therapies was—and continues to be—the Internet. With a laptop or smart phone, current information on complementary and alternative products and services is now just a click away. For example, a paper presented at a conference in Germany on the health benefits of reflexology might become available worldwide the next day. The Internet has increased not only information, but also communication among people with similar health concerns. A pregnant woman who has just begun to experience first trimester nausea can now join a chat group debating the advantages and disadvantages of ginger tea. Infertile couples can share a technique claiming to increase fertility that they learned on a trip to Asia. Suddenly, it has become easy for people to integrate complementary and alternative therapies into their own unique approach to their healthcare concerns.

Growing Integration with Conventional Western Medicine

In this new century, it seems clear that the future of American health care will see an ever increasing integration between conventional medicine and complementary therapies. Some obvious examples of this new integration in perinatal settings include the acceptance of certain herbal teas for antepartal discomforts; the use of massage, Reiki, or Therapeutic Touch during the first stage of labor; the use of music and aromatherapy during labor and childbirth; and the increased emphasis on skin-to-skin, mother-to-baby bonding in the immediate postpartum period.

Further evidence of this increased integration was the establishment in 1992 of the Office of Alternative Medicine (OAM) at the National Institutes of Health. The OAM was mandated by Congress to promote research into complementary and alternative therapies and dissemination of information to consumers. In 1998 the OAM was incorporated into a new National Center for Complementary and Alternative Medicine (NCCAM) with an expanded mission and increased funding. NCCAM is dedicated to exploring complementary and alterna-

tive healing practices in the context of rigorous science, training CAM researchers, and disseminating authoritative information to the public and professionals (NCCAM, 2008). Recently, NCCAM recognized a new domain of integrative medicine. **Integrative medicine** is an approach that combines mainstream medical therapies with complementary therapies for which there is evidence of safety and effectiveness (NCCAM, 2008). Many studies of complementary and alternative therapies are currently under way at the NCCAM, which can be accessed via the Internet.

Benefits and Risks of Complementary and Alternative Therapies

Complementary and alternative therapies undisputedly have many benefits for the childbearing family and other healthcare consumers. However, many of these remedies have associated risks that must be considered thoughtfully before a decision is made to use them.

Benefits

Many complementary and alternative therapies emphasize prevention and wellness and place a higher value on holistic healing than on physical cure. In addition, many are noninvasive and have few side effects, and many are more affordable and available than conventional therapies.

Emphasis on Prevention and Wellness

The therapies of conventional Western medicine—pharmaceuticals and surgery—are typically prescribed after a disease has already manifested in symptoms. These therapies are, of course, entirely appropriate—and may be lifesaving—in certain circumstances; for example, albuterol for an acute asthma attack or an appendectomy for appendicitis. However, they may be limited in effectiveness for subacute conditions.

In contrast, most complementary and alternative therapeutic systems emphasize maintenance of wellness and prevention of illness. For example, a woman consulting a medical doctor for fatigue might be tested for iron deficiency anemia. If the lab test came back negative, the woman might be advised simply to try to get more sleep, and the physician might prescribe a sedative to help achieve a full night's rest. In contrast, a woman consulting a practitioner of complementary and alternative medicine (CAM) would likely be asked dozens of questions about every aspect of her life, including her childhood, relationships, work habits, diet, lifestyle, stressors, and even how she feels about sunny days versus rainy days (Table 3-1). These questions would attempt to unearth the underlying cause of even the most subtle complaints and to prescribe remedies in several domains (acupuncture, homeopathic treatments, herbs, nutritional modifications, lifestyle modifications, massage, color therapy, and so forth) early enough in the process of breakdown to restore wellness before significant disease manifests.

Emphasis on Healing Versus Cure

This holistic approach extends to the goal of therapy as well; that is, the goal of many complementary therapies is not curing an illness but rather healing the patient's psyche, spirit, body, and even community. The physician and author Dr. Rachel Naomi Remen describes healing as the leading forth of wholeness in people. "Sometimes people heal physically, and they don't heal emotionally, or mentally, or spiritually. And sometimes people heal emotionally, and they don't heal physically . . . People can heal and live, and people can heal and die" (Moyers, 1993, p. 344).

TABLE 3-1 Concerns of the Holistic Healer

The holistic healer may be concerned with the following aspects of the patient's life:

- Exercise, breathing, and posture
- Self-care, including dental care
- Nutrition, hydration, use of dietary supplements, and method of food preparation
- Digestion and elimination
- Sleep/wake cycles
- Stress and emotional responses
- Purity of air, food, water, and environment
- Use of alcohol, tobacco, caffeine, and other substances
- Employment and unemployment
- Hobbies, sports, and other recreational activities
- Home life and relationships
- Spirituality
- Type and age of bed and bedding
- Types of clothing, cosmetics, and personal care products used
- Pets
- Exposure to and use of sound and music
- Reactions to weather and seasons
- Electromagnetic phenomena and exposure to radiation
- Exposure to sunlight and artificial light
- Travel
- Personality and temperament
- Fears (e.g., of heights, of death, etc.)

Source: Compiled from data in Lockie, P., & Geddes, N. (2000). Complete guide to homeopathy: The principles and practice of treatment. *New York, NY: DK.*

Noninvasive Approaches

In part because of this emphasis on healing versus cure, many of the therapeutic techniques offered by complementary systems are noninvasive and potentially enriching on many levels. For example, imagery is often used to help people with cancer enhance their immune function, but also to help increase their optimism and gain new access to feelings of love and nurturance that may have been buried by fear of their diagnosis. Meditation, hypnosis, and biofeedback are other mind-based therapies that are entirely noninvasive and can affect the patient on several levels. Massage and the other body-based therapies noninvasively promote healing of both the physical body and the patient's psyche. Music, light, colors, magnets, gems, and fragrances are also noninvasive and likely achieve their effects by subtly influencing the neurochemistry, circulation, memories, and/or emotions of the patient. Indeed, only a very few of the complementary therapies are invasive: these include acupuncture, certain techniques used in ayurveda, foods and dietary supplements, herbs, and homeopathic remedies, which are highly diluted substances.

Cost and Access

Complementary and alternative therapies may be less expensive and more readily available than conventional remedies. For example, most homeopathic remedies cost less than $15 for a vial

of 100 pellets or tablets. Essential oils, herbs, and dietary supplements also tend to be far less expensive than most conventional pharmaceuticals. In fact, some complementary and alternative therapies—including meditation, prayer, visualization, dietary modifications, and regular physical exercise—are free.

Visits to complementary healers are usually somewhat less expensive than visits to medical doctors; however, most insurance carriers do not cover complementary therapies unless the primary care physician has prescribed them. On the other hand, in some cases it is far easier to access complementary healers than conventional physicians, whether in the community or via their Web sites. By searching the Internet, it is possible for a childbearing family to glean tips on everything from relieving first-trimester nausea to preventing plugged ducts during breastfeeding.

Risks

These benefits of complementary and alternative therapies notwithstanding, it is critical that all consumers—and especially childbearing families—be aware of their not-insignificant risks. These include lack of standardization, lack of regulation and research substantiating safety and effectiveness, inadequate training and certification of some healers, and financial and health risks of unproven methods.

Lack of Regulation and Standardization

Pharmaceuticals prescribed by a Western physician or nurse practitioner have been tested and approved by the Food and Drug Administration (FDA). All preparations of an FDA-approved pharmaceutical, whether a brand-name drug or a generic version, have to contain identical quantities of certain precisely regulated, purified substances.

In contrast, herbs and dietary supplements do not undergo FDA testing or need FDA approval before they are marketed. Currently, the FDA is considering adopting new regulations for products that are marketed with health claims, but no such regulations are in place at this time. This lack of regulation means that non–FDA-approved products may vary dramatically from one manufacturer to another. For example, preparations of herbs may use the flowers, leaves, or stems, all of which vary in potency, and preparations may contain various concentrations of the actual herb versus carrier materials. Additionally, some manufacturers use such harsh chemicals to process herbs that their healthful properties are reduced or lost. Some herbs lose their potency over time with different types of storage, whereas others vary in strength according to the soil in which they were grown or the season in which they were harvested. This lack of standardization means that one preparation may be highly potent, whereas another is ineffective.

Lack of Research

Claims made by manufacturers of non–FDA-approved remedies may not be backed by valid, reliable research. The National Center for Complementary and Alternative Medicine (NCCAM) cautions: "While some scientific evidence exists regarding some CAM therapies, for most there are key questions that are yet to be answered through well-designed scientific studies—questions such as whether these therapies are safe and whether they work for the diseases or medical conditions for which they are used" (NCCAM, 2007e).

Approval by the FDA guarantees that a drug has been subjected to—and passed—a rigorous process requiring, in most cases, double-blind research studies substantiating the safety and effectiveness of the drug for the purpose under investigation. For this reason, when a childbearing woman is told that a certain drug will safely relieve her nausea or induce labor, she can accept these statements with confidence.

In contrast, the claims to effectiveness and safety of some complementary therapies may be largely unsubstantiated, resting on flawed or inadequate research, testimonials, tradition, or merely the healer's say-so. Thus, the consumer choosing these therapies often has little valid and reliable evidence that they will work effectively and safely.

The current inadequacy of research into complementary and alternative therapies is often due to lack of funding. When drug manufacturers commit millions of dollars to research and development of new pharmaceuticals, they do so knowing that, if they succeed in developing a safe and effective drug, their financial gain will more than cover their investment. In contrast, no one profits financially from consumers who use meditation, prayer, visualization, dietary modifications, exercise, water therapy, music, or sunlight. Even the profits from herbs, dietary supplements, or the body-based therapies are minimal compared with the costs of research studies to substantiate their use. Fortunately, as noted earlier, NCCAM is now funding research into several of these therapies.

Research into complementary and alternative therapies is also hindered by the very nature of these therapies. It is comparatively easy to provide a control group with either the drug being studied or a placebo and then to measure reduction in symptoms, but how does one design a reliable, valid study of therapies that attempt to maintain wellness or prevent illness; that value healing rather than cure; that claim to work on subtle, vibrational levels; or that admit to the necessity of a therapeutic relationship with the healer? Currently there is so little understanding of the cultural, psychologic, emotional, and spiritual aspects of healing that investigators trained in quantitative research methodologies may be unprepared even to design valid studies. On the other hand, it is interesting to note that several qualitative nursing research studies over the past decade have studied complementary and alternative therapies with some success.

Inadequate Training and Certification

Many complementary modalities require rigorous training and testing before applicants receive certification as practitioners. For example, naturopathic, homeopathic, and chiropractic physicians usually complete a typical undergraduate premedical program before enrolling in a 4-year graduate school in their specialty. Acupuncturists, certified massage therapists, Reiki practitioners, and some other complementary therapists must complete a course of study at an approved school, achieve a certain number of hours of practice, and pass an exam before they are certified.

In contrast, many titles are unregulated. For example, many states do not require that people calling themselves "coun-

selors," "nutritionists," "healers," "intuitives," or "consultants" have any particular education or license. Thus, consumers who purchase the services of such therapists must beware.

Financial and Health Risks of Unproven Methods

As noted earlier, complementary and alternative remedies and techniques may cost considerably less than conventional pharmaceuticals and procedures. However, consumers may make a considerable investment in unproven methods and products that may not, in the end, improve their well-being, prevent illness, or promote healing.

Although few complementary and alternative therapies actually harm consumers directly, consumers' health may indeed suffer if their belief in the therapy or healer causes them to delay or forgo conventional medical treatments. Tragically, each year in the United States, cases of fetal demise occur among childbearing families who choose to use unlicensed birth attendants in home settings.

Types of Complementary and Alternative Therapies

The following review of complementary and alternative therapies is meant as an introduction. The list is not exhaustive, and the descriptions are exceedingly brief.

The categories under which particular therapies are discussed here are somewhat arbitrary. For example, homeopathy is categorized as a complementary therapeutic system, but it could also be considered an energy therapy. Therapeutic Touch and Reiki are both energy based and body based. Massage is a sense therapy in that it employs touch, yet it is classified with the body-based therapies. In truth, the holistic nature of these therapies means that they affect the patient in many different ways.

Complementary Therapeutic Systems

The complementary therapeutic systems described here are complex and multidimensional, incorporating different techniques into a holistic approach to wellness, prevention, and healing.

Homeopathy

Homeopathy is best understood in contrast to conventional Western medicine, which is also called *allopathic medicine.* The term *allopathy* is derived from the Greek words *allos,* meaning "different," and *pathos,* meaning "suffering." Thus, allopathic medicine, which has been dominant in the United States for over 100 years, uses remedies that produce effects differing from—or in opposition to—those of the disease being treated. For example, allopathic healthcare practitioners may prescribe an anti-inflammatory to reduce swelling or a sedative to relieve insomnia.

In contrast, the term **homeopathy** is derived from the Greek word *homos,* meaning "the same." Thus, it is often described as a healing system that uses like to cure like; that is, homeopathic remedies are minute dilutions of substances that, if ingested in larger amounts, would produce effects *similar* to the symptoms of the disorder being treated. For example, *Cantharis vesicatoria* is a species of beetle (commonly called Spanish fly) whose poison causes, among other things, burning urinary tract pain and a continuous urge to urinate. Homeopathic *Cantharis* is a minute dilution of this toxin and is thus a remedy of choice for women suffering from cystitis.

Founded by the German physician Samuel Hahnemann in the late 18th century, homeopathy traces its roots to Hippocrates, who was the first physician known to have observed the principle of like curing like. Homeopathic remedies are believed to achieve their effects by stimulating the patient's immune system to mount a response against the diluted substance. Thus, it is the individual's own body, rather than the ingested remedy, that opposes the symptoms. Indeed, homeopathic physicians advise that an initial worsening of symptoms indicates that the correct remedy has been given.

It is important to note that, although homeopaths do rely on certain standard remedies such as *Cantharis* for cystitis, they believe that physical symptoms manifest disturbances on far deeper levels. Thus, they work to peel away ever-more subtle layers of disturbance, thereby effecting holistic healing.

Naturopathy

Naturopathy is commonly referred to as *natural medicine.* Its central beliefs are that nature has healing power, and that the human body has the innate power to maintain or return to a state of health—and thus to heal itself (NCCAM, 2007c). Naturopathic physicians are eclectic, employing a variety of therapies in their practice. These might include clinical nutrition, exercise, botanical medicine, homeopathy, counseling for lifestyle modification, and other therapies. Moreover, they believe that physicians should be educators as well, so they teach their patients how to nurture themselves and encourage self-responsibility (American Association of Naturopathic Physicians, 2009).

Traditional Chinese Medicine

Traditional Chinese medicine (TCM) developed more than 3000 years ago in the Chinese culture and then gradually spread with modifications to other Asian countries, including Japan, Vietnam, Tibet, and Korea. Its goal is to promote health and well-being so the underlying focus of TCM is prevention, although diagnosis and treatment of disease also play an important role.

TCM seeks to ensure the balance of energy, which is called *chi* or *qi* (pronounced "chee"). Chi is the invisible flow of energy in the body that maintains health and energy and enables the body to carry out its physiologic functions. Chi flows along certain pathways or meridians, which are discussed further in the acupressure and acupuncture section.

Another important concept in TCM is that of *yin* and *yang,* opposing internal and external forces that, together, represent the whole (Figure 3-1 ■). Yin is the female force—passive, cool, wet, and close to the earth. Yang is the masculine force—aggressive, hot, dry, and celestial. Yin and yang cannot exist independently because they are complementary and both are essential. Certain foods, behaviors, and environmental factors are believed to increase yin, whereas others increase yang. Well-being occurs when

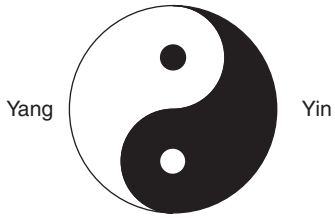

Figure 3-1 ■ Traditional Chinese symbol of the opposing forces of *yin* and *yang* in perfect balance, representing integration and wholeness.

these two opposing forces are in balance, and illness can result if this balance is disturbed over a period of time.

TCM includes the following therapeutic techniques:

- Acupuncture (discussed on p. 55)
- Herbal therapy
- Nutrition
- Acupressure (Chinese massage) (discussed on p. 54)
- *Moxibustion,* which involves the application of heat from a small piece of burning herb
- *Qigong* (pronounced "chee-goong"), which is a self-discipline that involves the use of breathing, meditation, self-massage, and movement. Typically practiced daily, the movements are nontiring and are designed to stimulate the flow of chi (Figure 3-2 ■).
- T'ai chi (pronounced "ty chee"), which is a form of martial art. It originally focused on physical fitness and self-defense but is currently used more as a health discipline. T'ai chi is helpful in improving balance.

Figure 3-2 ■ Pregnant woman practices the movements of *Qigong.*

> "I am so glad that complementary therapies are becoming more accepted. I don't plan to stop going to see my doctor, but now that I am pregnant I like doing things on my own to improve my health. I used acupressure wrist bands early on and felt they really helped my nausea. I'm taking prenatal yoga classes now and I feel terrific! I think I will definitely continue doing yoga after the baby is born."

Ayurveda

The classical system of Hindu medicine is known as **ayurveda**. The term *ayurveda* is derived from the Sanskrit words *ayus,* meaning "life, health, and vitality," and *veda,* meaning "knowledge." Thus, ayurveda is the knowledge of how to live a vital, healthful life. Ayurvedic physicians believe that the five elements of ether, wind, fire, water, and earth take form in the body as three tendencies, called *doshas:* vata, pitta, and kapha. Each person's constitution is believed to reflect some combination of these three doshas. For example, vata reflects the elements of ether and wind; thus, a person in whom vata is dominant may be flighty and anxious, with dry skin, eyes, and respiratory membranes. The primary element in kapha is water, and so it is not surprising that pregnancy is considered a kapha condition.

An important part of the ayurvedic physician's job is to balance the doshas by suppressing the dosha that is dominating the patient and stimulating the dosha that is sluggish. The physician does this by addressing virtually all aspects of the patient's life. For example, a fatigued woman in whom kapha is too dominant may be prescribed hot foods and spices, certain herbs, warm colors, energizing music, pungent aromas, an earlier bed time and waking time, exercise, and other changes to stimulate her internal fire (pitta) and burn away some of her internal water (kapha). This is a simplistic example of a highly complex system, but the important thing to bear in mind about ayurveda is that, like homeopathy, naturopathy, and TCM, it approaches the patient holistically.

Mind-Body Therapies

This section discusses therapies engaging the mind in activities such as imagination, reflection, communication, and relaxation.

Biofeedback

Biofeedback is a method used to help individuals learn to control their physiologic responses based on the concept that the mind controls the body. An individual is hooked up to a system of highly sensitive instruments that relay information about the body back to that person. The effectiveness of biofeedback has been proven in countless studies, and it is now considered a conventional therapy more than a complementary one. For example, biofeedback may focus on temperature or thermal feedback, especially in treating certain vascular diseases or in promoting relaxation. It may focus on galvanic skin response, which measures sweat gland activity in the fingers or palms, in helping people learn to deal with stress. It may use electromyo-

graphy (EMG) to provide feedback about muscle tension to help in the treatment of muscle spasm or tension headache, or electroencephalography (EEG) to gain feedback about brain wave activity to help with insomnia or pain.

Hypnosis

Hypnosis, whether guided by a trained hypnotherapist or induced through self-hypnosis, is a state of great mental and physical relaxation during which a person is very open to suggestions. Because hypnosis cannot make people do something against their will, it will not work unless an individual is really interested in changing. Studies have shown that self-hypnosis during invasive medical procedures such as breast biopsy can significantly reduce a patient's pain and anxiety (NCCAM, 2007a).

Meditation and Prayer

Many people think of meditation as sitting quietly with legs crossed and eyes closed, repeating a *mantra* or counting one's breaths to still the mind and bring peace. In contrast, the great spiritual teacher J. Krishnamurti (1895–1986) defined *meditation* far more simply, as something one can do every day at any moment. For Krishnamurti (2000), "Meditation is to perceive the truth each second . . ." by simply observing without judgment. When patients allow their family values, education, social conditioning, knowledge, desires, expectations, and all other "accumulations" to fade away, and listen receptively in a state of not knowing, they experience an emptiness that is itself transformative and healing (Figure 3-3 ■).

Whereas meditation is often likened to listening, *prayer* is an act of silently or vocally addressing a deity such as Allah, Jesus, Shiva, or the Great Spirit, or for those outside of a particular religious tradition, simply "talking to the Universe." Prayer specifically for health reasons is the most commonly used complementary therapy (NCCAM, 2005). The effect of prayer on healing has been studied and documented and more research is under way.

Figure 3-3 ■ Meditation does not have to be practiced in a particular pose but can be incorporated into each day. People who meditate regularly find it helpful to assume a comfortable position in a quiet area free of distractions. Eyes may be open or closed. This woman, 8 months pregnant, has chosen a comfortable position with her arms and legs supported. She is gazing into the distance, unfocused. Her goal is to open her mind and move into a receptive state.

Visualization and Guided Imagery

A complementary therapy, **visualization** has been used since ancient times. In visualization a person goes into a relaxed state and focuses on or "visualizes" soothing or positive scenes such as a beach or a mountain glade. Visualization helps reduce stress and encourage relaxation. For example, a therapist may work with a woman before childbirth to help her create positive images of labor.

Guided imagery is a state of intense, focused concentration used to create compelling mental images. It is sometimes considered a form of hypnosis. Guided imagery is useful in imagining a desired effect such as weight loss or in mentally rehearsing a new procedure or activity. Skill in using guided imagery improves with practice so people who wish to use it should set aside 5 to 20 minutes of quiet time once or twice daily and practice creating images that are personal and meaningful.

Manipulative and Body-Based Therapies

Therapies requiring practitioner manipulation of the body are discussed here, along with hydrotherapy, hatha yoga, and regular physical exercise.

Chiropractic Therapy

Chiropractic, the third largest independent health profession in the United States (behind medicine and dentistry), is based on concepts of spinal manipulation. It was developed by Daniel David Palmer, a self-taught American healer, in the late 19th century. Palmer believed that many diseases and illnesses were the result of abnormal nerve transmissions caused by misalignment of the spine (subluxation). He postulated that spinal manipulation could correct these vertebral misalignments.

To practice chiropractic in the United States, practitioners must earn a Doctor of Chiropractic (DC) degree, which typically requires 4 years of postgraduate study and clinical experience. Currently chiropractors are licensed in all 50 states and are regulated by state boards. Chiropractic has earned a higher level of insurance coverage than most other alternative therapies. Many health maintenance organizations (HMOs) and private health insurance plans, as well as Medicare, cover chiropractic treatment (NCCAM, 2007b).

Chiropractors focus on the close relationship between structure and function but also stress the importance of proper nutrition and regular exercise to good health. A number of studies have shown chiropractic to be effective in treating problems such as lower back pain. During pregnancy, chiropractic can help relieve the backache and physical stress resulting from increased body weight and a changing center of gravity.

Massage for Pregnancy

Massage Therapy

Massage has been used for centuries as a form of therapy. **Massage therapy** involves the manipulation of the soft tissues of the body to reduce stress and tension, increase circulation, diminish pain, and promote a sense of well-being. Different techniques have been developed, including, for example, Swedish massage, shiatsu massage, Rolfing, trigger point massage, Thai massage, and sports massage. Most forms of massage use approaches such as pressing, kneading, gliding, circular motion, tapping, and vibrational strokes.

Certification and/or licensure for massage therapists varies from state to state although most states require at least 500 hours of training. Massage therapists who have passed the written examination given by the National Certification Board for Therapeutic Massage and Bodywork (NCBTMB) are nationally certified. Continuing education is then required for recertification.

Certain massage therapists specialize in massage for women during pregnancy (Figure 3-4 ■). Massage is often helpful as women adapt to the discomforts of their changing bodies. In addition, certified nurse-midwives often use perineal massage before labor to stretch the muscles of the perineum around the vaginal opening and thereby prevent tearing of the tissues during childbirth. During labor, massage of the back and buttocks by the nurse, labor coach, or doula can help the woman relax and may help decrease her discomfort.

Infant massage has become increasingly popular in the United States (Figure 3-5 ■). The calm, soothing strokes of baby massage can help soothe an infant and minimize crying. In addition, research has demonstrated that massage can improve immune function, relieve pain, reduce anxiety, and promote relaxation and sleep (Sinclair, 2005).

Figure 3-4 ■ Pregnant woman receiving massage. Massage is often useful in helping a pregnant woman cope with the discomforts of pregnancy.

Source: Alfred Wekelo/Shutterstock.

Figure 3-5 ■ Infant massage.

> "I got into infant massage when Ryan was born. I loved the time we spent together, and I am convinced it was part of the reason he was such a good baby."

Reflexology

Reflexology is a form of massage that involves the application of pressure to designated points or reflexes on the patient's feet, hands, or ears using the thumb and fingers. Eunice Ingham, a physical therapist, mapped the specific reflex zones and is credited with spreading the practice of reflexology.

Reflexology most often involves manipulation of the feet. Practitioners believe that distinct areas of the feet correspond to particular organs or body systems. The stimulation of the appropriate region is intended to eliminate energy blockages thought to produce pain or disease. Organs on the right side of the body are represented on the right foot and organs on the left side are represented on the left foot (Figure 3-6 ■). Although they are used less frequently, the hands and ears have also been mapped.

Hydrotherapy

Hydrotherapy is the term used to describe therapy that makes use of hot or cold moisture in any form. Hydrotherapy is used to relax muscles, promote rest, decrease pain, reduce swelling, promote healing, cleanse wounds and burns, reduce fever, lessen cramps, and improve well-being. The major types of hydrotherapy include the following:

- ***Compresses*** (ice packs, hot water packs, towels or dressings soaked in hot or cold water and wrung out). Compresses are applied locally and are often alternated between hot and cold compresses. They are especially effective in improving circulation to a given area, thereby reducing swelling and promoting healing. They are also helpful in reducing pain or achiness in a given area.
- ***Baths*** (local, such as a foot bath or sitz bath, or full immersion bath). Baths serve many of the same functions as com-

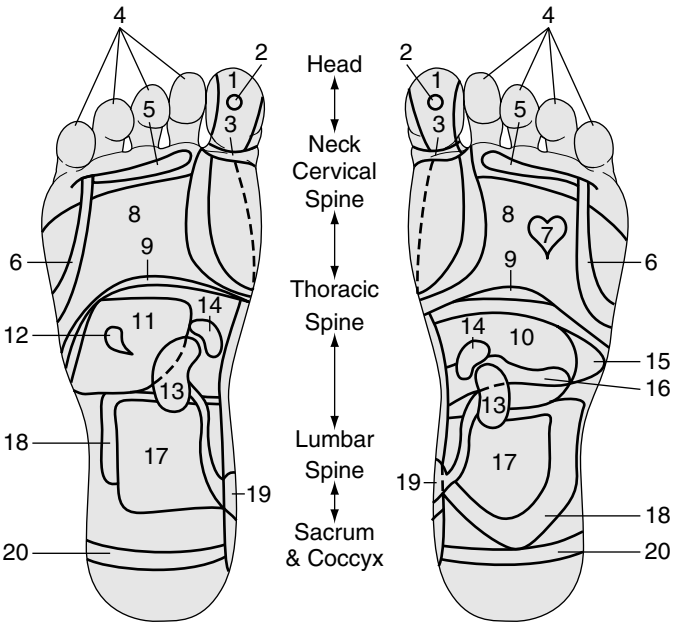

Figure 3-6 ■ Foot reflexology points.

Source: Fontaine, K. L. Complementary and Alternative Therapies for Nursing Practice, *2nd ed., 2005. p. 225. Printed and electronically reproduced by permission of Pearson Education, Upper Saddle River, NJ.*

presses but also are effective in cleansing. Warm baths are often used to promote comfort during labor.

- ***Sweat baths*** (steam bath or sauna). Sweat baths are used to open pores and induce sweating, which is thought to promote the elimination of toxins, drugs, and salts from the body. Because high heat has been associated with neural tube defects, pregnant women should not do steam baths or saunas, especially in the first trimester (Fontaine, 2011).

Hatha Yoga

When they hear the word *yoga,* most people think of people in leotards moving through a series of postures, such as the cat stretch or the salute to the sun. In reality, the term *yoga* comes from the Sanskrit word for "union," and implies a path toward union with God. **Hatha yoga** is the physical branch of yoga, and in the United States, it is commonly practiced for wellness, illness prevention, and healing. In hatha yoga, the individual moves through a series of gentle stretches and postures (called *asanas*) coordinated with deep, rhythmic breathing techniques that promote oxygenation of all body tissues.

Certain yoga positions are especially beneficial during pregnancy and can be practiced safely by most women. These techniques coordinate breathing with movement while increasing strength and suppleness, providing valuable preparation for childbirth. In many communities, yoga teachers offer classes specifically designed for pregnant women (Figure 3-7 ■).

Regular Physical Exercise

As more and more people are recognizing, regular physical exercise plays an important role in maintaining health and fitness. Exercise is important in maintaining muscle tone and strength, controlling weight, promoting cardiovascular health, improving digestion and elimination, reducing stress, promoting sleep, preventing a variety of chronic health problems, and providing an overall sense of fitness and well-being. In addition, exercise programs are an important component of ongoing therapy for a variety of health conditions.

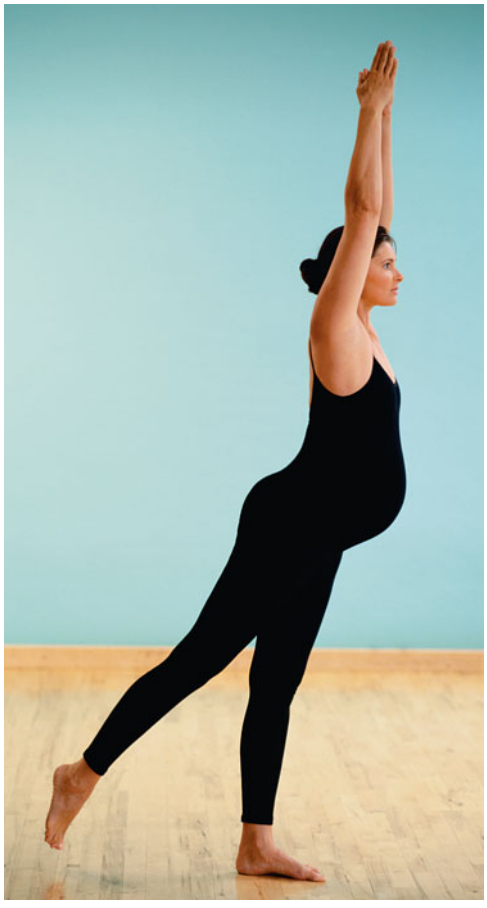

Figure 3-7 ■ Pregnant woman doing a hatha yoga stretch.

For further discussion of exercise during pregnancy, please refer to chapter 16 ∞.

Nutritional and Herbal Therapies

The nutritional and herbal therapies include the use of particular foods as remedies; the use of vitamins, minerals, and other supplements; and the use of herbs.

Dietary Therapies

It has long been recognized that foods have nutrients that are necessary for health. However, the value of a nutritious diet in maintaining health is becoming more widely recognized and concerns are growing about the quality of some of the food products available today.

As part of their quest for optimum health, people make choices about their diets: whether to choose vegetarianism, a high-protein, low-carbohydrate diet, or a more balanced combination based on the U.S. Department of Agriculture's (USDA's) MyPyramid (see chapter 18 ∞); whether to consume alcohol in moderation or no alcohol at all; whether to include processed foods in the diet or not; whether to incorporate dietary supplements or not, and so forth. The literature offers a wealth of information about nutrition and diet therapy. Some of

this information is grounded in data and research; other advice relies more on tradition and hearsay.

The importance of good nutrition for pregnant women and for infants and children cannot be overemphasized. Please refer to chapter 18 ∞ for a discussion of nutrition for women during pregnancy and the postpartum period and to chapter 32 ∞ for a discussion of newborn nutrition.

Use of Supplements

A *dietary supplement* is any product (excluding tobacco) intended to supplement the diet. It may be available for ingestion in the form of a powder, capsule, geltab, liquid, extract, and so forth, and it contains one or more of the following ingredients: a mineral, vitamin, herb, amino acid, other botanical supplements, or extracts and ingredients of animal and plant origin. Dietary supplements are not presented as conventional food products and they are not intended to be the sole item of a meal or of the diet (Office of Dietary Supplements, 2009).

Dietary supplements, sometimes called natural food supplements, are used to achieve a specific purpose. Perhaps the most widely used form of supplement is a multivitamin tablet or capsule. Other commonly used supplements are fish oil, flaxseed oil, ginseng, and garlic. Women who are pregnant should discuss the use of supplements with their caregiver or with a registered dietitian.

Herbal Therapies

An herb is a plant or plant part (such as leaves, flowers, or seeds) that is used for its flavor, scent, or therapeutic properties (NCCAM, 2009b). Like vitamins and minerals, herbs are a form of dietary supplement; thus, herbal formulations are not subject to Food and Drug Administration (FDA) premarket testing for safety and effectiveness. The FDA does have the authority to pull a product off the market if it is proven to be dangerous.

The use of herbs during pregnancy and breastfeeding is an especially important consideration for nurses working with childbearing families. Pregnant and lactating women interested in using herbs are best advised to consult with their healthcare provider before taking any herbs, even as teas. Lists identifying common herbs that women are advised to avoid or use with caution during pregnancy and lactation are available. For further information on specific herbs, visit the NCCAM Web site.

DEVELOPING CULTURAL COMPETENCE

Herbal Therapies

The World Health Organization estimates that 80% of the earth's population depends on plants to treat common ailments. Herbalism is an essential part of ayurvedic (Indian), traditional Asian, Native American, and naturopathic medicines. Many homeopathic remedies are also developed from herbs.

Sense Therapies

Most practitioners who use the sense therapies are trained in several. For example, to boost immunity, one healer might prescribe a varied menu of aromas, colors, and sounds.

Aromatherapy

Aromatherapy is the use of certain essential oils, derived from plants, whose odor or aroma is believed to have a therapeutic effect. Essential oils are typically diluted in a carrier oil such as sweet almond oil, olive oil, or vegetable oil before they are applied to the skin. Essential oils can also be inhaled (a few drops in warm water) or added to bath water. Essential oils are used for balancing mood, alleviating stress, relieving pain, and improving sleep.

Opinion varies about the use of essential oils during pregnancy because certain oils may pose a risk to the woman or her fetus. A pregnant woman who is considering aromatherapy should first discuss it with a healthcare provider who is knowledgeable about aromatherapy or a skilled aromatherapist (Fontaine, 2011).

Color Therapy

Chromotherapy or *color therapy* is designed to use colors to help restore the body to harmony. Color therapists believe that, because all matter is a form of energy, the application of energy to the body in the form of light can have therapeutic results. Because light can be split into colors, it is possible to deliver this energy at very precise levels and in easily controlled doses. After assessment, the color therapist exposes the patient to a particular color of light to promote healing.

Sound and Music Therapies

Sound therapy is based on the premise that when the body is exposed to the correct sound frequency (including some very low and very high frequencies that humans cannot normally hear) the body restores itself. A simple application of sound therapy is to encourage a woman in childbirth to moan on as low a pitch as possible during contractions. This opens the jaw, throat, and chest, and many women report that it promotes feelings of relaxation and power. In contrast, high-pitched squealing or screaming tightens the body and may promote feelings of fear. *Music therapy* can be considered a form of sound therapy. Music has been used during pregnancy and labor and birth to help soothe women and decrease their anxiety by stimulating endorphin release.

Energy Therapies

The energy therapies work at the most subtle level of the body to enhance immunity, reduce allergy, improve circulation, and improve neural integration.

Acupressure and Acupuncture

Both acupressure and acupuncture were originally part of traditional Chinese medicine. These practices are based on the traditional Eastern belief that the body's life energy, chi, which was discussed previously, flows along certain pathways known as meridians. The meridians—14 in number—connect all parts of the body. The places where the meridians pass close to the skin's surface are called pressure points. Stimulating specific pressure points can promote wellness, relieve pain, and contribute to healing.

Acupressure (sometimes called Chinese massage) uses pressure from the fingers and thumbs to stimulate pressure points.

Acupressure is easy to learn and is often used for self-treatment of tension-related ailments such as headaches, muscle aches, and tension due to stress. Pregnant women often use acupressure wristbands to help relieve the nausea of early pregnancy.

Acupuncture, considered the stronger technique, uses very fine (hairlike) stainless steel needles to stimulate specific points depending on the patient's medical assessment and condition. A treatment typically involves the placement of 6 to 12 needles. Acupuncture is used to treat a variety of conditions. Recent research indicates that acupuncture may improve rates of pregnancy when given with embryo transfer in women undergoing in vitro fertilization (NCCAM, 2009a).

Reiki

A Japanese technique founded in 1922 by Mikao Usui, **Reiki** is a form of hand-mediated therapy designed to promote healing, reduce stress, and encourage relaxation. Reiki practitioners place their palms on or just above specific problem areas and transfer energy to their patients to restore the balance of the patient's energy fields. Although the technique is entirely safe, the value of Reiki remains unproven (Lee, Pittler, & Ernst, 2008).

Therapeutic Touch

Therapeutic Touch is a complementary therapy designed to interface with conventional medical care. It was developed in the early 1970s by Dr. Delores Krieger, a nursing professor at New York University, and Dora Kunz, a clairvoyant healer. Therapeutic Touch is grounded in the belief that people are a system of energy with a self-healing potential. The Therapeutic Touch practitioner, often a nurse, can modulate his or her energy field with that of the patient's, directing it in a specific way to promote well-being and healing. Proponents of Therapeutic Touch believe that a strong desire to help the recipient is essential as is a conscious use of self to act as a link between the universal life energy and the other person (Fontaine, 2011). Many small studies of Therapeutic Touch have suggested its effectiveness in a wide variety of conditions, including wound healing, osteoarthritis, migraine headaches, and anxiety in patients with burns (NCCAM, 2007d). See Table 3-2 for more information about Therapeutic Touch.

Like many other conventional and complementary therapies, Therapeutic Touch should be applied cautiously to pregnant women and newborns by trained providers (Figure 3-8 ■).

TABLE 3-2 Facts About Therapeutic Touch (TT)

- Therapeutic Touch is taught in more than 100 colleges and universities worldwide and has been taught to more than 40,000 healthcare providers.
- The North American Nursing Diagnosis Association (NANDA) recognizes "energy field disturbance" as a nursing diagnosis, and professional organizations such as the American Nurses Association and the National League for Nursing have supported TT as a nursing intervention.
- TT is used as a complementary therapy for virtually all medical and nursing diagnoses as well as for surgical procedures.
- TT is best known for its ability to relieve pain and anxiety.

Nursing Care of the Childbearing Family Using Complementary Therapies

Some form of complementary and alternative medicine (CAM) is currently being used by 38% of adults in the United States. Women use CAM more often than men do, as do people with higher educational levels and incomes. By race, American Indian/Alaska Natives are the greatest users of CAM, followed by whites (NCCAM, 2008).

As knowledge of complementary and alternative therapies grows, the number and type of people using one or more of them will probably increase as well. Thus, it is likely that the majority of childbearing families are using some form of CAM even though they do not share that information.

Assessing a Patient's Use of Complementary Therapies

The reality that women may use CAM and not reveal it raises some concern. Many CAM modalities are not likely to cause adverse effects during pregnancy. However, the possibility exists that there might be an adverse interaction between an herbal therapy and a medication prescribed by the caregiver. In addition, a few herbal remedies, such as cat's claw, are dangerous during pregnancy. Similarly, complications might develop from the use of certain vitamin supplements, especially if taken in megadoses.

Nurses who create a climate of respect and openness tend to be more effective in gathering information about a woman's use

Application: Internet Information on Complementary Therapies

of complementary or alternative therapies. The following recommendations may be useful to nurses in taking a history:

- Ask questions that are direct and nonjudgmental in seeking information about the patient's use of CAM.
- Ask questions about specific therapies, including the use of herbal therapy and homeopathy. Because many people consider herbs to be natural substances and because they are often sold as dietary supplements, patients may not think to mention them.
- Avoid making negative or disparaging comments about CAM. Such comments send the message that CAM is not desirable and may discourage people from disclosing their use of CAM therapies.

Case Study: Complementary Therapies

Care Plan Activity: Use of CAM in High-Risk Adolescent Pregnancy

PROFESSIONALISM IN PRACTICE

CAM Awareness

All nurses practicing today need to have at least an awareness of complementary and alternative therapies. The NCCAM Web site is an excellent resource for healthcare providers and for childbearing women and their families.

CLINICAL JUDGMENT

Case Study: Sally Redwing

Sally Redwing is a 31-year old Native American software engineer visiting the women's health clinic for the first time. When asked the reason for her visit, she explains that she and her husband had been trying to conceive for the past year and that 2 months ago, her mother had convinced her to try her grandmother's "special herbs" to induce pregnancy. She had been taking the preparation once weekly for a few weeks when she noticed that her period was late. Yesterday she had used an over-the-counter pregnancy test kit, and the results were positive, so she was here to get "a real test" to confirm her pregnancy. When the nurse asks Sally the ingredients in her grandmother's mixture of "special herbs," Sally says she has no idea and asks whether or not the nurse thinks she should continue to use the herbs "for a while, to keep the pregnancy going."

Critical Thinking

What should the nurse advise Sally about continuing to use the herbs?

See www.nursing.pearsonhighered.com for possible responses.

Incorporating Complementary Therapies into Maternal-Newborn Nursing Care

Because the practice of nursing is holistic in nature, many nurses are open to and supportive of the use of complementary and alternative therapies. However, nurses in the United States need to know whether the nurse practice act in their state specifically addresses CAM therapies because some states do, whereas others do not. For example, in Louisiana registered nurses (RNs) may initiate and use complementary therapies for patients who seek the therapies as part of the nursing plan of care to meet goals such as relief of pain, comfort, reduction of stress, relaxation, improved coping mechanisms, and increased sense of well-being, if the individual has given informed consent. Written policies are required in all practice settings that permit the RN to perform such modalities. Nurses also need to be knowledgeable about any legal requirements that govern their use of CAM.

In working with childbearing families, or indeed with any patients, nurses who use CAM therapies should choose those methods that are within the scope of nursing practice in their state and not limited by the licensure of other providers (such as massage therapists). Nurses are also best advised to use CAM therapies that are considered somewhat mainstream and for which there is research supporting their safety and effectiveness. For example, nurses working with a pregnant woman might safely suggest acupressure wristbands for the treatment of nausea. Other therapies that nurses often employ include exercise and movement, Therapeutic Touch, visualization and guided imagery, prayer, meditation, music therapy, massage, hydrotherapy, and aromatherapy.

Nurses who use complementary modalities should document their use within the context of nursing practice. This is most effective when the modality is identified as an intervention to address a specific nursing diagnosis. Thus, music therapy might be used for a laboring woman to address the identified nursing diagnosis of pain.

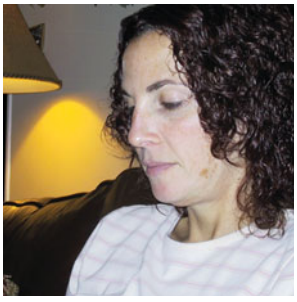
Many certified nurse-midwives (CNMs) incorporate complementary and alternative therapies into their clinical practice with childbearing families. Research suggests that CNMs who prescribe CAM do so for the following reasons: nausea and vomiting, labor stimulation, perineal discomfort, lactation disorders, postpartum depression, preterm labor, postpartum hemorrhage, and labor analgesia. Research on CAM sparks great interest in the public, and momentum is increasing to design and carry out well-developed research on alternative modalities. Nurses have a role in conducting and supporting research of this type. Because of the variety of CAM therapies in use, research is needed in a host of areas.

The results of research on CAM can be found in professional journals and at the NCCAM Web site. As the evidence supporting the use of certain interventions grows, nurses and other healthcare providers are incorporating the results as part of their evidence-based practice.

FOCUS YOUR STUDY

- A complementary therapy is an adjunct to conventional medical treatment, whereas an alternative therapy is used in place of prescribed medical therapy.
- The National Center for Complementary and Alternative Medicine (NCCAM) promotes research into complementary and alternative therapies and disseminates the information to consumers and professionals.
- Integrative medicine combines mainstream medical therapies with complementary therapies for which there is some high-quality scientific evidence of safety and effectiveness.
- Use of complementary and alternative medicine (CAM) therapies may be beneficial. Many of them emphasize prevention and wellness, place a higher value on holistic healing than on physical cure, are noninvasive, and have few side effects. In addition, many are more affordable and available than conventional therapies.
- Risks of CAM include lack of regulation and standardization, lack of research substantiating safety and effectiveness, inadequate training and certification of some healers, and financial and health risks of unproven methods.
- The term *homeopathy* is derived from the Greek word *homos,* meaning "the same." It is a healing system that uses like to cure like; that is, homeopathic remedies are minute dilutions of substances that, if ingested in larger amounts, would produce effects *similar* to the symptoms of the disorder being treated.
- Traditional Chinese medicine (TCM) seeks to ensure the balance of energy, called *chi* or *qi.* Techniques of TCM include acupuncture, moxibustion, herbal therapy, nutrition, acupressure, Qigong, and t'ai chi.
- Ayurveda is the classical system of Hindu medicine. It promotes balance of the three primary forces thought to influence human health and well-being.
- Biofeedback is a method used to help individuals learn to control their physiologic responses based on the concept that the mind controls the body.
- Hypnosis, whether guided by a trained hypnotherapist or induced through self-hypnosis, is a state of great mental and physical relaxation during which a person is very open to suggestions.
- Guided imagery is a state of intense, focused concentration used to create compelling mental images.
- Chiropractic, a profession practiced by licensed chiropractors, is based on concepts of manipulation, especially spinal manipulation.
- Massage therapy involves the manipulation of the soft tissues of the body to reduce stress and tension, increase circulation, diminish pain, and promote a sense of well-being. Reflexology is a specific form of massage that involves the application of pressure to designated points on the patient's feet, hands, or ears.
- Hydrotherapy makes use of hot or cold moisture in any form to relax muscles, promote rest, decrease pain, reduce swelling, promote healing, cleanse wounds and burns, reduce fever, lessen cramps, and improve well-being.
- Hatha yoga, the physical branch of yoga, is commonly practiced to improve health and well-being, to prevent illness, and to promote healing.
- A *dietary supplement* is any product (excluding tobacco) intended to supplement the diet. It contains one or more of the following ingredients: a mineral, vitamin, herb, amino acid, other botanical supplements, or extracts and ingredients of animal and plant origin.
- Herbs, a form of dietary supplement, are used to treat the symptoms of specific ailments or to enhance overall health. Pregnant and lactating women should inform their primary care provider about any herbs they plan to take.
- Acupressure (sometimes called Chinese massage) uses pressure from the fingers and thumbs to stimulate pressure points. Acupuncture, considered the stronger technique, uses very fine needles to stimulate specific points.
- Therapeutic Touch is based on the belief that people are a system of energy with a self-healing potential. The Therapeutic Touch practitioner, often a nurse, can unite his or her energy field with that of the patient's, directing it in a specific way to promote well-being and healing.
- Many nurses are open to and supportive of complementary and alternative therapies. Nurses who incorporate such therapies into their care of patients must be certain that they are practicing within the framework of their nurse practice act and with the informed consent of their patients.

CRITICAL THINKING IN ACTION



Rommy Startorius, a 34-year-old woman who has never been pregnant, is being seen for her annual gynecologic examination. As part of the health history you ask her whether she is using any forms of treatment for her health that are new since she was seen last year. Initially she reports that she has been getting massage therapy for low back pain and then, as the conversation progresses, she reports that she has been having acupuncture as well. She asks you how "regular" doctors feel about acupuncture and other forms of alternative therapy.

1. How would you describe the role of CAM in health care today?
2. What information could you provide about the use of acupuncture?
3. Mrs. Startorius asks you how she can learn about CAM therapies that have some research support for their effectiveness. How would you reply?

See www.nursing.pearsonhighered.com for possible responses.

Women's Care: Social Issues 145

CHAPTER 9
Violence Against Women 165

CHAPTER 4

Health Promotion of Women Across the Lifespan

This is a great time to be a woman. I feel like I can accomplish just about whatever I put my mind to. There are more opportunities for women now in education, sports, and involvement in the community. I intend to take good care of this body and mind and strive for something great.

LEARNING OUTCOMES

1. Discuss the key points a nurse should consider in taking a sexual history.
2. Summarize information that women may need in order to implement appropriate self-care measures for dealing with menstruation.
3. Identify causes of amenorrhea.
4. Contrast dysmenorrhea and premenstrual syndrome.
5. Delineate the physical and psychologic aspects of menopause.
6. Explain the relationship between menopause and osteoporosis.
7. Identify medical and complementary therapies to alleviate the discomforts of menopause.

KEY TERMS

Amenorrhea *64*
Climacteric *69*
Dysmenorrhea *65*
Hormone therapy (HT) *72*
Menopause *67*
Osteoporosis *70*
Perimenopause *69*
Premenstrual dysphoric disorder (PMDD) *66*
Premenstrual syndrome (PMS) *66*

A woman's healthcare needs change throughout her lifetime. As a young girl she requires health teaching about menstruation, sexuality, and personal responsibility. As a teen she needs information about reproductive choices and safe sexual activity. During this time she should also be introduced to the importance of healthcare practices such as breast self-examination and regular Pap smears. The mature woman may need to be reminded of these self-care issues and prepared for physical changes that accompany childbirth and aging. By educating women about their bodies, their healthcare choices, and their rights and responsibilities, nurses can help women be knowledgeable consumers who assume responsibility for the health care they receive.

This chapter, the first of six devoted to women's health, focuses primarily on wellness care. Chapter 5 ∞ considers issues related to family planning. Chapter 6 ∞ focuses on infections women may encounter, and chapter 7 ∞ addresses some of the common gynecologic issues and conditions a woman may face. Chapter 8 ∞ explores some of the major social issues women face, and chapter 9 ∞ focuses on violence against women.

Community-Based Nursing Care

Women's health refers to a holistic view of women and their health-related needs within the context of their everyday lives. It is based on the awareness that a woman's physical, mental, and social statuses are interdependent and determine her state of health or illness. The woman's perception of her situation, her assessment of her needs, her values, and her beliefs are valid, important factors to be incorporated into any healthcare intervention.

CLINICAL TIP

In making decisions about effective methods for communicating with a family about healthcare issues, remember that a woman's views frequently influence the health care of her entire family because women typically coordinate the family's healthcare needs.

Nurses can provide health teaching and information about self-care practices in schools, during routine examinations in a clinic or office, at senior centers, at meetings of volunteer organizations, through classes offered by the local health department or community college, or in the home. Nurses can also help women with various forms of disability to address their unique healthcare needs and optimize their state of wellness. This community-based focus is the key to providing effective nursing care to women of all ages.

In reality, the vast majority of women's health care is provided outside of acute care settings. Nurses oriented to community-based care are especially effective in recognizing the autonomy of each individual and in dealing with patients holistically. This approach is important in addressing not only physical problems but also major health issues such as violence against women, which may go undetected unless care providers ask women specifically about violence and are alert for signs of it.

DEVELOPING CULTURAL COMPETENCE

Developing Effective Communication

The United States' population includes many ethnic and cultural groups. As a nurse you will be caring for women and families from diverse cultures. It is important to avoid ethnocentrism and to approach the childbearing woman with an openness to learning about her traditions and cultural preferences. Understanding subtle differences in various cultures will help you initiate conversation and ask questions that will allow the woman to offer information about her preferences. It is easy to misconstrue simple cultural differences. There will be times as a nurse when you say or do something that the patient or the family interprets as inappropriate and perhaps even offensive. Being sensitive to body language and facial expressions will alert you that this may have happened. Stopping what you are doing and asking questions will convey a sense of caring and can encourage communication, thus allowing the woman and her family to express concerns or misunderstandings.

The Nurse's Role in Addressing Issues of Women's Wellness and Sexuality

Women expect the nurses who care for them to be knowledgeable not only about gynecologic health, but about a wide variety of health topics. Thus it is important that nurses expand their knowledge about the issues healthy women and their families may face. These include, for example, a general knowledge of normal growth and development; recommended screening procedures for both women and men, and the ages at which these procedures are indicated; signs and symptoms of substance abuse, including alcoholism; health issues that well men face; signs of emotional stress and depression; community resources; and a variety of other topics. By keeping abreast of issues well families may face, the nurse becomes a more complete resource and acts to promote overall health.

On occasion, most women experience concern and even anxiety about some aspect of menstruation, contraception, or sexual activity. Societal standards and pressures can cause girls and adolescents to evaluate and compare with others their experiences with menstruation, sexual attractiveness, and beliefs and values about engaging in sexual activity. Young adults may be more concerned about the reproductive and health implications of sexual intercourse. The desire to achieve or avoid pregnancy and the fear of sexually transmitted infections may cause many women to modify their sexual practices and activities. Although older women share many of these same concerns, they may also experience anxiety about the onset of menopausal changes and wonder how these changes will affect their sexuality. Furthermore, throughout the lifespan women may have concerns, problems, and questions about sex roles, sexual orientation, behaviors, inhibitions, morality, and related areas such as family planning. Recently divorced or widowed women who have been in long-term marriages may need education about sexual activity and sexually transmitted infections if they are reentering the dating world.

Women frequently voice these concerns to the nurse in a clinic or ambulatory setting. Thus the nurse may need to assume the role of counselor on sexual and reproductive matters.

Nurses who assume this role must be secure about their own sexuality. They must also develop an awareness of their own feelings, values, and attitudes about sexuality so that they can be more sensitive and objective when they encounter the values and beliefs of others. Nurses also need to know about the structures and functions of the female and male reproductive systems. In addition, they should have accurate, up-to-date information about topics related to menstruation, sexuality, sexual practices, cultural differences, menopause, and common gynecologic problems.

Staying up to date on issues of sexuality and women's health requires constant vigilance: Regular journal review, attendance at reputable conferences, library and Internet searches, and diligent perusal of women's health literature are essential activities. Continuing education for the practicing nurse and appropriate courses in undergraduate and graduate nursing education programs can also help nurses achieve and maintain the requisite knowledge. These activities enhance the nurses' knowledge about these topics and improve their effectiveness in teaching and providing care for their patients.

Taking a Sexual History

Nurses today are often responsible for taking a woman's initial history, including her gynecologic and sexual history. To be effective in this role, the nurse must have good communication skills and should conduct the interview in a quiet, private place free of distractions. The sexual history is one part of a lengthier health history and covers personal and intimate topics.

CLINICAL TIP

When taking a history, start your interview with less intimate areas, such as medical and surgical history, and then proceed to the sexual history toward the end of the history-taking session. This approach helps the woman develop a comfort level with you before disclosing personal information.

Opening the sexual history discussion with a brief explanation of the purpose of such questions is often helpful. For example, the nurse might say, "As your nurse I'm interested in all aspects of your well-being. Often women have concerns or questions about sexual issues, especially as their life situations change. I will be asking you some questions about your sexual history as part of your general health history." This explanation will help women understand the nature of this part of the history and allow for more open, honest answers.

It may be helpful to use direct eye contact as much as possible unless the nurse knows it is culturally unacceptable to the woman. The nurse should do little, if any, writing during this part of the interview. Open-ended questions are often useful in eliciting information. For example, "What, if anything, would you change about your sex life?" will elicit more information than "Are you happy with your sex life now?" The nurse should also clarify terminology to ensure accurate information is being conveyed. Proceeding from easier topics to those that are more difficult will help a natural flow of information. Throughout the interview, the nurse should be alert to the patient's body language and nonverbal cues. It is essential that the nurse listen, react in a nonjudgmental manner, and use teachable moments to educate women about their bodies. It is also important that the nurse not assume the woman is heterosexual. Nurses should be respectful of all patients when discussing their sexuality; some women will be open to this discussion, whereas others will be very reserved until a sense of trust in the caregiver is established.

After completing the sexual history, the nurse assesses the information obtained. If there is a concern that requires further medical tests and assessments, the nurse refers the woman to a nurse practitioner, certified nurse-midwife, physician, or counselor as necessary. In many instances the nurse alone will be able to develop a nursing diagnosis and then plan and implement an appropriate intervention. For example, if the nurse determines that a woman who is interested in conceiving a child does not have a clear understanding of when she ovulates, the nurse may formulate the nursing diagnosis ***Deficient Knowledge*** related to lack of information about the timing of ovulation. The nurse can implement a plan of care to evaluate the woman's knowledge, and then provide the necessary education.

The nurse must be realistic in making assessments and planning interventions. It requires insight and skill to recognize when a woman's problem requires interventions that are beyond a nurse's preparation and ability. In such cases, the nurse must make appropriate referrals.

Menstruation

Girls today begin to learn about puberty and menstruation at a young age. Unfortunately, the source of their "education" is sometimes their peers and sometimes the media; thus the information is frequently incomplete, inaccurate, and sensationalized. Nurses who work with girls and adolescents recognize this and are working hard to provide accurate health teaching and to correct misinformation about *menarche* (the onset of menses) and the menstrual cycle.

Cultural, religious, and personal attitudes about menstruation are part of the menstrual experience and often reflect negative attitudes toward women. In the past, many misconceptions surrounded menstruation. Women were often isolated or restricted to the company of other women during their monthly flow because they were considered "unclean." Currently in the Western world there are few customs associated with menstruation, although some women remain uncomfortable about discussing it. Sexual intercourse during menstruation is a common practice and is not generally contraindicated. For most couples, the decision is one of personal preference. (The physiology of menstruation is discussed in chapter 10 ∞.)

Counseling the Premenstrual Girl About Menarche

The average age of menarche is about 12.5 years for girls in the United States, but it may occur between the ages of 8 and 16. For about 2 years before menarche, a girl experiences a series of

Case Study: Premenstrual Girl

physical changes as her body develops. Maturity level and self-concept often influence a young girl's comfort in discussing these changes. However, the most critical factor in successful adaptation to menarche is the preteen's or adolescent's level of correct information and preparedness. The nurse is an excellent source of information about puberty and menarche. Information should be clear and straightforward and offered as it relates to each girl's individual situation and maturation level. The following basic information is helpful for young patients:

- ***Cycle length:*** Cycle length is determined from the first day of one menses to the first day of the next menses. Initially, cycle length may be irregular. It is not unusual for cycles to be unpredictable for the first year. Once established, the cycle is about 28 to 30 days, but the normal length may vary from 21 to 35 days. Cycle length often varies by a day or two from one cycle to the next, although greater normal variations may also occur.
- ***Amount of flow:*** The average amount of flow is approximately 25 to 60 ml per period. Usually women characterize the amount of flow in terms of the number of pads or tampons used. Flow is often heavier at first and lighter toward the end of the period.
- ***Length of menses:*** Menses usually lasts from 3 to 5 days, although the length may vary, and may last up to 7 days (American College of Obstetricians and Gynecologists [ACOG], 2007a).

The nurse should make it clear that variations in age at menarche, length of cycle, and duration of menses are normal, because girls are likely to be concerned if their experiences vary from those of their peers. It also is helpful to acknowledge the negative aspects of menstruation (messiness and embarrassment) while stressing its positive role as a symbol of maturity and womanhood.

Cultural factors may play an important role in menstruation for girls and women of some cultures. See Developing Cultural Competence.

Educational Topics

The nurse's primary role is to provide accurate information and assist in clarifying misconceptions so that girls will develop positive self-images and progress smoothly through this phase of maturation.

Pads and Tampons

Since early times women have made pads from cloth or rags, which required washing but were reusable. Some women made them from gauze or cotton balls. Commercial tampons were introduced in the 1930s.

Today adhesive-stripped, disposable minipads and maxipads and flushable tampons are readily available. However, the deodorants and increased absorbency that manufacturers have added to both sanitary napkins and tampons may prove harmful. The chemicals used to deodorize and increase absorbency can create irritation of the vulva and inner aspects of the vagina. This irritation may cause an external rash or internal sores from trauma to the tender mucosal lining of the vagina.

Interest is growing in the use of eco-friendly menstrual products including reusable menstrual pads made of washable cotton, menstrual cups, and menstrual sponges. These products are becoming more readily available at pharmacies and major discount stores.

When taking a menstrual history, the nurse should attempt to determine the amount of bleeding each month. The woman can be asked what type of pad or tampon she uses, how frequently she changes, and how much blood has been absorbed. Women should be advised to change pads frequently, every 3 to 6 hours when awake, regardless of the amount of blood that is absorbed. If a woman reports that she supersaturates a maxipad every 1 to 2 hours for 2 to 3 days, she may be experiencing a gynecologic problem, requiring the need for further evaluation. Heavy menstrual flow is a leading cause of anemia in women.

The use of super absorbent tampons has been linked to the development of toxic shock syndrome (TSS). Women may prevent problems by using tampons with the minimum absorbency needed to control menstrual flow, changing them every 3 to 6 hours, and avoiding using them for vaginal discharge or abnormal bleeding. Women should be instructed on proper hygiene techniques for insertion and removal of tampons to decrease the risk of bacterial toxins being spread from hands to the vagina. Specifically, a woman should wash her hands before inserting or removing a tampon. After the tampon is unwrapped she should avoid touching the portion of the tampon to be inserted into the vagina. Most toilet systems become clogged if tampons are flushed. Thus, when a tampon is removed, it should first be wrapped in toilet tissue or placed in a disposable bag and then discarded in a trash receptacle or designated container. Finally the woman should again wash her hands.

In the absence of a heavy menstrual flow, tampons absorb moisture, leaving the vaginal walls dry and subject to injury; therefore, their use should be discouraged when the flow is too light to warrant a tampon. The absorbency of regular tampons varies. If the tampon is hard to pull out or shreds when removed, or if the vagina becomes too dry, the tampon is probably too absorbent. If a woman is worried about accidental spotting, she can check the diagrams on the packages of regular tampons. Those that expand in width are better able to prevent leakage without being too absorbent.

A woman may want to use tampons only during the day and switch to pads at night to avoid vaginal irritation. If a woman experiences vaginal irritation, itching, or soreness or notices an unusual odor while using tampons, she should stop using them and be evaluated for infection.

The choice of sanitary protection must meet the individual's needs and feel comfortable, whether it be pads or tampons. Young women should be taught to track their periods and to carry feminine hygiene products when their menses is due so that they are prepared for its onset.

Vaginal Sprays and Douching

Vaginal sprays are unnecessary and can cause itching, burning, rashes, and other problems. Healthcare providers do not generally recommend that women use them. If a woman chooses to use a spray, she needs to know that these sprays are for external

use only, should be used infrequently, and should never be applied to irritated or itching skin.

Douching as a hygiene practice is unnecessary, because the vagina has numerous glands that provide a natural cleansing. Caregivers generally advise against it. The vagina has naturally occurring bacteria that aid in maintaining a pH balance to keep fungal and bacterial growth at bay. Douching upsets this vaginal flora, which can make the vagina more susceptible to infection. Douching with one of the perfumed or flavored douches can cause an allergic reaction. Propelling water up the vagina may force bacteria and germs from the vagina into the uterus. It is essential that women avoid douching during menstruation, because the cervix is dilated to permit the downward flow of menstrual fluids from the uterine lining. Douching is also contraindicated during pregnancy.

DEVELOPING CULTURAL COMPETENCE

Islamic Women and Menstruation

Islamic women who are menstruating are not allowed to enter a mosque for prayer, touch the Qur'an, or fast during Ramadan. These restrictions are based on the belief that menstruation is unclean. These women are also encouraged to limit their contact with others (Blumenthal, 2007).

Cleansing the Perineum

The secretions that continually bathe the vagina are completely odor free while they are in the vagina; only when they combine with perspiration and become exposed to the air does odor develop. Keeping one's skin clean and free of bacteria with plain soap and water is the most effective method of controlling odor. Bathing is as important (if not more so) during menses as at any other time. A long leisurely soak in a warm tub may also help to relieve cramps.

A woman can ensure herself of adequate ventilation by wearing cotton panties and clothes loose enough to allow air to circulate. After using the toilet, a woman should always wipe herself from front to back and, if necessary, follow up with a moistened paper towel or toilet paper.

The most important thing to remember is that if an unusual odor persists despite these efforts, a visit to one's healthcare provider is indicated. Certain conditions, such as vaginitis, produce a foul-smelling discharge that women often describe as having a "fishy" odor.

Associated Menstrual Conditions

A variety of menstrual irregularities have been identified. Several of them are discussed in chapter 7 ∞ in the section on dysfunctional uterine bleeding. Others are addressed in the following sections.

These terms are used to describe variations in uterine bleeding:

- ***Hypomenorrhea:*** short duration of menstrual flow or, in other words, uterine bleeding at normal intervals but in decreased amounts
- ***Hypermenorrhea:*** an abnormally long or heavy menstrual flow at normal menstrual intervals (sometimes used interchangeably with menorrhagia)
- ***Oligomenorrhea:*** bleeding, often irregular, occurring at intervals greater than 40 days
- ***Polymenorrhea:*** bleeding, either regular or irregular, occurring at intervals of less than 22 days
- ***Menorrhagia:*** bleeding that is excessive in amount and duration, which occurs at regular intervals (see hypermenorrhea)
- ***Metrorrhagia:*** bleeding, usually of a normal amount, occurring at irregular intervals
- ***Menometrorrhagia:*** bleeding that is excessive in amount and duration, which occurs at either regular or irregular intervals
- ***Intermenstrual bleeding:*** bleeding occurring between regular menstrual cycles

Amenorrhea

Amenorrhea, the absence of menses, is classified as primary or secondary. Primary amenorrhea is said to occur if menstruation has not been established by 16 years of age. Secondary amenorrhea is said to occur when an established menses (of longer than 3 months) ceases. Typically, the causes of amenorrhea are categorized into one of four groups:

1. ***Hypothalamic dysfunction:*** Several types of hypothalamic disorders can occur. Some are very rare disorders and may be related to a failure of the central structures of the hypothalamus to develop properly. Other disorders may be caused by a tumor. More common forms of hypothalamic dysfunction are triggered by systemic stress related to marked weight loss (anorexia, bulimia, fad dieting), excessive exercise (associated with long-distance runners, dancers, and other athletes with a low body fat ratio), and severe or prolonged stress.
2. ***Pituitary dysfunction:*** Pituitary disease and pituitary tumors, such as a pituitary adenoma, can cause changes in the many hormones, including prolactin, that the pituitary manufactures. A variety of medications, including several used to treat anxiety and other psychiatric disorders, can induce a mild increase in prolactin levels, resulting in amenorrhea. Amenorrhea may also be related to low prolactin levels resulting from pituitary failure. Sheehan's syndrome, head trauma, and cancer are also serious causes of hypopituitarism.
3. ***Chronic anovulation or ovarian failure:*** Some forms of ovarian failure are caused by genetic disorders often related to the sex chromosomes and are not treatable. Turner syndrome (see chapter 12 ∞) is one of the most common genetic disorders. Causes of chronic anovulation include polycystic ovarian syndrome or thyroid or adrenal disorders. Ovarian failure is related to exposure to radiation, chemotherapy, viral infection, and surgical removal of the ovary.
4. ***Anatomic abnormalities:*** This category includes a variety of structural disorders such as congenital absence of the uterus, ovaries, or vagina; congenital obstruction; or imperforate hymen.

Diagnosis begins with a thorough history and careful physical examination. For women who have had periods, this evaluation begins with a pregnancy test. For a woman who has

never menstruated, the pelvic examination is a crucial assessment tool in determining that she has a normal vagina, uterus, and ovaries. Regardless of type of amenorrhea, based on initial findings, further, more specific tests are usually done. To evaluate pituitary function, a serum prolactin level is often obtained as a screening test. If serum prolactin levels are elevated, magnetic resonance imaging (MRI) will be ordered to rule out a pituitary tumor. Other pituitary hormones can be evaluated if necessary. Similarly, elevated serum follicle-stimulating hormone (FSH) levels indicate ovarian failure. A thyroid-stimulating hormone (TSH) level is assessed to rule out thyroid disease. A condition known as polycystic ovarian syndrome (PCOS) should be ruled out based on several diagnostic parameters as well (see chapter 7 ∞).

Treatment is dictated by the causative factors. Some conditions, such as imperforate hymen, are easily corrected. Other causes are not treatable. The nurse can explain that once the underlying condition has been corrected—for example, when the patient gains sufficient body weight—menses will resume. Female athletes and women who participate in strenuous exercise routines may be advised to increase their caloric intake or reduce their exercise levels for a month or two to see whether a normal cycle resumes. If it does not, medical referral is indicated.

Dysmenorrhea

Dysmenorrhea, or painful menstruation, occurs at, or a day before, the onset of menstruation and disappears by the end of menses. Dysmenorrhea is classified as primary or secondary.

Primary dysmenorrhea is defined as cramps without underlying disease. Prostaglandins F_2 and $F_{2\alpha}$, which are produced by the uterus in higher concentrations during menses, are the primary cause. They increase uterine contractility and decrease uterine artery blood flow, causing ischemia. The end result is the painful sensation of cramps. Dysmenorrhea typically disappears after a first pregnancy and may not occur if cycles are anovulatory.

Treatment of primary dysmenorrhea includes oral contraceptives (which inhibit ovulation); nonsteroidal anti-inflammatory drugs (NSAIDs) (such as ibuprofen, aspirin, and naproxen), which act as prostaglandin inhibitors; and self-care measures such as regular exercise, rest, application of heat, and good nutrition. Biofeedback has also been used with some success.

Secondary dysmenorrhea is associated with pathology of the reproductive tract and usually appears after menstruation has been established. Conditions that most frequently cause secondary dysmenorrhea include endometriosis, residual pelvic inflammatory disease (PID), cervical stenosis, uterine fibroids, ovarian cysts, benign or malignant tumors of the pelvis or abdomen, or the presence of an intrauterine device (IUD). Because primary and secondary dysmenorrhea may coexist, accurate differential diagnosis is essential for appropriate treatment.

Dysmenorrhea sometimes occurs in women who are also experiencing menometrorrhagia. In such cases, a careful examination is necessary to determine what is causing both symptoms. Testing may include transvaginal ultrasound, hysterosalpingography, and hysteroscopy. If the examination shows an endometrial polyp, treatment is removal of the polyp with a dilation and curettage (D&C) of the uterus.

For women with severe dysmenorrhea, use of continuous oral contraceptive therapy, which does not allow ovulation or menstruation to occur, may be of benefit. Hysterectomy may be the treatment of choice if there are anatomic disorders and childbearing is not desired. Presacral neurectomy may control severe dysmenorrhea caused by endometriosis.

SELF-CARE MEASURES FOR DYSMENORRHEA Some nutritionists suggest that vitamins B and E help relieve the discomforts associated with menstruation. Vitamin B_6 may help relieve the premenstrual bloating and irritability some women experience. Vitamin E, a mild prostaglandin inhibitor, may help decrease menstrual discomfort. Avoiding salt can decrease discomfort from fluid retention.

Heat is soothing and promotes increased blood flow. Any source of warmth, from sipping herbal tea to soaking in a hot tub or using a heating pad, may be helpful during painful periods. Massage can also soothe aching back muscles and promote relaxation and blood flow.

Daily exercise can ease existing menstrual discomfort and help prevent cramps and other menstrual complaints. Aerobic exercise—jogging, cycling, aerobic dancing, swimming, and fast-paced walking—is especially helpful (Figure 4-1 ■). Persistent discomfort should be medically evaluated.

Figure 4-1 ■ Regular exercise is an important part of therapy for dysmenorrhea.

Premenstrual Syndrome

Premenstrual syndrome (PMS) refers to a symptom complex characterized by behavioral and physical changes that occur during the luteal phase of the menstrual cycle, anywhere from several days to 2 weeks before the onset of menstrual flow. The symptoms are relieved once the flow has started. It is estimated that clinically significant symptoms, resulting in emotional distress that impairs work, relationships, and activity levels, occur in only 12.6% to 31% of menstruating women. The majority of women seeking help with these symptoms are in their mid-20s to late 30s. A diagnosis of PMS occurs when a woman experiences one to three troublesome symptoms (Freeman, 2007).

Premenstrual dysphoric disorder (PMDD), a more serious form of PMS categorized as a depressive disorder, affects 5% to 8% of women of reproductive age (Freeman, 2007). Women with PMDD must experience at least five specific symptoms listed in the *Diagnostic and Statistical Manual,* 4th edition (DSM-IV) in the given time frame. These symptoms are relieved by menstruation and occur in most menstrual cycles.

Premenstrual symptoms include, but are not limited to, the following:

- ***Psychologic:*** irritability, lethargy, depression, low morale, anxiety, sleep disorders, crying spells, hostility, decreased concentration
- ***Neurologic:*** classic migraine, vertigo, syncope
- ***Respiratory:*** rhinitis, hoarseness
- ***Gastrointestinal:*** nausea, vomiting, constipation, abdominal bloating, increased appetite or food cravings
- ***Urinary:*** retention and oliguria
- ***Dermatologic:*** acne
- ***Mammary:*** swelling and tenderness
- ***Musculoskeletal:*** joint or muscle pain

The exact cause of PMS is unknown, although a variety of theories have been put forth to explain it. Evidence suggests that progesterone and estradiol levels are involved, although no consistent differences in these levels have been identified. Newer theories suggest that some women have an abnormal sensitivity to the normal changes of these hormones during the menstrual cycle. Central nervous system–mediated interactions between neurohormones and sex steroids may also account for the occurrence of PMS. Certain risk factors such as stress, genetics, obesity, or a history of depression or other psychiatric disorders may predispose women to these disorders (Freeman, 2007).

Diagnosis is generally made after having the woman keep a menstrual calendar for 3 months on which she carefully records daily symptoms, rating them on a scale of 0 to 4, with 0 used for no symptoms and 4 used for severe, debilitating symptoms. The information provided by the diary should be very helpful. In some cases, the diary may reveal that a woman has psychologic symptoms that are present throughout her cycle but intensify premenstrually. This is not a diagnosis of PMDD but an exacerbation of an underlying disease that should be referred for psychiatric evaluation. Except in very severe cases, treatment focuses, at least initially, on lifestyle changes and natural approaches. These are discussed in the following section. Some women will have a degree of resolution of symptoms with vitamin supplements or dietary changes, although relief will vary considerably from woman to woman.

Women with PMDD may benefit from selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine hydrochloride (Prozac), sertraline hydrochloride (Zoloft), and paroxetine CR (Paxil CR) taken during the entire cycle or intermittently (half the cycle) (Endicott, 2007). The Food and Drug Administration (FDA) has also approved the use of an oral contraceptive called YAZ for PMDD. YAZ may be a good choice for women who choose an oral contraceptive as their method of contraception and who experience side effects from SSRIs or dislike the idea of taking them (Rapkin, 2008).

NURSING CARE MANAGEMENT

The nurse can help the woman identify specific symptoms and develop healthy behavior. After assessment, the nurse may advise the woman to restrict her intake of foods containing methylxanthines, such as chocolate, cola, and coffee. It is advisable for the woman to restrict her intake of alcohol, nicotine, red meat, animal fats, and foods containing salt and sugar. Concurrently, she should increase her intake of complex carbohydrates (such as whole grains, brown rice, oatmeal), protein, fruits, vegetables, and vegetable oils and increase the frequency of meals.

Supplementation with 50 to 100 mg daily of Vitamin B_6 may help women with some symptoms. A calcium supplement of 1200 mg per day is occasionally effective in reducing physical and psychologic symptoms of PMS. A magnesium supplement of 400 mg daily may help reduce fluid retention and bloating. Vitamin E taken in 400 international units daily may reduce cramping and breast tenderness. Herbal remedies such as black cohosh, ginger, red raspberry leaf, and evening primrose oil may reduce the effects of PMS. Underlying health conditions may contraindicate the use of herbal or vitamin supplements, however, and must be considered when recommending them. Natural progesterone creams derived from wild yams or soybeans may provide relief to some women; however, no scientific studies have shown this to be true (Mayo Clinic Staff, 2007).

A program of aerobic exercises such as fast walking, jogging, or aerobic dancing is generally beneficial. In fact, women who exercise regularly tend to have fewer, less severe symptoms.

An empathic relationship with a healthcare professional to whom the woman feels free to voice concerns is highly beneficial. The nurse can also encourage the woman to keep a journal to help identify life events associated with PMS. Stress reduction education, self-care groups, and self-help literature can also help women gain control over their bodies.

Health Promotion Education for Well Women

Healthcare providers are becoming increasingly aware of the value of health maintenance and disease prevention, as are

many consumers of healthcare services. Women can make lifestyle choices that promote health and well-being. These choices involve a variety of factors, including:

- Eating a nutritious, balanced diet.
- Maintaining normal weight for height (no fad dieting).
- Performing regular aerobic exercise and weight training several times a week.
- Getting adequate sleep.
- Avoiding smoking and/or stopping smoking.
- Consuming alcohol in moderation.
- Managing stress effectively.
- Developing enjoyable hobbies and leisure activities.
- Developing an inner life in some form through religion, spirituality, personal reflection, yoga, and so forth.
- Fostering bonds of support and affection with family and friends.
- Obtaining regular health screenings and assessments.
- Ensuring that immunizations are up to date.

Health screening recommendations vary by age. Table 4-1 from the National Women's Health Information Center (2009) identifies general screening and immunization guidelines for low-risk women based on their ages. Nurses can share this information with well women so that they can be aware of indicated screening procedures.

Body Piercing and Tattoos

Body piercing and tattooing, often called *body art,* are rapidly becoming commonplace in today's culture among people of all ages (Figure 4-2 ■).

Tattooing is the application of minute amounts of pigments into the skin with indelible inks. The ritual of tattooing appears far back in history in most ancient cultures (Donohoe, 2006). Body piercing sites include earlobes and ear cartilage, lips, nose, tongue, eyebrow, nipples, umbilicus, and the external genitalia for the purpose of displaying some form of adornment or jewelry. Estimates suggest that in the United States as many as 50% of undergraduates have had some form of body piercing (Donohoe, 2006).

Each of these forms of body art carries with it an element of health risk. For tattooing and body piercing, risks include infections such as HIV and hepatitis B and C because of the use of inadequately sterilized equipment, as well as allergic reactions, local swelling and burns, granulomas, and keloid formation (more common in people of African descent). Tattooing has also been associated with a variety of risk-taking behaviors in adolescents (Donohoe, 2006). Oral piercing has been associated with tooth and gum damage. Among pregnant or breastfeeding women, nipple piercing has been associated with mastitis, damaged milk ducts, difficulty with breastfeeding, and galactorrhea (Camann, 2006).

Educating patients about the risks associated with these practices should include information about infection, permanent scarring, keloid formation, and care afterward. It is important for the nurse to avoid passing judgment or making generalizations about individuals who have these types of body alterations.

Menopause

Menopause, defined as the absence of menstruation for 1 full year, is a time of transition for a woman, marking the end of her reproductive abilities. Although it usually occurs between 45 and 52 years of age, the current median age of menopause in the United States is approximately 50 to 51 years of age (Curran,

Application: Menopause

A B

Figure 4-2 ■ Tattoos vary greatly in size, complexity, and meaning to the individual. A. This tattoo, on the ankle of a young woman, is purely decorative. B. This tattoo, on the shin of a young man, is the Chinese symbol for honor. He chose it to express a personal commitment to live a life of integrity.

TABLE 4-1 Recommended Screenings and Immunizations for Women at Average Risk for Most Diseases

SCREENING TEST	AGES 18–39	AGES 40–49	AGES 50–64	AGES 65 AND OLDER
General Health				
Full checkup, including weight and height	Discuss with your doctor or nurse	Discuss with your doctor or nurse	Discuss with your doctor or nurse	Discuss with your doctor or nurse
Thyroid test	Start at age 35, then every 5 years	Every 5 years	Every 5 years	Every 5 years
HIV test	Get this at least once to find out your HIV status. Ask your doctor if and when you need the test again.	Get this at least once to find out your HIV status. Ask your doctor if and when you need the test again.	Get this at least once to find out your HIV status. Ask your doctor if and when you need the test again.	Discuss with your doctor or nurse.
Heart Health				
Blood pressure test	At least every 2 years	At least every 2 years	At least every 2 years	At least every 2 years
Cholesterol test	Start at age 20, discuss with your doctor or nurse.	Discuss with your doctor or nurse.	Discuss with your doctor or nurse.	Discuss with your doctor or nurse.
Bone Health				
Bone density screen		Discuss with your doctor or nurse.	Discuss with your doctor or nurse.	Get a bone mineral density test at least once. Talk to your doctor or nurse about repeat testing.
Diabetes				
Blood glucose test	Discuss with your doctor or nurse.	Start at age 45, then every 3 years.	Every 3 years	Every 3 years
Breast Health				
Mammogram (x-ray of breast)		Every 1–2 years. Discuss with your doctor or nurse.	Every 1–2 years. Discuss with your doctor or nurse.	Every 1–2 years. Discuss with your doctor or nurse.
Clinical breast exam	At least every 3 years starting in your 20s	Yearly	Yearly	Yearly
Reproductive Health				
PAP test	Every 1–3 years if you have been sexually active or are older than 21	Every 1–3 years	Every 1–3 years	Discuss with your doctor or nurse.
Pelvic exam	Yearly	Yearly	Yearly	Yearly
Chlamydia test	Yearly until age 25 if sexually active. Older than 26, get this test if you have new or multiple partners.	Get this test if you have new or multiple partners.	Get this test if you have new or multiple partners.	Get this test if you have new or multiple partners.
Sexually transmitted infection (STI) tests	Both partners should get tested for STIs, including HIV, before initiating sexual intercourse	Both partners should get tested for STIs, including HIV, before initiating sexual intercourse	Both partners should get tested for STIs, including HIV, before initiating sexual intercourse	Both partners should get tested for STIs, including HIV, before initiating sexual intercourse
Mental Health				
Mental health screening	Discuss with your doctor or nurse.	Discuss with your doctor or nurse.	Discuss with your doctor or nurse.	Discuss with your doctor or nurse.
Colorectal Health				
(use one of the following methods)				
Fecal occult blood test			Yearly	Yearly. Older than 75, discuss with your doctor.
Flexible sigmoidoscopy (with fecal occult blood test)			Every 5 years	Every 5 years. Older than 75, discuss with your doctor.
Colonoscopy			Every 10 years	Every 10 years. Older than 75, discuss with your doctor.
Eye and Ear Health				
Complete eye exam	At least once between the ages of 20–29; at least twice between the ages of 30–39; any time that you have a problem	Get an exam at age 40, then every 2–4 years or as your doctor advises	Every 2–4 years or as your doctor advises	Every 1–2 years
Hearing test	Starting at age 18, then every 10 years	Every 10 years	Every 3 years	Every 3 years
Skin Health				
Mole exam	Monthly mole self-exam; by a doctor as part of a routine full checkup starting at age 20.	Monthly mole self-exam; by a doctor as part of a routine full checkup.	Monthly mole self-exam; by a doctor as part of a routine full checkup.	Monthly mole self-exam; by a doctor as part of a routine full checkup.

Immunizations				
Influenza vaccine	Discuss with your doctor or nurse.	Discuss with your doctor or nurse.	Yearly	Yearly
Pneumococcal vaccine				One time only
Tentanus-diptheria booster vaccine	Every 10 years	Every 10 years	Every 10 years	Every 10 years
Human papilloma virus (HPV) vaccine	Up to age 26, if not already completed vaccine series; discuss with your doctor or nurse.			
Meningococcal vaccine	Discuss with your doctor or nurse if attending college			
Herpes zoster vaccine (to prevent shingles)			Starting at age 60, one time only. Ask your doctor if it is okay for you to get it.	Starting at age 60, one time only. Ask your doctor if it is okay for you to get it.

Source: The National Women's Health Information Center. (2009). Recommended screenings and immunizations for women at average risk for most diseases. *Washington, DC: Office of Women's Health, U.S. Department of Health and Human Services.*

2008). Not all of the physiologic mechanisms initiating menopause are precisely understood; however, it is known that the onset occurs when estrogen levels drop because of cessation of ovarian function. In addition, most researchers agree that the age of onset is influenced by such factors as the woman's overall health, weight, nutrition, lifestyle, culture, and genetic factors.

Climacteric, or *change of life* (often used synonymously with *menopause*), refers to the host of psychologic and physical alterations that occur around the time of menopause. These aspects are discussed separately.

Perimenopause

Perimenopause refers to the period of time before menopause during which the woman moves from normal ovulatory cycles to cessation of menses. Women in perimenopause will generally begin having menstrual irregularities and changes in estrogen and follicle stimulating hormone (FSH). The perimenopause can last 2 to 8 years (Freeman, 2008).

Symptoms of perimenopause vary significantly in women. It is estimated that more than 80% of women in the perimenopause report some degree of vasomotor symptoms (hot flashes). It is important that women in this age group be screened thoroughly to rule out other causes of vasomotor symptoms. Mood and cognitive changes are also a common complaint, with women expressing concern over emotional instability and a decrease in memory. These may, in fact, be the more concerning symptoms women express to their healthcare providers. Changes in sexuality are common and may include decreased libido, vaginal lubrication, and comfort with sexual intercourse. Estimates indicate that nearly 75% of perimenopausal women experience these changes to some degree (Freeman, 2008).

Contraception remains a major concern for many perimenopausal women. Although a growing number of women are choosing to delay childbearing, 38% of pregnancies for women ages 40 and higher are unplanned (Speroff & Wysocki, 2009). As women age fertility decreases and the risk of spontaneous abortion increases. In women who delay pregnancy until after age 40, risks for pregnancy complications are approximately twofold to sixfold higher. These complications include hypertensive disorders, diabetes, placenta previa, and placental abruption. These complications in turn increase the rate of preterm birth, intrauterine growth restriction, and serious neonatal complications (ACOG, 2006).

In the United States, female sterilization is, in general, the most commonly used method of contraception among couples over age 35 (Sufrin & Korn, 2009). In 2002 the Food and Drug Administration approved a nonsurgical method of female sterilization known as the Essure method (see chapter 5 ∞) (Sufrin & Korn, 2009).

However, combined hormonal contraceptives (the pill, patches, and vaginal rings) continue to be popular forms of contraception during this time in a woman's reproductive life. Combined hormonal contraceptives prevent pregnancy and provide noncontraceptive benefits. Healthy nonsmokers benefit from effective contraception; regulation of menses; treatment of anovulatory bleeding; relief of symptoms of estrogen deficiency and variability such as hot flashes, sleep disturbances, menorrhagia, and vaginal dryness; and a decreased risk of endometrial and ovarian cancer. They may also experience less acne and hirsutism (abnormal hair growth, often on the face and neck) and decreased osteopenia. Thus they are considered by many to be an optimal approach to this transition, even when contraception is not a concern. Other contraceptive options for perimenopausal women include sterilization; contraceptive intrauterine devices (IUDs); progestin-only methods of contraception; and barrier methods of contraception such as male and female condoms, diaphragm, cervical cap, and spermicides (Speroff & Wysocki, 2009). (See chapter 5 ∞ for a discussion of these methods.)

Women describing problems that suggest perimenopause should be referred to their care providers. If oral contraceptives are not an option, other alternatives are available. Exercise, calcium and vitamin D, and other supplements or medications may be effective.

Psychologic Aspects of Menopause

A woman's psychologic adaptation to menopause and the climacteric is multifactorial. It is often further complicated because women of this age may be dealing with other life circumstances such as adjustment to an "empty nest" or caring for aging parents. Numerous personal factors influence a woman's ability to transition and cope with these changes, such as self-concept, physical health, marital stability, relationship with others, and cultural values. Some women express disappointment in approaching this time of their lives, whereas others may see it as a positive transition that offers freedom from menses or concern about contraception. Women who are dealing with aging, ill parents may have increased stressors that affect their emotional health and ability to deal with their symptoms. Often night sweats and insomnia affect a woman's capability to cope because of increased fatigue.

As a nurse, understanding the basic physiology of menopause offers an opportunity to provide education, supportive resources, and encouragement to women at this time in their lives. Suggesting exercises and teaching proper nutrition are critical for overall health and may help these women improve the emotional aspects associated with menopause. It is important to help women understand the changes that come with menopause and deal with their feelings during this period. Moreover, caregivers need to be alert for signs that distinguish between the mood swings that are related to hormonal changes and true clinical depression.

Today the average woman in the United States will live one third of her life after menopause (Curran, 2008). The changing perceptions of menopause and beyond are enabling menopausal women to cope more effectively and to view menopause as a time of personal growth.

> "My personal response to menopause has surprised me a little. Suddenly 52 doesn't really seem old. I look at pictures of my mother in her early 50s and she seems so much older. I imagine each generation looks back and thinks the same thing. I do wish I had known at 22 what I know now, but I still see myself as learning and growing. I know I have a lot to offer and a lot of choices in how to accomplish that. One thing I'm committed to is trying to live each day as well as I can, to stay positive, and to keep looking forward."

Physical Aspects of Menopause

Changes in the Reproductive System

The physical characteristics of menopause are linked to the shift from a cyclic to a noncyclic hormonal pattern. Beginning 2 to 8 years before menopause, women experience episodes of anovulation; reduced fertility; decreased or increased menstrual flow; menstrual cycle irregularities; and then, ultimately, amenorrhea. Generally ovulation ceases 1 to 2 years before menopause, but individual variations exist. FSH levels rise, and ovarian follicles cease to produce estrogen. As estrogen levels decline, physiologic changes occur within the reproductive organs. The uterine lining, or endometrium, thins and the uterine muscle layer, or myometrium, atrophies. The fallopian tubes and ovaries atrophy. The vaginal mucosa loses its elasticity and becomes thinner and smoother. The loss of cervical gland function leads to dryness of the mucous membranes of the vagina, which can lead to burning and itching. The vaginal pH level increases as the number of Döderlein's bacilli decreases. This change in the vaginal ecology can lead to a condition known as atrophic vaginitis and increases the woman's risk of vaginal infections.

Pubic hair thins, turns gray or white, and may ultimately disappear. The labia shrink and lose their heightened pigmentation. Menopausal women may experience a general loss of pelvic tone and support, which can lead to prolapse of reproductive and urinary tract organs and subsequent urinary incontinence (Curran, 2008). Kegel exercises and regular sexual activity help prevent this change. Breasts lose their density and are replaced by fat, which makes them more pendulous and less firm.

Sexual functioning declines with age; however, more than 75% of the middle-aged women in the Study of Women's Health Across the Nation (SWAN) cited sex as being moderately to extremely important. Contributing factors to the decline in both interest and occurrence of sexual activity are widespread. Pain during intercourse due to lack of lubrication and thinning vaginal walls is a common cause. Other factors may include a lack of partners, stress in current relationships, psychosocial factors, and a decline in general health. A positive attitude about aging and menopause as well as the overall good health of the women in the study had a highly positive effect on sexual activity and satisfaction (Avis et al., 2009). Completing a good sexual history will help the nurse to assess the woman's sexual health and allow the woman to ask questions and express concerns or frustrations.

Vasomotor Changes

Many women who are perimenopausal or menopausal experience a vasomotor disturbance commonly known as a *hot flash.* Hot flashes are typically described as a feeling of heat rising from the chest and spreading to the neck and face. Hot flashes at night are often accompanied by sleep disturbances triggered by profuse sweating (*night sweats*) in which a woman awakens with drenched night clothes and bedding. These episodes may occur as often as 20 to 30 times a day and generally last 3 to 5 minutes or less. Some women also experience dizzy spells, palpitations, and weakness. Many women find their own most effective ways to deal with the hot flashes. Some report that dressing in layers, using a fan, avoiding alcoholic beverages, or drinking a cool liquid helps relieve distress. Still others seek relief through hormone therapy or complementary therapies such as herbs or acupuncture.

Changes in the Musculoskeletal System and Skin

Osteoporosis, a decrease in bone strength related to diminished bone density and bone quality, is a major health concern for women, particularly after menopause. An estimated 10 million U.S. adults have osteoporosis; of those, 80% are women (Reiter,

2008). Women who experience menopause at a younger age and those with less bone mass when entering menopause, predicatively will have the most severe bone loss (Curran, 2008). This change is associated with lowered estrogen levels; however, the greatest influencing factor is a family history of osteoporosis. Osteoporosis puts an individual at increased risk for fractures of the hip, forearm, and vertebrae. Risk factors associated with osteoporosis are identified in Table 4-2.

As skin ages, collagen and elastin, which are what maintain firmness of the skin, weaken. The skin appears looser and thinner and wrinkles. Past sun exposure and tobacco use influence the amount of skin changes that occur. As women age, the skin becomes drier and may need increased moisturizing. Nurses, as a part of general counseling, can remind women to wear sunscreen with a sun protection factor (SPF) of at least 30 to provide 97% ultraviolet B (UVB) filter and prevent damage. Recommending annual dermatologic screening for serious skin changes is also important (Baron, Kirkland, & Santo Domingo, 2008).

Evidence suggests that estrogen regulates weight and fat metabolism in women (Kohrt, 2009), and during menopause a change in fat distribution occurs. In postmenopausal women compared to premenopausal women total body fat increases by 22%. More specifically the increase in fat accumulation occurs in the trunk region. Nurses should be especially concerned about central body obesity, which is a predictor of the development of chronic illness. This is done by calculating a waist-to-hip ratio, or dividing the woman's waist measurement by the hip measurement. Women should maintain a waist-to-hip ratio of less than 0.80 to decrease their risk for chronic disease (Grubbs, 2009).

Changes in the Cardiovascular System

An important long-range physical change of menopause is a shift in lipid and lipoprotein levels. The presence of normal estrogen levels before menopause contributes to higher levels of high-density lipoprotein cholesterol (HDL-C) or the "good" cholesterol and lower levels of low-density lipoprotein cholesterol (LDL-C) or "bad" cholesterol. Levels of HDL-C of less than 50 mg/ml are the most important predictor of coronary heart disease in women (Reiter, 2008). As estrogen levels fall during menopause, this protective mechanism ceases, which potentially places a woman at increased risk for coronary heart disease, hypertension, and strokes. During menopause women should be encouraged to have their cholesterol monitored on an annual basis if normal and every 3 to 6 months if abnormal.

TABLE 4-2 Risk Factors for Osteoporosis

- Personal history of fracture after age 50
- Current low bone mass
- History of fracture in a first-degree relative
- Being female
- Being thin (weight less than 127 lb and/or having a small frame)
- Advanced age
- Family history of osteoporosis, especially a maternal hip fracture
- Use of certain medications (e.g., corticosteroids, chemotherapy, anticonvulsants)
- Abnormal absence of menses, early onset of menopause
- Anorexia nervosa
- Low lifetime intake of calcium
- Vitamin D deficiency
- Current cigarette smoking, excessive alcohol use
- Inactive lifestyle
- Being Caucasian or Asian

TABLE 4-3 Risk Factors for CHD in Women

- Family history of heart disease
- Advancing age—over 55 or postmenopausal
- Overweight and obesity
- Cigarette smoking and/or tobacco use
- Sedentary lifestyle
- Hypertension
- Diabetes
- Elevated cholesterol
- Race (highest incidence in African American women)

Although viewed as a higher risk in men, cardiovascular disease (CVD) is still the number one killer of women in the United States. Coronary heart disease (CHD) is the major cause of heart attacks in women. In fact, approximately 50% of all deaths in women are a result of CHD. Many women perceive breast cancer as the greatest threat to their health; however 1 in 30 women will die from breast cancer, while 1 in 6 women will die from CHD (Rowe, 2007). Risk factors for CHD are identified in Table 4-3.

Metabolic syndrome is a major predisposing factor for CHD and is defined through a collection of risk factors. Clinical characteristics are waist measurement greater than 35 inches, triglycerides greater than 150 mg/dl, HDL less than 50, blood pressure over 130/85, and fasting glucose levels greater than 100 mg/dl (Conway & Green, 2009).

Changes in Cognitive Function

Memory and cognitive function change with advancing age. There is suggestion that the brain benefits from circulating estrogen and that declining estrogen levels might contribute to loss of this function as well as to the development of dementia (Curran, 2008). This change is also influenced by lifestyle, genetics, and socioeconomic status. In the United States, Alzheimer disease (AD) is the most commonly occurring form of dementia, estimated to affect 5.2 million Americans. Projections indicate that by the year 2030, 7.7 million Americans over the age of 65 will have AD. The prevalence of AD in individuals over the age of 80 is at least 40%.

The cause of Alzheimer disease is unknown although there is belief that risk factors other than advancing age may play a role. These risk factors include specific genotypes, obesity, insulin resistance, elevated cholesterol, hypertension, and inflammation. Genetic forms of Alzheimer disease account for less than 7% of all cases (Anderson, 2009).

Numerous treatments for AD have been explored, including ginkgo biloba, estrogen therapy, cholesterol-reducing medications, nonsteroidal anti-inflammatory drugs, and antioxidants. None of these treatments have proven effective. At present there

are no therapies that slow the progression of the disease; only symptomatic therapies are available. Cholinesterase inhibitors and N-methyl-D-aspartate antagonists are the only medications approved by the Food and Drug Administration (FDA) to treat cognitive dysfunction. Antidepressants have been used to treat secondary symptoms of depression or mood disorders, which occur in more than 30% of all patients with AD. No special dietary considerations are important in the management of Alzheimer disease (Anderson, 2009).

Premature Menopause

Premature ovarian insufficiency (POI) is a devastating event and is not well understood. It occurs in about 0.1% of women by the age of 30, 0.25% of women by the age of 35, and 1% of women by the age of 40 (Popat & Nelson, 2007). It is defined as 4 to 6 months of no menses in women under the age of 40 years who have elevated FSH and low estradiol levels. Women who receive this diagnosis may not necessarily experience total loss of ovarian function because the rate of progression is variable (Welt, 2008). POI is different from menopause in that women with POI retain intermittent ovarian function, and although difficult, pregnancy may occur. Women with POI who desire pregnancy may experience emotional trauma and require extra sensitivity from caregivers. Concern for the patient's long-term health should be a consideration. Women should be encouraged to engage in weight-bearing exercises for 30 minutes at least 3 days per week to strengthen muscle and maintain bone mass. Adequate intakes of calcium and vitamin D are also important. Premature ovarian insufficiency is treated with estrogen and progesterone therapy and should be monitored annually until discontinuation of treatment at the usual age of menopause (Popat & Nelson, 2007). Other forms of premature menopause occur with anorexia, chemotherapy or radiation treatments, and oophorectomy (surgical removal of the ovaries).

Medical Therapy

Menopausal Hormone Therapy (HT)

Hormone therapy (HT), formerly called *hormone replacement therapy (HRT)*, refers to the administration of specific hormones to alleviate symptoms associated with the changes of menopause. Estrogen therapy (ET) and combined estrogen-progestogen therapy (EPT) are the individual types currently in use. Hormone therapy containing estrogen only is given to women who have undergone a hysterectomy (surgical removal of the uterus), whereas hormone therapy containing estrogen and progestogen (encompasses both progesterone and progestin) is used for women with an intact uterus. Estrogen alone, in a woman with a uterus (unopposed estrogen), increases the risk of endometrial (the lining of the uterus) cancer by eightfold and, therefore, is never given without progesterone in these women.

In 2002 the advisability of HT, specifically EPT, was called into question because of the results of the Women's Health Initiative (WHI) study, which suggested that the risks of HT outweigh its benefits, especially for long-term use, because of the slightly increased risk of breast cancer, thromboembolic disease, and stroke (Writing Group for the Women's Health Initiative Investigators, 2002). Previously HT was thought to provide protection against cardiovascular disease, the number one cause of death for women over age 50. Currently there are studies underway to further define the risks and benefits of HT.

The North American Menopause Society (NAMS), a nonprofit scientific organization, currently recommends that hormone therapy should be considered only when there is an indication for therapy and contraindications for its use have been ruled out. Adequate discussion about the risks and benefits should take place to ensure an informed decision to use HT. HT is a proven therapy for the relief of moderate to severe vasomotor symptoms, vulvar and vaginal atrophy, and dyspareunia (pain with intercourse). Proven risks of HT use include increased risk of venous thrombosis and breast cancer. HT is not currently recommended solely to prevent coronary heart disease. Extended use of HT may be an option for women with a demonstrated reduction in bone mass, whether or not menopausal symptoms exist, to prevent further bone loss or prevent the development of osteoporotic fractures in women when usual therapies are not appropriate or when they cause side effects; and when the benefits of extended use of HT are believed to outweigh the risks (North American Menopause Society [NAMS], 2010).

HT can be prescribed in a number of ways, including orally; transdermally (patch); topically as a gel, lotion, mist, or creams; and through a vaginal ring. It is given in a continuous manner, daily administration of both estrogen and progestogen, or as a cyclic or sequential therapy, with estrogen use daily and a progestogen added on a set sequence (NAMS, 2010). Combination estrogen-progestogen preparations are also available.

Research, though still preliminary, does seem to indicate that postmenopausal women experiencing decreased libido experience improved sexual desire, responsiveness, and frequency when testosterone is added to their HT. Options for providing testosterone in doses low enough for women are still limited and are not approved by the FDA. Estratest, a combined estrogen-androgen pill, is used by some women. Custom-compounded testosterone preparations are available by prescription. Proctor & Gamble has developed a low-dose testosterone transdermal patch for women called Intrinsa that is available by prescription in Europe. Another testosterone product, a gel called LiBiGel, is currently undergoing testing.

A great deal of attention has been given to "bioidentical" hormones lately because of current views, which are not supported by medical literature, that these "more natural" hormones are safer and more effective. A bioidentical hormone refers to a hormone that is structurally identical to those found in the body, more specifically, those produced by the ovaries. These hormones are compounded by a specialty pharmacy and are not approved by the FDA, nor have they been proven to have a better safety profile (Altman, Moore, Speroff, et al., 2009).

In light of the findings from more recent clinical trials and a secondary analysis of the WHI, NAMS convened an advisory panel to develop recommendations about the clinical management of postmenopausal hormone therapy. Among their recommendations they suggested the following (NAMS, 2010):

- The treatment of moderate to severe menopausal vasomotor symptoms (hot flashes and night sweats) is the primary indica-

RESEARCH EVIDENCE IN PRACTICE

The Safety of Estrogen/Progesterone Therapy When Initiated Soon After Menopause

CLINICAL QUESTION

Can the timing of the initiation of estrogen/progesterone replacement therapy reduce the known risks associated with postmenopausal hormone therapy?

RESEARCH EVIDENCE

Current guidelines suggest that estrogen therapy for treatment of the symptoms of menopause (e.g., vasomotor symptoms such as hot flashes and night sweats) is associated with an increased risk of breast cancer, thromboembolism, and stroke. If hormone therapy is necessary for the relief of severe symptoms, care standards dictate that therapy be prescribed at the lowest effective dose for the shortest period. Some providers hypothesized that initiating estrogen/progesterone therapy immediately after the onset of postmenopausal symptoms may not carry the same risk of adverse outcomes as delaying treatment. Three large-scale multisite studies involving thousands of postmenopausal women studied the association of disease conditions and the timing of hormone therapy.

Breast cancer and total cancer were both increased in women who took estrogen/progesterone therapy, regardless of the timing of the treatment. Among these women, use of estrogens appeared to produce elevations in venous thromboembolism and stroke. There was a reduction in hip fracture among women undergoing hormone therapy, but it was unrelated to timing.

There has also been a question as to whether estrogen combined with progesterone avoided these outcomes. These studies demonstrated that adding progesterone did not protect the woman from morbidity. In fact, combination therapy increased the long-term risk of breast cancer. Regardless of the timing of initiation of hormone therapy, the longer durations of treatment were associated with a greater increase in breast cancer risk. In some of these women, though, even short durations of hormone therapy were associated with an increase in the breast cancer rate.

WHAT QUESTIONS REMAIN UNANSWERED?

The delivery method of estrogen/progesterone may influence negative outcomes. One European study demonstrated that transdermal estrogen may have the potential for fewer health risks than oral estrogen therapy, but it had a relatively small sample. Replication of this study on a larger sample is needed before any delivery method of estrogen can be recommended.

WHAT IS BEST PRACTICE?

Nonhormonal treatments for the relief of postmenopausal vasomotor symptoms are the standard for safe care. Timing of treatment does not reduce the risk of breast cancer, thromboembolism, and stroke and, in some cases, may increase the long-term risk. Even short periods of treatment increase risk, but longer courses of treatment are clearly associated with increased risk of adverse conditions.

CRITICAL THINKING

What are some nonhormonal interventions that the nurse can offer to the postmenopausal woman to deal with the vasomotor symptoms of menopause?

tion for HT. Local vaginal estrogen is generally recommended when HT is considered solely to treat urogenital atrophy.

- Progestogen is prescribed only to protect the endometrium from unopposed estrogen. Thus women with a uterus who are taking estrogen should also have a prescription for adequate progestogen coverage (HT). Women without a uterus who are taking estrogen (ET) should *not* have a progestogen prescribed.
- No estrogen therapy regimen (ET or EPT) should be used solely to prevent coronary heart disease. Alternative prevention regimens should be used instead (weight control, regular exercise, no smoking, healthy diet, etc.).
- HT has been used for the prevention of osteoporosis. However, because of the associated risks, alternative approaches to preventing and treating osteoporosis should be considered first. In certain situations HT may play a role in the treatment of osteoporosis.
- HT use should be limited to the shortest duration feasible in light of treatment goals, benefits, and risks for an individual woman.
- The therapeutic goal should be to prescribe the lowest effective dose of estrogen that is consistent with treatment goals and an analysis of benefits and risks.
- Alternate routes of administration of HT may provide advantages, but at present the long-term risk benefit ratio has not been shown.
- HT may be recommended for women who experience premature menopause and premature ovarian insufficiency at least until they reach the median age of natural menopause.
- Therapy decisions should be made individually based on each woman's symptoms and identified risks.
- Women should be informed of the known risks.

At present, HT is still recognized as the most effective therapy for women who experience moderate to severe menopausal symptoms. For women taking short-term (1 to 4 years) HT therapy to relieve symptoms, the benefits are likely to outweigh the risks.

Before starting HT the woman should undergo a thorough history; physical examination including Pap smear; measurement of cholesterol, lipids, and liver enzyme levels; and baseline mammogram. An initial endometrial biopsy is no longer routinely recommended for all women beginning HT; however, biopsy is indicated for women with an increased risk of endometrial cancer and if excessive, unexpected, or prolonged

vaginal bleeding occurs. Caregivers who prescribe HT should teach their patients to report immediately any signs of complications such as headaches, visual changes, signs of thrombophlebitis, or signs of myocardial infarction that are common in women (see later discussion).

Prevention and Treatment of Osteoporosis

Osteoporosis is rapidly becoming a significant health risk for older adults (see Table 4-2). According to the American College of Obstetricians and Gynecologists (ACOG, 2007b) more than 1.5 million fractures occur in the United States each year. Most of these fractures occur in women. Fifty percent of all women over the age of 50 will experience an osteoporosis-related fracture in their lifetime. These numbers are especially worrisome because osteoporosis is a largely preventable disease and a source of significant risk for fracture and subsequent health decline.

Bone mineral density (BMD) testing is useful in identifying individuals who are at risk for osteoporosis. A variety of guidelines are available for BMD testing. ACOG (2008) recommends BMD testing for the following:

- All postmenopausal women aged 65 or older regardless of risk factors
- All postmenopausal women with fractures
- Postmenopausal women under age 65 with one or more risk factors

BMD testing may also be indicated for premenopausal or postmenopausal women with certain medical conditions such as eating disorders, thyroid disorders, leukemia, rheumatoid arthritis, and multiple sclerosis and for those women on certain medications such as corticosteroids or anticonvulsants.

This quick, painless test assesses whether a woman has normal bone mass or has decreased bone density (osteoporosis) or increased bone porosity or softening (osteomalacia). Optimum screening is done using a central dual-energy x-ray absorptiometry (DEXA) scan to measure bone density at the hip and lumbar spine. Figure 4-3 ■ shows a sample bone density testing result.

The woman's height should be measured at each visit, because a loss of height is often an early sign that vertebrae are being compressed because of reduced bone mass. A variety of conditions, including malabsorption syndrome, cancer, cirrhosis of the liver, chronic use of cortisone, and rheumatoid arthritis, can cause secondary arthritis, which resembles osteoporosis. If these secondary causes are ruled out, treatment for osteoporosis is instituted.

Prevention of osteoporosis is the primary goal. It should include encouraging women to adopt lifestyle practices that reduce the risk of bone loss such as regular weight-bearing and muscle-strengthening exercise, smoking cessation, moderation of alcohol intake, and fall prevention strategies (ACOG, 2007b). Women are also advised to maintain an adequate calcium intake. The National Institutes of Health recommends that postmenopausal women have a daily intake of 1200 mg of calcium, increasing to 1500 mg if they are not on hormone therapy. Most women require supplements to achieve this level. Calcium supplementation is most effective when single doses do not exceed 500 mg and when taken with a meal.

Vitamin D is a fat-soluble vitamin that has its greatest effect on maintaining adequate levels of serum calcium. It is primarily metabolized by the body through sunlight or dietary intake. The use of sunscreen can result in decreased production of vitamin D in the skin. Low bone density and certain autoimmune diseases are associated with vitamin D deficiency. It is recommended that adults take a vitamin D supplement of 1000 to 2000 international units per day to reduce the incidence of low bone density (Malone & Kessenich, 2008).

The effectiveness of estrogen in preventing osteoporosis is well documented. Women with no contraindications to estrogen who are showing evidence of bone loss are good candidates for HT. For women who are unable or unwilling to take estrogen, other medications available to treat or help prevent osteoporosis include the following:

1. *Bisphosphonates* have potent antiresorptive effects and are the gold standard in alleviating postmenopausal osteoporosis (Waxman, 2007). These medications are taken upon arising in the morning on an empty stomach with a large glass of water. The woman should sit upright or stand for about 30 minutes after taking the medication and before eating. These medications are dosed daily, once weekly, or once monthly depending on the formulation. New bisphosphonates may offer women alternatives that eliminate the undesirable gastrointestinal side effects. For example, in 2002, an intravenous bisphosphonate, zoledronic acid (Zometa), was approved by the FDA for use in the treatment of metastatic bone cancer. It is the most recent medication approved for the treatment of osteoporosis. The drug, administered intravenously (IV) once a year, seems to achieve the same results in treating osteoporosis as other bisphosphonates taken daily or weekly without the troublesome gastrointestinal side effects. Although many patients may prefer the yearly dosing option, there has been reported increased risk of deterioration of the jaw bone with the use of this medication over extended periods (Waxman, 2007).
2. *Selective estrogen receptor modulators (SERMs)* have estrogen-like properties. The SERM approved for osteoporosis treatment, raloxifene (Evista), acts like estrogen by protecting against osteoporosis but does not stimulate uterine or breast tissue. Raloxifene does not relieve other menopausal symptoms and may increase hot flashes, so it is indicated in asymptomatic women who want preventive therapy for osteoporosis.
3. *Salmon calcitonin* is a calcium regulator that may inhibit bone loss and is approved for use to treat osteoporosis in women who are 5 years postmenopause. Administered as a nasal spray, its value is less clear than that of the other medications listed.
4. *Parathyroid hormone,* a daily subcutaneous injection, activates bone formation, which results in substantial increases in bone density.

The National Osteoporosis Foundation (NOF) provides a wealth of information about osteoporosis diagnosis and management.

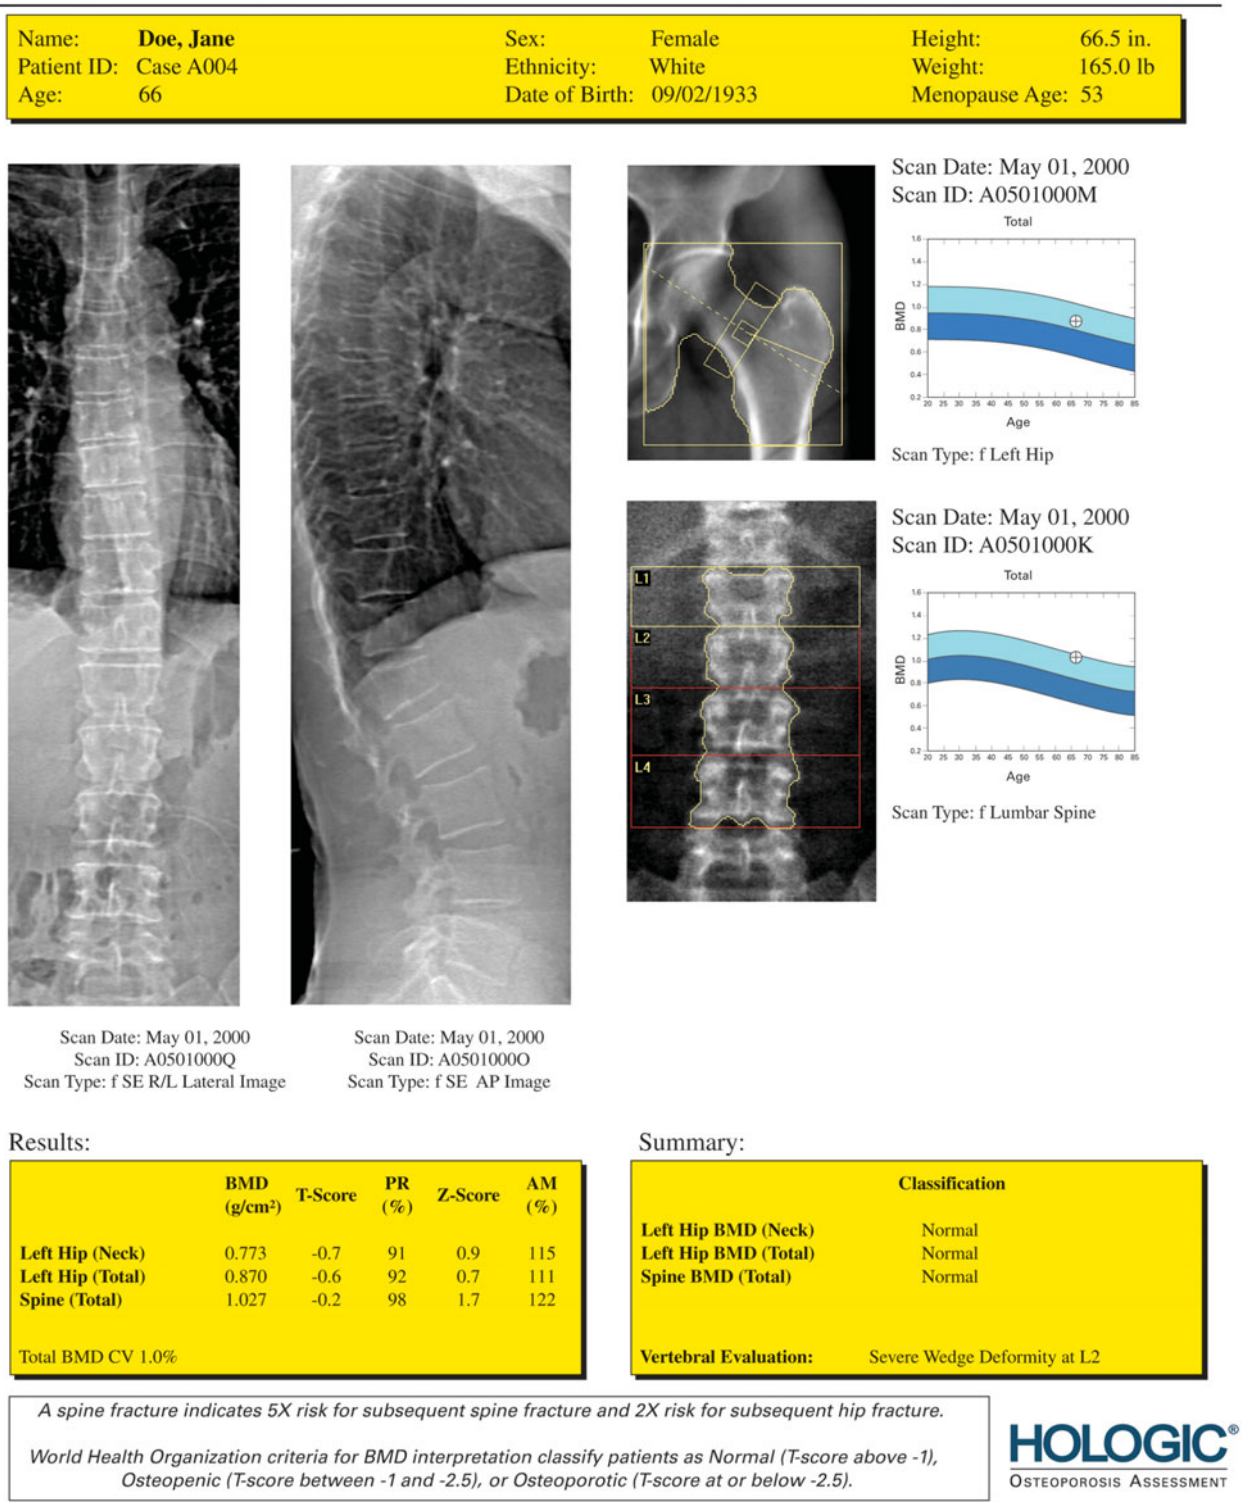

Figure 4-3 ■ For osteoporosis assessment, published studies demonstrate that up to 30% of patients needing treatment are missed using BMD results of the spine and hip alone. The standard of care for assessing osteoporotic fracture risk is combining BMD results with imaging of the thoracic-lumbar spine. The osteoporotic assessment examination presented here shows a 66-year-old postmenopausal woman who has not received hormone replacement therapy because of a personal history of breast cancer. Although her bone mineral density (BMD) results are within normal limits, she does have an identifiable vertebral fracture at L2. This fracture places her at increased risk for future vertebral fractures and, therefore, in need of treatment for osteoporosis.

CLINICAL JUDGMENT

Case Study: Janet Turner

Mrs. Turner, a 68-year-old woman, presents for her annual well-woman examination. She is 5 foot 4 inches tall and weighs 120 pounds. In taking her history she states that she has recently gotten out of a cast for a broken wrist. She states that she fell while gardening. She has not used hormone replacement therapy in several years and has no complaints of menopause symptoms other than mild vaginal dryness, which is relieved with vaginal lubricants.

Critical Thinking

What further questions would you ask in your history taking? What recommendation would you make for Mrs. Turner?

See www.nursing.pearsonhighered.com for possible responses.

Prevention of Coronary Heart Disease

Prevention is the key to dealing with CHD. Prevention begins with lifestyle choices and with lifestyle modifications as necessary. This includes maintaining ideal body weight, exercising regularly, eating a nutritious diet, avoiding smoking, managing stress effectively, obtaining regular healthcare screenings as indicated, and developing a strong social support system.

It is critical that women be familiar with the signs of myocardial infarction (heart attack) that are commonly seen in women. These include pain in the neck, back, or epigastric region; loss of appetite; shortness of breath; nausea or vomiting; and weakness in the shoulder, arms, and chest. Research indicates that women are more likely than men to delay seeking treatment. They are also more likely to die from the attack (Rowe, 2007). Thus it is important for nurses to stress the need to seek immediate treatment if symptoms develop.

Complementary and Alternative Therapies

As women evaluate their feelings about the use of HT in light of the recent findings in clinical trials, they may wish to explore alternative therapies for control of their symptoms. A variety of therapeutic modalities have been proposed as alternative or complementary treatment or prevention measures for the discomforts and ailments of the perimenopausal and postmenopausal years. These include nutrition supplements, such as a diet rich in calcium and vitamins E, D, and B complex.

Very little scientific research has been done on complementary alternative therapy for the treatment of menopause. Black cohosh has received the most scientific attention. Mixed results, however, have been found for the use of black cohosh for the relief of hot flashes and night sweats. Experts agree that safety is an issue for women using black cohosh if they have a liver disorder or develop symptoms of liver trouble.

Dong quai has had one randomized clinical study done on it and was not found to have any effect on hot flashes. Dong quai is known to interact with blood thinning medication (warfarin) and can lead to bleeding complications in women taking this medication.

Ginseng, although not helpful for hot flashes, may help with other menopausal symptoms such as moodiness and sleep disturbances. Kava may decrease anxiety, although the FDA has issued a warning about kava for potential liver damage.

Phytoestrogens are plant products that have estrogen-like properties. Examples of foods and botanicals containing phytoestrogens are carrots, yams, soy, and red clover. After five controlled studies, red clover was not found to reduce hot flashes. Soy has had inconsistent results in studies in reducing hot flashes. There is some question that daily intake of soy may reduce slightly the levels of LDL or bad cholesterol. Ongoing studies are underway to examine the effects of soy on women's arteries and bones after menopause (National Center for Complementary and Alternative Medicine [NCCAM], 2008). Women who have endometriosis or uterine fibroids should be cautioned on the use of these products as should women who have had or are at risk for diseases that are affected by hormones, such as breast, uterine, or ovarian cancer (NCCAM, 2008).

DHEA is a dietary supplement that is changed in the body to the hormones estrogen and testosterone. A few small studies have suggested that DHEA might have some benefit for hot flashes and decreased sexual arousal, although randomized controlled trials do not support this. Scientists are not certain whether the use of DHEA increases the risk for breast and prostate cancer (NCCAM, 2008).

A randomized, controlled study of acupuncture treatment for hot flashes was conducted and suggests that this may be an effective therapy to reduce the frequency of hot flashes in some women (Avis et al., 2008).

DEVELOPING CULTURAL COMPETENCE

Filipina Women and Aging

In the Philippines, menopause is viewed as a positive and liberating event. As women age, they are more respected and admired for their years of gained experiences. Older women gain status and importance as they age and are widely embraced by the younger generations within their family. (Comments from a Filipino nursing student.)

Weight-bearing exercise, including such activities as walking, jogging, tennis, and running, is a means of increasing bone mass and potentiating the effect of estrogen on bone mass. Exercise also improves cholesterol profiles and contributes to overall health (Figure 4-4 ■). Pelvic floor, or Kegel, exercises can help maintain vaginal muscle tone and increase blood circulation to the perineal area. Vaginal lubricants and adequate foreplay can be helpful in maintaining a satisfactory sexual experience.

Relaxation techniques, including yoga, meditation, deep breathing, visualization, massage, or acupuncture, may provide a sense of well-being. Menopausal women should avoid foods that may trigger symptoms, including caffeine, alcohol, and spicy foods. Overall, healthy lifestyle, proper nutrition, and adequate exercise will maximize health and decrease health risks and symptoms.

Figure 4-4 ■ Regular exercise is important, especially for postmenopausal women.

NURSING CARE MANAGEMENT

Some menopausal women may need counseling to adjust successfully to this developmental phase of life. Others have no difficulty with this life transition. Reaction to menopause is determined to a large extent by the kind of life the woman has lived, by the security she has in her feminine identity, by her feelings of self-worth and self-esteem, and by her relationships with others.

Nurses and other healthcare professionals may be able to help the menopausal woman achieve high-level functioning at this time in her life. Of paramount importance is the nurse's ability to understand and provide support for the woman's views and feelings. Whether the woman expresses relief and delight or tearfulness and fear, the nurse needs to use an empathetic approach in counseling, health teaching, or providing physical care.

Women may discuss areas of deep concern, including a history of sexual abuse, current distress, or life problems. Nurses should have appropriate referrals to domestic violence hotlines and to professional therapists who work with women. Women may also be dealing simultaneously with chronically ill parents, divorce or the death of a spouse, troubled or handicapped children, children leaving home, job stressors, and/or generalized fear and anxiety. Nurses can be of assistance with referrals to support groups and counselors who are specific to each woman's need. Although this is a challenge, it is the responsibility of the nurse caring for women to be prepared to meet their needs.

Nurses should explore the question of the woman's comfort during sexual intercourse. In counseling, the nurse may say, "After menopause many women notice that their vaginas seem drier, and sex of any kind can be uncomfortable. Have you noticed any changes?" This gives the woman information and may open discussion. The nurse can then go on to explain that the woman can address dryness and shrinking of the vagina by using a water-soluble lubricant to help provide relief. Use of estrogen, orally or in vaginal creams, may also be indicated. Increased frequency of sexual activity will maintain some elasticity in the vagina. When assessing the menopausal woman, the nurse needs to address the question of sexual activity openly but tactfully, because the woman may have been socialized to be reticent in discussing sex. Heterosexual women who do not wish to become pregnant should be counseled to use a method of contraception for 1 year after their last menstrual period. They should also be advised to report any bleeding after 1 year of amenorrhea because this may indicate a problem and requires evaluation.

The crucial need of women in the perimenopausal period of life is for adequate information about the changes taking place in their bodies and their lives and support in adjusting to the changes that occur. Supplying that information and providing support as needed present both a challenge and an opportunity for nurses.

Additional information about the most current approaches to the management of menopause and the postmenopausal period can be found at the Web site of the North American Menopause Society.

PROFESSIONALISM IN PRACTICE

Personalizing Care During Menopause

Women respond differently to the experience of menopause, so it is important to avoid generalizations. During menopause women are in varying stages of life. In working with menopausal women, being sensitive to their place in life, such as caring for aging parents, empty nest, or change in marital status will personalize their care and offer appropriate measures to help them through this process.

FOCUS YOUR STUDY

- Nurses should provide girls and women with clear information about menstrual issues, such as the use of pads and tampons (including warnings regarding deodorant and absorbency); vaginal spray and douching practices; and self-care comfort measures during menstruation, such as maintaining good nutrition, exercising, and applying heat and massage.
- Dysmenorrhea usually begins at, or a day before, the onset of menses and disappears by the end. Hormone therapy (e.g., combined oral contraceptives), nonsteroidal anti-inflammatory drugs, or prostaglandin inhibitors can alleviate dysmenorrhea. Self-care measures include improving nutrition, exercising, applying heat, and getting extra rest.
- Premenstrual syndrome occurs most often in women over 30. The most pronounced symptoms occur 2 to 3 days before onset of menstruation and subside as menstruation starts, with or without treatment. Medical management usually includes prostaglandin inhibitors and calcium supplementation. Self-care measures include improving nutrition (taking vitamin B complex and E supplements and avoiding methylxanthines, which are found, for example, in chocolate and caffeine), undertaking a program of aerobic exercise, and participating in self-care support groups. In some cases, pharmacologic agents such as selective serotonin reuptake inhibitors may be indicated.
- During her adult years, a healthy woman should make healthful lifestyle choices such as avoiding smoking and exercising regularly. She should also participate in regular health screenings, following a recommended schedule.
- Menopause is a physiologic, maturational change in a woman's life. Physiologic changes include the cessation of menses and a decrease in circulating hormones. Hormonal changes sometimes bring unsettling emotional responses. The more common physiologic symptoms are "hot flashes," palpitations, dizziness, and increased perspiration at night. The woman's anatomy also undergoes changes, such as atrophy of the vagina, reduction in size and pigmentation of the labia, and myometrial atrophy. Osteoporosis becomes an increasing concern.
- Osteoporosis is becoming a significant health problem in the United States. Prevention is the preferred approach to addressing the issue. This includes adequate calcium intake, regular weight-bearing exercise, and HT. For women who have already developed osteoporosis, medications are available as a treatment option.
- Coronary heart disease is the number one killer of women in the United States. Prevention is the goal of therapy.
- Current management of menopause centers on hormone replacement therapy, complementary therapies, and patient healthcare education. Decisions regarding the use of HT should be made individually, based on each woman's symptoms and risks, and women should be advised of the known risks.

CRITICAL THINKING IN ACTION

You are working at a local clinic when Joy Lang, age 20, presents for her first pelvic exam. You obtain the following GYN history; menarche age 12 menstrual cycle 28–30 days lasting 4–5 days, heavy one day, then lighter. She tells you that she needs to use superabsorbent tampons on the first day of her period and then she switches to a regular absorbency tampon for the remaining days. She confirms that she changes the tampon every 6 to 8 hours, never leaving it in overnight. She denies premenstrual syndrome, dysmenorrhea, or medical problems and says that she is not taking any medication on a regular schedule. She tells you that she recently got married, but would like to wait before getting pregnant. She'd like to discuss birth control methods. Joy tells you that doctors make her nervous and she admits to being anxious about her first pelvic exam.

1. What steps would you take to reduce Joy's anxiety relating to the pelvic exam?
2. What position is best to relax Joy's abdominal muscles for the pelvic exam?
3. What precaution should be taken when obtaining a Pap smear?
4. Explain the purpose of the Pap smear.
5. What factors do you include in a discussion of the type of birth control that Joy could practice?

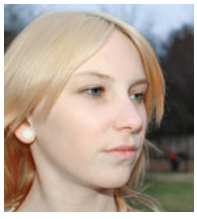
CHAPTER 5

Women's Health: Family Planning



I was 15 when I fell in love with Joe, a handsome, 17-year-old senior on our high school basketball team. My friends were so envious. We didn't plan on becoming sexually involved. It just happened. I knew I should have used some method of birth control, but I didn't know where to go. I couldn't talk to my mother. She wouldn't understand. Joe tried condoms, but he didn't like the way they felt. Several months went by and nothing happened. Then one month my period was late. I was SCARED. It really hit me that a pregnancy would be so hard to handle. I was only a sophomore. My best friend took me to see her nurse practitioner. My pregnancy test was negative. The nurse practitioner encouraged me to talk. She taught me about my body and how to protect myself against an unwanted pregnancy and sexually transmitted infections. She helped me build my self-esteem. I realize now that I'm not ready to be in a sexual relationship yet.

LEARNING OUTCOMES

1. Describe the reasons why women and couples choose to use contraception.
2. Discuss types of fertility awareness-based methods such as natural family planning.
3. List the spermicide preparations currently available in the United States.
4. Compare the barrier methods of contraception with regard to correct use and advantages and disadvantages.
5. Summarize the key points that women who use combined oral contraceptives should know, including the correct procedure for taking pills, common side effects, warning signs, and noncontraceptive benefits.
6. Compare other hormonal methods of birth control, including Depo-Provera, NuvaRing, Ortho Evra, Implanon, and the progestin-only minipill.
7. Identify the appropriate time frame for initiating postcoital emergency contraception (EC).
8. Delineate the advantages and disadvantages of an IUD as a method of contraception.
9. Contrast the forms of sterilization—tubal ligation, Essure, and vasectomy—with regard to risk, effectiveness, advantages, and disadvantages.
10. Compare medical and surgical approaches to pregnancy termination.

KEY TERMS

Coitus interruptus *84*
Combined oral contraceptives (COCs) *90*
Condoms *85*
Depo-Provera *92*
Diaphragm *87*
Fertility awareness-based (FAB) methods *82*
Implanon *92*
Intrauterine devices (IUDs) *88*
Postcoital emergency contraception (EC) *92*
Spermicides *84*
Sterilization *93*
Tubal ligation *93*
Vasectomy *93*

Family planning refers to actions an individual or a couple takes to avoid a pregnancy, to space future pregnancies for a specific reason, or to gain control over the number of children conceived. Thus at a given time a woman may choose one method of contraception and at a later time may elect to use a different method. For example, birth control pills are an excellent method of contraception for women who are healthy and have no medical contraindications. A woman in a stable sexual relationship may choose to use an intrauterine device (IUD), whereas a woman who has no desire for further children may elect permanent sterilization for herself or her male partner may choose such for himself. Although women have several contraceptive methods available, currently, contraceptive methods for men are limited to condoms and vasectomy. This chapter focuses on contraceptive methods currently available, including the advantages and disadvantages of each.

Overview of Family Planning

Demographics

In 2006 there were 66.4 million women in the United States of childbearing age (13 to 46 years) (Guttmacher Institute, 2009). Of these women of childbearing age 62% practiced contraception, whereas 31% did not because they were not sexually active, were infertile, were pregnant or trying to become pregnant, were postpartum, or had never had intercourse. The remaining 7% of these women were not using any contraception (Guttmacher Institute, 2008a.)

Nevertheless in the United States nearly half of all pregnancies are unintended, and of these, 4 in 10 are terminated by abortion. Among women who obtain abortions, 50% are younger than 25—33% are aged 20 to 24 and 17% are teenagers; 30% percent are black, 36% are non-Hispanic white, 25% are Hispanic, and 9% are of other races. About 61% of all abortions are for women who have one or more children (Guttmacher Institute, 2008b).

In 2006, 36.2 million women in the United States were in need of contraceptive services (Guttmacher Institute, 2009). Contraceptive services may be paid for out of pocket, by insurance companies, or by federal employers; contraceptive coverage by insurance companies is mandated in 26 states (Guttmacher Institute, 2008a). Yet, more than 17.5 million women remained in need of publicly funded contraceptive care, with Medicaid continuing to be the largest payer followed by state appropriations. Publicly funded contraceptive services helped prevent 1.94 million pregnancies that could have resulted in 860,000 unintended births and 810,000 abortions (based on statistical projections). For every $1 spent on publicly funded contraceptive care, an average of $4.02 is saved in Medicaid expenditures related to unintended pregnancies, proving the cost-effectiveness of contraceptive care (Guttmacher Institute, 2009).

In the developing world, 137 million women have an unmet need for contraception, and an additional 64 million women have an unmet need for a modern contraceptive method. Although there has been a decline in the unmet needs for contraception across the developing world, it remains high in sub-Saharan Africa, where maternal mortality rates continue to constitute half of all maternal deaths (Sonfield, 2006; World Health Organization [WHO], 2007).

Maternal morbidity and mortality remain a major health challenge in the developing world. Daily 1500 women die or suffer from pregnancy-related problems. In 2005, an estimated 536,000 women died in childbirth or from pregnancy-related problems worldwide; 99% of these deaths occurred in the developing world and many were preventable (WHO, 2007).

HEALTH PROMOTION EDUCATION: CONTRACEPTION

Family planning using a contraceptive method is an important component of women's health. Worldwide, women who are able to use contraception and plan the number of pregnancies they have, as well as the interval between those pregnancies, benefit in several ways (Guttmacher Institute, 2002):

- They enjoy improved health and a lower incidence of sexually transmitted infections, including HIV.
- They have lower rates of induced, sometimes unsafe, abortions.
- They have fewer unwanted pregnancies and births.
- They have the opportunity to get more education and to find jobs, which enhances their economic and social status and improves the well-being of their families.

Most of the causes of maternal mortality are treatable or preventable with adequate health care, including contraceptive services. Thus, it is essential that maternal healthcare services improve if maternal mortality and morbidity are to be reduced. Up to 150,000 maternal deaths per year could be avoided if contraception was available and used by women who did not desire children (United Nations Population Fund [UNPFA], 2008).

Choosing a Method of Contraception

The decision to use a method of contraception may be made individually by a woman (or, in the case of condoms or vasectomy, by a man) or jointly by a couple. Attitudes about contraceptive methods vary considerably. The two leading contraceptive methods in the United States are the combined oral contraceptive pill for women younger than 35 years of age and sterilization for women over the age of 35 (National Center for Health Statistics [NCHS], 2010). Use of the condom and other barrier methods has increased because of the prevalence of sexually transmitted infections (Martinez, Chandra, Abma, et al., 2006).

Decisions about contraception should be made voluntarily with full knowledge of advantages, disadvantages, effectiveness, side effects, contraindications, and long-term effects. Many outside factors influence this choice, including cultural practices, religious beliefs, personality, cost, effectiveness, availability, misinformation, practicality of method, and self-esteem. Different methods of contraception may be appropriate at different times in a person's life (Table 5-1). In choosing a specific method, consistency of use outweighs the absolute reliability of the given method.

TABLE 5-1 Factors to Consider in Choosing a Method of Contraception

- Effectiveness of method in preventing pregnancy
- Safety of the method:
  Are there inherent risks?
  Does it offer protection against sexually transmitted infections (STIs) or other conditions?
- Patient's age and future childbearing plans
- Any contraindications in patient's health history
- Religious or moral factors influencing choice
- Personal preferences, biases
- Lifestyle:
  How frequently does patient have intercourse?
  Does she have multiple partners?
  Does she have ready access to medical care in the event of complications?
- Is cost a factor?
- Partner's support and willingness to cooperate
- Personal motivation to use method

Care Plan Activity: Fertility Awareness

Fertility Awareness-Based Methods

Fertility awareness-based (FAB) methods are based on an understanding of the changes that occur throughout a woman's menstrual cycle and require recording of certain events to identify fertile days. FAB methods take into account the lifespan of sperm (2–7 days) and the ovum (1–3 days) in the female reproductive tract. Maximum fertility for the woman occurs approximately 5 days before ovulation and decreases rapidly the day after. Therefore, the couple must abstain from intercourse, or use a barrier method, during the fertile days (Hatcher et al., 2007).

If the couple using a FAB method also uses a barrier method during fertile days, it is known as fertility awareness-combined methods. If the couple abstains completely from intercourse during fertile days, it is known as natural family planning (NFP) (Hatcher et al., 2007). Other FAB methods include the basal body temperature method, ovulation method, calendar rhythm method, and symptothermal method.

NFP is free, safe, and acceptable to many whose religious beliefs prohibit other methods. It provides an increased awareness of the menstrual cycle, involves no artificial substances or devices, encourages a couple to communicate about sexual activity and family planning, and is useful in helping a couple plan a pregnancy.

To be used effectively, all FAB methods require extensive initial counseling and are best suited for women with regular menstrual cycles. FAB methods may interfere with sexual spontaneity, require the couple to maintain records for several cycles before beginning use, may be difficult or impossible for certain groups of women to use, and may not be as reliable in preventing pregnancy as other methods. Women for whom a FAB method might not be an ideal choice of contraception include those with irregular menstrual cycles, those who are breastfeeding, or those in the perimenopause.

In conjunction with a FAB method or NFP, women may choose to augment identification of their fertile days by use of an over-the-counter ovulation prediction kit (e.g., OvuKit). They may also use a temperature computer (e.g., Bioself 2000) or a hormone computer (e.g., Persona) to help predict fertile days (Hatcher et al., 2007).

Basal Body Temperature Method

The *basal body temperature (BBT)* method is incorporated into the symptothermal method and provides an objective record of fertile days. The BBT method is used to detect ovulation by temperature changes during the menstrual cycle. It requires that the woman take her temperature every morning upon awakening (before any activity) and record the findings on a temperature graph. After 3 to 4 months of recording her temperatures, if she has regular cycles, she should be able to predict when ovulation will occur by a retrospective review of her temperature charts. This method is based on the fact that the temperature almost always rises and remains elevated after ovulation because of the production of progesterone, a thermogenic (heat-producing) hormone, produced by the corpus luteum cyst. Figure 5-1 ■ shows a sample BBT chart.

To avoid conception, the woman and her partner abstain from intercourse, or use a barrier method, on the day of the temperature rise and for 3 days following. Because the temperature rise does not occur until after ovulation, if the woman had intercourse just before the rise she may be at risk of pregnancy.

Ovulation Method

The *ovulation method,* sometimes called the *cervical mucus method* or the *Billings method,* involves the assessment of cervical mucus changes that occur during the menstrual cycle. The amount and character of cervical mucus change because of the influences of estrogen and progesterone. During the follicular phase of the cycle (from the end of menses until just before ovulation) cervical mucus is thick, white, and sticky. This progesterone-dominant mucus is not friendly to sperm and is known as "hostile" mucus. At the time of ovulation, estrogen-dominant mucus is more clear, watery, and stretchable (a quality called *spinnbarkheit*). It has an "egg-white" appearance and is known as "fertile mucus"; it is friendly to sperm, because it assists passage through the cervix and uterus up into the fallopian tubes. It also shows a characteristic fern pattern when placed on a glass slide and allowed to dry. During the luteal phase, cervical mucus is again thick, white, and sticky (progesterone-dominant mucus) and forms a network that traps sperm, making their passage difficult.

Before using the cervical mucus method, the woman abstains from intercourse for one entire menstrual cycle, during which time she assesses her cervical mucus daily for amount, feeling of slipperiness or wetness, color, clearness, and spinnbarkheit. Abstinence is essential during this time, not only so that the woman avoids pregnancy, but also because the presence of ejaculate in the vagina in the hours following intercourse could interfere with the woman's assessment of her cervical mucus.

When using this method, the woman assumes that the peak day of wetness and clear, stretchable mucus is the day of ovulation. However, she abstains from intercourse from the time she *first* notices that the mucus is becoming clearer, more elastic, and slippery until 4 days *after* the peak wet mucus (ovulation) day. Because this method evaluates the effects of hormonal changes, women with irregular cycles can use it.

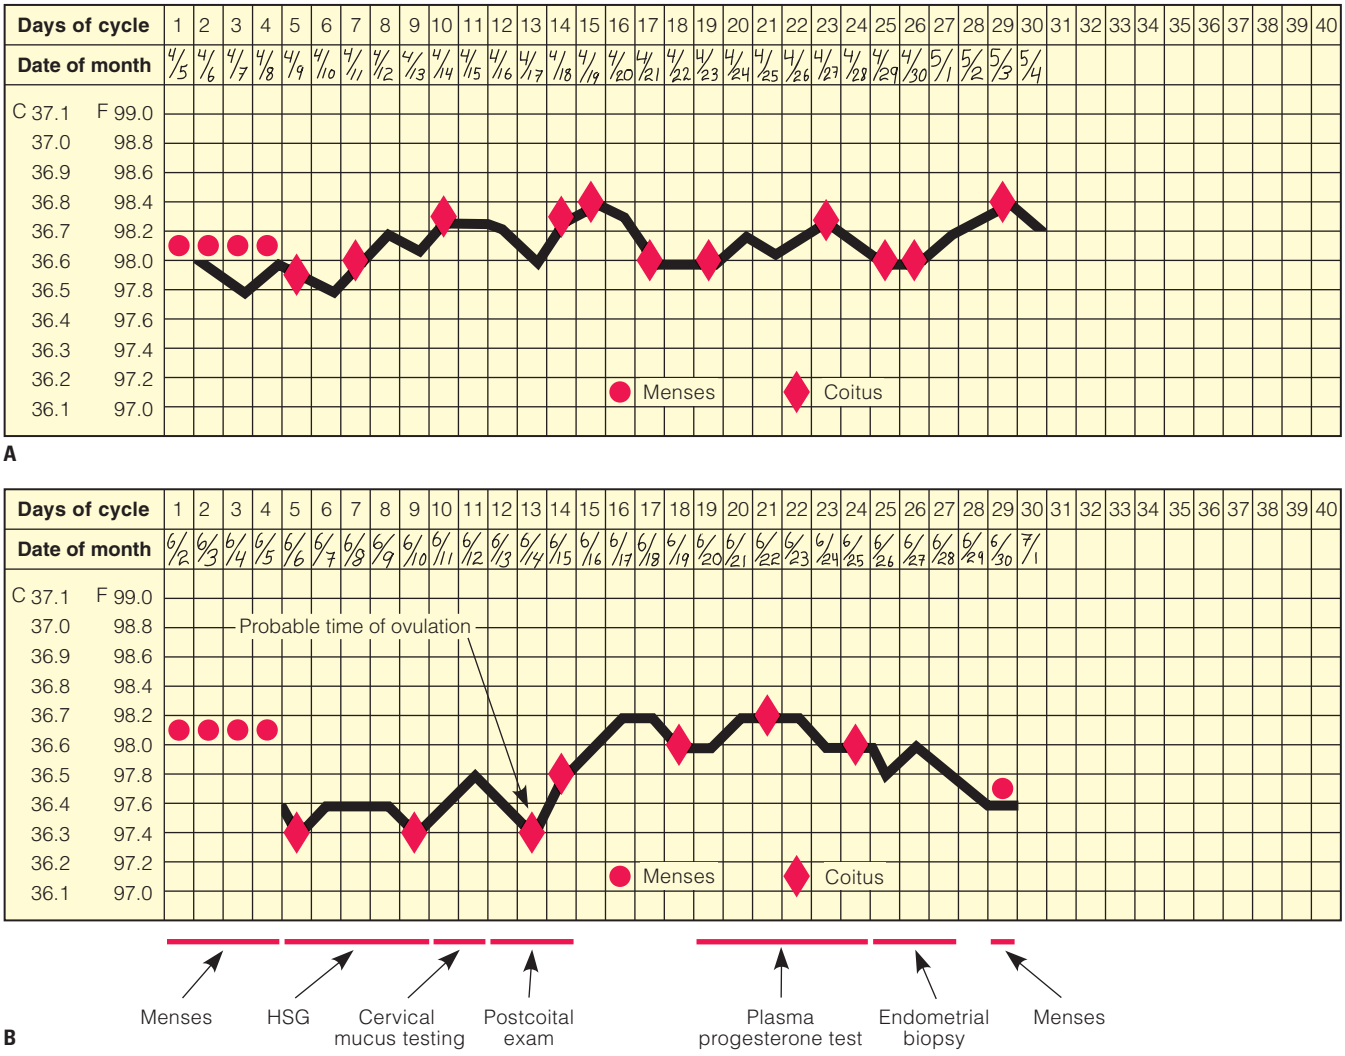


Figure 5-1 ■ A. Monophasic, anovulatory basal body temperature (BBT) chart. B. Biphasic BBT chart illustrating probable time of ovulation, the different types of testing, and the time in the cycle that each would be performed.

Women who feel uncomfortable testing their mucus should be encouraged to use another method.

Calendar Rhythm Method

The *calendar rhythm method (CRM)* is based on the assumption that ovulation tends to occur 14 days (plus or minus 2 days) before the start of the next menstrual period. To use this method, the woman must record her menstrual cycle for 6 months to identify the shortest and longest cycles. The first day of menstruation is the first day of the cycle. The fertile phase is calculated from 18 days before the end of the shortest recorded cycle through 11 days from the end of the longest recorded cycle. For example, if a woman's cycle lasts from 24 to 28 days, the fertile phase would be calculated as day 6 through day 17. Once this information is obtained, the woman can identify the fertile and infertile phases of her cycle. For effective use of this method, she must abstain from intercourse during the fertile phase or use a barrier method. CRM is the *least reliable* of the FAB methods and has largely been replaced by approaches based on objective data.

Symptothermal Method

The *symptothermal method* consists of recording various indicators of fertility by the couple for a number of months. These include: cycle length; frequency and timing of coitus; cervical mucus changes; secondary signs of ovulation such as increased libido, abdominal bloating, mittelschmerz (midcycle abdominal pain); and changes in BBT. In retrospect, using the indicators, the couple learns to recognize signs that indicate ovulation. This combined approach tends to improve the effectiveness of FAB as a method of contraception and is best taught by an expert in the method. For couples interested in the symptothermal method, especially for use as a natural family planning (NFP) method, training courses are available through the Couple to Couple League.

Other Options

The *standard days method* is good for women with regular cycles between 26 and 32 days. Intercourse is avoided, or a barrier method used, between cycle days 8 through 19 (Hatcher et al., 2007).

The *lactational amenorrhea method* is based on a woman breastfeeding exclusively for the first 6 months after childbirth. High levels of prolactin in the woman's body during breastfeeding should prevent ovulation. The woman should breastfeed on demand and the newborn should empty both breasts of milk to prevent ovulation. If a formula supplement is used often, a barrier method should be used concurrently. When the woman stops breastfeeding, resumes her menses, or her newborn becomes 6 months old, she should select another method of contraception. This method is most reliable in the United States when used with a barrier method. In developing countries, it is a useful method of "pregnancy spacing" (Hatcher et al., 2007).

Application: Abstinence Support Resources

Contraception Online

Situational Contraceptives

Certain practices such as coitus interruptus (withdrawal) and douching are considered situational contraceptives because they are activities an individual uses in a given situation to avoid pregnancy without benefit of clinical guidance or medical care. Abstinence, a lifestyle choice, is also considered a situational contraceptive.

Abstinence

Abstinence can be considered a method of contraception and is described as primary or secondary. A woman who, by personal choice, has never had sexual intercourse is practicing primary abstinence. Abstinence may also be culturally dictated before marriage. Secondary abstinence occurs when the woman, who has had sexual intercourse, chooses to abstain for a period of time. This may occur due to the unavailability of her partner, while she waits for a more reliable method of contraception, or it may be the cultural norm during the postpartum period (Hatcher et al., 2007).

Coitus Interruptus

Coitus interruptus, or withdrawal, is one of the oldest methods of contraception. This method requires that the male withdraw from the female's vagina when he feels that ejaculation is impending. He then ejaculates away from the external genitalia of the woman. Failure tends to occur for two reasons:

- This method demands great self-control on the part of the man, who must withdraw just as he feels the urge for deeper penetration with impending orgasm.
- After a recent ejaculation, sperm remain in the urethra. For couples who engage in repeated episodes of orgasm within a short period, this preejaculatory fluid may contain sperm that escape from the penis during the excitement phase before ejaculation. Although the number of sperm is low, this scenario poses the risk of an unintended pregnancy.

Couples who use this method should be aware of postcoital emergency contraceptive options should the man fail to withdraw in time. Such options are discussed later in the chapter.

Douching

Douching after intercourse is an ineffective method of contraception and is *not* recommended. Moreover, it may actually facilitate conception by pushing sperm farther up the birth canal.

Spermicide

The **spermicide** approved for use in the United States, nonoxynol-9 (N-9), is available as a cream, jelly, foam, vaginal film, or suppository. The spermicide is inserted into the vagina before intercourse. It destroys sperm by disrupting the cell membrane. A spermicide that effervesces in a moist environment offers more rapid protection, and coitus may take place immediately after it is inserted. A suppository may require up to 30 minutes to dissolve and will not offer protection until it has done so. The nurse instructs the woman to insert any of these spermicidal preparations high in the vagina and maintain a supine position.

N-9 is minimally effective when used alone, but its effectiveness increases in conjunction with a barrier method of contraception such as the diaphragm, FemCap, contraceptive sponge, or male and female condoms. The major advantages of spermicidal preparations include availability, lack of systemic side effects, and low local toxicity.

In the past, N-9 was thought to offer a modest level of protection against several sexually transmitted infections. However, research suggests that N-9 does not offer protection against the organisms that cause gonorrhea and chlamydia or against HIV, the organism that causes HIV/AIDS (Hatcher et al., 2007). Moreover, N-9 may actually increase a woman's risk of HIV infection because it has a negative effect on the integrity of vaginal cells, making them more susceptible to invasion by organisms such as HIV.

Barrier Methods of Contraception

Barrier methods of contraception prevent the transport of sperm to the ovum, immobilize sperm, or are lethal against them. They include male and female condoms, diaphragms, cervical caps, vaginal sponges, and intrauterine devices. Barrier methods are often used in conjunction with a spermicide, which some authorities consider a form of chemical barrier.

Barrier methods are clearly related to an individual's sexual behavior. Each act of intercourse demands that one or both partners consciously decide whether to use a barrier contraceptive and then take action. Thus these methods require motivation on the part of the user and cooperation from the partner. They may be used less consistently than non–coitus-related methods of contraception, for example, use of the diaphragm only during a woman's fertile days versus taking a pill every day. Because they have few side effects, they are very safe methods and do offer a level of protection against some bacterial sexually transmitted infections.

Barrier methods of contraception are a good choice for women who:

- Have a contraindication to using a specific method such as combined oral contraceptives (COCs), intrauterine devices (IUDs), the subdermal implant (Implanon), and the like.
- Are opposed to taking systemic medications or chemicals such as COCs, injections (Depo-Provera), and so forth.
- Are in the early postpartum period or are lactating.
- Need a backup method of contraception for a period of time such as when beginning COCs, after an IUD has been inserted, or when a male partner has just had a vasectomy.

- Have intercourse rarely or sporadically.
- Are perimenopausal but smoke and thus are not good candidates for COCs.

Before inserting any female barrier contraceptive, a woman should wash her hands with soap and water to prevent the introduction of organisms. Women who use vaginal barrier methods should avoid using oil-based products such as mineral oil or baby oil and vaginal medications such as Monistat cream (for yeast infection) and estrogen creams because they can have a negative effect on latex.

Many barrier methods are made of latex, so women who are allergic should avoid products made of this material and tell their healthcare provider. Nonlatex barrier methods made of silicone, polyurethane, and lambskin are available.

Barrier methods such as the diaphragm, FemCap, and Lea's Shield can be worn for 24 to 48 hours, should be cleaned with soap and water after use, and should not be shared with other women. After the last act of intercourse, these devices should remain in place for a minimum of 6 to 8 hours to prevent pregnancy.

In general, female barrier methods are more effective when used with a male condom. However, a male condom should not be used with a female condom. Women who use barrier methods should be alert for signs of toxic shock syndrome (TSS) such as high fever, sore throat, vomiting and/or diarrhea, faintness, weakness, muscle aches, and a rash (see chapter 7 ∞).

Male Condom

The male **condom** offers a viable means of contraception when used consistently and properly (Figure 5-2 ■). Acceptance has been increasing for two reasons: a growing number of men are assuming responsibility for regulation of fertility, and condoms provide protection from sexually transmitted infections (STIs) for both men and women. For women, regardless of age, an STI increases the risk of pelvic inflammatory disease (PID) and resultant infertility. Many women insist that their sexual partners use condoms, and many women carry condoms with them.

The condom is applied to the erect penis, rolled from the tip to the end of the shaft, before vulvar or vaginal contact. Most condoms have a reservoir tip to allow for collection of ejaculate. When using a condom without a reservoir end, a small space must be left at the end to collect the ejaculate, so that the condom does not break at the time of ejaculation. If the condom or vagina is dry, water-soluble lubricants, such as K-Y jelly or Astroglide, should be used to prevent irritation and possible condom breakage. Care must be taken in removing the condom after intercourse. For optimal effectiveness, the man should withdraw his penis from the vagina while it is still erect and hold the condom rim to prevent spillage. If after ejaculation the penis becomes flaccid while still in the vagina, the man should hold onto the edge of the condom while withdrawing to avoid spilling the semen and to prevent the condom from slipping off.

The effectiveness of male condoms is largely determined by their use. The condom is small, lightweight, disposable, and inexpensive. It has no side effects (if not allergic to latex), requires no medical examination or supervision, and offers visual evidence of effectiveness. Most condoms are made of latex. Thus, their use is contraindicated if the male or his partner has a latex allergy. Polyurethane and silicone rubber condoms are also manufactured and recommended for individuals allergic to latex. Condoms are available with ribbed or smooth sides, tapered or straight-sided, lubricated or unlubricated, with or without spermicide. They come in a variety of colors, sizes, and flavors. "Natural skins" (lambs' intestines) are available; they are used primarily by individuals with latex allergies. All condoms except natural skin condoms offer protection against sexually transmitted infections (STIs). Moreover, a systematic research review indicates that

A

B

Figure 5-2 ■ A. An unrolled condom with reservoir tip. B. Correct use.

consistent use of condoms results in an 80% reduction of the incidence of HIV (Weller & Davis-Beatty, 2009). Concurrent use of a vaginal spermicide with the male condom increases the overall effectiveness in the prevention of pregnancy.

Misplacement, risk of breakage, perineal or vaginal irritation, and dulled sensation are possible disadvantages of male condoms. Condoms should not be stored in hot conditions because heat accelerates their deterioration, making them more susceptible to breaking. Thus, men should avoid placing them in their car glove box or in their wallets in a rear pants pocket.

Female Condom

The *Reality female condom* (Figure 5-3 ■) is a thin polyurethane sheath with a flexible ring at each end. The inner ring, at the closed end of the condom, serves as the means of insertion and fits over the cervix like a diaphragm. The second ring remains outside the vagina and covers a portion of the woman's perineum. It also covers the base of the man's penis during intercourse. A woman needs to be careful not to twist the sheath when she inserts the condom because twisting makes male penetration impossible.

Available over the counter and designed for one-time use, the condom may be inserted up to 8 hours before intercourse. The inner sheath is prelubricated but does not contain spermi-

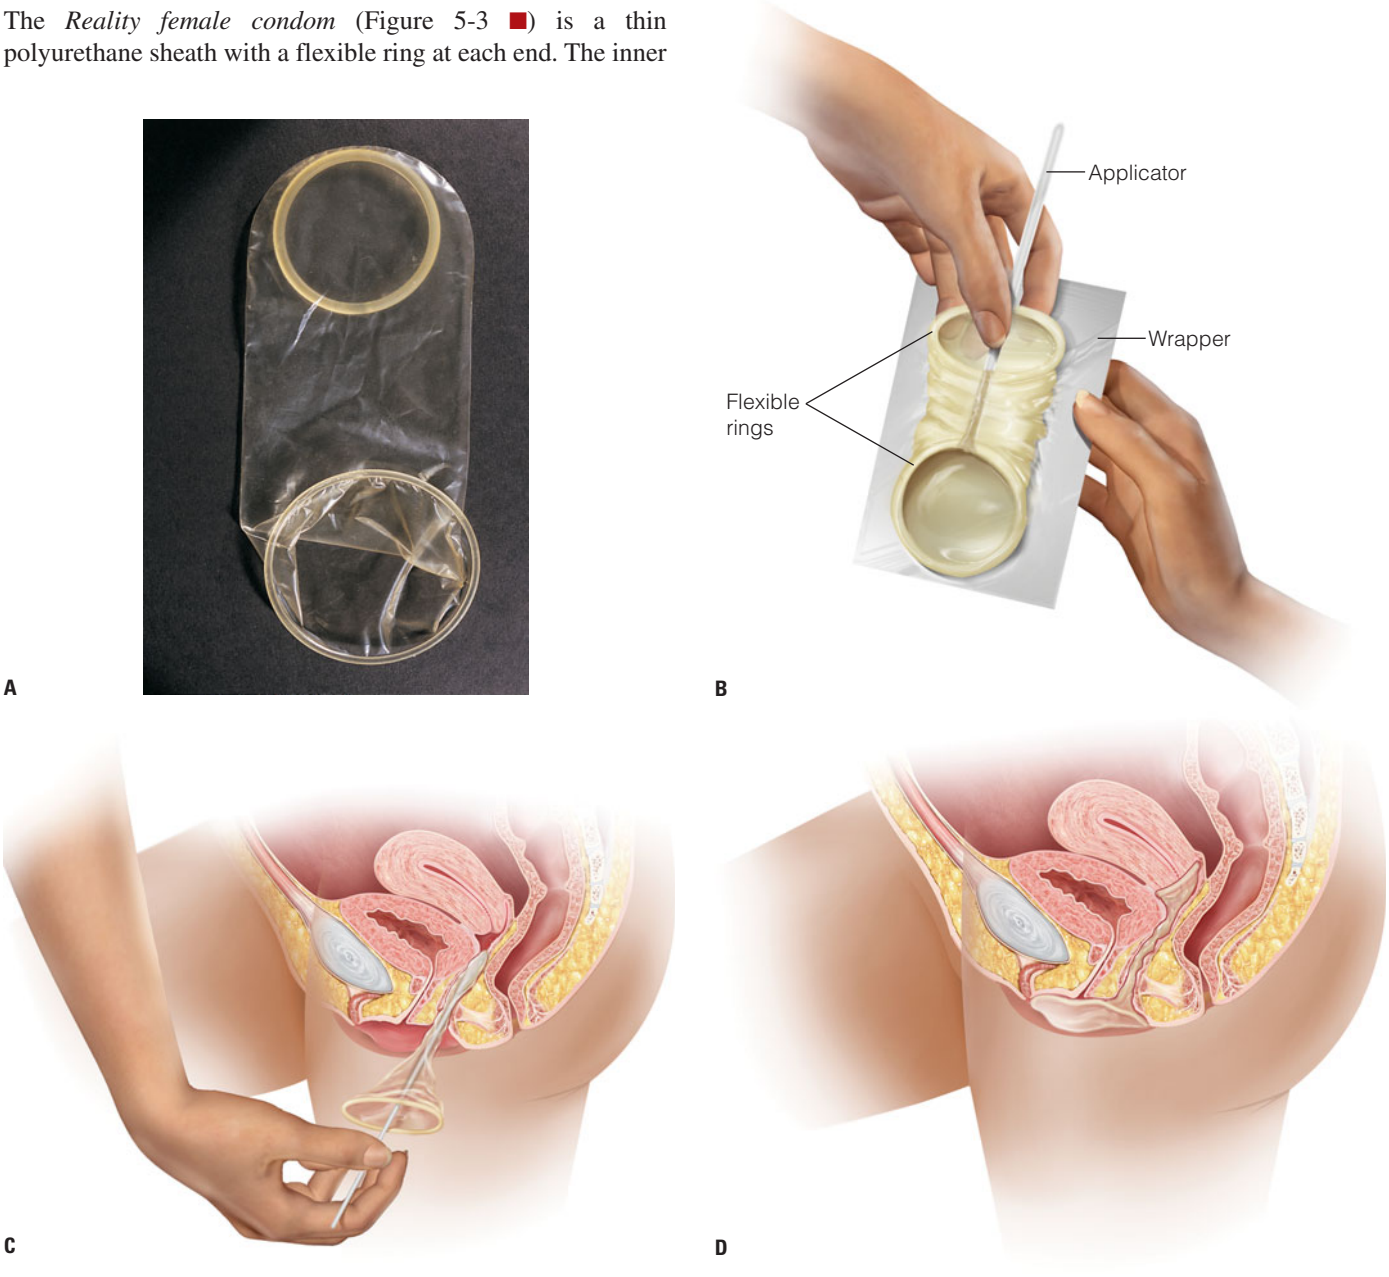

Figure 5-3 ■ A. The female condom. To insert the condom: B. Remove condom and applicator from wrapper by pulling up on the ring. C. Insert condom slowly by gently pushing the applicator toward the small of the back. D. When properly inserted, the outer ring should rest on the folds of skin around the vaginal opening, and the inner ring (closed end) should fit loosely against the cervix.

cide and is not designed to be used with a male condom. Because it also covers a portion of the vulva it probably provides better protection than other methods against some of the pathogens that cause STIs. High cost, noisiness during intercourse, and the cumbersome feel of the device make acceptability a problem for some couples.

Diaphragm

The **diaphragm** is a barrier method that consists of a steel band that forms a ring and is covered with latex or silicone so that when the diaphragm is inserted, the ring lodges high in the vagina with the latex or silicone covering the cervix. It is used with spermicidal cream or jelly and offers a good level of protection from conception. Currently it is used by 0.3% of U.S. women (Guttmacher Institute, 2008a).

Three types of diaphragms are available—the flat spring, the coil spring, and the arcing spring. Each type has its own advantages, and the type of coil makes the different diaphragms better suited to some women than to others. A woman must be fitted with a diaphragm and given instructions by trained personnel. The diaphragm should be rechecked for correct size after each childbirth and whenever a woman has gained or lost 10 to 15 pounds or more. Most diaphragms are made of latex; for allergic women, Milex® produces the WIDE-SEAL Silicone Diaphragm.

The diaphragm must be inserted before intercourse, with approximately one teaspoonful (or 1.5 inches from the tube) of spermicidal jelly placed around its rim and in the cup (Figure 5-4 ■). This chemical barrier supplements the mechanical barrier of the diaphragm. The diaphragm is inserted through the vagina and covers the cervix. The last step in insertion is to push the edge of the diaphragm under the pubic symphysis, which may result in a "popping" sensation. When fitted properly and correctly in place, the diaphragm should not cause discomfort to the woman or her partner. Correct placement of the diaphragm can be checked by touching the cervix with a fingertip through the cup. The cervix feels like a small rounded structure and has a consistency similar to that of the tip of the nose. The center of the diaphragm should be located over the cervix.

If more than 6 hours elapse between insertion of the diaphragm and intercourse, additional spermicidal jelly should be inserted into the vagina, although no evidence supports this (Hatcher et al., 2007). It is necessary to leave the diaphragm in place for at least 6 hours after the act of coitus. If intercourse is desired again within the 6 hours, another type of contraception must be used or additional spermicidal jelly placed in the vagina with an applicator, taking care not to disturb the placement of the diaphragm. The diaphragm should not remain in the vagina for more than 24 hours because of the risk of toxic shock syndrome.

Periodically the diaphragm should be held up to the light or filled with water and inspected for tears or holes. If properly maintained, it can last for several years, so it is a cost-effective method of contraception. The diaphragm should be washed and dried well after each use and then stored in a clean, dry container. Talcum powder should not be used with a latex diaphragm because it contributes to the deterioration of the rubber.

Some couples feel that the use of a diaphragm interferes with the spontaneity of intercourse. The nurse can suggest that the partner insert the diaphragm as part of foreplay or the woman may choose to insert it herself before intercourse. Diaphragm use potentially reduces the incidence of cervical gonorrhea and chlamydia. Its use does protect against human papilloma virus (HPV) infection, which can cause cervical neoplasia (Hatcher et al., 2007).

Women who object to touching their genitals to insert the diaphragm, check its placement, and remove it may find this method unsatisfactory. Women who are very obese or who have short fingers may find the diaphragm difficult to insert. It is not recommended for women with a history of urinary tract infection (UTI), because pressure from the diaphragm on the urethra may interfere with complete bladder emptying and lead to recurrent UTIs. These women should be given information about other methods of contraception. As mentioned previously, women with a history of toxic shock syndrome should not use diaphragms or any of the barrier methods left in place for prolonged periods. For the same reason, the diaphragm should not be used during a menstrual period or if a woman has abnormal vaginal discharge.

Cervical Caps

The Prentif Cavity Rim cervical cap or *FemCap* looks like a small sailor's cap and is made of soft silicone. The "dome" of the cap fits over the cervix, while the soft "brim" flares out slightly and conforms to the shape of the vagina. A strap placed over the dome permits easier removal. The cap, which is no longer available in the United States, is available in three sizes and should be used with a spermicide. Advantages, disadvantages, and contraindications are similar to those associated with the diaphragm.

A systematic research review indicates that the FemCap is not as effective as a diaphragm in preventing pregnancy; however, both forms are medically safe to use (Gallo, Grimes, Schulz, et al., 2010).

Lea's Shield is a reusable, silicone, one-size-fits-all vaginal barrier method that completely covers the cervix. It contains a centrally located valve that permits the passage of cervical secretions and air. It is held in place by the vaginal walls. It is available by prescription in the United States. A spermicide should be used with it and it should not be worn for more than 48 hours.

Vaginal Sponge

The Today *vaginal sponge,* available without a prescription, is a pillow-shaped, soft, absorbent synthetic sponge containing a spermicide. It is made with a concave or cupped area on one side, which is designed to fit over the cervix. It has a loop to permit easy removal. The sponge acts as a contraceptive by releasing the spermicide N-9 gradually over a 24-hour period.

The sponge is moistened thoroughly with water before use to activate the spermicide and is then inserted into the vagina

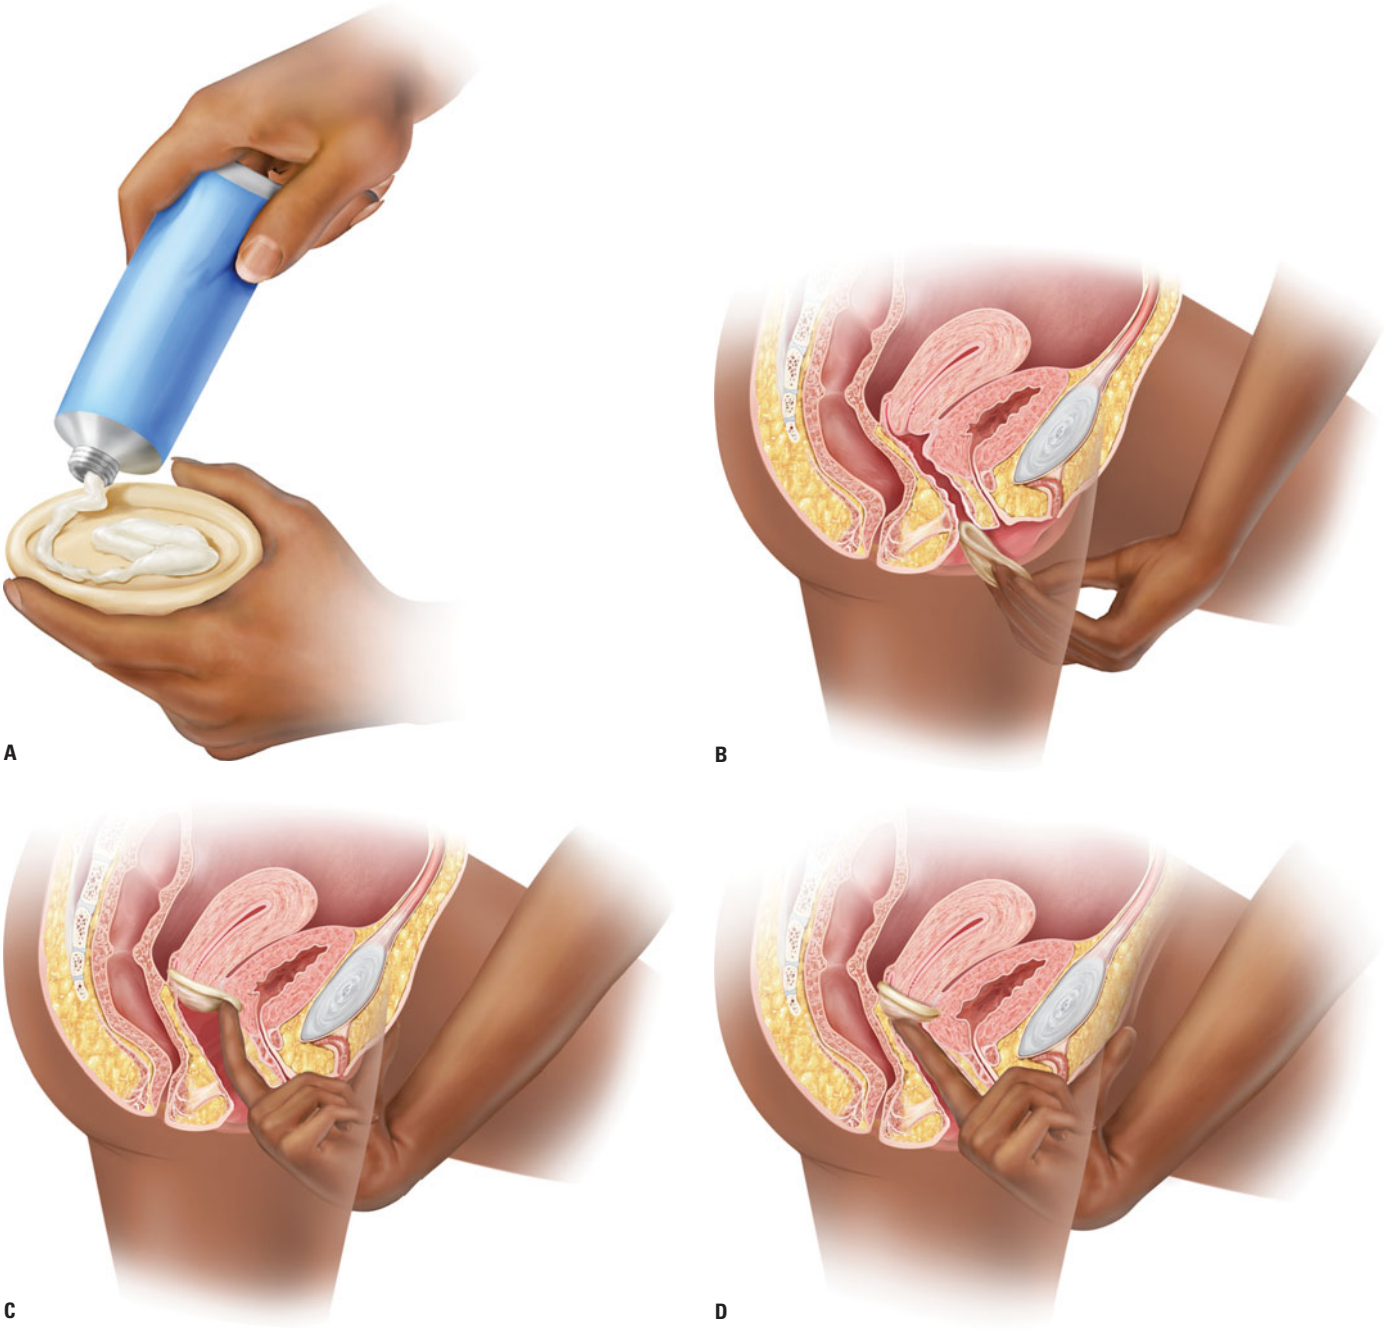

Figure 5-4 ■ Inserting the diaphragm. A. Apply jelly to the rim and center of the diaphragm. B. Insert the diaphragm. C. Push the rim of the diaphragm under the pubic symphysis. D. Check placement of the diaphragm. The cervix should be felt through the diaphragm.

so that the cupped side fits snugly against the cervical os (Figure 5-5 ■). This decreases the chance of the sponge being dislodged during intercourse. The sponge may be worn for up to 24 hours. It should be left in place for at least 6 hours after intercourse and then removed and discarded.

Advantages of the sponge include the following: professional fitting is not required; it may be used for multiple acts of coitus for up to 24 hours; one size fits all; and it acts as both a barrier method and a spermicide agent. Problems associated with the sponge include difficulty removing it and irritation or allergic reactions. Some women also report a problem because the sponge absorbs vaginal secretions, contributing to vaginal dryness. For women without children the failure rate is comparable to that of the diaphragm. The failure rate is higher for women who have borne children, possibly because of changes in the shape of the cervix.

Intrauterine Devices

Both of the **intrauterine devices (IUDs)** available in the United States are designed to be inserted into the uterus by a qualified healthcare provider and left in place for an extended period, providing continuous contraceptive protection. The Copper IUD (ParaGard T380A) provides effective contraception for 10 years, whereas the Mirena levonorgestrel intrauter-

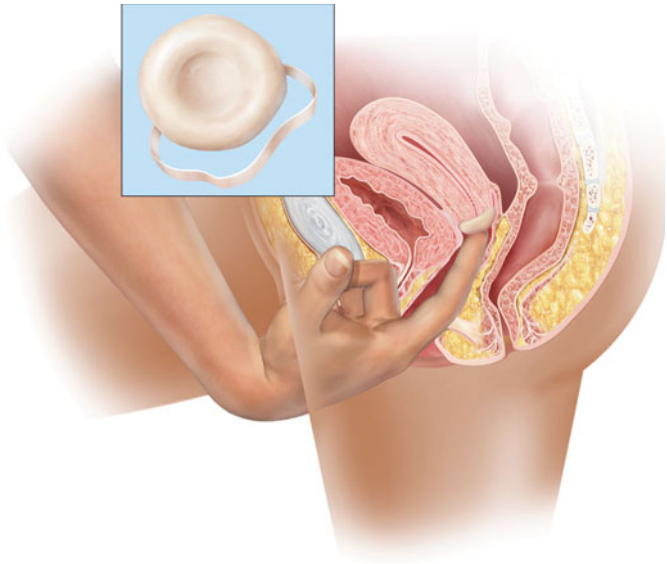

Figure 5-5 ■ The contraceptive sponge is moistened well with water and inserted into the vagina with the concave portion positioned over the cervix.

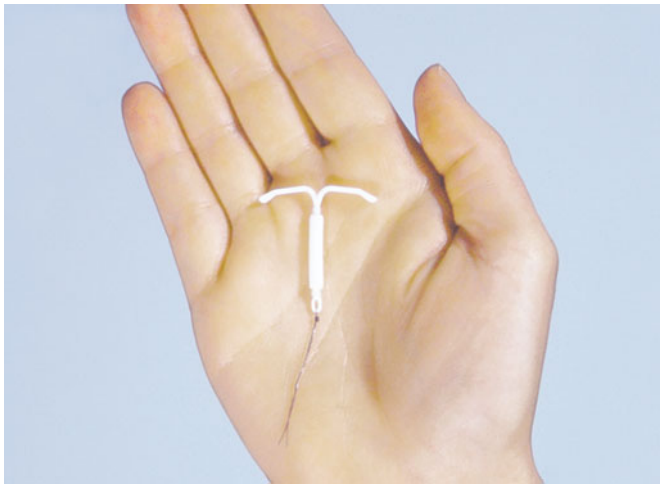

Figure 5-6 ■ The Mirena Intrauterine System, which releases levonorgestrel gradually, may be left in place for up to 5 years.

Source: Courtesy of Berlex Laboratories, Wayne, NJ.

ine system (LNG-IUS) provides 5 years of protection. The exact mechanism of either IUD is not clearly understood. Traditionally, it was believed to act by preventing the implantation of a fertilized ovum. Thus, it was considered an abortifacient or abortion-causing method. This belief is not accurate; both IUDs are truly contraceptive. The Copper IUD is known to have local inflammatory effects on the endometrium and to impair sperm from functioning properly. The Mirena IUD causes the lining of the uterus (endometrium) to become atrophic. It also produces thick cervical mucus that is "hostile" or unfriendly to sperm. Both IUDs produce a spermicidal intrauterine environment (Speroff & Darney, 2005).

Both IUDs available today, contrary to common myth, do not increase the risk of ectopic pregnancy or cause pelvic inflammatory disease (PID). In reality, infections in IUD users are probably related more to the woman's lifestyle than to the presence of the IUD. Advantages of both IUDs include a high rate of effectiveness, continuous contraceptive protection, non–coitus-related contraception, and relative inexpensiveness over time. Possible adverse reactions to both IUDs include discomfort to the wearer (possible cramping), increased bleeding during menses, increased risk of pelvic infection for about 3 weeks following insertion, perforation of the uterus during insertion, unscheduled bleeding, dysmenorrhea, and expulsion of the device.

The Copper IUD (ParaGard T380A) is a small T-shaped device that has copper covering parts of its stem and arms. This IUD is not an option for women allergic to copper but is an excellent choice for women who have medical conditions that preclude use of other contraceptives, hormonal or barrier. The Mirena (LNG-IUS) (Figure 5-6 ■) is a small, T-shaped frame with a reservoir that releases levonorgestrel on a daily basis. After 3 months of Mirena use, bleeding and length of menstrual cycles are reduced. In fact, 14% to 20% of women have amenorrhea, which they often welcome once they are advised that the absence of menses is safe and not an indication of pregnancy. The LNG-IUS is an excellent choice for women who are allergic to copper or who have heavy menses and desire amenorrhea.

There are few women for whom either IUD is contraindicated. A current pregnancy or current STI or pelvic infection would be contraindications. Women who have had children have a deeper uterine cavity that accepts placement of either IUD more readily. However, women who have not had children can be candidates for insertion of the IUD if the cavity of their uteri are deep enough (6–9 cm). If the woman has multiple sexual partners, she should be cautioned to use a condom in addition to her IUD. However, because the Mirena causes thick cervical mucus, it may have a protective effect against STIs (Hatcher et al., 2007).

The IUD is inserted into the uterus with its strings protruding through the cervix into the vagina. It may be inserted at any time during the woman's cycle, providing she is not pregnant, or during the 6-week postpartum check. After insertion, the clinician instructs the woman to check for the presence of the strings once a week for the first month and then after each menses. She does this by inserting her index finger or middle finger into her vagina to feel the strings; this ensures the IUD is still in the uterus. She is told that she may have some cramping or bleeding intermittently for 2 to 6 weeks and that her first few menses may be irregular. Follow-up examination is suggested 4 to 8 weeks after insertion.

Women with IUDs should contact their healthcare providers if they are exposed to an STI or if they develop the following warning signs: late period, abnormal spotting or bleeding, dyspareunia (pain with intercourse), abdominal pain, abnormal discharge, signs of infection (fever, chills, malaise), missing strings, or lengthening of the strings. If a woman becomes pregnant with an IUD in place, the device should be removed as soon as possible to prevent infection (Schorge et al., 2008).

Hormonal Contraceptives

Hormonal contraceptives are available in a variety of forms. They may be progestin-only hormones, most often using a synthetic form of progesterone, or a combination of estrogen and a progestin.

Combination Estrogen-Progestin Approaches

The use of a combination of the hormones estrogen and a progestin is a highly successful, very safe birth control method and readily reversible when stopped. Hormonal contraceptives work by inhibiting the release of an ovum, by creating an atrophic endometrium, and by maintaining thick cervical mucus that slows sperm transport and inhibits the process that allows sperm to penetrate the ovum. There are several forms available, including combined oral contraceptives (COCs), a transdermal patch, and a vaginal ring.

Combined Oral Contraceptives

Combined oral contraceptives (COCs)—commonly called birth control pills or "the pill"—are a combination of a synthetic estrogen and a progestin. COCs are one of the most popular contraceptive options available to women in the United States because they are safe, highly effective, and rapidly reversible. Most COCs are taken daily for 21 or 28 days, following one of these methods:

1. ***Day 1 start.*** The woman begins taking the pill on the first day of her menstrual cycle. This method prevents ovulation in the first cycle, so no backup method of contraception is needed.
2. ***Sunday start.*** The woman begins taking the pill on the Sunday after the first day of the menstrual cycle and ends the packet on a Saturday. In most cases a hormonally mediated menses (known as a "withdrawal" bleed) will occur 1 to 4 days after the last pill is taken. The Sunday start is common because it tends to prevent periods on weekends. However, a backup method of contraception is necessary during the first 7 days of use.
3. ***Quick start.*** The woman begins taking the pill in the practitioner's office if she is reasonably certain she is not pregnant. A backup method is necessary for 7 days. New COC users are more likely to still be using this method 3 months later with this start (Hatcher et al., 2007).

COCs are packaged with 21 or 28 pills. Seven days after taking her last pill, the woman using the 21-day pack of pills restarts the next cycle of pills. The 28-day pack includes seven "blank" pills so that the woman never stops taking a pill and thus never forgets to start a new pack a week later. Women who use either the 21- or 28-day COC pack will always begin a new pack on the same day. The pill should be taken at approximately the same time each day—usually on arising or before retiring in the evening.

Seasonale® and Seasonique® are the two COCs marketed for extended use. Women who choose Seasonale take 84 active pills containing estrogen and a progestin followed by 7 "blank" pills, and those who take Seasonique take 84 active pills and 7 pills with a reduced dosing of estrogen intended to promote less bleeding. Women taking either extended use COC have 4 withdrawal bleeds per year rather than 12. Extended use reduces the side effects of COCs such as bloating, headache, breast tenderness, cramping, and swelling (Hatcher et al., 2007).

Irregular pill taking is one of the major causes of breakthrough bleeding, a side effect that leads many women to discontinue COCs. Also, although they are highly effective when taken correctly, improper use of COCs can contribute to an unintended pregnancy. COCs may also be less reliable in obese women.

Birth control pills have been available for more than 45 years. In the United States, the estrogen component of the pill is either ethinyl estradiol (EE) or mestranol. Of the two, EE is by far the more commonly used estrogen. Initially, COCs contained high levels of estrogen and were linked with an increased risk for myocardial infarction (MI), thromboembolic disorders (blood clots), and stroke. Lowering the estrogen dose in the formulation decreased these risks. Based on this understanding, over the years the estrogen component of COCs has been decreased from 150 mcg/day to the lowest dose currently available—20 mcg/day (Speroff & Darney, 2005).

Currently nine different formulations of progestins are available. These progestins vary with respect to their biologic activity including inhibition of ovulation. Synthetic progestins can have androgenic, antiandrogenic, estrogenic, and antiestrogenic effects. These effects are responsible for the varying progestin-related side effects.

COCs are among the most studied medications available. The current generation of low-dose pills is very safe and would be even safer if smokers over age 35 did not take them. In an effort to reduce complications such as myocardial infarction, stroke, blood clots, and hypertension, regimens have been developed that use very low doses of estrogen (20 or 25 mcg) and progestins that are less androgenic in effect. These very-low-dose pills may result in weaker cycle control, which leads to more irregular or "breakthrough" bleeding. These low-dose pills do provide the same noncontraceptive benefits as the pills that contain 30 to 35 mcg of EE, and it is recommended that smokers of all ages who wish to take the pill be prescribed 20 mcg COCs to reduce serious complications.

Side effects are generally identifiable as estrogen related or progestin related. Thus it is possible to modify some side effects by choosing a different oral contraceptive preparation. The side effects associated with COCs are identified in Table 5-2.

Absolute contraindications to the use of oral contraceptives include pregnancy, previous history of thrombophlebitis or thromboembolic disease, acute or chronic liver disease of cholestatic type with abnormal liver function tests, presence of estrogen-dependent carcinomas, undiagnosed uterine bleeding, heavy smoking, gallbladder disease, hypertension, diabetes, migraine with visual disturbances, hypercoagulable disorders, and hyperlipidemia. Women with relative contraindications may initiate COC use; however, they require close and frequent monitoring. These include women with migraine headaches without visual disturbances, epilepsy, depression, oligomenorrhea, and amenorrhea. Women who choose this method of contraception should be fully advised of the potential side effects and complications. Generic preparations of COCs are as effective as brand-name COCs (Hatcher et al., 2007).

Oral contraceptives have several important noncontraceptive benefits. Many women who use COCs experience relief of uncomfortable menstrual symptoms and premenstrual syndrome;

TABLE 5-2 Side Effects Associated with Oral Contraceptives

ESTROGEN EFFECTS	PROGESTIN EFFECTS
Alterations in lipid metabolism	Acne, oily skin
Breast tenderness, engorgement or increased breast size	Breast tenderness; increased breast size
Cerebrovascular accident	Decreased libido
Changes in carbohydrate metabolism	Decreased high-density lipoprotein (HDL) cholesterol levels
Chloasma	Depression
Fluid retention; cyclic weight gain	Fatigue
Headache	Hirsutism
Hepatic adenomas	Increased appetite; weight gain
Hypertension	Increased low-density lipoprotein (LDL) cholesterol levels
Leukorrhea, cervical erosion, ectropion	Oligomenorrhea, amenorrhea
Nausea	Pruritus
Nervousness, irritability	Sebaceous cysts
Telangiectasia	
Thromboembolic complications—thrombophlebitis, pulmonary embolism	

cramps diminish, flow decreases, and the cycle becomes more regular. Mittelschmerz is eliminated. More important, there is a reduction in the incidence of ovarian cancer, endometrial cancer, colorectal cancer, menstrual migraines, and iron deficiency anemia. In addition, hormonal contraceptives can be effective in improving bone mineral density and in treating acne or hirsutism, pelvic pain due to endometriosis, and bleeding due to leiomyomas (American College of Obstetricians and Gynecologists [ACOG], 2010). Currently, oral contraceptives assist with some of the physiologic changes experienced by women during the perimenopause (such as hot flashes) as well as provide contraception. COCs can be used by nonsmoking women until they transition into menopause, at which time hormone therapy may be necessary to control vasomotor symptoms, such as hot flashes (Hatcher et al., 2007). Because of an increased risk of MI (heart attack), women over age 35 who smoke should not take oral contraceptives.

The woman using oral contraceptives should contact her healthcare provider if she becomes depressed, develops a breast lump, becomes jaundiced, or experiences any of the following warning signs: severe abdominal pain, severe chest pain or shortness of breath, severe headaches, dizziness, changes in vision (vision loss or blurring), speech problems, or severe leg pain.

Transdermal Hormonal Contraception

Combined hormonal contraception can now be provided transdermally using a weekly *contraceptive skin patch* called Ortho Evra, manufactured by Ortho-McNeil-Janssen Pharmaceuticals. Roughly the size of a silver dollar, but square, this patch is applied weekly for 3 weeks on one of four sites: the woman's abdomen, buttocks, upper outer arm, or trunk (excluding the breasts). During the fourth week, no patch is applied and menses typically occurs. The patch is highly effective in women who weigh less than 198 pounds (Hatcher et al., 2007). Patch users apply their first patch on the first day of their menses or on the Sunday following; if the latter is chosen a backup method for 7 days is necessary.

The patch is as safe and effective as COCs and has a better rate of user compliance. Generally, women who are candidates for COCs are candidates for the patch unless they weigh greater than 198 pounds or have skin disorders that may result in reactions at the site of application. Product labeling was changed in 2008 to include a greater risk of venous thromboembolism (VTE) for women using the patch versus those taking COCs. The United States Food and Drug Administration (FDA) considers the patch a safe method of contraception for women not at risk of a VTE (U.S. FDA, 2008).

Vaginal Contraceptive Ring

NuvaRing vaginal contraceptive ring (manufactured by Organon), another form of low-dose, sustained-release combined hormonal contraceptive, is a flexible, soft vaginal ring that is inserted for 3 weeks (Figure 5-7 ■). The ring is left in place for 21 days and then removed for 7 days (Hatcher et al., 2007). This one-size ring fits virtually all women. Women with marked vaginal prolapse should be cautioned to check for expulsion of the ring during early use. Women who use the NuvaRing should begin its use in the same way as described for the patch. Replacement rings should be kept in the refrigerator to maintain integrity.

Progestin Contraceptives

Progestin-Only Pills

Another oral contraceptive is the progestin-only pill, also called the *minipill.* It is used primarily by nursing mothers, because it

Figure 5-7 ■ The NuvaRing vaginal contraceptive ring.

Source: Merck & Co., Inc. Organon Pharmaceuticals.

does not interfere with breast milk production. It is also used by women who have a contraindication to the estrogen component of the combination preparation, such as history of thrombophlebitis or hypertension or estrogen-related side effects, but are strongly motivated to use this form of contraception. The major problems with progesterone-only pills are amenorrhea or irregular bleeding patterns. They are slightly less effective than a COC. They must be taken consistently at the same time every day (Hatcher et al., 2007).

Long-Acting Progestin Contraceptives

Long-acting progestin-only contraceptives include Depo-Provera and Implanon. Progestin-only contraceptive methods are recommended for lactating women, women who cannot use estrogen or the intrauterine device (IUD), women who forget to take COCs daily, and women who are not bothered by unscheduled bleeding (irregular spotting or bleeding). These are safe, reversible forms of contraception.

Depo-Provera or depot-medroxyprogesterone acetate (DMPA), manufactured by Pfizer, is a long-acting, injectable, progestin-only contraceptive. DMPA is manufactured in 2 dosings: DMPA-IM 150 mg for intramuscular use or DMPA-SC 104 mg for subcutaneous use. Both provide highly effective birth control for 3 months after administration with subsequent injections scheduled every 10 to 14 weeks. DMPA-SC may cause less pain than an intramuscular (IM) injection and could be self-administered, increasing compliance by not having to return every 3 months to the clinic.

DMPA, which acts primarily by suppressing ovulation, is safe, convenient, private, and relatively inexpensive. It also separates birth control from the act of coitus. It can be given to nursing mothers, because it contains no estrogen. DMPA provides blood levels of progesterone high enough to block the luteinizing hormone (LH) surge, thereby suppressing ovulation. It also thickens the cervical mucus to block sperm penetration. Side effects include menstrual irregularities, headache, weight gain, breast tenderness, hair loss, and depression. Return of fertility may be delayed for an average of 9 months (Hatcher et al., 2007). DMPA is associated with bone demineralization, especially during the first 2 years of use. The rate of calcium loss slows after this time, and bone loss is reversible after discontinuation of DMPA. All women should exercise daily and take 1200 mg of calcium with vitamin D.

Implanon, manufactured by Schering-Plough, is a single-capsule implant inserted subdermally in the woman's upper underarm. It is impregnated with etonogestrel, a progestin. It is good as a contraceptive method for 3 years, and its mechanism of action is to prevent ovulation. Implanon also stimulates the production of thick cervical mucus, which inhibits sperm penetration. Implanon provides effective continuous contraception removed from the act of coitus. Possible side effects include spotting, irregular bleeding or amenorrhea, an increased incidence of ovarian cysts, weight gain, headaches, fluid retention, acne, hair loss, mood changes, and depression. It was released in the United States in 2006. A minor surgical procedure is required to insert and remove the implant (Hatcher et al., 2007).

Postcoital Emergency Contraception

Postcoital emergency contraception (EC) is indicated when a woman is worried about pregnancy because of unprotected intercourse, sexual assault, or possible contraceptive failure (e.g., broken condom, slipped diaphragm, missed oral contraceptives, or too long a time between depot-medroxyprogesterone acetate [DMPA] injections). Research indicates that oral hormonal EC taken as soon as possible within 72 hours can reduce the risk of pregnancy after a single act of unprotected intercourse by 75% to 89%.

Two hormonal regimens for EC include a combined hormonal approach (levonorgestrel and ethinyl estradiol), and Plan B, a progestin-only approach (levonorgestrel). Though sometimes called the "morning-after pill," the phrase is misleading because the woman actually takes her first dose as soon after intercourse as possible and a second dose 12 hours later. The combined hormonal approach uses high-dose combined oral contraceptives. The progestin-only approach uses a high dose of one progestin, levonorgestrel. Both methods should inhibit ovulation, although other mechanisms are thought to play a part (Hatcher et al., 2007).

Plan B, manufactured by Duramed as One-Step, is an EC method that is more effective than the combined hormonal EC; it also has a much lower incidence of associated nausea and vomiting. If it is available, it should be used instead of the combined regimen (ACOG, 2007a). Plan B comes as 2 tablets of 0.75 mg levonorgestrel to be taken at once, or as Plan B One-Step, 1 tablet that contains 1.5 mg of levonorgestrel. Both dosings should be taken as soon after coitus as possible. It is available over the counter, without prescription, to any woman 17 years or older.

The combined regimen remains an option because many women knowledgeable about EC can use their unused combined oral contraceptives (COCs) after consulting with their healthcare provider about the appropriate dosing. COCs are prescriptions that must be obtained from a healthcare provider. The high dose of estrogen may lead to nausea and vomiting. A prophylactic antiemetic may be useful.

Both regimens must be initiated within 72 hours after unprotected intercourse, although most research indicates they could be effective up to 5 days after coitus. Emergency contraceptive pills are safe for almost all women. The only contraindication is a diagnosed pregnancy because the pills are ineffective (Hatcher et al., 2007). The woman should have her normal menses 2 weeks after taking EC. If she does not, she should follow up with a pregnancy test. If the pregnancy test is negative, she should be counseled about reliable methods of birth control.

The medical abortion-inducing drug, mifepristone, is very effective in providing emergency contraception. However, its use is highly restricted and it is not currently approved for emergency contraception (Benagiano & vonHertzen, 2010).

Placement of the Copper IUD within 5 days after unprotected intercourse may reduce pregnancy risk by as much as 99% (ACOG, 2007a; ACOG, 2007b; Hatcher et al., 2007).

RESEARCH EVIDENCE IN PRACTICE **Emergency Contraception**

CLINICAL QUESTION

What are the predictors and outcomes of emergency contraception use after unprotected intercourse?

RESEARCH EVIDENCE

A variety of factors influence the use of emergency contraception to prevent an unintended pregnancy after unprotected intercourse. In one large, multisite study of emergency contraception use, receiving counseling about emergency contraception from a healthcare provider was the strongest predictor of its appropriate use. Yet only 3% of women in this study reported that a clinician had discussed emergency contraception with them in the past year. A woman's likelihood of receiving counseling was further reduced if she was over the age of 30, Hispanic, black, or married.

In a large study of provider attitudes about emergency contraception and subsequent patient counseling, barriers to provision of emergency contraception included staff prejudgment that the woman did not need it, time constraints of office visits, and staff beliefs that the patient did not have the ability to use the method. However, in a study of provider behaviors that enhanced contraception use, the only intervention that was successful in improving use of contraception was providing the woman with contraception during the provider visit.

WHAT QUESTIONS REMAIN UNANSWERED?

Little research has been conducted on the effects of repeated use of emergency contraception as a method of preventing unintended pregnancy. What are the long-term outcomes of emergency contraception for the woman? What is the effect of repetitive emergency contraception on later childbearing?

WHAT IS BEST PRACTICE?

Women are more likely to use emergency contraception if they are counseled about its use by their healthcare provider and if a dose is provided during the clinic visit.

CRITICAL THINKING

How can counseling about emergency contraception be introduced during the routine gynecologic examination? What patient education about emergency contraception will enhance its appropriate use?

Currently there is considerable debate about the best ways to improve access to EC. It is essential that healthcare providers counsel women about the availability of EC during routine screenings and appointments. This approach ensures that women are familiar with the method before an emergency occurs. It is also helpful to have printed literature on EC available in the waiting area. Information about postcoital emergency contraception is available through the Emergency Contraception Hotline (1-888-NOT-2-LATE), and on the World Wide Web.

Operative Sterilization

Operative **sterilization** is an inclusive term that refers to surgical procedures that permanently prevent pregnancy. In the man, sterilization is achieved through a procedure called *vasectomy.* In the woman, sterilization is done by *tubal ligation.*

Before sterilization is performed on either partner, the clinician provides a thorough explanation of the procedure. Each person needs to understand that sterilization is not a decision to be taken lightly or entered into at times of psychologic stress, such as separation or divorce. Even though both male and female procedures are theoretically reversible, the permanency of the procedure should be stressed and understood.

Vasectomy

Male sterilization is achieved through a relatively minor procedure called a **vasectomy**. This involves surgically severing the vas deferens in both sides of the scrotum. It takes about 4 to 6 weeks and 6 to 36 ejaculations to clear the remaining sperm from the vas deferens. During that period, the couple is advised to use another contraceptive method and to bring in two or three semen samples for a sperm count. When the sperm count is negative the couple can safely have unprotected sex. The man is rechecked at 6 and 12 months to ensure that fertility has not been restored by recanalization. Side effects of a vasectomy include pain, infection, hematoma, sperm granulomas, and spontaneous reanastomosis (reconnecting).

Vasectomies can sometimes be reversed by using microsurgery techniques. Restored fertility, as measured by a subsequent pregnancy, ranges from 38% to 82% (Hatcher et al., 2007; Schorge et al., 2008).

Tubal Ligation

Voluntary female sterilization is accomplished by **tubal ligation**. Three procedures are common in the United States:

- Laparotomy following a cesarean birth or other abdominal surgery
- Minilaparotomy in the postpartum period soon after a vaginal birth
- Laparoscopy done postabortion or during an "interval period," when the woman is not pregnant or postpartum

Tubal ligation can be done at any time. However, the postpartal period is an ideal time to perform a tubal ligation because the uterus is enlarged and the tubes are easy to locate. During these procedures the tubes are ligated, clipped, electrocoagulated, banded, or plugged. This interrupts the patency of the fallopian tube, thus preventing the ovum and the sperm from meeting.

Application: Contraceptive Services for Minors

Case Study: Family Planning

Complications of female sterilization procedures include coagulation burns on the bowel, bowel perforation, pain, infection, hemorrhage, and adverse anesthesia effects. Reversal of a tubal ligation depends on the type of procedure performed. Achievement of a pregnancy after successful tubal sterilization reversal may vary from 45% to 90%; 10% of women will have an ectopic pregnancy (Schorge et al., 2008).

Nonoperative Sterilization

The *Essure* method of permanent sterilization by Conceptus requires no surgical incision. Under hysteroscopy, a stainless steel microinsert is placed into the proximal section of each fallopian tube. Within 3 months, these microinserts create a benign tissue response that occludes the fallopian tubes. Three months after placement, tubal occlusion is confirmed by hysterosalpingogram. One of the materials used in the production of the implants is a nickel-titanium alloy; therefore, *women allergic to nickel should consult their healthcare provider before placement.* It is the only sterilization method approved in the United States that will yield no surgical scar (Schorge et al., 2008).

Male Contraception

The vasectomy and the condom, discussed previously, are currently the only forms of male contraception available in the United States. Developing reversible methods of contraception for men is a challenge because healthy men produce sperm continuously, whereas women produce eggs cyclically. It is easier to devise a reversible method that interrupts a cyclic process than it is to find ways to interrupt continuous fertility.

Hormonal contraception for men has yet to be developed, although studies are under way using weekly injections of testosterone, a synthetic hormone that significantly inhibits sperm production in most men. Too much testosterone has significant side effects on the man such as feminization, an unfavorable lipid profile, loss of libido, and more, which makes it largely unacceptable. A combination injection of testosterone and DMPA, the progestin found in Depo-Provera, is also under way. If it is successful, injections may only be needed monthly. Investigational approaches include gonadotropin-releasing hormone analogues and sex steroids (Hatcher et al., 2007).

> "I think I'm like a lot of women. During my life I've used a variety of contraceptive methods. I took the pill until I was married and ready to have children, used spermicidal foam without a diaphragm and subsequently had a baby, and later used spermicidal cream and condoms more successfully. I never wanted a tubal, but my husband refuses to consider a vasectomy, so the IUD was a perfect alternative for us. I am 37 and I like using something I don't have to think about every time we want to make love. Maybe someday there will be more contraceptives for men—it seems only fair—but I'm glad that at least I've had some choices."

NURSING CARE MANAGEMENT

In most cases, the nurse who provides information and guidance about contraceptive methods works with the woman, because most contraceptive methods are female oriented. Because a man can purchase condoms without seeing a healthcare provider, only in the case of vasectomy does a man require counseling and interaction with a nurse. However, men should be encouraged to participate in contraceptive services. The nurse can play an important role in helping a woman and her partner choose a method of contraception that is acceptable to both.

In addition to completing a history and assessing for any medical contraindications to specific methods, the nurse can spend time with a woman learning about her lifestyle, personal attitudes about particular contraceptive methods, religious and cultural beliefs, personal biases, and plans for future childbearing to help the woman select a particular contraceptive method. (See Developing Cultural Competence.)

Once the woman chooses a method, the nurse can help her learn to use it effectively. "Patient Teaching: Using a Method of Contraception" provides guidelines for helping women use a method of contraception effectively.

The nurse also reviews any possible side effects and warning signs related to the method chosen and counsels the woman about what action to take if she suspects she is pregnant. In many cases, the nurse is involved in telephone counseling of women who call with questions and concerns about contraception. Thus it is vital that the nurse be knowledgeable about this topic and have resources available to find answers to less common questions.

Clinical Interruption of Pregnancy

Abortion, the termination of a pregnancy, was legalized in the United States in 1973. However, the associated controversy over moral and legal issues continues. This controversy is as readily apparent in the medical and nursing professions as in other groups.

Many women are strongly opposed to abortion for religious, ethical, cultural, or personal reasons. Other women feel that abortion provides a legally available alternative to a pregnancy. A number of physical and psychosocial factors influence a woman's decision to seek an abortion. The presence of a disease or health state that jeopardizes the mother's life and serious, life-threatening fetal problems are frequently suggested as indications for abortion. In other instances, the timing or cir-

PROFESSIONALISM IN PRACTICE

Using Contraception Resources During Patient Teaching

In your role as teacher, it is important to have resources on hand for women seeking a method of contraception. Have informational handouts available for the various methods of contraception. Describe correct use, side effects, warning signs, and important tips for effective use. Women can then refer to the sheets at home. Be sure to include the office or clinic phone number.

DEVELOPING CULTURAL COMPETENCE

Birth Control Attitudes

Attitudes about birth control may be influenced by cultural factors. Although it is impossible to attribute one attitude to an entire group of people, the following general information may be helpful as a starting point in working with women from a particular ethnic group (Blumenthal, 2007):

- *Deference to authority figures* is not uncommon in traditional Chinese, Arab, Latina, and East Indian women, especially if the nurse is male. The nurse should use active listening when counseling.
- *Gender inequities* may prohibit some Arab, Latina, and Eastern Indian women from seeking out or using a contraceptive method unless their husbands do not object. After being given appropriate information, the nurse may suggest the couple discuss contraceptive options in private.
- *Acquiescence* to the nurse's decision for the woman may occur, especially if the woman is Asian. The nurse should engage the woman in a conversation and use active listening to ascertain *her* attitude toward different contraceptive methods.
- *Attitudes toward bleeding* affect a woman's duties to her family and partner. Vaginal bleeding may be seen as "unclean" by Muslim and Orthodox Jewish women. Any contraceptive method that involves irregular bleeding might not be acceptable. On the other hand, among women who feel a monthly period is necessary, any method that ultimately causes amenorrhea would not be acceptable.
- The Roman Catholic Church considers all artificial methods of contraception unacceptable. Natural family planning might be an acceptable method for women who closely follow the Church's teaching. Among American Catholics, however, attitudes about the proscription regarding birth control may vary, and it is important to determine the woman's beliefs on the subject.
- Large families are valued in many cultures, and contraception may not be desired. Unplanned pregnancies may be welcomed in the Hispanic culture, and unplanned adolescent pregnancies do not necessarily carry a negative stigma for African Americans.

cumstance of the pregnancy creates an inordinate stress on the woman, prompting her to choose an abortion. Some of these situations may involve contraceptive failure, sexual assault, or incest. Usually the decision is best made by the woman or couple involved. A woman whose life is threatened by the pregnancy may choose to continue the pregnancy, whereas one with no obvious threat may choose to have an abortion.

Globally, the legal status of abortion varies greatly, although 1 in 5 pregnancies ends in abortion worldwide. Countries with restrictions on abortion may still have a high rate of abortion. The rate of abortion in Africa, where abortion is illegal, is about the same as it is in parts of Europe, where abortion is permitted. Western and Northern Europe, where abortion is readily available to women, have some of the lowest rates of abortion in the world. Worldwide, between 1995 and 2003, the number of induced abortions declined from nearly 46 million to 42 million, mostly due to the availability of contraceptive methods (Guttmacher Institute, 2008c). The contraceptive needs of women worldwide are a priority.

Medical Interruption of Pregnancy

Medical abortion is now available in the United States and provides an effective alternative to surgical abortion for many women with unintended pregnancies. Three regimens are available: mifepristone combined with misoprostol, methotrexate combined with misoprostol, and misoprostol by itself (Association of Reproductive Health Professionals [ARHP], 2008). The regimen of mifepristone and misoprostol is Food and Drug Administration (FDA) approved for use up to 49 days after the last menstrual period. Mifepristone (Mifeprex or RU 486), an anti-progesterone, and misoprostol, a prostaglandin analogue that causes smooth muscle to contract, lead to complete abortion in approximately 92% of women. Abortion success rates differ when these medications are taken at different gestational ages: 96% to 98% in pregnancies up to 42 days; 91% to 95% in pregnancies from 43 to 49 days' gestation; and less than 85% in pregnancies past 49 days (American College of Obstetricians and Gynecologists [ACOG], 2009). Some clinicians support the use of a slightly modified dosage regimen through 63 days' gestation (ACOG, 2009).

Mifepristone blocks the action of progesterone, thereby altering the endometrium. After the length of the woman's gestation is confirmed, she takes a dose of oral mifepristone in her caregiver's office. One to 3 days (depending on gestation) later she returns to her caregiver and takes an oral or vaginal dose of the prostaglandin misoprostol, which induces contractions that expel the embryo/fetus. About 14 days after taking the misoprostol, the woman is seen a third time to confirm that the abortion was successful.

Endometritis is a risk with any abortion. Since 2001, five deaths may possibly have been related to the oral mifepristone-vaginal misoprostol regimen. Three of these deaths were related to an infection caused by a rare organism, *Clostridium sordelli* (U.S. FDA, 2009). Therefore, *any* woman who has taken the oral mifepristone-vaginal misoprostol regimen and within 24 hours develops stomach pain, weakness, nausea, vomiting, or diarrhea (with or without fever) should contact her healthcare provider *immediately* (U.S. FDA, 2009). Currently, mifepristone is still considered safe, and use of routine prophylactic antibiotics is not recommended.

Although methotrexate is not labeled for medical abortion, 20 years of experience with it has led to its use in the first 7 weeks of pregnancy. Methotrexate stops cell division, and when used with misoprostol, it can be up to 96% effective in terminating a pregnancy (ACOG, 2009). However, ACOG (2009) states that mifepristone-misoprostol regimens are preferable to those using methotrexate-misoprostol or misoprostol alone for medical abortion.

Surgical Interruption of Pregnancy

Surgical abortion in the first trimester (less than 13 weeks' gestation) is technically easier and safer than abortion in the second trimester. The cervix is anesthetized with local anesthesia using a paracervical block. It then must be dilated either mechanically

PATIENT TEACHING Using a Method of Contraception

PATIENT GOALS At the completion of the teaching, the woman will be able to:

1. Confirm for herself that the chosen method of contraception is appropriate for her.
2. List the advantages, disadvantages, and risks of the chosen method.
3. Describe (or demonstrate) the correct procedure for using the chosen method.
4. Cite warning signs that should be reported to the caregiver.

TEACHING PLAN

Content	Teaching Method
Discuss the factors that a woman should consider in choosing a method of contraception (see Table 5-1). Stress that the different methods may be appropriate at different times in the woman's life. Review the woman's reasons for selecting a particular method and confirm any contraindications to specific methods.	Contraception is a personal decision, so the discussion should take place in a private area free of interruptions. Create a supportive, warm, and comfortable atmosphere by attitude and communication style—both verbal and nonverbal. Provide accurate information in an open, nonjudgmental way.
Discuss the advantages, disadvantages, and risks of the chosen method.	Focus on open discussion. It may help to have written information about the method chosen. If a signed permit is required (as with sterilization, an IUD insertion, or Implanon), the provider should also discuss the advantages, disadvantages, and risks.
Describe the correct procedure for using a method. Go through step by step. Periodically stop and have the woman review the information. If a technique is to be learned (as with inserting a diaphragm or charting basal body temperature), demonstrate and then have the woman do a return demonstration as appropriate. (*Note:* If certain aspects are beyond the nurse's level of expertise, the nurse can review the content and confirm that the woman has the opportunity to do a return demonstration. For example, an office nurse who does not do FemCap fittings may cover information on its use, have the woman try inserting the cap herself, and then have the placement checked by the nurse practioner, nurse-midwife, or physician.)	Learning is best accomplished when material is broken down into smaller steps. Have a model or chart available to enable the woman to visualize what is being described. Have a sample of the chosen method available: a package of oral contraceptives, an open IUD, or a symptothermal chart.
Provide information on what the woman should do if unusual circumstances arise (she forgets a pill or misses a morning temperature).	Provide a written handout identifying the warning signs of her chosen method and listing the actions a woman should take. The handout should also cover actions the woman should take if an unusual situation develops. For example, what should she do if she vomits or has diarrhea while taking oral contraceptives?
Stress warning signs that require immediate action on the part of the woman and explain why these signs indicate a risk. Carefully delineate the actions the woman should take.	Arrange to talk with the woman again soon, either on the phone or at a return visit, to determine if she has any questions about the method and to ensure that no problems have arisen.

Evaluation

Evaluate the woman's learning by asking her to describe the method she has chosen, its contraindications and warning signs, and the procedure for using it correctly. In some cases, a return demonstration is useful.

with metal dilators or laminaria or medicinally with misoprostol or mifepristone. A cannula is placed through the cervix and suction is applied to recover all the products of conception. Mechanical scraping of the uterine contents with a sharp curette can be an alternative to suction, or these two procedures can be done together. The major risks include perforation of the uterus, laceration of the cervix, systemic reaction to the anesthetic agent, hemorrhage, retained products of conception, and infection (Schorge et al., 2008).

Second trimester abortion (greater than 13 weeks' gestation) may be done medically or surgically. Medical termination includes the use of a mifepristone-misoprostol regimen, and the woman will need to labor and pass the fetus in the hospital. Surgical termination is done using dilation and evacuation (D&E). This procedure combines vacuum aspiration with the use of appropriate instrumentation to remove the contents of the uterus.

NURSING CARE MANAGEMENT

The woman deciding to terminate a pregnancy may choose to do so based on an unwanted/unintended pregnancy, sexual assault, lack of finances, her health, or the health of the

fetus. The nurse should assess the woman's need for support and/or counseling. If the decision was difficult for the woman, the nurse should assist her in finding postprocedure support.

Patient selection is an important factor in medical abortion. Pregnancy needs to be verified early, by 5 weeks' gestation if possible. The woman needs to understand clearly that medical abortion takes time and follow-up is important. Moreover, women need accurate information about the cramping, bleeding, and pain that occur so that they are prepared to deal with both the discomfort and the sight of the blood and possible uterine contents.

In general, important aspects of nursing care for a woman who chooses to have an abortion include providing information about the methods of abortion and associated risks as well as counseling regarding available alternatives to abortion and their implications. Nursing care also includes encouraging the woman to verbalize her feelings; providing support before, during, and after the procedure; monitoring vital signs, intake, and output; providing for physical comfort and privacy throughout the procedure; and teaching the patient self-care, the importance of the postabortion checkup, and use of a reliable contraceptive (including methods that can be started immediately after the procedure).

FOCUS YOUR STUDY

- The fertility awareness-based (FAB) method, natural family planning (NFP), is a "natural," noninvasive method of contraception often used by people whose religious beliefs prevent them from using artificial methods.
- Other FAB methods can be used in conjunction with a barrier method during the woman's fertile days.
- Situational contraceptives such as coitus interruptus (withdrawal) and douching are activities an individual uses in a given situation to avoid pregnancy without benefit of clinical guidance or medical care. Abstinence is also considered a situational contraceptive.
- Barrier contraceptives such as the contraceptive sponge, diaphragm, FemCap, Lea's Shield, and condom act by blocking the transport of sperm. These methods are often used in conjunction with a spermicide.
- N-9, the spermicide available in the United States, is far less effective in preventing pregnancy when it is not used with a barrier method.
- The Copper IUD (intrauterine device) is a mechanical contraceptive. Although its exact method of action is not clearly understood, research suggests it acts by immobilizing sperm or by impeding the progress of sperm from the cervix to the fallopian tubes. In addition, the IUD does have a local inflammatory effect.
- The Mirena levonorgestrel-releasing IUS (LNG-IUS) is both a hormonal and mechanical contraceptive. Its action is similar to that of the Copper IUD; it also secretes a progestin, levonorgestrel, that helps the endometrium to become atrophic, the cervical secretions to become thick, and the menstrual flow to be decreased.
- Combined oral contraceptives (the "pill") are combinations of estrogen and a progestin. When taken correctly, they are one of the most effective and reversible methods of fertility control.
- The progestin-only subdermal implant, Implanon, is an excellent choice for women desiring long-term contraception who cannot take estrogen.
- Other combined hormonal options (estrogen and progestin) such as the patch (Ortho Evra) and the vaginal ring (NuvaRing) have broadened the range of contraceptive options available.
- The "patch" is under investigation for its potential role in increased venous thromboembolism, associated with greater systemic absorption of estrogen, but is still a safe method for women not at risk.
- The long-acting progestin-only injection, Depo-Provera IM 150 mg or Depo-Provera SC 104 mg, is available for lactating women, or those who cannot take estrogen.
- Permanent sterilization is accomplished by tubal ligation for women and vasectomy for men. Although theoretically reversible, patients are advised that the method should be considered irreversible. Essure offers a nonoperative approach to permanent blockage of the fallopian tubes.
- The termination of pregnancy through abortion may now be achieved by either medical or surgical means.

CRITICAL THINKING IN ACTION

Linda Knoll, 35 years old, presents to you at the GYN clinic for her annual physical and pelvic exam. You obtain the following menstrual history: LMP 8 days ago. Periods occur every 29 days and last 5 days. She tells you that she uses superabsorbent tampons during the first 2 days of her period and then changes to regular absorbency tampons for the duration, and that she currently has an IUD in place for contraception. She tells you that her husband has been complaining for the last few months that she seems irritable, tense, and moody near "that time of the month." Linda admits that she doesn't feel well before her period and describes having low pelvic discomfort, breast tenderness, "bloating," and some constipation. She seems to cry easily 2 to 3 days before her period. She has noticed this pattern over the last 4 or 5 months. You recognize these symptoms as related to premenstrual syndrome (PMS). Linda asks you if these changes are due to female hormones.

1. How would you answer Linda's question concerning female hormones?
2. After reviewing Linda's diet with her, what would you recommend to help?
3. Linda has an IUD in place. What other type of contraceptive might help reduce the symptoms of PMS?
4. What other activities can you suggest to help Linda reduce PMS symptoms?
5. What should you tell Linda about using tampons during heavy menstrual flow?

Women's Health: Commonly Occurring Infections

CHAPTER 6

I just wanted to have a good time when I was young. I only had sex with people I "knew" but eventually I got herpes. Now I am 32, with two children, and married to a great man who loves me. He has never had herpes but we are very careful because I don't want him infected because of me. How much simpler life would be if I didn't carry that virus. Too bad that we can't change the past.

LEARNING OUTCOMES

1. Compare vulvovaginal candidiasis and bacterial vaginosis.
2. Summarize modes of transmission, treatments, and descriptions of the most commonly occurring sexually transmitted infections (STIs).
3. Describe the health teaching that a nurse needs to provide to a woman with an STI.
4. Relate the implications of pelvic inflammatory disease (PID) for future fertility to its pathologic origin, signs and symptoms, and treatment.
5. Contrast cystitis and pyelonephritis.
6. Compare the different types of viral hepatitis.

KEY TERMS

Bacterial vaginosis (BV) *100*
Chlamydial infection *104*
Condylomata acuminata *106*
Gonorrhea *105*
Herpes genitalis *105*
Pelvic inflammatory disease (PID) *110*
Sexually transmitted infection (STI) *103*
Syphilis *106*
Trichomoniasis *103*
Urinary tract infection (UTI) *111*
Vulvovaginal candidiasis (VVC) *101*

Many women seek health care because of infections of one sort or another, including those that are sexually transmitted. The nurse caring for a woman with an infection can be most helpful by providing accurate, sensitive, and supportive health care and health information. Additionally, the nurse is uniquely able to provide nonjudgmental health promotion, education, and counseling to influence the woman's future health behaviors positively. To meet the woman's needs, the nurse needs to have up-to-date information about a variety of infections, including how they are spread, diagnosed, and treated, and their long-term implications.

This chapter focuses on several types of infections with an emphasis on sexually transmitted infections. It is designed to provide current information to help nurses provide more effective health care for women and their families.

Centers for Disease Control

Care of the Woman with a Lower Genital Tract Infection (Vaginitis)

Vaginitis is the most common reason women seek gynecologic care. Symptoms of vaginitis, or vulvovaginitis, may include increased vaginal discharge, vulvar irritation and pruritus, external dysuria, dyspareunia (painful sexual intercourse), bleeding with intercourse, or a foul odor. Women with vaginitis may have either infectious abnormal organisms or an abundance or overgrowth of vaginal microorganisms such as *Gardnerella vaginalis, Mycoplasma hominis, Ureasplasma urealyticum, Mobiluncus, Bacteroides,* and *Peptostreptococcus* species (Akhter, Beckmann, & Gorelick, 2009; Centers for Disease Control and Prevention [CDC], 2006b).

Bacterial Vaginosis

Bacterial vaginosis (BV) is the most prevalent form of vaginal infection in the United States and worldwide. BV is more prevalent in sexually active women; however, the debate continues as to whether BV is a sexually transmitted infection, because it has also been detected in virginal women. The etiology of BV is related to a change in the normal vaginal flora. Normal hydrogen peroxide-producing lactobacilli are reduced with an overgrowth of vaginal anaerobes and subsequent rise in vaginal pH.

This process is poorly understood and the causes leading to overgrowth are not clear. Frequent sexual intercourse without condom use (sperm and seminal fluid has pH greater than 7), trauma from douching, cigarette smoking, having a new sexual partner or multiple partners, and an upset in normal vaginal flora are all predisposing or contributing factors. BV can also occur in women who have never had sexual intercourse. Research also suggests that increased psychosocial stress is associated with an increased incidence and greater prevalence of BV (Nansel et al., 2006). In pregnancy, maternal vitamin D deficiency (Bodner, Kohn, & Simhan, 2009) and increased dietary fat intake have been positively associated with BV, while an increased dietary intake of folate, vitamin A, and calcium (Neggers et al., 2007) are inversely related to BV risk. The *Gardnerella vaginalis* and *Mycoplasma hominis* organisms have been found in the vast majority of cases, along with an increased concentration of anaerobic bacteria.

The infected woman often notices an excessive amount of thin, watery, white or gray vaginal discharge with a foul odor sometimes described as "fishy." However, nearly 50% to 75% of women with BV are asymptomatic. (The characteristic "clue cells" are seen on a wet-mount preparation, and leukocytes are conspicuously absent [Figure 6-1 ■]). The addition of a 10% potassium hydroxide (KOH) solution to the vaginal secretions, called the "whiff" test, releases a strong, fishy, amine-like odor. The vaginal pH is usually greater than 4.5 (normal vaginal pH should be between 3.8 and 4.2). Women with BV have an increased risk of pelvic inflammatory disease (PID), HIV disease, abnormal cervical cytology, postoperative cuff infections after hysterectomy, and postabortion PID. BV infections are associated with negative pregnancy outcomes as preterm birth, preterm rupture of the membranes, amniotic infections, and postcesarean endometritis (CDC, 2006b).

The nonpregnant woman who is symptomatic is generally treated with metronidazole (Flagyl) 500 mg orally twice a day for 7 days (see Drug Guide: Metronidazole [Flagyl]) or one full applicator of metronidazole gel, 0.75% intravaginally, once daily for 5 days. Both these routes are equally effective. Alternatively the woman can be treated with 2% clindamycin (Cleocin) vaginal cream, one full applicator at bedtime for 7 days although clindamycin is slightly less effective (CDC, 2006b). It is not recommended that clindamycin be used with latex condoms and diaphragms for 5 days because the cream is oil based and may weaken the barrier method. Follow-up visits are not necessary unless symptoms recur, which occurs in approximately 30% of patients (Chan & Johnson, 2008). Routine treatment of sex partners is not recommended.

For many years, metronidazole was regarded as a potential teratogen, particularly in the first trimester, and its use was generally avoided, especially in early pregnancy. However, the CDC (2006b) now reports that multiple studies have not demonstrated

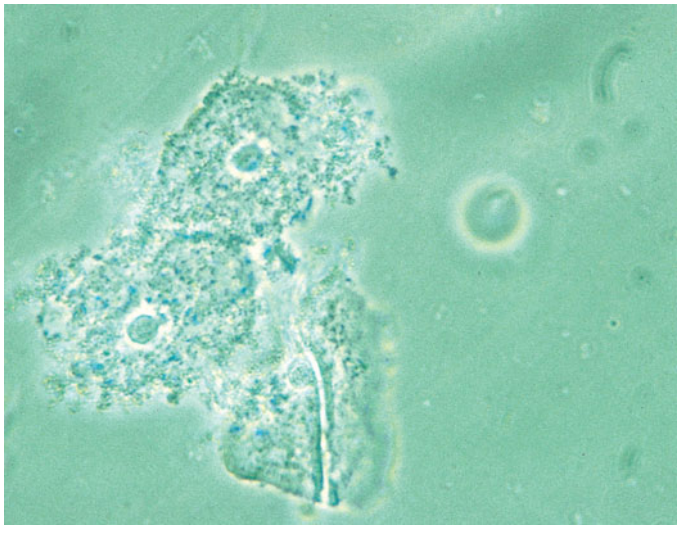

Figure 6-1 ■ The characteristic "clue cells" seen in bacterial vaginosis.

DRUG GUIDE Metronidazole (Flagyl)

OVERVIEW OF ACTION

Metronidazole is an antiprotozoal and antibacterial agent. It possesses direct trichomonacidal and amebicidal activity against *T vaginalis and E histolytica.* Metronidazole is active in vitro against most obligate anaerobes but does not appear to possess any clinically relevant activity against facultative anaerobes or obligate aerobes. It is used in the treatment of various infections caused by organisms that are sensitive to this drug. It is used predominantly to treat the following infections in women: *T vaginalis,* bacterial vaginosis, endometritis, endomyometritis, tubo-ovarian abscess, and postsurgical vaginal cuff infection (Facts & Comparisons, 2010).

ROUTE, DOSAGE, FREQUENCY

Trichomoniasis—nonpregnant woman: 1 day treatment 2 g orally in a single dose; 7-day treatment: 500 mg orally twice a day for 7 consecutive days (CDC, 2006b).

Amebiasis—Adults: 750 mg orally 3 times a day for 5–10 days; children: 35–50 mg/kg/24 hours orally divided into 3 doses for 10 days.

Bacterial vaginosis—nonpregnant woman: 500 mg orally twice a day for 7 consecutive days or one full applicator of metronidazole gel 0.75% intravaginally once daily for 5 days (CDC, 2006b).

CONTRAINDICATIONS

Blood dyscrasias

Breastfeeding women (drug secreted in breast milk)

Impaired kidney or liver function

Active central nervous system (CNS) disease

SIDE EFFECTS

Convulsive seizures
Peripheral neuropathy
Weakness
Insomnia
Nausea/Vomiting
Headache
Anorexia
Diarrhea
Epigastric distress
Abdominal cramping
Constipation
Metallic taste in mouth
Dizziness
Vertigo
Uncoordination
Ataxia
Confusion
Irritability
Depression
Cystitis
Dysuria
Reversible neutropenia and thrombocytopenia
Flattening of the T wave on electrocardiogram (ECG)
Polyuria
Incontinence
Pelvic pressure
Proliferation of *Candida* in the vagina and mouth
Joint pains
Decreased libido
Dryness in the mouth, vulva, and vagina
Dyspareunia

NURSING CONSIDERATIONS

- Inform the woman about potential side effects.
- Stress the importance of contraceptive compliance during course of treatment.
- Obtain baseline renal and liver function tests as ordered.
- Teach the woman about the signs, symptoms, and treatment of vulvovaginal candidiasis.
- Counsel the woman to avoid alcoholic beverages while taking the medication.
- If the woman is taking oral contraceptives, a backup nonhormonal contraceptive method is recommended during treatment.
- Take a thorough history to rule out the woman's exposure to this medication within the last 6 weeks.
- Teach the woman to monitor the signs and symptoms of her infection.
- Encourage cooperation with the entire course of treatment.

a consistent relationship between metronidazole use during pregnancy and teratogenic effects on the newborn. Nevertheless, some providers still do not treat patients with metronidazole in the first trimester due to the potential for fetal anomalies (Briggs, Freeman, & Yaffe, 2008). Thus, currently the recommended treatment during pregnancy is metronidazole 500 mg orally twice a day or metronidazole 250 mg orally 3 times a day or clindamycin 300 mg orally twice daily. All these regimens should be taken for 7 days (CDC, 2006b). Most providers recommend screening of all pregnant women for BV because it has been associated with preterm labor and birth; others recommend screening only those pregnant women at increased risk for preterm birth. An optimal treatment regimen has not been established. In either case, if a pregnant woman is found to be positive for BV she should be treated.

Vulvovaginal Candidiasis

Vulvovaginal candidiasis (VVC), also known as a candidiasis, or fungal and yeast infection, is a very common vaginal infection. It is estimated that in their lifetime, 75% of women will have at least one episode of VVC, whereas 40% to 45% of women will have two or more episodes (CDC, 2006b; Chan & Johnson, 2008). *Candida albicans* is responsible for the vast majority of vaginal yeast infections. Non-*albicans* species of *Candida,* such as *C glabrata, C tropicalis,* and *C krusei,* can also cause vulvovaginal symptoms and they are becoming more prevalent. There is evidence that some of these strains are developing resistance to therapies such as fluconazole. Predisposing factors to yeast infections include glycosuria, use of oral contraceptives, use of antibiotics, pregnancy, diabetes mellitus, and the use of immunosuppressant drugs.

The woman with VVC often complains of nonmalodorous, thick, white (cottage cheese-like) vaginal discharge, severe itching, dysuria (external versus urethral), and dyspareunia. A male sexual partner may experience a rash or excoriation of the skin of the penis and possibly pruritus. The male can be symptomatic and the female asymptomatic.

On physical examination, the woman's labia may be swollen and excoriated if pruritus has been severe. A speculum examination usually reveals thick, white, tenacious, curd-like patches

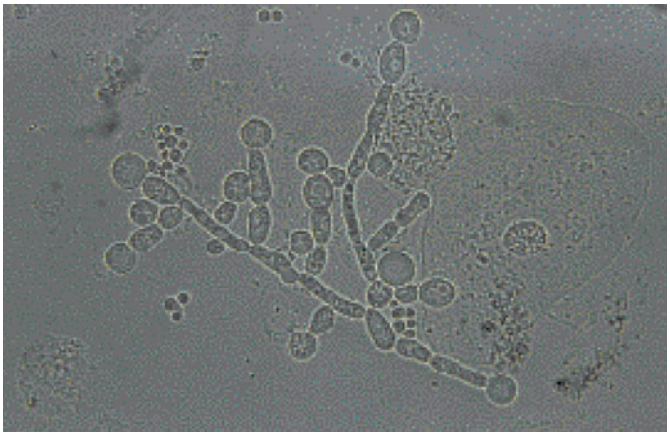

Figure 6-2 ■ Hyphae and spores of *Candida albicans.*
Source: Courtesy of Centers for Disease Control and Prevention.

adhering to the vaginal mucosa. The diagnosis is made by observing mycelia or pseudohyphae upon direct microscopy in a 10% KOH preparation (Figure 6-2 ■). A Gram stain or culture positive for the fungus is a more accurate way of diagnosing the causative organism. The pH of the vagina remains 4 to 4.5 or less (the normal pH of the vagina is about 3.8 to 4.2). This vaginal pH level is in contrast to the pH noted with BV or Trichomonas.

Local vaginal treatment with intravaginal butoconazole, clotrimazole, miconazole, nystatin, terconazole, or tioconazole in the appropriate cream, tablet, or suppository form is recommended. Single-dose and short-course approaches (3 days) are effective for 80% to 90% of women with uncomplicated VVC. One-day regimens include oral fluconazole 150 mg in a single dose, itraconazole capsules (200 mg) twice a day, clotrimazole vaginal tablets 500 mg at bedtime, and tioconazole 6.5% vaginal ointment (5 g) at bedtime (CDC, 2006b). All of these treatments are effective for mild VVC (CDC, 2006b; Chan & Johnson, 2008). There are also 3-day, 5-day, and 7-day treatment regimens. Women with severe symptoms may require a longer course of treatment up to 14 days with vaginal or oral azole agents (Chan & Johnson, 2008). If the vulva is also infected, the cream is applied topically. Women with recurrent infections may be advised to use long-term clotrimazole or fluconazole therapy. The use of vaginal application of lactobacilli products remains unproven and controversial. Some of these medications are available over the counter. They are indicated for women with a history of yeast infections who are able to correctly recognize true VVC symptoms.

Treatment of the male partner is generally not indicated although it may be recommended for partners of women who have recurrent infection. For men who have candidal balanitis (inflammation of the glans penis) treatment with a topical antifungal medication is indicated (CDC, 2006a).

Recurrent VVC, defined as four or more episodes of symptomatic VVC in 1 year, affects less than 5% of women (CDC, 2006b). If a woman experiences frequent recurrences of monilial vaginitis, she should be tested for an elevated blood glucose level to determine whether a diabetic or prediabetic condition is present and evaluated for immunosuppression. Women at high risk for sexually transmitted infections should also be tested for HIV infection. In the absence of other risk factors, recurrent VVC treatment should include confirmation of the organism by culture, followed by an intensive regimen of topical agents for 7 to 14 days or oral doses of fluconazole every third day for 3 doses (days 1, 4, and 7), followed by maintenance antifungal therapy using oral ketoconazole 100 mg every day for 6 months (Chan & Johnson, 2008) or oral fluconazole weekly for 6 months or clotrimazole suppository once weekly for 6 months (CDC, 2006b). Treatment of the sexual partner is not recommended.

Pregnant women with VVC should be treated only with topical azole preparations applied for 7 days (CDC, 2006b). Infection at the time of birth may cause thrush (a *candidal* infection of the mouth) in the newborn.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse caring for the woman should suspect VVC if the woman complains of intense vulvar itching and a thick, nonodorous white discharge. Women who are HIV-positive, immunosuppressed, pregnant, or have diabetes mellitus are especially susceptible to this infection; the nurse should be alert for symptoms in these women. In some areas nurses are trained to do speculum examinations and wet-mount preparations and can confirm the diagnosis themselves. In most cases, however, the nurse who suspects a vaginal infection reports it to the woman's healthcare provider.

Nursing diagnoses that might apply to the woman with VVC include the following:

- ***Risk for impaired skin integrity*** related to scratching secondary to discomfort of the infection
- ***Readiness for enhanced knowledge:*** Information about yeast infection related to an expressed desire to know about ways of preventing the development of VVC

Nursing Plan and Implementation

The nurse discusses with the woman the factors that contribute to the development of VVC and suggests ways to prevent recurrences, such as wearing cotton underwear and cotton-crotch pantyhose, avoiding tight-fitting clothing, and avoiding douching and vaginal powders or sprays that can irritate the vulva. Women taking antibiotics should be advised about the possibility of developing VVC and encouraged to seek treatment early if symptoms develop. Some providers encourage women to ingest 8 ounces of yogurt with *Lactobacillus acidophilus* culture daily to reestablish normal vaginal flora (Chan & Johnson, 2008).

Evaluation

Expected outcomes of nursing care include the following:

- The woman's symptoms are relieved, and the infection is cured.
- The woman is able to identify self-care measures to prevent further episodes of VVC.

Care of the Woman with a Sexually Transmitted Infection

The occurrence of **sexually transmitted infection (STI)**, or sexually transmitted disease (STD), has increased over the past few decades. In fact, vaginitis and STIs are the most common reasons for outpatient, community-based treatment of women. More than one STI can occur at the same time. All symptomatic women should be tested for other infections. Table 6-1 provides a summary of vulvovaginal candidiasis (VVC) and bacterial vaginosis (BV) as well as the common STIs.

Prevention of Sexually Transmitted Infections

Effective prevention and control of STIs is based on the following concepts (CDC, 2006b):

1. Education and counseling for people at risk on ways to practice safer sexual behavior.
2. Identification of infected, asymptomatic individuals and of people with symptoms of STI who are not likely to seek diagnostic and treatment services.
3. Effective diagnosis and treatment of people with an STI.
4. Evaluation, treatment, counseling, and education for individuals who are the sex partners of people with an STI.
5. Preexposure vaccination of individuals at risk for vaccine-preventable STIs.
6. Expedited partner therapy (EPT), whereby partners are treated, is recommended by the CDC (2006a). Infected individuals deliver medications or prescriptions to their partners to manage and decrease the reinfection rates of STIs. The legal status of EPT has not been determined in all states.

Individuals are at lowest risk for an STI if they abstain from sexual intercourse (whether vaginal, anal, or oral sex) and if they are in a long-term, monogamous relationship with a partner who is free of infection. Ideally, before entering a new sexual relationship, both partners should be tested for STIs, including HIV infection. If a person decides to have sex without knowing the partner's infection status, a new condom should be used before each act of intercourse (CDC, 2006b).

Nurses can play an important role in educating and counseling individuals who have an STI, who are at risk for one, or who are the partners of an infected individual. Information should be tailored to individual needs and specific risk factors. It can include details about actions a person can take to avoid exposure to an STI or to avoid transmitting one. Nurses need to be nonjudgmental and respectful and draw on their counseling skills in sharing information. In addition, nurses may find teaching opportunities by listening attentively to patients to clarify misconceptions about sexual and reproductive health (Wynn, Foster, & Trussell, 2009).

Trichomoniasis

Trichomoniasis is a commonly occurring STI caused by *Trichomonas vaginalis,* a microscopic motile protozoan that

TABLE 6-1 Summary of Sexually Transmitted Infections*

			TREATMENT	
DISEASE	**ORGANISM**	**DIAGNOSIS**	**NONPREGNANT**	**PREGNANT**
Vulvovaginal candidiasis (VVC)	*Candida albicans*	Wet-mount hyphae	Topically applied azole drugs	Topically applied azole drugs
Bacterial vaginosis (BV)	*Gardnerella vaginalis* and *Mycoplasma hominis*	Wet-mount clue cells	Metronidazole	Metronidazole or clindamycin
Trichomoniasis	*Trichomonas vaginalis*	Wet-mount trichomonads	Metronidazole	Metronidazole
Syphilis	*Treponema pallidum*	Dark-field examination Venereal Disease Research Laboratories (VDRL), Rapid Plasma Reagin (RPR), or microhemagglutination assay-Treponema pallidum (MHA-TP)	Benzathine Penicillin G	Benzathine Penicillin G
Herpes genitalis	Herpes simplex virus	Herpes culture or titer	Acyclovir	Acyclovir
Chlamydia	*Chlamydia trachomatis*	Chlamydia culture	Doxycycline or azithromycin*	Azithromycin or amoxicillin
Gonorrhea	*Neisseria gonorrhoeae*	Gonorrhea culture	Ceftriaxone, cefixime, cefotaxime, ceftizoxime	Ceftriaxone, cefixime, cefotaxime, ceftizoxime
AIDS	HIV	Enzyme-linked immunosorbent assay (ELISA) test and Western blot	Varies	Varies
Condylomata acuminata	Human papilloma virus	Virapap, biopsy, Pap smear, colposcopy	Cryotherapy, trichloroacetic acid (TCA), bichloroacetic acid (BCA), podophyllin, podofilox, excision	Cryotherapy Trichloroacetic acid
Pediculosis pubis	*Phthirus*	Microscopic identification of lice or nits	Permethrin 1% liquid or malathion 0.5% lotion	Permethrin 1% liquid
Scabies	*Sarcoptes scabiei*	Confirmation of symptoms or scraping of furrows	Permethrin 5% cream or crotamiton 10% cream or lotion	Permethrin 5% cream

* *Note:* VVC and BV are included for comparison even though they are not spread primarily by sexual contact.

thrives in an alkaline environment. In young, sexually active women, trichomonas is the most common curable sexually transmitted infection with estimates ranging from 3.1% to 13% (Allsworth, Ratner, & Peipert, 2009). The single-celled parasite, called a trichomonad, is an anaerobe that has the ability to generate hydrogen, which combines with oxygen to create an anaerobic environment. Most infections are acquired through sexual intimacy. Fomite transmission by shared bath facilities, wet towels, or wet swimsuits may also be possible. Coinfection with other sexually transmitted infections is common and HIV has been shown to be transmitted more easily with trichomoniasis present (Allsworth et al., 2009).

Often women with trichomoniasis are asymptomatic or have only mild symptoms. More pronounced symptoms of trichomoniasis can include a yellow-green, frothy, odorous discharge and vulvar itching. The woman may also complain of dysuria and dyspareunia. Occasionally, subepithelial hemorrhages on the cervix (strawberry-like red spots) can be seen with the naked eye; smaller areas of hemorrhage are generally visible with a colposcope. Microscopic visualization of mobile trichomonads and increased leukocytes, a vaginal pH of 0.5 or higher, and a positive whiff test are diagnostic of *T vaginalis* (Figure 6-3 ■). Pregnant women with trichomoniasis may be at increased risk for premature rupture of membranes, preterm birth, and low birth weight. Pregnant women who are symptomatic should be treated with a single 2-g dose of metronidazole orally to relieve their symptoms (CDC, 2006b). Some providers prefer to order metronidazole 500 mg twice daily to decrease the risk of gastrointestinal side effects (Chan & Johnson, 2008).

Recommended treatment for trichomoniasis is metronidazole (Flagyl) administered in a single 2-g dose or tinidazole in a single 2-g dose or, alternatively, metronidazole 500 mg twice daily for 7 days for both male and female sexual partners (CDC, 2006b). Tinidazole is equivalent to or superior to metronidazole with less gastrointestinal symptoms but is more costly (CDC, 2006b; Huppert, 2009). Partners should avoid intercourse until both are cured (therapy is completed and both are symptom free). The woman and her partner should be cautioned to avoid alcohol for 24 hours after taking metronidazole and 72 hours after taking tinidazole; the combination has an effect similar to that of alcohol and disulfiram (Antabuse)—abdominal pain, nausea, flushing, or tremors (CDC, 2006b).

Chlamydial Infection

Chlamydial infection, caused by *Chlamydia trachomatis,* is the most common bacterial STI in the United States (CDC, 2009b). It is found most frequently in sexually active adolescents and young adults. Transmission commonly occurs through vaginal sex. The organism is an intracellular bacterium with different immunotypes. Immunotypes of chlamydia are responsible for lymphogranuloma venereum and trachoma, which is the world's leading cause of preventable blindness.

Chlamydia is a major cause of nongonococcal urethritis (NGU) in men. In women it can cause infections similar to those that occur with gonorrhea. However, asymptomatic infection is common in both men and women. In women, chlamydia can infect the fallopian tubes, cervix, urethra, and Bartholin's glands. Severe sequelae can result from untreated chlamydial infection, including pelvic inflammatory disease (PID), infertility, and ectopic pregnancy. In men, chlamydial infection can result in epididymitis and infertility. In addition, chlamydia infection is associated with an increased risk of acquiring and transmitting HIV infection (CDC, 2009b). In the United States, newborn exposure to chlamydia in the birth canal of the mother is the most common cause of ophthalmia neonatorum (CDC, 2006b). Chlamydial conjunctivitis responds to erythromycin ophthalmic ointment. The newborn may also develop chlamydial pneumonia.

Symptoms of chlamydia include a thin or mucopurulent discharge, cervical ectropia, friable cervix (bleeds easily), burning and frequency of urination, and lower abdominal pain. However, up to 50% of women are asymptomatic (Chan & Johnson, 2008). Of the laboratory tests currently available to diagnose chlamydia, nucleic acid amplification testing (NAAT) is the most sensitive. Other tests used for diagnosis include culture, direct immunofluorescence, enzyme immunoassay (EIA), and nucleic acid hybridization tests (CDC, 2006b). Diagnosis is frequently made after treatment of a male partner for NGU or in a symptomatic woman with a negative gonorrhea culture. Routine screening is recommended in all sexually active women less than 25 years of age (Chan & Johnson, 2008).

The recommended treatment is a single dose of azithromycin 1 g orally or doxycycline 100 mg by mouth twice a day for 7 days. Doxycycline costs less than azithromycin and has been used for a longer period. However, azithromycin administered at the clinic or office visit is an excellent choice for people who do not adhere well with treatment or who are erratic about completing a course of medication. Sexual partners should also be treated and the couple should abstain from intercourse for 7 days after taking the single-dose treatment or for the entire 7 days of the doxycycline therapy (CDC, 2006b). Doxycycline is contraindicated during pregnancy, but azithromycin 1 g orally or amoxicillin 500 mg orally 3 times daily for 7 days may be ordered (CDC, 2006b; Chan & Johnson, 2008). For pregnant women, patients with persisting symptoms, or those with medication nonadher-

ence concerns, repeat testing is recommended 3 weeks after completion of the prescribed medication as a test of cure. Patient education includes information about the need for abstinence for 7 days following treatment (Akhter et al., 2009). Because so many males and females who have chlamydia are asymptomatic, the CDC and medical specialty organizations such as the American College of Obstetricians and Gynecologists (ACOG) recommend screening as the primary method of decreasing the incidence of chlamydia. Specifically, annual screening is recommended for these groups (CDC, 2006b):

- All sexually active adolescent females and women ages 20 to 25 even if they are asymptomatic.
- Women over age 25 who are at risk for chlamydia (history of STIs, multiple sexual partners, new sexual partner, inconsistent use of barrier contraceptives).
- ACOG also recommends screening for high-risk pregnant women at their first prenatal visit or during the third trimester of pregnancy, or both. Practitioners routinely screen all pregnant women.

Screening using a nucleic amplification test can be done on endocervical, urethral, or urine specimens. The urine tests are an attractive alternative for women who are not comfortable with pelvic exams or in clinics where access to gynecologic examination facilities is limited or lacking (Chan & Johnson, 2008).

Gonorrhea

Gonorrhea, an infection caused by the bacterium *Neisseria gonorrhoeae,* is the second most commonly reported STI in the United States with an estimated 336,742 people infected in 2008, with the highest rates in females aged 15 to 24 years of age (CDC, 2009b). Most men seek treatment for gonorrhea early because of symptoms but many women with the infection are asymptomatic until complications such as PID occur. Transmission can occur through vaginal, anal, or oral sex.

If a pregnant woman becomes infected after the third month of gestation, the mucous plug in the cervix generally prevents the infection from ascending, and it remains localized in the urethra, cervix, and Bartholin's glands until the membranes rupture. Then it can spread upward. A newborn exposed to a gonococcal-infected birth canal is at risk of developing ophthalmia neonatorum. Eye prophylaxis for all newborns is provided to prevent this complication.

About 80% of women with gonorrhea are asymptomatic (Little, 2006). Thus it is accepted practice to screen for this infection by doing a cervical culture during the initial prenatal examination. For women at high risk, the culture may be repeated during the last month of pregnancy. Cultures of the urethra, throat, and rectum may also be required for diagnosis, depending on the body orifices used for intercourse.

The most common symptoms of gonorrheal infection, when they occur, include a purulent, greenish-yellow vaginal discharge, dysuria, and urinary frequency. Some women also develop inflammation and swelling of the vulva. The cervix may appear swollen and eroded and may secrete a foul-smelling discharge in which gonococci are present. Bilateral lower abdominal or pelvic pain may also occur.

Treatment for nonpregnant women consists of antibiotic therapy with ceftriaxone 125 mg intramuscularly or cefixime 400 mg orally in a single dose for uncomplicated gonococcal infections of the cervix, urethra, and rectum (CDC, 2007b). For patients with disseminated gonococcal infection the recommended regimen is ceftriaxone 1 g intramuscularly or intravenously every 24 hours (CDC, 2007b). Gonococcal and chlamydial infections often coexist. Treatment recommendations include testing for chlamydia or treatment for chlamydia as previously discussed if chlamydia is not ruled out (CDC, 2007b). Additional treatment may be required if the cultures remain positive 7 to 14 days after completion of treatment. All sexual partners must be treated, or the woman can become reinfected. Pregnant women should be treated with a recommended cephalosporin, usually ceftriaxone intramuscularly or cefixime orally. This is combined with azithromycin or amoxicillin to address the risk of coinfection with chlamydia (CDC, 2006b). As with chlamydia, nurses should recommend abstinence for 7 days following treatment (Akhter et al., 2009).

For uncomplicated gonococcal infections test of cure is not recommended. Retesting is recommended 3 months following treatment secondary to increasing prevalence and the potential for PID (CDC, 2009b). Women should be informed of the need for reculture to verify cure and the need for abstinence or condom use until cure is confirmed. Both sexual partners should be treated if either has a positive test for gonorrhea. Women should also be informed of signs that the infection is worsening (sharp abdominal pain, fever, or chills) and encouraged to seek further care if any of these develop.

Herpes Genitalis

The herpes simplex virus (HSV) causes herpes infections, which are recurrent, lifelong infections. Two serotypes of HSV cause human infections: HSV-1 and HSV-2. HSV-2 causes most cases of recurrent genital herpes and is spread through vaginal, anal, or oral sex. It can also be spread through skin-to-skin contact with an infected site such as a finger (herpetic whitlow). The clinical symptoms and treatment of both types are the same. At least 50 million people in the United States have been diagnosed with genital HSV-2 infection—**herpes genitalis** (Akhter et al., 2009). Even so, most people infected with genital herpes have not been diagnosed because they have mild or unrecognized infections but shed the virus intermittently (CDC, 2006b). HSV-1 infections are often orally acquired as children, while HSV-2 infections are primarily acquired sexually (Akhter et al., 2009); however, genital HSV-1 infections are increasing (Kriebs, 2008).

The primary episode (first outbreak) of herpes genitalis is characterized by the development of single or multiple blisterlike vesicles, which usually occur in the genital area and sometimes affect the vaginal walls, cervix, urethra, and anus. The vesicles may appear within a few hours to 20 days after exposure and rupture spontaneously to form very painful, open, ulcerated lesions. Inflammation and pain secondary to the presence of herpes lesions can cause difficult urination and urinary retention. Enlargement of the inguinal lymph nodes may be present. Flulike symptoms and genital pruritus or tingling also

may be noticed. Primary episodes usually last the longest and are the most severe. Lesions heal spontaneously in 2 to 4 weeks.

After the lesions heal, the virus enters a dormant phase, residing in the nerve ganglia of the affected area. Some individuals never have a recurrence, whereas others have regular recurrences. Recurrences are usually less severe than the initial episode and seem to be triggered by emotional stress, menstruation, ovulation, pregnancy, and frequent or vigorous intercourse; patients with poor health status, a generally run-down physical condition, or who are immunocompromised can experience more frequent recurrences. Diagnosis is made on the basis of the clinical appearance of the lesions, culture of the lesions, polymerase chain reaction (PCR) identification, and glycoprotein G-based type-specific assays (Herpe Select™, Biokit HSV-2, & Sure Vue HSV-2) (CDC, 2006b).

No known cure for herpes exists; however, medications are available to partially control the symptoms of herpes and prevent complications from secondary infection (Akhter et al., 2009). The recommended treatment of the first clinical episode of genital herpes is oral acyclovir, valacyclovir, or famciclovir. These same medications, in somewhat different dosages, are also recommended for recurrent herpes infection and for daily suppressive therapy for people who have frequent recurrences. Therapy should be started during the prodromal period (time before the onset of lesions) for the greatest benefit (Akhter et al., 2009).

The safety of acyclovir, valacyclovir, and famciclovir in pregnancy has not been established. However, because there is more documented information on acyclovir during pregnancy, it can be administered orally to pregnant women with first episode genital herpes or severe recurrent herpes. Its use in the third trimester may reduce the frequency of cesarean births by decreasing the incidence of recurrences at term (CDC, 2006b). Sometimes 2% lidocaine (Xylocaine) is used to decrease intense pain at the site of the lesions. Keeping the genital area clean and dry, wearing loose clothing, taking sitz baths, and wearing cotton underwear or none at all will promote healing. Primary or recurrent lesions will heal without treatment.

New onset of maternal HSV infections has a 30% to 50% probability of neonatal HSV infection with transmission occurring during labor (85%) (Kriebs, 2008). The majority of providers recommend that women with herpetic lesions intrapartally give birth by cesarean section to prevent neonatal herpes. Note that cesarean birth does not completely prevent the risk of neonatal transmission. See chapter 20 for more detail.

Syphilis

Syphilis is a chronic infection caused by the spirochete *Treponema pallidum.* The rate of primary and secondary syphilis in women is 1.5 cases per 100,000 population; the rate in men is 7.6 cases (CDC, 2009b). Syphilis is commonly acquired through vaginal, oral, or anal sex. Less commonly, it can result from nonsexual exposure to exudates from an infected individual. Congenital transmission through transplacental inoculation may also occur. The incubation period varies from 10 to 90 days, and even though no symptoms or lesions are noted during this time, the blood contains spirochetes and is infectious.

Syphilis is divided into early and late stages. During the early stage (primary), a chancre (painless ulcer) appears at the site where the *T pallidum* organism entered the body. Symptoms include slight fever, loss of weight, and malaise. The chancre persists for about 4 weeks and then disappears. In 6 weeks to 6 months, secondary symptoms appear. Skin eruptions called condylomata lata, which resemble wartlike plaques and are highly infectious, may appear on the vulva. Other secondary symptoms are acute arthritis, enlargement of the liver and spleen, nontender enlarged lymph nodes, iritis, and a chronic sore throat with hoarseness. Transplacentally transmitted syphilis is as high as 95% in the primary and secondary stages but decreases to 10% in the late latent phase. Congenital syphilis can cause intrauterine growth restriction, preterm birth, and stillbirth.

As a result of the disease's impact on the fetus, serologic testing of every pregnant woman is recommended; most state laws require it. Testing is done at the initial prenatal screening and may be repeated in the third trimester. Blood studies may be negative if blood is drawn too early in the pregnancy.

During the early primary stage, the diagnosis is made by dark-field microscopic examination of the chancre for spirochetes and direct fluorescence antibody testing. Blood tests such as Venereal Disease Research Laboratories (VDRL), Rapid Plasma Reagin (RPR), or the more specific fluorescent treponemal antibody absorption test (FTA-ABS) are commonly done. Nontreponemal test antibody titers correlate with disease activity and are used to guide treatment while treponemal tests remain positive for life (CDC, 2006b).

For pregnant and nonpregnant women with syphilis of less than a year's duration (early latent syphilis), the CDC (2006b) recommends 2.4 million units of benzathine penicillin G intramuscularly in a single dose. If syphilis is of long duration (more than 1 year) or of unknown duration, 2.4 million units of benzathine penicillin G are given intramuscularly once a week for 3 weeks. If a woman is allergic to penicillin and nonpregnant, doxycycline or tetracycline can be given. Patients who are allergic to penicillin whose cooperation with treatment and follow-up are questionable should be desensitized to penicillin and then treated with it. Similarly, the pregnant woman with syphilis who is allergic to penicillin should be desensitized and then treated (CDC, 2006b). Maternal serologic testing can remain positive for 8 months, and the newborn can have a positive test for 3 months.

Patients receiving initial treatment for primary or secondary syphilis should be advised that they might experience a Jarisch-Herxheimer reaction within 6 to 12 hours of initial treatment. This reaction is characterized by fever, malaise, sweating, headache, anxiety, and a temporary increase in symptoms, which may be misdiagnosed as an allergic reaction. It generally subsides within 24 hours.

Human Papilloma Virus/Condylomata Acuminata

Condylomata acuminata, also called genital warts, is a common STI caused by the human papilloma virus (HPV) with approximately 60 genotypes that are related to genital warts (McCutcheon, 2009). Transmission can occur through vaginal, oral, or anal sex.

Annually 1 million new cases of condylomata acuminata are diagnosed. Of these, two thirds are in women. Estimates suggest that 1% of sexually active adults have genital warts (Dinh, Sternberg, Dunne, & Markowitz, 2008). Because of the increased evidence of a link between HPV and cervical and anorectal cancers, the condition is receiving increasing attention. Over 120 HPV subtypes have been identified; of these, about 30 types can infect the genital tract (Kennedy & Boardman, 2008). Most HPV infections are unrecognized, asymptomatic, or subclinical. HPV types 6 and 11 most commonly cause 90% of genital warts, but they have a low cancer-causing potential (Dinh et al., 2008). Approximately 15 specific types of HPV are considered high risk for high-grade cervical dysplasia and anogenital cancer (Kennedy & Boardman, 2008). Patients with visible genital warts can be infected concurrently with different HPV types.

Often a woman seeks medical care after noticing single or multiple soft, grayish pink, cauliflower-like lesions in her genital area (D'Ambrogio et al., 2009) (Figure 6-4 ■). These warts are often asymptomatic; however, depending on their location and size, they may cause itching (pruritus), be friable (bleed easily), or be painful. The moist, warm environment of the genital area is conducive to the growth of the warts, which may be present on the vulva, perineum, vagina, cervix, urethra, and anus. The incubation period following exposure is 3 weeks to 3 years, with the average being about 3 months.

Because condylomata sometimes resemble other lesions and can become cancerous, all atypical, pigmented, and persistent warts should be biopsied and treatment instituted promptly. Diagnosis is usually made by visual appearance. However, vaginal and cervical warts are more common than warts of the external genitalia. Most of these are flat lesions visible only by colposcopy. Subclinical diagnosis can be made if characteristic changes are present on a Pap smear.

Figure 6-4 ■ Condylomata acuminata on the vulva.

Source: Courtesy of Centers for Disease Control and Prevention.

The CDC (2006b) does not specify a treatment of choice for genital warts but recommends that treatment be determined based on patient preference, available resources, and experience of the healthcare provider. No single treatment is best for all types of warts or for all patients. Patient-applied therapies include 0.5% podofilox solution or gel or imiquimod 5% cream. For these methods to be effective, the patient must be able to reach and identify the warts being treated. Provider-administered therapies include cryotherapy with liquid nitrogen or cryoprobe; topical podophyllin (10% to 25%); trichloroacetic acid (TCA); bichloroacetic acid (BCA); and surgical removal by tangential scissors excision, shave excision, curettage, or electrosurgery. Alternative therapies include intralesional interferon or laser surgery (CDC, 2006b). Imiquimod, podophyllin, and podofilox are not used during pregnancy because they are thought to be teratogenic. TCA, BCA, and surgical removal are safe during pregnancy and may be used secondary to the size of the warts and patient discomfort. Genital and vulvar warts do not warrant cesarean birth. More recently, topical sinecatechin ointments, botanicals made from green tea extracts, have demonstrated wart clearance rates of approximately 50% (Tatti et al., 2008). Sinecatechins exert antiviral and antioxidant properties.

Women with HPV infections should have frequent Pap smears to monitor cervical cellular changes. Sex partners are probably infected and do not require treatment unless large exophytic lesions are present. Moreover, no research to date indicates that reinfection plays a role in recurrence (CDC, 2006b). The use of condoms can reduce the risk of transmitting the virus to an uninfected partner. In 2006 the United States Food and Drug Administration approved the first vaccine designed to protect against four HPV types, which, when considered together, are responsible for 90% of genital warts and 70% of cervical cancers. The vaccine—Gardasil®—given in 3 doses over 6 months is approved by the Food and Drug Administration (FDA) for females 9 to 26 years of age (Bornstein, 2009). Gardasil is a quadrivalent vaccine against HPV types 6, 11, 16, and 18. It is injected intramuscularly in the deltoid muscle or the anterolateral thigh. A second vaccine, a bivalent vaccine (Cervarix®) effective against HPV types 16 and 18, received FDA approval in late 2009. At present, both vaccines have demonstrated high antibody levels for greater than 5 years (Bornstein, 2009).

> "I've finally come to terms with the fact that I carry HPV. I know I will always run the risk of recurrence, but it's just a virus. It doesn't define me as a person."

Case Study: Pediculosis Pubis

Pediculosis Pubis (Pubic or Crab Lice)

Pediculosis pubis is caused by *Phthirus,* a grayish, parasitic "crab" louse that lays eggs that attach to the hair shaft. Transmission is primarily by sexual contact, although shared towels and bed linens are also possible sources.

Symptoms include itching, usually in the pubic area. It is treated by applying 1% permethrin liquid or malathion (0.5%) lotion. Permethrin is applied to clean hair, saturating the hair, removing it after 10 minutes with warm water. Some providers recommend combing the pubic hair with a fine-toothed comb before rinsing off the permethrin. Malathion can be applied to dry hair, massaged in, and allowed to air dry. Because the lotion is flammable due to the high alcohol content, drying with high heat as with a hair dryer is contraindicated (Lehne, 2010). After 20 minutes, the lotion is removed. Over-the-counter medications such as Rid, Nix, and malathione lotion can also be used. Retreatment may be necessary. Both partners must be treated and tested for other STIs. Bed linens, towels, clothing, and other objects should be machine washed and dried in a hot dryer for 20 minutes or dry-cleaned or sealed in an airtight bag for 2 weeks. Sexual contact should be avoided until the woman and her partner(s) have been treated and cured.

Scabies

Sarcoptes scabiei is a parasitic itch mite. The female mite burrows under the skin to deposit her eggs. Transmission by intimate sexual contact is common in adults but scabies in children is not generally sexually acquired (CDC, 2006b).

Symptoms include itching that worsens at night or when the individual is warm. Noticeable erythematous, papular lesions or furrows may be present. The recommended treatment for scabies is permethrin cream 5% applied to all body areas from the neck down and washed off after 8 to 14 hours. Treatment is repeated in 14 days if live mites still exist. Alternate therapy includes crotamiton cream or lotion, which has scabicidal and antipruritic actions. Crotamiton is applied in a thin layer to all areas of the body from the neck down, with attention to body creases, and reapplied 24 hours after the first application. Lindane is no longer recommended as a first line treatment for lice or scabies due to an increased risk of seizures. Permethrin 5% is used in pregnant women. Clothing and bed linens should be washed and dried in a hot dryer or dry-cleaned. Sexual contacts and close household contacts need to be examined and treated for scabies as appropriate.

Viral Hepatitis

Hepatitis is an inflammatory process of the liver caused by infection by one of the five distinct viruses: A, B, C, D, and E. Currently, immunizations are only available for hepatitis A and B. Table 6-2 compares the five forms of viral hepatitis.

Hepatitis A is characterized by symptoms of jaundice, anorexia, nausea, vomiting, malaise, and fever. It is self-limiting and is not a chronic condition. A vaccine is available to prevent hepatitis A.

Hepatitis B, C, and D have symptoms similar to those of hepatitis A and can also include arthralgias, arthritis, and skin eruptions or rash. Unlike hepatitis A infection, those of B, C, and D infections are chronic. See Table 19-5 on page 445 for information about hepatitis B and pregnancy.

Hepatitis E occurs primarily in South Central Asia and the Middle East, and its symptoms are like those of hepatitis A. It is also a self-limiting disease and not a chronic condition.

COMPLEMENTARY AND ALTERNATIVE THERAPIES

Hepatitis C is a common bloodborne infection that is transmitted primarily by contact with infected blood. People at high risk for the infection include intravenous (IV) drug users, healthcare workers who receive a needle stick, and people with multiple sexual partners. To date, no complementary or alternative medical (CAM) therapy has proven effective in treating hepatitis C or its complications, and conventional medical therapy should *not* be replaced with an unproven CAM therapy (National Center for Complementary and Alternative Medicine [NCCAM], 2009).

Milk thistle (*Silybum marianum*), a plant of the aster family, has been used in Europe to treat liver disease since the 16th century. It may offer some protection for the liver by promoting the growth of liver cells. Currently NCCAM is supporting research on the effectiveness of Silymarin for preventing and reversing the complications of chronic hepatitis C (NCCAM, 2009).

Acquired Immunodeficiency Syndrome (AIDS)

Acquired immunodeficiency syndrome (AIDS) is a fatal disorder caused by HIV, which can be transmitted sexually. A medical-surgical text more fully describes this condition. HIV alters the presentation of STIs and can complicate the treatment of an STI. This is a bidirectional relationship because STIs can facilitate the transmission of HIV (Naresh, Beigi, Woc-Colburn, et al., 2009). However, because the diagnosis of HIV/AIDS or the presence of the HIV antibody has implications for a fetus if the woman is pregnant, HIV/AIDS is discussed in greater detail in chapter 19.

TABLE 6-2 Types of Viral Hepatitis

FORM	PRIMARY ROUTE OF TRANSMISSION	INCUBATION PERIOD	CHRONIC INFECTION	IMMUNIZATION AVAILABLE?
Hepatitis A	Fecal-oral, contaminated food/water	15–50 days	No	Yes
Hepatitis B	Blood/body fluids	45–160 days	Yes	Yes
Hepatitis C	Blood/blood products	14–180 days	Yes	No
Hepatitis D	Blood/body fluids	45–160 days	Yes	No
Hepatitis E	Fecal-oral	15–60 days	No	No

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse working with women must become adept at taking a thorough history and identifying women at risk for STIs. Risk factors include multiple sexual partners; a partner's involvement with other partners; high-risk sexual behaviors, such as intercourse without barrier contraception or anal intercourse; partners with high-risk behaviors; and young age at onset of sexual activity. The nurse should be alert for signs and symptoms of STI and be familiar with diagnostic procedures if it is suspected.

Although each STI has certain distinctive characteristics, the following complaints suggest the possibility of infection and warrant further investigation:

- Presence of a "sore" or lesion on the vulva
- Increased vaginal discharge or malodorous vaginal discharge
- Burning with urination
- Dyspareunia
- Bleeding after intercourse
- Pelvic pain

In many instances the woman is asymptomatic but may report symptoms in her partner, especially painful urination or urethral discharge. It is often helpful to ask the woman whether her partner is experiencing any symptoms.

Nursing diagnoses that may apply to a woman with an STI include the following:

- ***Interrupted family processes*** related to the effects of a diagnosis of sexually transmitted infection on the couple's relationship
- ***Readiness for enhanced knowledge:*** Information on preventing STIs related to an expressed desire to avoid infection

While it is important that nurses learn to effectively communicate with all young adults about STIs, it is especially critical with those of minority groups. Efforts to provide effective screening and treatment of STIs need to be expanded, and teaching and prevention strategies that are culturally sensitive need to be developed. These endeavors will contribute to decreasing the long-term consequences of STIs, such as ectopic pregnancy and infertility, and will also help decrease healthcare costs.

DEVELOPING CULTURAL COMPETENCE

STI Rates in the United States

Racial minorities continue to have the highest rates of STIs in the United States with African Americans most significantly impacted. Gonorrhea rates in blacks are 20 times greater than in whites; rates for chlamydia are similar and reflect the same trends. While blacks represent approximately 12% of the population of the United States, in 2008 they accounted for 71% of reported cases of gonorrhea, 48% of chlamydia, and 49% of syphilis cases (CDC, 2009a & 2009b). American Indian/Native American populations followed by Hispanic populations report significantly greater rates of gonorrhea and chlamydia than whites (CDC, 2009a & 2009b).

Nursing Plan and Implementation

In a supportive, nonjudgmental way, the nurse provides the woman who has an STI with information about the infection, methods of transmission, implications for pregnancy or future fertility, and importance of thorough treatment. If treatment of her partner is indicated, the woman must understand that it is necessary to prevent a cycle of reinfection. She should also understand the need to abstain from sexual activity, if necessary, during treatment.

Some STIs, such as trichomoniasis or chlamydia, may cause a woman concern but once diagnosed are rather simply treated. Other STIs can also be fairly simple to treat medically but may carry a stigma and be emotionally devastating for the woman. Thus the nurse should stress prevention with all women and encourage them to require partners, especially new partners, to use condoms.

The sensitive nurse can be especially helpful in encouraging the woman to explore her feelings about the diagnosis. She may experience anger or feel "betrayed" by a partner; she may feel guilt or see her diagnosis as a form of "punishment"; or she may feel concern about the long-term implications for future childbearing or ongoing intimate relationships. She may experience a myriad of emotions that she never expected. Opportunities to discuss her feelings in a nonjudgmental environment can be especially helpful. The nurse can offer suggestions about support groups, if indicated, and assist the woman in planning for her future with regard to sexual activity.

PROFESSIONALISM IN PRACTICE

Attitudes About STIs

Many women deal matter-of-factly with an STI diagnosis; other women find it embarrassing and possibly even shameful. The nurse's attitude of straightforward acceptance conveys to the woman that she is still an acceptable person who happens to have an infection and can help the woman deal effectively with her diagnosis and its implications.

Health Promotion Education

Table 6-3 provides a summary of basic information the nurse should share with women who have an STI. STIs that can have an impact on pregnancy or the fetus/newborn are discussed in chapter 20 ∞.

Evaluation

Expected outcomes of nursing care include the following:

- The infection is identified and cured, if possible. If not, supportive therapy is provided.
- The woman and her partner can describe the infection, its method of transmission, its implications, and the therapy.
- The woman copes successfully with the impact of the diagnosis on her self-concept.

Care Plan Activity: Gynecologic Infection

TABLE 6-3 Health Promotion Education: Preventing STIs and Their Consequences

The risk of contracting an STI increases with the number of sexual partners. Because of the extended time between infection with HIV and evidence of infection, intercourse with an individual exposes a female or male to all the other sexual partners of that individual for the past 5 or more years. Because of this risk, it is important to take the following actions:

- Plan ahead, review decision-making skills, and develop strategies to refuse sex (especially important for adolescents who may be less confident about saying "no" to casual sexual encounters), because abstinence is the best method of preventing STIs.
- Limit the number of sexual contacts and practice mutual monogamy.
- The condom is the best contraceptive method currently available (other than abstinence) for protection from STIs. Use one for every act of vaginal and anal intercourse. Other contraceptives such as the diaphragm, cervical cap, and spermicides also offer some protection against STIs.
- Plan strategies for negotiating condom use with a partner.
- Reduce high-risk behaviors. Use of recreational drugs and alcohol can increase sexual risk taking.
- Refrain from oral sex if your partner has active sores in the mouth, vagina, or anus or on the penis.
- Seek care as soon as you notice symptoms and make sure your partner gets treatment if indicated. Absence of symptoms or disappearance of symptoms does not mean that treatment is unnecessary if you suspect an STI. Take all prescribed medications completely.
- The presence of a genital infection can lead to an abnormal Pap smear. Women with certain infections should have more frequent Pap tests according to a schedule recommended by their caregiver. Ask your healthcare provider if you need more frequent Paps.

Care of the Woman with an Upper Genital Tract Infection (Pelvic Inflammatory Disease)

Pelvic inflammatory disease (PID) occurs in approximately 1% of women between ages 15 and 39, although sexually active young women between 15 and 24 have the highest infection rate. In the United States, an estimated 1 million cases of PID are diagnosed annually, and more than 100,000 women become infertile as a result of it (CDC, 2007a).The disease is more common in women who have had multiple sexual partners, a history of PID, early onset of sexual activity, or recent insertion of an intrauterine device (IUD) and in women who douche regularly (CDC, 2007a). In the past, PID infections were primarily caused by gonorrhea and chlamydia trachomata. Newer pathogens that must be considered in the treatment regimen include *Mycoplasma genitalium* and bacterial vaginosis (BV) (Judlin, 2010). PID usually produces a tubal infection (salpingitis) that may or may not be accompanied by a pelvic abscess. However, perhaps the greatest problem of PID is postinfection tubal damage, which is closely associated with infertility.

PID is defined as a clinical syndrome of inflammatory disorders of the upper female genital tract that includes any combination of endometritis, salpingitis, tubo-ovarian abscess, pelvic abscess, and pelvic peritonitis (CDC, 2006b). The organisms most frequently identified with PID include *C trachomatis* and *N gonorrhoeae* with a coinfection rate (both organisms are present) of 60%. Other pathogens associated with PID include *M genitalium*, BV, and multiresistant gonococci (Judlin, 2010). Symptoms of PID include bilateral sharp, cramping pain in the lower quadrants, fever greater than 101°F, chills, mucopurulent cervical or vaginal discharge, irregular bleeding, cervical motion tenderness during intercourse, malaise, nausea, and vomiting. However, it is also possible to be asymptomatic and have normal laboratory values.

Diagnosis consists of a clinical examination to define symptoms. Laboratory tests include vaginal, cervical, and possibly rectal cultures for *N gonorrhoeae*, *C trachomatis*, and other pathogens as well as blood tests, including a complete blood count (CBC) with differential and Rapid Plasma Reagin (RPR) or Venereal Disease Research Laboratories (VDRL) to test for syphilis. A woman with PID often has an elevated C-reactive protein and elevated sedimentation rate. Microscopic examination of the vaginal secretions may reveal white blood cells. Physical examination usually reveals direct abdominal tenderness with palpation and, on bimanual examination, adnexal tenderness, and cervical and uterine tenderness with movement (Chandelier sign). A palpable mass is evaluated with ultrasonography. In confounding cases, laparoscopy can be used to confirm the diagnosis and to enable the examiner to obtain cultures from the fimbriated ends of the fallopian tubes.

Currently, there is no evidence comparing parenteral versus oral treatment, and outpatient treatment is an option. The decision to hospitalize a woman is based on clinical judgment. The woman should be hospitalized if the diagnosis is uncertain, ectopic pregnancy or appendicitis is suspected, the woman is severely ill (nausea, vomiting, high fever, dehydration), there has been little response to oral therapy after 48 to 72 hours, there are complications from pelvic abscesses or pelviperitonitis, the patient is a young adolescent, or the woman is unable to return for follow-up care. Treatment includes intravenous (IV) fluids, pain medication, and administration of IV antibiotics. Intravenous cefotetan (2 g IV every 12 hours) or cefoxitin (2 g IV every 6 hours), plus doxycycline (100 mg IV or by mouth every 12 hours), is one treatment regimen. Intravenous therapy can be discontinued once acute symptoms resolve but oral doxycycline 100 mg twice daily to complete the 14-day therapy must be taken (CDC, 2006b). Ambulatory or outpatient treatment includes ceftriaxone 250 mg intramuscularly once followed by doxycycline 100 mg twice a day for 14 days (CDC, 2006b). Other supportive measures that may be helpful include increased oral fluids (up to 2 liters per day), continued bed rest or pelvic rest, acetaminophen for fever, and pain relievers for abdominal pain. Follow-up visits are important within 48 to 72 hours, sooner if symptoms worsen. The sexual partner should also be treated. If the woman has an IUD, it is generally removed 24 to 48 hours after antibiotic therapy is started.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse is alert to factors in a woman's history that put her at risk for PID. Even though fewer types of IUDs are available, there is an upsurge in their use by many women. The nurse should ques-

tion the woman about possible symptoms, such as aching pain in the lower abdomen, foul-smelling discharge, malaise, and dyspareunia. The woman who is acutely ill has obvious symptoms, but a low-grade infection is more difficult to detect.

Nursing diagnoses that may apply to a woman with PID include the following:

- ***Acute pain*** related to peritoneal irritation
- ***Deficient knowledge*** related to a lack of information about the possible effects of PID on fertility

Nursing Plan and Implementation

The nurse plays a vital role in helping to prevent or detect PID. Accordingly, the nurse spends time discussing risk factors related to this infection. The woman who uses an IUD for contraception and has multiple sexual partners needs to understand clearly the risk she faces.

The nurse should strongly recommend that the IUD be removed and another method of contraception used. The nurse discusses signs and symptoms of PID with women at high risk and stresses the importance of early detection.

The woman who develops PID needs to understand the importance of completing her antibiotic treatment and of returning for follow-up evaluation. She should also understand that one outcome of the infection may be decreased fertility or infertility.

Evaluation

Expected outcomes of nursing care include the following:

- The woman describes her condition, her therapy, and the possible long-term implications of PID on her fertility.
- The woman completes her course of therapy and the PID is cured.

Care of the Woman with a Urinary Tract Infection

Urinary tract infection (UTI) is defined as significant bacteriuria in the presence of symptoms. Approximately 60% of women will experience a UTI in their lifetime (ACOG, 2008). A UTI can be life threatening or a mere inconvenience. Bacteria usually enter the sterile environment of the urinary tract by way of the urethra. The organisms are capable of migrating against the downward flow of urine. The shortness of the female urethra facilitates the passage of bacteria into the bladder. Other conditions that are associated with bacterial entry are relative incompetence of the urinary sphincter, frequent enuresis (bed-wetting) before adolescence, pregnancy, and urinary catheterization. Wiping from back to front after urination may transfer bacteria from the anorectal area to the urethra.

Voluntarily suppressing the desire to urinate is also a predisposing factor. Retention overdistends the bladder and can lead to an infection. There also seems to be a relationship between recurring UTI and new onset of sexual activity. General poor health or lowered resistance to infection can increase a woman's susceptibility to UTI. The rate of urinary tract infections increases as women age. For postmenopausal women, a lifetime history of urinary tract infection is a risk factor for urinary tract infection. Factors that may inhibit bacterial growth include a low pH (5.5 or less) resulting in more acidic urine, high urea concentration, and the presence of organic acids from food such as fruits and proteins. Urinary tract infections can be classified by location or as complicated or uncomplicated.

Asymptomatic bacteriuria (ASB) refers to bacteria in the urine actively multiplying without accompanying clinical symptoms. This becomes especially significant if the woman is pregnant because it is found in up to 11% of pregnancies, and as many as 40% of pregnant women with untreated ASB will develop pyelonephritis (Chan & Johnson, 2008). ASB is almost always caused by one organism. If more than one type of bacteria is cultured, the possibility of urine-culture contamination must be considered. The most common cause of ASB is *Escherichia coli.* Less commonly causative organisms include *Klebsiella* and *Proteus,* and *Pseudomonas* and *Staphylococcus* species.

CLINICAL JUDGMENT

Case Study: Tamara Williams

Tamara Williams, a 16-year-old G2P0, is approximately 14 gestational weeks (GW) when she is first seen by the nurse provider in a community health department prenatal clinic. Tamara's only complaints are occasional nausea, which she indicates has become much better in the last 3 weeks. Her prenatal laboratory results, including blood work and urine testing, reveal a urine sample with greater than 100,000 bacteria. When questioned, she denies urgency, frequency, and dysuria. Her healthcare provider tells her that she has asymptomatic bacteriuria and writes a prescription for nitrofurantoin (Macrodantin) 50 mg by mouth 4 times a day for 7 days.

The nurse overhears Tamara tell another woman in the clinic, "I'm not getting this medication. There's nothing wrong with me."

Critical Thinking

What should the nurse discuss with Tamara about obtaining the medication and taking it?

See www.nursing.pearsonhighered.com for possible responses.

A woman who has had a UTI is susceptible to recurrent infection. Although the role of ASB in pregnancy complications remains controversial, the majority of evidence supports the view that bacteriuria does not, as an isolated factor, lead to low birth weight or prematurity. However, an untreated ASB can progress to a UTI in approximately 30% to 40% of pregnant women (Blackburn, 2007). A number of structural and functional changes occur during pregnancy that predispose pregnant women to urinary tract infections. Ureters elongate and are laterally displaced by the gravid uterus. In addition, progesterone, which relaxes smooth muscles, can facilitate hypertrophy of the distal ureters with resulting ureteral stenosis and dilation, especially in the second half of pregnancy. Though the bladder has an increased capacity in pregnancy, it also has a decreased tone because progesterone relaxes the smooth muscle. Estrogen causes the bladder mucosa to become hyperemic and more susceptible to trauma and infection. Lastly, the intravesical pressure may be

RESEARCH EVIDENCE IN PRACTICE

Treatment for Symptomatic Urinary Tract Infections During Pregnancy

CLINICAL QUESTION

What is the most effective treatment for symptomatic urinary tract infections during pregnancy?

RESEARCH EVIDENCE

Urinary tract infections (UTIs) are among the most common health problems during pregnancy with an incidence between 17% and 20% of pregnancies. Yet they are not innocuous infections. UTI has been associated with premature rupture of the membranes, preterm labor, chorioamnionitis, postpartum fever, and neonatal infections. UTI can lead to serious maternal complications such as aseptic shock, respiratory insufficiency, fluid imbalance, chronic renal insufficiency, and even death.

There are many available drugs for the treatment of UTI. The ideal drug will be of proven effectiveness, active against a broad range of pathogens, inexpensive, well-tolerated, and safe for the fetus. Two large multisite randomized trials and a Cochrane Review focused on the relative effectiveness of five classes of antibiotics used to treat UTI. The cure rates for these treatments have been reported as between 70% and 100%. Drugs in these studies were delivered by IV or oral routes and in single-dose or multi-day regimens.

Only one class of drugs—the cephalosporins—had better cure rates and fewer recurrences than the other drugs. However, the size of difference was small and unlikely to have a broad clinical impact. Among all drugs, a single dose was less effective than a 3-, 5-, or 7-day regimen.

WHAT QUESTIONS REMAIN UNANSWERED?

Do any of these drugs produce effects for the child over the course of time? What is the effect of multiple courses of treatment during pregnancy if the infection is recurrent?

WHAT IS BEST PRACTICE?

Since all treatments had effective cure rates with very rare complications, it is reasonable to give the simplest and least costly available treatment. A single dose in the clinic will be the least effective, so women should be counseled to complete the entire course of treatment.

CRITICAL THINKING

What clinical evaluations can help the provider detect asymptomatic urinary tract infection? What education can help assure the mother will complete the entire medication regimen?

decreased due to the displacement of the bladder and ureters. With micturation, the pressure may increase with urine regurgitating into the ureters. Therefore, changes in the bladder and ureters and hormonal influences both contribute to the propensity of pregnant women to develop urinary tract infections (Blackburn, 2007).

Treatment in pregnant women includes amoxicillin-clavulanate, nitrofurantoin, cefixime, or fosfomycin (Chan & Johnson, 2008).

Lower Urinary Tract Infection (Cystitis and Urethritis)

Because UTIs ascend, it is important to recognize and diagnose a lower UTI early to avoid the sequelae associated with upper UTI. One common lower UTI is cystitis, or infection of the urinary bladder. Several factors place a woman at increased risk for cystitis, including sexual intercourse, the use of a diaphragm and a spermicide, pregnancy, and a history of a recent UTI.

E coli is present in 80% of women with UTIs. *Staphylococcus saprophyticus, Klebsiella, Proteus, Enterobacter,* and *Pseudomonas* are also causative pathogens. Infections without bacteriuria may indicate urethritis and are usually caused by *C trachomatis, N gonorrhoeae,* and herpes simplex.

When cystitis develops, the classic initial symptoms are often acute and include dysuria, specifically at the end of urination, as well as urgency and frequency. Suprapubic or low back pain may also occur. Cystitis is usually accompanied by a low-grade fever (38.3°C, or 101°F, or lower), and hematuria is occasionally seen. Urine specimens often contain an abnormal number of leukocytes and bacteria and may contain protein.

The diagnosis can be made with a urine culture. Bacteriuria dipstick screening tests are quick office screening tests; however, they have high false-positive and false-negative rates. Before treatment, the diagnosis should be confirmed by clinical evaluation and urine culture and sensitivity results. The treatment depends on the causative pathogen. Oral trimethoprim-sulfamethoxazole, trimethoprim, ciprofloxacin, norfloxacin, and levofloxacin are frequently used in twice daily dosing 3-day regimens. Second line drugs may include nitrofurantoin and fosfomycin for 7-day and 1-day regimens, respectively (Lehne, 2010).

Cystitis occurs in 0.3% to 1.3% of pregnant women (Chan & Johnson, 2008). A positive association exists between women with urinary tract infections and preterm birth. Pregnant women complaining of dysuria, urgency, and frequency with a urine culture greater than 10^2/ml from a midstream urine specimen would be diagnosed with cystitis. The most common treatment regimens include (Lehne, 2010):

- Nitrofurantoin (Macrodantin) 100 mg twice a day
- Cefpodoxime (Vantin) 500 mg twice a day to 4 times a day
- Amoxicillin-clavulanate (Augmentin) 500 mg twice a day or 250 mg 3 times a day, all for 3 to 7 days
- Fosfomycin 3 g by mouth as a single dose

For any of these medications, it is important to emphasize completion of the course of treatment.

Upper Urinary Tract Infection (Pyelonephritis)

Pyelonephritis (inflammatory disease of the kidneys) is less common but more serious than cystitis and is often preceded by lower UTI. It is more common during the second and third trimesters (80% to 90%) of pregnancy or early postpartum and poses a serious threat to maternal and fetal well-being (Archabald, Friedman, Raker, & Anderson, 2009). Women with pyelonephritis during pregnancy are at significantly increased risk of preterm labor, preterm birth, development of adult respiratory distress syndrome, and septicemia (Archabald et al., 2009). Acute pyelonephritis has a sudden onset with chills, high temperature of 39.6 to 40.6°C (103 to 105°F), and costovertebral angle tenderness or flank pain, which can be unilateral or bilateral. Nausea, vomiting, and general malaise may ensue. With accompanying cystitis, the woman may experience frequency, urgency, and burning with urination.

Edema of the renal parenchyma or ureteritis with blockage and swelling of the ureter may lead to temporary suppression of urinary output. This is accompanied by severe colicky (spastic, intense) pain, vomiting, dehydration, and ileus of the large bowel. The woman with acute pyelonephritis generally will have significant bacteria in her urine culture, pyuria, and the presence of white blood cell casts.

The woman may be hospitalized depending on the severity of her symptoms and started on intravenous (IV) antibiotics. Therapy also includes IV hydration, urinary analgesics such as Pyridium, pain management, and medication to manage fever. In the case of obstructive pyelonephritis, a blood culture is necessary. The woman is kept on bed rest. If signs of urinary obstruction occur or continue, the ureter may be catheterized to establish adequate drainage.

Initial IV treatment options include ceftriaxone (1 g IV every day), followed with oral ciprofloxacin, ofloxacin, levofloxacin, or gatifloxacin for 10 to 14 days. IV therapy should continue until the woman is afebrile for 48 hours. Oral antibiotics are given to complete the 10 to 14 days of therapy (Chan & Johnson, 2008). With appropriate drug therapy, the woman's temperature should return to normal, the pain subside, and the urine show no bacteria within 2 to 3 days. Follow-up urinary cultures are needed to determine that the infection has been eliminated completely.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

During the woman's visit, the nurse obtains a medical history, including a sexual history, to determine whether she is at risk for UTI. Additionally, the nurse notes any complaints from the woman of painful urination or other urinary difficulties and systemic complaints such as fever, chills, nausea, vomiting, flank or back pain. A clean-catch urine sample is obtained to evaluate for the presence of bacteriuria.

Nursing diagnoses that may apply to the woman with a UTI include the following:

- ***Acute pain*** related to dysuria, systemic discomforts, flank or back pain secondary to lower or upper urinary tract infection
- ***Deficient knowledge*** related to lack of understanding about ways of preventing UTIs related to an expressed desire to avoid recurrence
- ***Fear*** related to the possible long-term effects of the disease

Nursing Plan and Implementation

Most bacteria enter through the urethra after having spread from the anal area. Therefore, the nurse should make sure that the woman is aware of good hygiene practices and provide information on other ways to avoid UTI (Figure 6-5 ■ and Table 6-4). Additionally, the nurse provides the woman with information to help her recognize the signs and symptoms of a UTI to facilitate early identification and treatment of future infections. The nurse should also reinforce instructions and answer any additional questions the woman may have regarding the prescribed antibiotic and the reasons for

Figure 6-5 ■ The nurse counsels the woman about measures for preventing urinary tract infection.

TABLE 6-4 Health Promotion Education: Measures for Preventing Cystitis

- If you use a diaphragm for contraception, try changing methods or using another size diaphragm.
- Avoid bladder irritants, such as alcohol, caffeine products, and carbonated beverages.
- Make regular urination a habit; avoid long waits.
- Practice good genital hygiene, including wiping from front to back after urination and bowel movements.
- Be aware that initial, vigorous, or frequent sexual activity may contribute to urinary tract infection.
- Complete medication regimens even if symptoms decrease.
- Do not use medication left over from previous infections.
- Drink cranberry juice or take cranberry tablets to acidify the urine. This has been found to relieve symptoms in some cases.

these treatments. UTIs usually respond quickly to treatment, but follow-up clinical evaluation and urine cultures are important. Recurrent urinary tract infection can result from reinfection (80%) or relapse (Lehne, 2010). With frequent reinfections, defined as three or more infections yearly, long-term prophylaxis may be needed and can decrease the risk of recurrence by 95% (ACOG, 2008).

Evaluation

Expected outcomes of nursing care include the following:

- The woman implements self-care measures to help prevent recurrent UTI as part of her personal routine.
- The woman completes her prescribed course of antibiotic therapy.
- The woman can identify signs of recurrent UTI or signs and symptoms of worsening urinary symptoms that would require follow-up care.
- The woman's infection is cured.

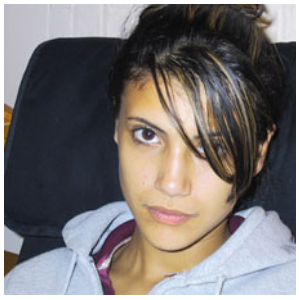
CLINICAL TIP

Evidence supports the value of drinking cranberry juice or taking cranberry tablets to decrease urinary tract infections (ACOG, 2008).

FOCUS YOUR STUDY

- Vulvovaginal candidiasis (moniliasis), a vaginal infection most often caused by *Candida albicans,* is most common in women who use oral contraceptives, are taking antibiotics, are currently pregnant, are immunosuppressed, or have diabetes mellitus. It is generally treated with intravaginal miconazole or clotrimazole suppositories or fluconazole orally.
- Bacterial vaginosis (BV), a common vaginal infection, is diagnosed by its characteristic fishy odor and by the presence of "clue" cells on a vaginal smear. It is treated with metronidazole.
- Chlamydial infection is difficult to detect in a woman but can result in pelvic inflammatory disease (PID) and infertility. It is treated with antibiotic therapy. It often coexists with gonorrhea.
- Gonorrhea, a common sexually transmitted infection, can be asymptomatic in women initially but can cause PID if not diagnosed early. The treatment of choice is ceftriaxone intramuscularly or cefixime orally. This is combined with azithromycin or amoxicillin to address the risk of coinfection with chlamydia.
- Herpes genitalis, caused by the herpes simplex virus, is a recurrent infection with no known cure. Acyclovir (Zovirax) may reduce the symptoms.
- Syphilis, caused by *Treponema pallidum,* is a sexually transmitted infection that is treatable if diagnosed. The characteristic lesion is the chancre. Syphilis can also be transmitted in utero to the fetus of an infected woman. The treatment of choice is penicillin.
- Condylomata acuminata (genital warts) are transmitted by the human papilloma virus (HPV). Treatment is indicated, because research has identified approximately 15 HPV genotypes linked with cervical cancer. The treatment chosen depends on the size and location of the warts and the woman's reproductive status. A vaccine is now available to prevent several types of HPV.
- Pelvic inflammatory disease can be life threatening and can lead to infertility. The organisms that cause PID most frequently include *C trachomatis* and *N gonorrhoeae. Mycoplasma genitalium* and bacterial vaginosis (BV) are increasingly being noted as pathogens causing PID.
- Women with an abnormal finding on a pelvic examination will need careful explanation of the finding and techniques of diagnosis and emotional support during the diagnostic period.
- The classic symptoms of a lower urinary tract infection (UTI) are dysuria, urgency, frequency, and sometimes hematuria. Oral sulfonamides are the treatment of choice except in middle to late pregnancy.
- An upper UTI is a serious infection that can permanently damage the kidneys if untreated. Generally the woman is acutely ill and may require supportive therapy as well as antibiotics.

CRITICAL THINKING IN ACTION



Cherelle Latkowski, age 18, was just diagnosed with gonorrhea by the nurse practitioner at the clinic where you work. Although she had been asymptomatic, she had come in for evaluation after her boyfriend was diagnosed with gonorrhea and started on antibiotics. Cherelle is treated with ceftriaxone administered intramuscularly plus doxycycline by mouth.

1. Cherelle asks you why she received two medications. How would you reply?
2. Cherelle asks you whether she is now immune to gonorrhea. Is she?
3. Cherelle asks whether she can now have sex with her boyfriend. Can she do so?

CHAPTER 7

Women's Health Problems

A friend was turning 42 years old a few months ago and knew that it was time for her annual gynecology exam. She had been putting off having her first mammogram because she had heard stories about how much it hurt. Finally, knowing that her nurse practitioner would ask her if she had gotten a mammogram, she scheduled the test the week before her annual gynecology exam. The mammogram detected a suspicious mass and she had a biopsy that confirmed intraductal carcinoma. She never had a palpable lump; she was not considered high risk for breast cancer; and she was an active, health-conscious woman. It never occurred to her that she could get breast cancer.

LEARNING OUTCOMES

1. Contrast the common benign and malignant breast disorders.
2. Describe the emotional reactions a woman may experience in regard to a diagnosis of breast cancer.
3. Summarize behaviors that help to minimize recurrence of some of the common lesions of the vulva.
4. Identify the implications of an abnormal finding during a pelvic examination.
5. Discuss abnormal uterine bleeding and abdominal masses.
6. Describe the role that human papilloma virus plays in abnormal Pap smears.
7. Discuss the importance of an annual Pap smear and appropriate follow-up for an abnormal finding.
8. Identify the risk factors, treatment options, and nursing interventions for a woman with toxic shock syndrome.
9. Discuss the signs and symptoms, medical therapy, and implications for fertility of endometriosis.
10. Discuss the signs and symptoms, diagnosis criteria, treatment options, and health implications of polycystic ovarian syndrome.
11. Compare the signs and symptoms and treatment options of the three forms of pelvic relaxation—cystocele, rectocele, and uterine relaxation.
12. Contrast laparoscope-assisted vaginal hysterectomy and abdominal hysterectomy with regard to indications for use and the advantages and disadvantages of each procedure.
13. Delineate the psychosocial responses a woman may experience when facing any of the common gynecologic procedures.

KEY TERMS

Breast self-examination (BSE) *117*
Colposcopy *132*

Pap smear *129*
Polycystic ovarian syndrome (PCOS) *137*
Toxic shock syndrome (TSS) *135*

From early childhood through adolescence, the active reproductive years, into menopause and the years beyond, a woman will likely face a variety of gynecologic or urinary problems. Some may be minor, whereas others have the potential to be quite serious, provoking a wide array of physical and psychologic responses. This chapter provides information about selected gynecologic problems that a woman may encounter during her lifetime with an emphasis on problems commonly addressed in community-based settings. Some of the issues are addressed in detail, and other topics are discussed more briefly. The chapter concludes with a brief description of common gynecologic surgical procedures. For a detailed discussion of gynecologic cancers, for more detailed information on any of the subjects covered in this chapter, or for more in-depth discussion of gynecologic procedures, please consult a specialized text.

Care of the Woman with a Disorder of the Breast

Throughout her lifetime a woman may experience a variety of breast disorders. Some, like mastitis, which is discussed in chapter 38 ∞, are acute disorders, whereas others, such as fibrocystic breast changes, also known as benign breast disease (BBD), are chronic. This section begins with breast screening techniques and then deals with some of the common breast disorders a woman may experience.

Screening Techniques for the Breasts

Despite their limitations, breast examination and mammography remain the most effective screening techniques available for disorders of the breast. However, the American Cancer Society (ACS) now recommends magnetic resonance imaging (MRI) in younger women who are at a higher risk for breast cancer due to gene mutations and/or a strong family history of breast cancer because they often develop breast cancer at a younger age (American Cancer Society [ACS], 2009a).

Breast Examination

Like the uterus, the breast undergoes regular cyclic changes in response to hormonal stimulation. Each month, in rhythm with the cycle of ovulation, the breasts become engorged with fluid in anticipation of pregnancy, and the woman may experience sensations of tenderness, lumpiness, or pain. If conception does not occur, the accumulated fluid drains away via the lymphatic network. *Mastodynia* or *mastalgia* (premenstrual swelling and tenderness of the breasts) is common and usually lasts for 3 to 4 days before the onset of menses. Some women may also experience mastalgia at the time of ovulation, about 14 days into her cycle; for other women the symptoms may persist throughout the month.

After menopause, connective breast tissue atrophies and is replaced by adipose tissue. The breasts lose elasticity and may droop and become pendulous. The recurring breast engorgement associated with ovulation ceases. If hormone therapy (HT) is used to counteract other symptoms of menopause, breast engorgement may resume.

Monthly **breast self-examination (BSE)** has been advocated for years as a good method for detecting breast masses early, and, in truth, a large percentage of women discover their breast cancer accidentally or during a BSE. Women at high risk for breast cancer are specifically encouraged to be attentive to the importance of early detection through routine BSE. BSE may also be of real value for younger women (under age 40) who do not yet get regular mammograms. The value of BSE, however, has been under continual scrutiny. The U.S. Preventive Services Task Force made a recommendation in November 2009 against teaching women breast self-examination. This was based on studies they reviewed that led the task force to believe that BSE did not reduce breast cancer mortality but resulted in additional imaging procedures and biopsies (U.S. Preventive Services Task Force, 2009). The American College of Obstetricians and Gynecologists (ACOG) continues to recommend that women begin performing monthly BSE at age 20 (ACOG, 2009b). The ACS recommends BSE be presented to the patient as an option with close attention to the patient's technique as reviewed at her annual examination (ACS, 2009a). Therefore, even in light of the conflicting recommendations, in the course of a routine physical examination, or during an initial visit to the caregiver, women are generally taught BSE technique. The effectiveness of BSE is determined by the woman's ability to perform the procedure correctly, by her knowledge of her own breast tissue, and by the density of her breast tissue. (See Patient Teaching: Breast Self-Examination.)

Advocates of BSE advise that it be performed on a regular monthly basis about 1 week after the onset of each menstrual period, when the breasts are typically not tender or swollen. BSE is most effective when it uses a dual approach incorporating both inspection and palpation. After menopause, BSE should be performed on the same day each month (chosen by the woman for ease of remembrance). The continuation of BSE during pregnancy and lactation is advised due to the increase in hormonal influence on the breast. Pregnancy-associated breast cancer (PABC) occurs in about 1 in 1000 pregnancies and about 3500 cases of PABC are diagnosed every year in the United States. PABC is classified as such if the diagnosis is made during pregnancy or within one year of giving birth (Logue, 2009).

Clinical breast examination (CBE) by a trained healthcare provider, such as a physician, nurse practitioner, or nurse-midwife, is an essential element of a routine gynecologic examination. Experience in differentiating among benign, suspicious, and worrisome breast changes enables the caregiver to reassure the woman if the findings are normal or move forward with additional diagnostic procedures or referral if the findings are suspicious or worrisome. The ACS (2009a) recommends CBE every 3 years for women age 20 to 39 with no abnormal findings or history of breast-related problems and CBE annually for women age 40 and older. In clinical practice, however, many caregivers advocate annual CBE for all women over age 20, which continues to be the recommendation of ACOG (ACOG, 2009b).

Mammography

A **mammogram** is a soft-tissue x-ray image of the breast taken without the injection of a contrast medium. It can detect lesions in the breast before they can be felt and has gained wide acceptance

PATIENT TEACHING Breast Self-Examination

PATIENT GOALS At the completion of the teaching, the woman will be able to:

1. Discuss her risk of breast cancer.
2. Describe the use of BSE in breast cancer detection.
3. Demonstrate the correct procedure for BSE.
4. List warning signs of breast cancer to be reported to the caregiver.
5. Incorporate monthly BSE into her personal routine.

TEACHING PLAN

Content	Teaching Method
Discuss the risk factors associated with breast cancer.	Breast cancer should be discussed in a private area free of interruptions. The room needs to have a mirror; a bed, a couch, or an examining table; pillows; a patient gown; and a private area for the woman to disrobe.
Stress the unique risk factors associated with the woman's personal history and lifestyle.	Create a supportive, warm, and comfortable atmosphere by attitude and communication style—both verbal and nonverbal. A discussion of breast cancer may bring forth many emotions in the woman, including grief for previous breast cancer–related losses.
Discuss the use of BSE in breast cancer detection.	Focus on open discussion. A brochure with statistics and illustrations may be useful. Stress the positive outcomes of early detection to counterbalance fears.

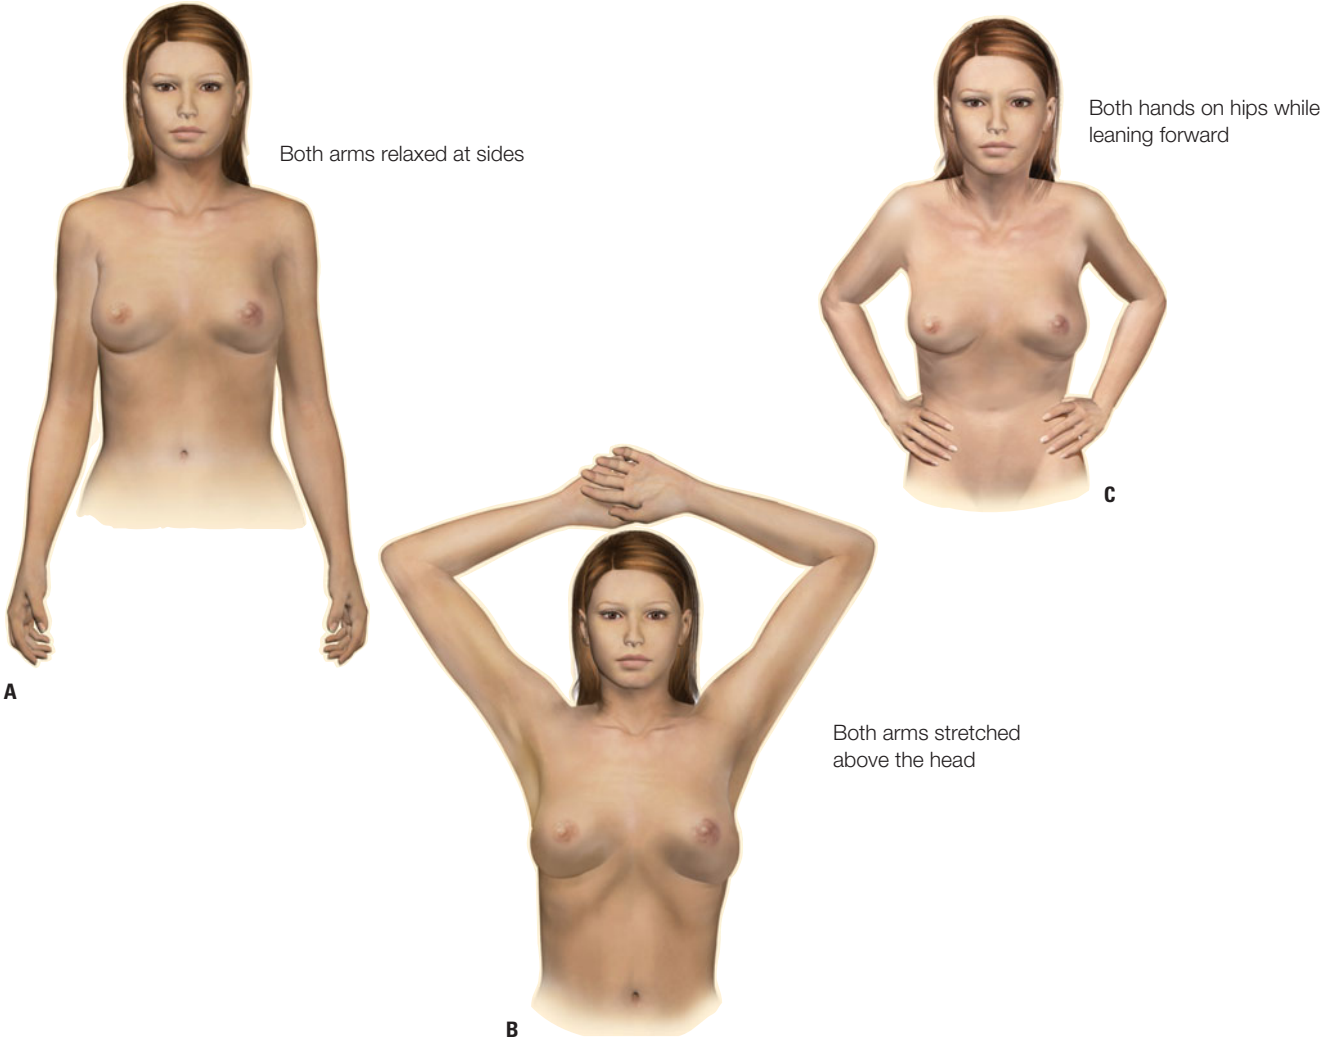

Figure 7-1 ■ Positions for inspection of the breasts. A. Both arms relaxed at sides. B. Both arms stretched above the head. C. Both hands on hips while leaning forward.

PATIENT TEACHING Breast Self-Examination continued

Describe and demonstrate the correct procedure for BSE.

A. Instruct the woman to inspect her breasts by standing or sitting in front of a mirror. She needs to inspect her breasts in three positions: with both arms relaxed down at her sides, both arms stretched straight over her head, and both hands placed on her hips while leaning forward (Figure 7-1 ■).

B. Advise the woman to look at her breasts individually and in comparison with one another. Note and record the following characteristics for each position:

Size and Symmetry of the Breasts

1. Breasts may vary, but the variations should remain constant during rest or movement—note abnormal contours.
2. Some size difference between the breasts is normal.

Shape and Direction of the Breasts

1. The shape of the breasts can be rounded or pendulous with some variation between breasts.
2. The breasts should be pointing slightly laterally.

Color, Thickening, Edema, and Venous Patterns

1. Check for redness or inflammation.
2. A blue hue with a marked venous pattern that is focal or unilateral may indicate an area of increased blood supply due to tumor. Symmetric venous patterns are normal.
3. Skin edema observed as thickened skin with enlarged pores ("orange peel") may indicate blocked lymphatic drainage due to tumor.

Surface of the Breasts

1. Skin dimpling, puckering, or retraction (pulling) when the woman presses her hands together or against her hips suggests malignancy.
2. Striae (stretch marks) red at onset and whitish with age are normal.

Nipple Size and Shape, Direction, Rashes, Ulcerations, and Discharge

1. Long-standing nipple inversion is normal, but an inverted nipple previously capable of erection is suspicious. Note any deviation, flattening, or broadening of the nipples.
2. Check for rashes, ulcerations, or discharge.

C. Instruct the woman to palpate (feel) her breasts as follows:

1. Lie down. Put one hand behind your head. With the other hand, using the three middle fingers with fingers flattened, gently feel your breast (Figure 7-2A ■).
2. Figure 7-2B ■ shows you how to check each breast. Begin as you see in B and follow the arrows, moving in an up and down pattern starting from the underarm and progressing toward the sternum. Be sure to cover all the tissue, going up to the collarbone and down until you feel the ribs. Feel gently for a lump or thickening.
3. Now repeat the same procedure sitting up, with the hand still behind your head (Figure 7-2C ■).
4. Squeeze the nipple between your thumb and forefinger. Look for any discharge—clear or bloody (Figure 7-2D ■).

D. Take the woman's hand and help her to identify her "normal lumps" (e.g., mammary ridge, ribs, and nodularity in the upper outer quadrants).

E. After she examines her breasts and identifies her normal lumps, instruct her to palpate her breasts once more to identify any areas that she may have questions about. If questions arise, the nurse should palpate the area and attempt to identify whether it is normal.

Learning is best accomplished when material is broken down into smaller steps and presented with multiple approaches. Prior to asking the woman to perform BSE, use a model or a chart to demonstrate the procedure. Then have the woman perform BSE. Be very supportive and give a lot of positive feedback because some women may be embarrassed. Demonstrate a nonjudgmental, accepting attitude.

Demonstrate "normal lumps" on the woman herself while guiding her hand and identifying the area. This will increase confidence that she will recognize an abnormal finding. Checking her immediately afterward will positively reinforce her and diminish the fear associated with BSE.

Figure 7-2 ■ Procedure for breast self-examination.

F. If a breast model is available, instruct the woman to palpate it and identify the lumps.

G. Provide information on the warning signs of breast cancer and what she should do if she identifies any of these signs during BSE.

(continued)

PATIENT TEACHING Breast Self-Examination continued

Timing

Instruct the woman to perform BSE on a monthly basis. Be specific based on whether she is premenopausal, pregnant, postmenopausal, or postmenopausal receiving hormone replacement therapy.

Evaluation

Evaluate the woman's learning through discussion and return demonstration. Learning has occurred if the woman performs BSE correctly and can identify timing, normal and abnormal findings, and follow-up activities.

Provide a written handout on the warning signs of breast cancer. The handout should also cover actions that the woman should take if a warning sign is discovered. Stress the positive effects of early detection.

Provide the woman with a reminder symbol for monthly BSE. The American Cancer Society provides such items to hang in the shower, place on a refrigerator, and so forth. Praise her commitment to do monthly BSE. Give the woman a follow-up telephone number (e.g., American Cancer Society) to use if she needs additional information or has questions.

Documentation

Documentation of patient teaching should include the teaching information discussed, the patient's verbalization of understanding, and specific interventions or warning signs that were given, along with the patient's understanding of follow-up if needed in the future.

as an effective screening tool for breast cancer. Research indicates that mammography detects about 90% of breast cancers in women who are symptom free, although it is slightly more accurate in postmenopausal women, as compared with premenopausal women (ACS, 2006). Currently the ACS (2009c) guidelines recommend that all women age 40 and over have an annual mammogram and, as discussed previously, an annual CBE. ACOG concurs with ACS recommendations. The National Cancer Institute (NCI) (2009a) recommends mammograms every 1 to 2 years for women age 40 and older. The NCI also recommends that women who are at higher than average risk of breast cancer should talk with their healthcare providers about whether to have mammograms before age 40 and how often to have them. If a woman has a history of breast cancer in a close relative (i.e., mother, sister) and the cancer was diagnosed before the relative was age 40, many clinicians advocate that the patient begin mammograms 10 years before the age of her close relative's diagnosis.

The sensitivity of mammography in accurately diagnosing a breast cancer increases with age (83% to 92%) and presence of a palpable mass (90%). It decreases in accuracy in women with increased breast density (35%). Overall it carries a 63% to 95% accuracy in women over 40 (Singhal, 2008). This is why clinicians favor the triple assessment protocol in women that starts with clinical breast examination to assess for lumps and lymph nodes. If a lump is found, the examination is then followed by a mammogram or ultrasound for further information on the consistency of the palpable lump. Fine-needle aspiration will follow if the lump in question appears suspicious on imaging (Singhal, 2008).

Breast sensitivity seems to vary from woman to woman and may be a factor in a woman's reluctance to have a mammogram.

Figure 7-3 ■ Recommended position for mammogram.
Source: Philip Bailey/CORBIS.

To help prevent any discomfort, the nurse can suggest that this x-ray study be scheduled when the woman's breasts are least sensitive, which is about 2 weeks after the onset of menses. In some cases, the woman can obtain relief by reducing caffeine intake from 5 to 7 days before the test. In most cases, a mammogram causes feelings of compression but not pain (Figure 7-3 ■). All women should be instructed to refrain from applying lotions, powders, deodorant, or other cosmetic substances to the torso on the day of the exam because the substances may appear as questionable areas on the mammogram and can interfere with accurate interpretation. The risk of radiation exposure with mammograms is low because strict guidelines are in place to ensure that the equipment is safe and uses the lowest dose of radiation possible. The level of radiation used does not significantly increase the risk for breast cancer (ACS, 2009c).

Benign Breast Conditions

Fibrocystic breast change, also known as benign breast disease (BBD), occurs in 50% to 60% of all women (Lee, 2009). Fibrocystic changes are the most common type of BBD and are most prevalent in women 20 to 50 years of age. Generally fibrocystic changes are not a risk factor for breast cancer. In some rare cases, if the change is proliferative and results in hyperplasia or buildup of the cells of the breast ducts, atypia may occur (Lee, 2009). There is a four- to five-fold increase in the risk of breast cancer in these women (Gordon et al., 2007). Fibrocystic changes may produce an asymptomatic mass but more often are accompanied by pain or tenderness and sometimes nipple discharge. Fluctuations in size and rapid appearance or disappearance of breast masses are common. Bilateral, cyclic breast pain is the most common symptom, and the nodularities may be unilateral or bilateral, often in the upper outer quadrants of the breasts.

The woman often reports pain, tenderness, and swelling that is cyclic, worsening in the late luteal phase of the menstrual cycle (just before menses) and improving about 1 to 2 days into the menstrual cycle. Physical examination may reveal only mild signs of irregularity, or the breasts may feel dense, with areas of irregularity and nodularity. Women often refer to this as "lumpiness." Some women may also experience spontaneous nipple discharge, which should be evaluated separately.

If the woman has a large, fluid-filled cyst, she may experience a localized painful area as the capsule containing the accumulated fluid distends coincident with her cycle. However, if small cysts form, the woman may experience not a solitary tender lump but a diffuse tenderness. Several characteristics help differentiate a cyst from a cancerous lesion. Cysts tend to be mobile and tender and do not cause skin retraction (pulling) in the surrounding tissue, whereas cancerous lesions tend to be fixed and painless and may cause skin retraction.

Mammography, sonography, magnetic resonance imaging (MRI), palpation, and fine-needle aspiration can be used to confirm fibrocystic breast changes. Often, fine-needle aspiration provides treatment as well as relief from the tenderness or pain. Palpable cysts are often treated conservatively with medical management; however, all discrete masses should have a tissue sample sent for biopsy. Women with mild symptoms may benefit from restricting sodium intake and taking a mild diuretic during the week before the onset of menses. This counteracts fluid retention, relieves pressure in the breast, and helps decrease the pain. In other cases, a mild analgesic is necessary. Oral contraceptives help alleviate symptoms for the majority of women, but, unfortunately, symptoms tend to recur when the oral contraceptives are discontinued. Oil of evening primrose is often recommended and may reduce the symptoms of premenstrual breast tenderness (Gordon et al., 2007).

In severe cases, the hormone inhibitor danazol is often helpful although it can cause several undesirable side effects such as nausea, depression, menstrual irregularities, headaches, and masculinization (Gordon et al., 2007). Women who do not respond to other treatment approaches may be given a trial of bromocriptine, a prolactin inhibitor. Some researchers suggest that methylxanthines (found in caffeine products such as coffee, tea, colas, chocolate, and some medications) and the use of tobacco may contribute to the development of fibrocystic breast changes and that limiting use of these substances will help decrease fibrocystic changes.

Fibroadenoma is the second most common benign breast lesion, occurring in 25% of women with the peak incidence at 15 to 35 years. It is an asymptomatic, mobile, well-defined, painless palpable mass with a rubbery texture. Women with no family history and a simple fibroadenoma are at no greater risk for breast cancer than the general population.

Ultrasound is the best method for imaging women under 35 with a palpable mass because of the density of their breast tissue. Most women can be observed and followed every 6 months with ultrasound for 2 years then once yearly thereafter. Some clinicians may prefer surgical excision to prove that it is benign (Lee, 2009).

The term for nipple discharge not associated with lactation (production of milk for breastfeeding) is **galactorrhea**. It is a common breast problem and has been reported in 10% to 15% of women. Nipple discharge can occur in patients of all ages and races and generally is a nonsignificant finding. Nonclinically significant nipple discharge occurs in women who have fibrocystic changes in the breast, who are using contraceptives,

or who are on hormone therapy (Azavedo, 2009). Certain medications that are used to treat psychiatric disorders have a side effect of galactorrhea.

The most common types of nipple discharge occur in both breasts, are secreted from several ducts, and vary in color from white to brown. The likelihood of malignancy increases with the presence of a spontaneous discharge arising from a single duct in one breast that is watery or bloody in nature and warrants further investigation. Cytologic evaluation of the fluid can be performed; however, false-positive and false-negative rates have been reported as high as 17.8%. Mammogram is used initially for evaluation. Ultrasound may be used if the nipple discharge is accompanied by a palpable mass or if positive findings are seen on the mammogram (Azavedo, 2009).

Intraductal papillomas are tumors growing in the terminal portion of a duct or, sometimes, throughout the duct system within a section of the breast. Symptoms may include a unilateral mass or a spontaneous, and often bloody, nipple discharge.

The majority of papillomas present as solitary nodules. These small ball-like lesions may be detected on mammography but often are nonpalpable. The presence of a papilloma is often frightening to the woman, because her primary symptom is a discharge from the nipple that may be serosanguineous or brownish green because of old blood. The location of the papilloma within the duct system and its pattern of growth determine whether nipple discharge will be present. They are typically benign but they are generally excised to rule out the possibility of cancer. A solitary papilloma carries a slightly increased risk of developing into a cancer (Lee, 2009).

Duct ectasia (comedomastitis), an inflammation of the ducts behind the nipple, commonly occurs during or near the onset of menopause and is not associated with malignancy. The condition typically occurs in women who have borne and nursed children. It is characterized by a thick, sticky nipple discharge of various colors and by burning pain, pruritus, and inflammation. Nipple retraction may also be noted, especially in postmenopausal women. Treatment is conservative with drug therapy aimed at symptomatic relief. The major central ducts of the breast occasionally have to be excised.

Table 7-1 provides a comparison of the most frequently seen benign breast disorders.

Malignant Breast Disease

Breast cancer constitutes 25% of all cancers in women, making it the most prevalent cancer in females. The lifetime risk of women developing breast cancer in the United States is 1 in 8. Breast cancer accounts for nearly 15% of all cancer deaths in women and is the leading cause of death in women between the ages of 44 and 50 years. Of women who receive a breast cancer diagnosis, 70% to 80% of them will have no family history (ACS, 2009a). The highest incidence of breast cancer occurs in North America and Western Europe with the lowest incidence in South America, Africa, and parts of Asia; immigrants to the United States take on the higher U.S. risk. In the United States it is most common in Caucasian women; African American and Hispanic women have lower occurrence rates (Singhal, 2008).

Predisposing Factors

Factors that predispose a woman to breast cancer include the following:

- Age. Incidence increases steadily with age.
- Female gender.
- History of previous breast cancer.

TABLE 7-1 Summary of Benign Breast Disorders

CONDITION	AGE	PAIN	CANCER RISK	NIPPLE DISCHARGE	LOCATION	CONSISTENCY AND MOBILITY	DIAGNOSIS AND TREATMENT
Fibrocystic breast changes	30–50	Yes	Yes: with proliferative disease and a typical hyperplasia	Varies: none at all or may be clear, milky, straw colored, or green	Upper outer quadrant	Multiple lumps occurring bilaterally, influenced by menstrual cycle, nodular	Needle aspiration, Pap smear of nipple discharge, observation, biopsy if unresolved mass exists or mammographic changes, sonography
Fibroadenoma	15–25, median age 20	No	No	No: but milky discharge in pregnancy	Nipple or upper outer quadrant along the lateral side	Solid, well defined, sharply delineated, rounded rubbery mobile	Mammography, observation, surgical excision
Intraductal papilloma	Menopausal 50–60	Yes: on palpation	Yes: with multiple papillomas	Yes: serous bloody, or brownish green	No specific location	Nonpalpable or small, ball-like, poorly delineated	Pap smear of nipple discharge, mammography ductogram; surgical, excision
Duct ectasia	45–55	Yes: burning and itching around the nipple	No	Yes: in perimenopausal women: thick, sticky, green, greenish brown or bloodstained	Mass behind or around the nipple	Poorly circumscribed inflammation, nipple retraction, axillary lymphadenopathy	Pap smear of breast discharge, mammography, drug therapy for symptoms, surgical excision, observation.

- Have a known BRCA1 or BRCA2 gene mutation, or have a first-degree relative with this gene mutation.
- Family history of mother, sister, or daughter with breast cancer. The lifetime risk is up to 4 times higher if mother or sister is affected (Singhal, 2008).
- Long-term (more than 5 years) postmenopausal combined estrogen and progestin HT (ACS, 2009a).
- Being overweight or obese after menopause.
- Alcohol consumption. This risk increases with the amount of alcohol consumed (ACS, 2009a).
- No history of pregnancy or first pregnancy after age 30.
- Never breastfeeding a child.
- Longer reproductive phase (early menarche [before age 12] and late menopause [after age 50]).
- History of high-dose radiation to the chest between the ages of 10 and 30 (ACS, 2009a).
- Physical inactivity.
- Ashkenazi Jewish descent.

DEVELOPING CULTURAL COMPETENCE

Breast Cancer Survival Rates

While death rates due to breast cancer continue to drop among African American women, the group continues to be diagnosed at advanced stages and have decreased survival rates at each stage of diagnosis compared to their white counterparts (ACS, 2009a).

Prevention

Women should be encouraged to take action to reduce modifiable risks for breast cancer. These include, for example, avoiding obesity, exercising regularly, reducing dietary fat, and limiting alcoholic intake. Women at high risk of breast cancer may choose to begin chemoprevention using the drug tamoxifen. Women at very high genetic risk may consider bilateral prophylactic mastectomy (ACS, 2009b).

Diagnosis

A malignant neoplasm may originate either in a duct or in the epithelium of the breast lobes. About 50% of breast cancers originate in the upper outer quadrant and spread or metastasize to the axillary lymph nodes. Common sites of distant metastasis are the lymph nodes, lungs, liver, brain, and bone.

As previously discussed, a cancerous lump may be discovered by the woman herself, by the clinician who palpates or observes an abnormality, or by mammogram. A painless mass or lump is the most important physical symptom of breast cancer, although up to 10% of women have breast pain but no palpable mass (ACS, 2009a). Early detection greatly improves the treatment options available and increases women's long-term survival rates.

Worrisome findings that point to a higher risk of breast cancer include dimpling of the breast tissue, recent or acute nipple inversion, change in breast size or shape, increase of size in breast mass, skin erosion or ulceration, or presence of an axillary lump. Routine mammography screening detects masses 2 to 3 years before clinical appearance. Other diagnostic modalities include fine-needle biopsy, ultrasonography, and MRI. Biopsy is essential for a diagnosis. Once the diagnosis is made and lymph node involvement is evaluated, clinical staging of the disease is determined and a treatment plan that coincides with the stage is initiated.

Clinical Therapy

Once breast cancer is diagnosed, the woman and her physician make treatment decisions together. The decision is based on a consideration of the following factors:

- Stage of cancer
- Optimal treatment for that stage
- Woman's age
- Personal preferences
- Risks and benefits of each treatment protocol

Most women diagnosed with breast cancer have some form of surgery. The primary goal of the surgery is to remove the cancer from the breast and the lymph nodes, if they are involved. Surgical treatment may consist of *simple* or *total mastectomy,* which involves removal of the entire breast. A *modified radical mastectomy* involves the removal of the breast and the axillary lymph nodes but does not include removal of any of the pectoral muscles of the chest wall. Women who undergo mastectomy are generally given the option of having breast reconstruction surgery. This surgery may be done at the time of the mastectomy or delayed until the prescribed chemotherapy and/or radiation is completed. *Lumpectomy,* or the removal of the cancerous tissue plus a rim of normal tissue, is a breast-sparing approach that is often used for women with stages I or II breast cancer. It is almost always followed by several weeks of radiation therapy to destroy any remaining cancerous cells.

Adjunctive therapy for breast cancer includes chemotherapy, radiation, and hormone therapy. Chemotherapy typically involves a combination of drugs known to combat breast cancer. As indicated previously, radiation is often used to destroy remaining cells following surgery, but it may also be used to reduce the size of a cancerous tumor before surgery. This is termed neoadjuvant therapy. Hormone therapy is based on the knowledge that the hormone estrogen, which is produced by the ovaries, stimulates certain types of breast cancer. Women who have a form of breast cancer that tests positive for estrogen receptors can be given the antiestrogen drug tamoxifen. Tamoxifen counters the effects of circulating estrogen in the body to reduce the risk that the cancer returns or spreads to another area of the body. It is also used for cancer prevention by women who are at high risk for developing breast cancer. This drug has side effects and women taking it need to be monitored closely. Women using tamoxifen are at a higher risk for uterine cancer and should be counseled to follow up with their healthcare provider if they experience any unusual vaginal bleeding or resume menstrual cycles if they are postmenopausal. Blood clots are another risk, and the patient should be counseled about signs and symptoms of this (ACS, 2009b).

Raloxifene, a selective estrogen receptor modulator (SERM), is used to prevent osteoporosis. However, it was shown to be even

more effective than tamoxifen in decreasing the risk of breast cancer in postmenopausal women who were taking it for osteoporosis.

Aromatase inhibitors are drugs that stop the body from making estrogen. These are given to postmenopausal women only and to those whose cancers were estrogen receptor positive (ACS, 2009b). These have been shown to prevent the return of breast cancer and are often given in place of tamoxifen or after the 5-year course of tamoxifen for further prevention. The studies show that when given after the completion of tamoxifen therapy, survival clearly improves (Kaunitz, 2008). The side effects of blood clots are much less than with tamoxifen and there is no risk for developing uterine cancer with this medication.

Herceptin, a newer drug, is a man-made version of an immune system protein. A growth-promoting protein called HER2/neu is found in small amounts on the surface of normal breast cells and in large amounts in some breast cancer cells. Herceptin is given to women whose breast cancers have too much HER2/neu to stop this protein from causing breast cancer cell growth. It is also thought to help the immune system better fight the breast cancer (ACS, 2009b).

Some women prefer a combined approach to treatment that draws on both allopathic and complementary medicine. These women elect to use complementary therapies, such as herbal remedies, Therapeutic Touch, acupuncture, aromatherapy, and massage, in combination with medical treatments.

When a woman is confronted with a breast cancer diagnosis, she must decide which therapy is worth what personal risk for her. Although prompt treatment is indicated, a second opinion is encouraged. Care of the woman with breast cancer involves a multidisciplinary approach, including a primary care provider, radiotherapist, surgeon, medical oncologist, and nursing specialists.

Psychologic Adjustment

The emotional feelings a woman experiences can range from fear of the loss of a body part, to fear of the ill effects of treatments, to fear of death and leaving children and family behind. The nurse should encourage the woman to discuss her feelings and concerns, informing her of all procedures, their pros and cons, and alternative options.

The course of adjustment confronting the woman with cancer has been described in four phases: shock, reaction, recovery, and reorientation. In the *shock* phase, women make statements such as "Everything is unreal" or "I can't understand why this is happening to me." Shock generally extends from the discovery of the lump through the process of diagnosis.

Reaction occurs in conjunction with the initiation of treatment. As treatment begins, the woman is compelled to face what has occurred and begins to take in what has happened. Coping mechanisms become evident during this phase. Reaction coincides with the length of treatment. For many women, radiation treatment or chemotherapy prolongs this period to months. Treatment reinforces the diagnosis of cancer and the immediate consequences of the disease. Denial of breast loss, if a mastectomy is done, and denial of the reality of the illness are common responses by the woman during the periods of diagnosis and treatment. Denial protects the woman, making therapy tolerable.

Recovery begins during convalescence following the completion of medical treatment. Anxiety about her illness diminishes and the woman looks to the future once more. She turns outward and gradually resumes her former activities. Conversely, depression and social isolation occur if the woman is unable to negotiate the recovery phase successfully.

A woman's family and friends significantly influence her recovery. Women often perceive their partners as their primary source of support. Both members of a couple must adjust to the woman's condition and its implications as well as to the effect of therapy on their sexual intimacy. Difficulties with psychosocial adjustment to breast cancer tend to be similar for women and their partners except in the area of role adjustments, where women have more difficulties. Many hospitals and community agencies sponsor support groups for women with breast cancer. Online support groups are also available and are of particular value to women in rural areas and in areas that lack adequate community support. In addition, the ACS sponsors support groups for cancer survivors and their families. They also have a highly successful program, "Reach to Recovery," for women following surgery.

Reorientation follows recovery and can be challenging. It is accomplished when the woman can acknowledge that breast cancer is part of her life; yet living, for her, has returned to or perhaps exceeded its former fullness and meaning.

For additional information on breast cancer, refer to a medical-surgical text.

> "The physician also felt the lump and thickening, and now I'm waiting to have my mammogram. My thoughts and feelings since I first felt the lump have been like a roller coaster. I'm 46 and I'm wondering if this is it. Am I dying? Now? I am afraid as I have not been afraid since one of our children was very ill."

NURSING CARE MANAGEMENT

Nursing care of the woman with breast cancer is multidimensional. It involves meeting the educational, psychosexual, and physical needs of the woman and, to a certain extent, those of her family. In meeting these needs, the nurse functions as a caregiver, counselor, educator, liaison, and advocate. Nurses need to support women in their efforts to provide self-care. This increases their self-esteem and sense of control. Nursing care changes as the woman progresses from the period of diagnosis to the period of recovery.

Nursing Assessment and Diagnosis

During the period of diagnosis of any breast disease, the woman may be extremely anxious. The nurse can use therapeutic communication to assess the significance the woman places on her breasts; her current emotional status, coping mechanisms used during periods of stress, and knowledge and beliefs about cancer; and other variables that may influence her coping and adjustment.

Assessment is an ongoing process. Sufficient data must be obtained to provide the nurse and other members of the healthcare team with increasing insight into the woman's physical, mental, emotional, and social situation.

Nursing diagnoses that may apply to a woman with a disorder of the breast include the following:

- ***Readiness for Enhanced Knowledge:*** Information about diagnostic procedures for suspected breast cancer related to an expressed wish for information
- ***Anxiety*** related to threat to body image or her life

Nursing Plan and Implementation

During the prediagnosis period, the nurse should provide emotional support, clarify misconceptions, encourage the woman to express her anxiety, and urge her to ask many questions. Once a diagnosis has been made, the nurse should ensure that the woman clearly understands her condition, its association to breast malignancy, and treatment options. The nurse can also locate appropriate resources in the community and encourage the woman to make use of them as she deals with this difficult time. The woman and her partner or support person should discuss the treatment alternatives with her healthcare provider. Nursing advocacy involves supporting the woman's right to make the best treatment decision for her. With the assistance of the nurse, the woman can explore her fears, clarify her values, and identify the treatment options that would be personally acceptable. The nurse can provide psychologic support for the woman with a troublesome diagnosis, supply her with patient education materials, and refer her to professional support groups.

For women who must undergo surgery, nursing care focuses on necessary perioperative interventions. Refer to a medical-surgical nursing textbook for detailed information on these aspects of nursing care.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to discuss her fears, concerns, and questions during the period of diagnosis.
- The diagnosis is made quickly and accurately, and treatment is initiated, if indicated.

Care of the Woman During a Pelvic Examination

Women have a pelvic examination performed for a variety of reasons, ranging from health maintenance to disease diagnosis. Many women perceive the pelvic exam as an uncomfortable and embarrassing procedure. These negative feelings may cause women to delay having yearly gynecologic examinations, and this avoidance may pose a threat to life and health.

A woman's first pelvic examination is especially important because a positive experience can help allay anxiety and make subsequent pelvic exams less threatening. Because the initial pelvic examination is typically done when a young woman is a teenager, nurses should be sensitive to a teen's attitudes and concerns. Teens are often shy about revealing their bodies and may feel very embarrassed by the procedure. Nurses can also help by being alert for atypical responses that might indicate a history of sexual abuse.

To make the pelvic exam less threatening, and hopefully improve the woman's health-seeking behavior, it is important to create a trusting atmosphere and incorporate practices that help the woman maintain a sense of control. Additionally, it is important for the nurse to assist in facilitating a nonjudgmental and safe environment in which the woman can be honest in response to the medical providers' inquiries. Some healthcare providers are offering to perform what is called an educational pelvic exam. During this type of exam the woman becomes an active participant and has an opportunity to learn about her body, voice her concerns, and share decisions about her care.

The educational exam includes offering the woman a mirror to watch the procedure, pointing out anatomic parts to her, and positioning and draping her to allow eye-to-eye contact with the practitioner. The woman is encouraged to participate by asking questions and giving feedback. The nurse can assist the woman by encouraging her to relax with specific advice such as "Keep your bottom flat against the table" and "Wiggle your toes if you find yourself beginning to tense your muscles."

Nurse practitioners, certified nurse-midwives, and physicians all perform pelvic examinations. Nurses assist the practitioner and the woman during the examination. Procedure 7-1 provides information on assisting with a pelvic examination.

The pelvic examination consists of three segments: inspection of the vulva; inspection of the vagina and the cervix via a speculum examination; and palpation of the cervix, uterus, and ovaries via a bimanual examination. Often a Papanicolaou (Pap) smear is obtained during the speculum examination. The Pap smear is discussed in the section on abnormal Pap smear results, which begins on page 129.

Vulvar Self-Examination

During the pelvic examination many caregivers also provide education about self-examination of the vulva. This procedure, like breast self-examination (BSE) (discussed previously), permits early detection of abnormalities, thereby maximizing the possibility of early diagnosis and treatment.

Self-examination of the vulva is simple to perform. The woman is advised to assume a sitting position on a bed or a chair. In good light she holds a mirror in one hand and uses the other hand to expose the tissues of her perineum while she carefully inspects and palpates the area. Pregnant or obese women may find it easier to inspect this area in a standing position with one foot elevated on a low stool. Figure 7-4 ■ shows the correct procedure for vulvar self-examination.

Initially, the woman inspects the entire perineum for symmetry, discharge, and lesions. She then gently pushes back the hood of the clitoris to inspect this area. Next she separates the labia to examine the inner tissues. The woman gently palpates the vulva using the flat part of one or two fingers. Then, using her thumb and index finger, the woman palpates the lateral aspects of the genitalia along the length of the vulva, noting any tenderness, masses, or lesions. Lastly, the woman examines the vaginal opening, compressing the tissues between the index

PROCEDURE 7-1 Assisting with a Pelvic Examination

NURSING ACTION

Preparation

- Ensure that the room is sufficiently warm by checking room temperature and adjusting the thermostat if necessary. If overhead heat lamps are available, turn them on.
- Explain the procedure to the woman. If she has never had a pelvic examination, show her the equipment to be used as part of the explanation.

  Rationale: *Explaining the procedure helps reduce anxiety and increase cooperation.*
- Ask the woman to empty her bladder and to remove clothing below the waist.

  Rationale: *An empty bladder promotes comfort during the internal examination.*
- Have padding on the stirrups. If stirrups are not padded, the woman may prefer to leave her shoes on during the procedure.

  Rationale: *Stirrups are padded to ease the pressure of the feet against the metal and to decrease the discomfort associated with cold stirrups. If they are not padded, wearing shoes accomplishes the same purpose.*
- Give the woman a disposable drape or sheet to use during the exam. Ask her to sit at the end of the examining table with the drape opened across her lap.
- Position the woman in the lithotomy position with her thighs flexed and abducted. Place her feet in the stirrups. Her buttocks should extend slightly beyond the edge of the examining table.

  Rationale: *This position provides the exposure necessary to conduct the examination effectively.*
- Drape the woman with the sheet, leaving a flap so that the perineum can be exposed.

  Rationale: *The drape helps preserve the woman's sense of dignity and privacy.*

Equipment and Supplies

- Vaginal specula of various sizes, warmed with water or on a heating pad prior to insertion
- Sterile gloves
- Water-soluble lubricant
- Materials for Pap smear or ThinPrep® Pap test and cultures
- Good light source

Note: *Lubricant may alter the results of tests and cultures and is not used during the speculum examination. Its use is reserved for the bimanual examination.*

Procedure: Sterile Gloves

1. The examiner dons gloves for the procedure. Explain each part of the procedure as the certified nurse-midwife, nurse practitioner, or physician performs it. Let the woman know that the examiner begins with an inspection of the external genitalia. The speculum is then inserted to allow visualization of the cervix and vaginal walls and to obtain specimens for testing (e.g., Pap smear). After the speculum is withdrawn the examiner performs a bimanual examination of the internal organs using the fingers of one hand inserted in the woman's vagina while the other hand presses over the woman's uterus and ovaries. The final step of the procedure is generally a rectal examination.
2. Ask the woman to breathe slowly and regularly and to use any method she finds effective in helping her to remain relaxed.

   Rationale: *Relaxation helps decrease muscle tension. Bearing down helps open the vaginal orifice and relaxes the perineal muscles.*
3. Let her know when the examiner is ready to insert the speculum and ask her to bear down.
4. After the speculum is withdrawn, lubricate the examiner's fingers prior to the bimanual examination.

   Rationale: *Lubrication decreases friction and eases insertion of the examiner's fingers.*
5. After the examiner has completed the examination and moved away from the woman, move to the end of the examination table and face the woman. Cover her with the drape. Apply gentle pressure to her knees and encourage her to move toward the head of the table. Assist her to remove her feet from the stirrups, then offer your hand to her and assist her to sit up.

   Rationale: *Assistance is important because the lithotomy position is an awkward one and many women, especially those women who are pregnant, obese, or older, may find it difficult to get out of the stirrups.*
6. Provide her with tissues to wipe the lubricant from her perineum.

   Rationale: *Vaginal secretions and lubricant may be discharged from the vagina when the woman sits upright.*
7. Provide the woman with privacy while she dresses. Be sure that she is not dizzy and that she is standing or sitting safely before leaving the room.

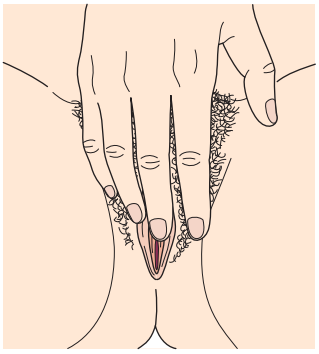
   Rationale: *Lying supine may cause postural hypotension.*

CLINICAL TIP

With the examiner's consent (obtained beforehand), offer the woman a hand mirror so that she can watch all or part of the examination. This practice removes the "mystery" from the procedure and enables the woman to become familiar with the appearance of her body.

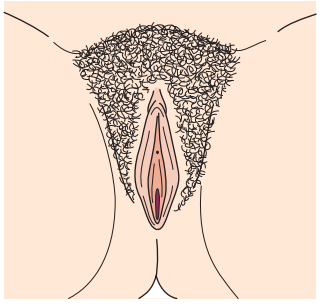
A

Choose a position that is comfortable and exposes the labia. To make viewing easier, use a mirror with a handle.



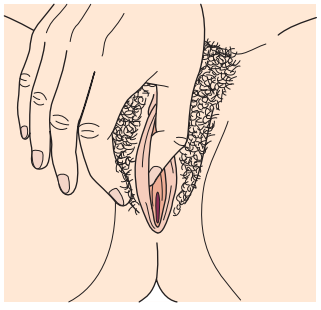
E

Press all areas of the vulva with the flat part of the fingers.



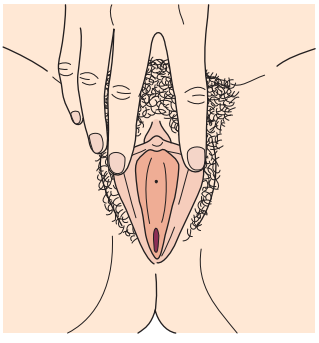
B

Observe the entire vulva and determine whether one side resembles the other.



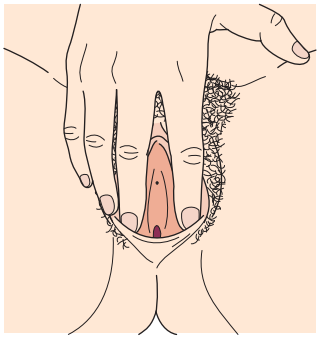
F

Insert the thumb inside the labia and palpate the area between the thumb and the index finger.



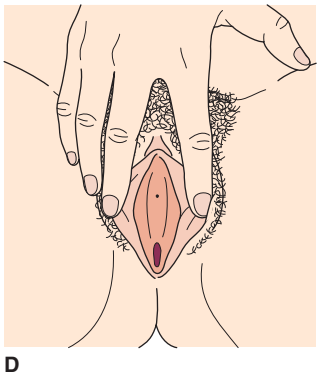
C

Gently push back the covering, or the hood, of the clitoris to inspect the area.



G

Encircle the vaginal opening with index and middle fingers and compress the tissue. The tissue should be soft, moist, elastic, and nontender.



D

Separate the labia with the fingers and examine the inner parts.

Figure 7-4 ■ Steps to follow to perform vulvar self-examination.

and middle fingers. The tissues should be soft, moist, nontender, and elastic. Any abnormalities should be reported to the woman's healthcare provider.

This exam should be performed monthly, at the same time as the BSE, in all sexually active asymptomatic women or women over the age of 18. Women with a history of vulvar lesions or women with adverse symptoms should inspect their vulva more frequently.

Care of the Woman with Vulvitis

The term *vulvitis* refers to an inflammation of the vulva or external female genitalia. Sometimes vulvar irritation is the result of nonpathologic factors such as:

- Frequent douching or use of over-the-counter douches
- Feminine deodorant spray
- Detergents, harsh soaps, or bubble bath
- Colored or perfumed toilet paper
- Contraceptive creams, foams, or suppositories
- Condoms, possibly related to a latex or nonoxynol-9 (spermicide) sensitivity
- Dye, such as found in new clothing
- Synthetic clothing, such as nylon pantyhose, underwear, or synthetic slacks that may trap moisture
- Tight clothing, such as jeans
- Some repetitive motion exercise, such as running or biking
- Frequent shaving of the perineum
- Frequent intercourse or intercourse without adequate lubrication
- Deodorant menstrual pads or tampons, or frequent use of menstrual pads or tampons
- Estrogen deprivation due to menopause, surgical menopause, or medication-induced menopause (such as chemotherapy)

Other times, external genital irritation may be the result of inflammation or infection of the vagina or cervix. The irritation results when increased vaginal or cervical secretions flow distally and create inflammation of the vulvar tissues. This condition is called *vulvovaginitis.*

Often it is difficult to differentiate, by symptoms alone, vulvitis from vaginitis. The nurse needs to understand that vulvitis can occur as a distinct entity from vaginitis, and that the previously mentioned practices may be significant contributing factors to both.

NURSING CARE MANAGEMENT

The nurse gathers data from the woman to help differentiate behaviors that may cause isolated vulvitis from those that may cause vaginal and cervical inflammation. Once the assessment of vulvitis has been made, the nurse plays a crucial role in providing education about contributing factors that may have led to the development of vulvitis. In addition, educating the woman about behaviors to avoid, strategies or therapies to improve symptoms, and signs of a worsening condition that require further evaluation are all part of the nurse's responsibilities.

Care of the Woman with an Abnormal Finding During Pelvic Examination

An abnormal finding resulting from pelvic examination may involve tissues of the vulva, vagina, or cervix; abnormal uterine bleeding; or ovarian or uterine masses.

Vulvar Lesion

The skin of the vulva is subject to diseases and changes, just as skin elsewhere on the body. Because cancer of the vulva may be present in a variety of different types of lesions, it is important that the external genitalia be examined carefully at the time of pelvic examination. A common benign condition of the vulva, atrophic vaginitis, which is caused by a lack of estrogen stimulation to the vulva and vagina, is discussed in chapter 4 ∞.

Bartholin's Gland Cyst

Infection of the Bartholin's gland resulting in inflammation of the gland itself is a common vulvovaginal lesion. The infection can be caused by a number of different organisms, the most common of which are gonorrhea and staphylococcus. Symptoms include unilateral pain and swelling of the Bartholin's gland, ranging from mild to moderate discomfort to severe pain. Treatment involves incision and drainage of the abscess, culture and sensitivity of the discharge, and appropriate antibiotic therapy.

Vitiligo of the Vulva

Vitiligo is a fairly common finding on the vulva. It is a depigmentation of the skin resulting in white patchy areas because of the absence of melanin. Vitiligo may appear anytime after puberty and anywhere on the body, but it is never associated with a systemic disorder. However, it can cause significant disfiguring cosmetic changes, particularly in dark-skinned individuals.

Lichen Sclerosus

Lichen sclerosus is a chronic disorder of the vulva that can occur at any age but is more common in women in their 40s and 50s. There is a strong link between lichen sclerosus and a variety of autoimmune-related disorders. Women with lichen sclerosus have a 4% to 5% increased risk for squamous cell carcinoma of the vulva (Boardman & Kennedy, 2009). Diagnosis is made by clinical exam and confirmed by biopsy. On examination, lichen sclerosus appears as white papules and plaques, often with areas of bruising or redness. Other finds may include fusion of the labia minora and clitoral hood. Treatment includes high-dose topical steroid cream twice daily for 2 to 3 weeks, and then decreased to once or twice weekly thereafter.

Vulvar Vestibulitis

Women with *vestibulitis* experience local irritation and inflammation of the vulvar vestibule, severe pain with vaginal penetration (tampons or intercourse), burning and itching, and sometimes urinary frequency or dysuria. Proposed precipitating factors are numerous and include history of recurrent vaginal infections; use of oral contraceptives, especially at an early age; and exposure to destructive treatments such as trichloroacetic

acid. There is some question if past sexual or physical abuse is a contributing factor. No definitive treatment exists so therapies are directed at comfort measures to relieve symptoms. Therapies include vaginal and introital lubricants; topical anesthetics; local interferon injections; oral antifungal medications; oral tricyclic antidepressants; biofeedback techniques; and in severe cases, surgical intervention (Boardman & Kennedy, 2009).

Malignant Tumors of the Vulva

Cancer of the vulva makes up 3% to 5% of all female genital cancers. It has been identified as 1 of 12 types of cancer that has shown an increase in occurrence with the most pronounced increase in younger women. Two types of vulvar cancer exist. Older women who have vulvar carcinoma have a keratinizing type in which human papilloma virus (HPV) is present in 2% to 23% of all cases. Younger women who develop vulvar carcinoma, however, show a 75% to 100% rate of HPV-related disease (Boardman & Kennedy, 2009). The woman may present with pruritus; a lump; a flat lesion; or, in the case of most HPV-related lesions, may be relatively asymptomatic. Risk factors include chronic vulvar inflammation, immunosuppression from chronic steroid use, smoking, diabetes, HPV infection or HIV, and history of lower genital tract cancer.

Clinical appearance can vary greatly and depends somewhat on the age of the patient. In younger women lesions may occur anywhere on the vulva, including around the anus and urethra. They may appear as flat or raised and may have a rough surface. They can vary in color from brown to white, gray or red. A colposcope, a microscope designed to look at the vulva and cervix (see p. 132), may be used to evaluate the tissue; a biopsy will need to be done. Lesions in older women generally are symptomatic and may include itching, burning, and pain; the woman may complain of chronic ulcerations or bleeding. As the disease becomes more invasive, a distinct tumor may present. Treatment usually involves surgery to remove the lesions and often the tissue surrounding the lesion; however, depending on the extent and degree of the lesion, the rate of reoccurrence is high (Boardman & Kennedy, 2009).

Cervicitis

Acute inflammation of the cervix is usually the result of infection from *Neisseria gonorrhoeae* or *Chlamydia trachomatis.* It may be caused by other organisms such as *Candida, Gardnerella vaginalis, Trichomonas,* herpes, staphylococci, or enterococci. Other causes may include use of intravaginal feminine hygiene products, frequent tampon use, frequent intercourse, or presence of a foreign body (such as an intrauterine device [IUD], contraceptive sponge, diaphragm, or tampon).

Symptoms often include a yellowish white vaginal discharge or copious purulent discharge that is sometimes malodorous, depending on the etiology. **Dyspareunia** (painful intercourse) is a common complaint with postcoital bleeding and occasional irregular vaginal bleeding. Sometimes there is a sense of pelvic heaviness and urinary symptoms such as urgency, frequency, and burning. Diagnosis and evaluation consist of a clinical pelvic examination, wet-mount smear, cultures, and a Pap smear. Treatment depends on the identified problem. It may include antibiotics to treat positive cultures (see chapter 6 ∞), removal of foreign bodies, and in some instances treatment of nonspecific inflammation with local medication (metronidazole gel or clindamycin cream).

Abnormal Pap Smear Results

Women tend to expect a normal Pap smear report but various abnormal findings are common. Notification of an abnormal result may cause significant anxiety in the woman. Therefore, results should be provided in a caring manner with an accurate explanation of the findings; reassurance that early detection of a problem allows early intervention; and information about expected further evaluation, treatment, and follow-up. The woman should be encouraged to ask questions and to voice her concerns.

Pap Smear

The purpose of the Papanicolaou smear (**Pap smear**) is to screen for the presence of cellular abnormalities by obtaining a sample containing cells from the cervix and the endocervical canal. Precancerous and cancerous conditions, as well as atypical findings and inflammatory changes, can be identified by a colposcopy.

Traditionally the test has been performed by preparing a Pap smear slide. However, the smear was often difficult to read because of obscuring factors such as blood, mucus, overlapping cells, and so forth. More recently, another test—the liquid-based medium Pap smear—was approved by the Food and Drug Administration (FDA). In this test, no slide is prepared; instead, the Pap smear is obtained using a speculum to reveal the cervix. The cervix is visualized and a smear is obtained using a plastic spatula on the surface of the cervix and a cytobrush, which is inserted into the cervical os or opening to obtain cells in the cervical canal. The brush and spatula are transferred directly to a vial of preservative fluid, thereby preserving the entire specimen. The specimen is sent to a laboratory where a special processor prepares a slide.

Liquid-based Pap smear preparations have become the method of choice for cervical cancer screening. These types of preparations allow for removal of debris from the sample, such as blood and mucus, thereby increasing the accuracy of the test. Additionally, these preparations allow for HPV screening and for some sexually transmitted infection (STI) screening. The Pap smear is a screening tool. A definitive diagnosis of cervical cancer is made by studying tissue samples obtained by biopsies.

PROFESSIONALISM IN PRACTICE

Pap Smear Preparation

Whenever you teach about pelvic examination and Pap smear, be certain that the woman understands that she should avoid having anything in her vagina for 24 hours before the examination—no intercourse, no tampons, no female hygiene products, and no douching—because this might interfere with the accuracy of the test.

Currently, both the American Cancer Society (ACS) and American College of Obstetricians and Gynecologists (ACOG) recommend that all women begin having Pap smears when they reach the age of 21. Additionally, it is now recommended that

screening before the age of 21 be avoided because it may lead to unnecessary evaluation and treatment in women at a very low risk for cervical cancer. ACOG further recommends repeat Pap smears for women between the ages of 21 and 29 years every 2 years. Women aged 30 years and older who have had three consecutive normal Pap smears, who do not have a history of abnormal Pap smears in the past with a precancerous biopsy, who do not have HIV, or were never exposed to diethylstilbestrol (DES) in utero (a hormone given to women to prevent miscarriage in the 1950s and 1960s) may extend the interval to every 3 years (ACOG, 2009a). Some caregivers are reluctant to extend the time between Pap smears, however, because they worry that women may delay the test beyond the recommended time frames.

The Bethesda System

The *Bethesda System* (Table 7-2) is a standardized method of reporting cytologic Pap smear findings. The most widely used method system in the United States for reporting Pap smear results, it provides a uniform format and classification of terminology based on current understanding of cervical disease.

Cervical Abnormalities

Cervical cancer is the second most common cancer in women worldwide with an estimated 400,000 to 500,000 new cases every year (Wysocki, Reiter, & Berman, 2007). However, 50 years ago cervical cancer was the leading type of cancer in women. Since the use of Pap smear screening in the United

TABLE 7-2 The Bethesda System for Classifying Pap Smears

Specimen Type

Indicate conventional smear (Pap smear) vs. liquid based vs. other

Specimen Adequacy

Satisfactory for evaluation *(describe presence or absence of endocervical/transformation zone component and any other quality indicators; e.g., partially obscuring blood inflammation, etc.)*

Unsatisfactory for evaluation *(specify reason)*

Specimen rejected/not processed *(specify reason)*

Specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of *(specify reason)*

General Categorization (optional)

Negative for intraepithelial lesion or malignancy.

Epithelial cell abnormality. See interpretation/result *(specify 'squamous' or 'glandular' as appropriate).*

Other: See interpretation result *(e.g., endometrial cells in a woman* greater than or equal to *40 years of age).*

Automated Review

If case examined by automated device, specify device and result.

Ancillary Testing

Provide a brief description of the test methods and report the result so that it is easily understood by the clinician.

Interpretation/Result

Negative for intraepithelial lesion or malignancy (when there is no cellular evidence of neoplasia, state this in the General Categorization above and/or in the Interpretation/Result section of the report, whether or not there are organisms or other nonneoplastic findings)

ORGANISMS:

Trichomonas vaginalis.

Fungal organisms morphologically consistent with *Candida* spp.

Shift in flora suggestive of bacterial vaginosis.

Bacteria morphologically consistent with *Actinomyces* spp.

Cellular changes associated with herpes simplex virus.

OTHER NONNEOPLASTIC FINDINGS *(Optional to report list not inclusive).*

Reactive cellular changes associated with

—inflammation (includes typical repair)

—radiation

—intrauterine contraceptive device (IUD)

Glandular cells status posthysterectomy

Atrophy

Other

Endometrial cells (in a woman greater than or equal to 40 years of age) *(specify if negative for squamous intraepithelial lesion)*

Epithelial Cell Abnormalities

SQUAMOUS CELL

Atypical squamous cells

—of undetermined significance (ASC-US)

—cannot exclude HSIL (ASC-H)

Low-grade squamous intraepithelial lesion (LSIL)

—encompassing HPV/mild dysplasia/CIN-1

High-grade squamous intraepithelial lesion (HSIL)

—encompassing: moderate and severe dysplasia CIS/CIN-2 and CIN-3

—with features suspicious for invasion (*if invasion is suspected*)

Squamous cell carcinoma

GLANDULAR CELL

Atypical

—endocervical cells *(NOS or specify in comments)*

—endometrial cells *(NOS or specify in comments)*

—glandular cells *(NOS or specify in comments)*

Atypical

—endocervical cells, favor neoplastic

—glandular cells, favor neoplastic

Endocervical adenocarcinoma in situ

Adenocarcinoma

—endocervical

—endometrial

—extrauterine

—not otherwise specified (NOS)

Other Malignant Neoplasms (specify)

Educational Notes and Suggestions (optional)

Suggestions should be concise and consistent with clinical follow-up guidelines published by professional organizations (references to relevant publications may be included).

Source: Courtesy of National Cancer Institute.

States and other countries that have a system of Pap smear screening, the incidence of and mortality due to cervical cancer have decreased dramatically. In 2009, 11,270 new cases of cervical cancer were diagnosed in the United States. Sadly, 4070 cases of cervical cancer related deaths occurred despite the performance of the Pap smear (NCI, 2009b).

Cervical cancer is considered a preventable disease because it is slow-growing, has a lengthy preinvasive state, has inexpensive and available screening programs, and has effective treatment approaches for preinvasive lesions. Unfortunately, several subgroups of women in the United States have never been screened or are not screened at regular intervals. One half of women with newly diagnosed cervical cancer have never had a Pap smear, and 10% have not had a Pap smear in the last 5 years (ACOG, 2009a).

Factors that place a woman at high risk for cervical cancer include:

- Coitus at an early age (first intercourse before 16 years of age increases the risk of cervical cancer twofold)
- History of multiple sexual partners
- Sex partner with a history of numerous sexual partners
- Exposure to STIs
- History of HPV infection
- History of immunosuppressive therapy (chemotherapy) or immunocompromised state (HIV)
- Long-term oral contraceptive use (greater than 5 years)
- Smoking
- Antenatal exposure to diethylstilbestrol (DES)
- History of dysplasia

Virtually all cases of cervical cancer are associated with cervical infection with high-risk HPV and are preceded by high-grade cervical dysplasia (Wysocki et al., 2007). As discussed in chapter 6 ∞, over 120 different types of HPV have been identified; 30 types are known to infect the genital tract.

> "Several years ago I was treated for HPV—I got the infection from my husband—and seemed to be doing well. But now I've had some abnormal Pap smears and my doctor is talking about doing a LEEP procedure. I was a virgin when I got married but my husband wasn't. I've done a lot of reading, and I know how common HPV is, so I guess I can't be too hard on the guy. Still I have to admit that I feel a little nudge of resentment—I'm the one with problems. He is symptom free."

The 2001 Bethesda System (ACOG, 2009a) identifies three categories for premalignant squamous cell lesions: atypical squamous cells (ASC), low-grade squamous intraepithelial lesion (LSIL), and high-grade squamous intraepithelial lesion (HSIL), which includes CIN 2 (moderate dysplasia) and CIN 3 (severe dysplasia and carcinoma in situ). The focus of the Pap smear is on the detection of high-grade cervical disease, especially *cervical intraepithelial neoplasia* (CIN). CIN refers to a lesion that may progress to invasive carcinoma (cancer). It is synonymous with the term *dysplasia.* To further support this objective, the ASC category is subdivided into two qualifiers that recognize the importance of detecting HSIL:

- Atypical squamous cells of undetermined significance (ASC-US)
- Atypical squamous cells—cannot exclude HSIL (ASC-H)

The category ASC-H includes those changes that are suggestive of a high-grade lesion but are lacking sufficient criteria for a definitive evaluation and interpretation. An immediate colposcopy is advised because women with this finding have a 20% to 50% risk of having a moderate to severe lesion (ACOG, 2008).

Another cervical cytology result is atypical glandular cells (AGUS), which represents cells that are glandular rather than squamous in origin. These are further subdivided into:

- Atypical endocervical cells
- Atypical endometrial cells
- Atypical glandular cells not otherwise specified

The workup for this type of finding is more aggressive because it may represent a more invasive form of disease (ACOG, 2009a).

The American Society for Colposcopy and Cervical Pathology has further defined the use of HPV genotyping to manage women 30 years and older and has developed an algorithm for clinicians to use. In women with HPV high-risk (HR) positive and negative cytology (normal cells on Pap smear), they can repeat the Pap and HR HPV test in 12 months. When the repeat Pap smear and HPV testing are negative on subsequent Pap smears, they can resume routine screening at 3 years. If the cytology is positive (abnormal cells on Pap smear) with high-risk HPV findings, a colposcopy is performed (ACOG, 2009a).

Evaluation of Abnormal Cytology

The following points summarize the primary guidelines for managing women with abnormal cancer screening results (Wright et al., 2007):

- Women with ASC-US can be treated in one of three ways: (a) referral for colposcopy; (b) repeat the Pap at 6-month intervals until two negative results are obtained with referral for colposcopy if the repeat Pap shows ASC or higher; or (c) deoxyribonucleic acid (DNA) testing for high-risk types of HPV infection with referral for colposcopy if the testing reveals a high-risk strain. If the HPV high-risk testing is negative, the woman should have a repeat Pap in 12 months.
- Women with ASC-H are at greater risk for CIN than women with ASC-US and should be referred directly for colposcopy.
- Women with either LSIL or HSIL are referred directly for loop electrosurgical excision (LEEP) or colposcopy with endocervical assessment. If CIN 2 or 3 is not identified histologically, follow-up may be done by either a diagnostic excisional procedure such as LEEP or conization or observation with colposcopy and Pap at 6-month intervals for a year. A diagnostic excisional procedure is recommended if the colposcopy is unsatisfactory or if the woman is pregnant.

Based on the results of the colposcopy, of endocervical curettage of the tissue, and of biopsy if performed, further treatment may be indicated or follow-up with repeat Pap smears may be recommended. These tests are discussed next.

Colposcopy, the direct, detailed visualization and examination of the cervix, is done in most gynecologic offices. A speculum is placed in the vagina and the cervix is isolated. A 3% acetic acid solution applied on the cervix causes the abnormal epithelial cells to take on a characteristic white appearance. The colposcope, with its bright light and various color filters, provides a 6 to 40 times magnification of the cervical tissues. Lesions or other abnormalities are identified and documented, and directed biopsies can be obtained at this time, if indicated. Sometimes, the biopsy itself can be therapeutic as well as diagnostic if the entire lesion can be removed.

Endocervical curettage (ECC) may also be done at this time to evaluate for extension into the cervical canal. This involves a scraping of the endocervix from the internal os to the external os to obtain endocervical cells for cytology. Histologic evaluation of tissue biopsies and ECC samples is necessary for a definitive diagnosis.

The woman may experience moderate to severe cramplike pains during and after the biopsy and/or ECC. To help alleviate this discomfort, nurses can advise women to premedicate with 600 mg ibuprofen about 30 minutes before the procedure. A small amount of bleeding, initially bright red and then becoming darker, is normal for up to 2 weeks. Bleeding as heavy as a menstrual period is not normal and should be reported to the woman's care provider.

Surgical Treatment for Abnormal Cytology

Premalignant (precancerous) and malignant (cancerous) lesions are often treated with surgical procedures, varying from simple biopsy of the cervix to radical surgery of the pelvic organs, depending on the diagnosis and extent of the disease. A diagnosis of cancer can only be made after a pathologic evaluation of tissue obtained via biopsy. The goals of management are to exclude the presence of invasive cancer, to determine the extent and distribution of noninvasive cancer, and to provide appropriate treatment.

The treatment of cervical cancer depends on the stage of the disease, which is determined by the extent of its spread to other tissues or structures. Surgical treatment of cervical cancer may include a total abdominal hysterectomy (TAH), bilateral salpingo-oophorectomy (BSO), and bilateral lymphadenectomy (discussed further in the section Care of the Woman Requiring Gynecologic Surgery on page 139). It may also include radiation therapy and chemotherapy.

Loop Electrosurgical Excision Procedure

Loop electrosurgical excision procedure (LEEP) can be used to treat cervical, vaginal, and vulvar intraepithelial neoplasia. When an abnormal Pap smear and a colposcopic evaluation indicate a premalignant lesion, a small electrically hot wire loop can be used to excise the entire lesion, squamocolumnar junction, and transformation zone. The cutting effect is created by a steam envelope that develops between the wire loop and the water-laden tissue. This procedure can be performed on an outpatient basis, often in the gynecologic office, under local anesthesia. Complications following LEEP are usually minimal, and it is virtually painless and bloodless. The woman can expect some slight bleeding, and possibly a malodorous dark brown discharge for 1 to 2 weeks after the procedure. The woman needs to know that moderate to heavy bleeding would be abnormal and should be reported to her care provider.

Cryosurgery

Cryosurgery is used to treat women with a small ectocervical lesion who have a negative ECC and no endocervical gland involvement. A double freezing method is advocated, using nitrous oxide or carbon dioxide to freeze the tissue below −20°C (−4°F), resulting in tissue destruction and necrosis. Cryosurgery is less widely used since the development of LEEP because it scars the cervix, making the transformation zone, or squamocolumnar junction, more difficult to evaluate with future colposcopies. It can easily be done in a gynecologic office or clinic without anesthesia. The woman may experience some mild cramping and should be told to expect a thin, watery, persistent, and sometimes heavy vaginal discharge for up to several weeks as the frozen tissue is sloughed. She should avoid tampon use and sexual intercourse while the discharge is present to minimize further damage to the cervix.

Laser Therapy

The carbon dioxide (CO_2) laser is used to treat cervical, vaginal, and vulvar intraepithelial lesions. The laser is used when all boundaries of the lesion are visible on colposcopy and when the ECC is negative. The invisible, highly concentrated beam is absorbed by water in the tissues, elevating the temperature in the tissues to above 100°C (212°F). The targeted tissue "boils" and the exploded cells are vaporized, leaving the normal tissue intact. Laser treatment can be done in outpatient or office settings without anesthesia. The woman may experience mild cramping and a slight discharge for 5 to 7 days; however, bleeding is minimal. She should avoid tampon use, intercourse, and douching for 2 weeks; complete healing may take up to 12 weeks. In many clinical settings, laser therapy has become less common with the advent and effective use of LEEP.

Conization

A cold knife *conization* of the cervix (also known as a "cone") is most commonly performed when the entire lesion cannot be visualized by colposcopic examination or when there is a positive ECC sampling. In this procedure, a cone-shaped section of cervical tissue is excised. The width and depth of the tissue removed varies depending on the extent of the lesion. A large amount of normal tissue is removed, as well as the abnormal tissue, and this procedure can often be diagnostic as well as therapeutic if the entire lesion is excised. Conization is usually done under general anesthesia with the woman in a lithotomy position. Immediate postoperative risks include infection and hemorrhage; long-term risks include spontaneous abortion, incompetent cervix, or preterm labor with future pregnancies. A prolonged or profuse menstrual period may occur in two or

three cycles following the procedure. Conization is used less frequently today because of the availability of LEEP.

Abnormal Uterine Bleeding

During the many years of a woman's reproductive period, she is likely to experience some form of abnormal uterine bleeding. It may occur as spotting between periods, missing several cycles followed by a heavy bleed, or menses that occur every 2 to 3 months. Heavy, unpredictable menstrual periods can cause a woman to experience fatigue, anemia, and embarrassment. Abnormal bleeding may be a symptom that accompanies infertility.

Abnormal uterine bleeding (AUB) is a common gynecologic problem. It makes up 5% to 10% of cases in the outpatient setting. It is a reflection of a disruption in the normal cyclic hormonal pattern of ovulation to the endometrium, or lining of the uterus. Many women who experience AUB are exposed to unnecessary surgical treatments before an adequate workup and medical therapy trial is complete. Women who experience repetitive episodes are predisposed to iron deficiency anemia. Endometrial cancer results in 1% to 2% of women with improperly managed anovulatory bleeding (Behera & Price, 2009).

Systemic diseases that cause AUB include coagulation disorders such as von Willebrand's disease, thrombocytopenia, acute leukemia, and advanced liver disease. Endocrine disorders include thyroid, hyperprolactinemia, polycystic ovarian syndrome, and Cushing's syndrome (Gordon et al., 2007).

Medications that may account for AUB include contraception, anticoagulants, antipsychotics, and chemotherapy. Trauma during intercourse or as a result of sexual abuse and foreign bodies may also result in abnormal bleeding (Gordon et al., 2007). Mechanical causes may include leiomyomata (fibroids), endometrial polyps, or adenomyosis.

Infection in the cervix (cervicitis), uterus (endometritis), vagina, or vulva (STI) may be a cause of abnormal bleeding. Endometrial cancer, or cancer of the lining of the uterus, or other genital tract cancers need to be ruled out with the presence of AUB (Gordon et al., 2007).

Evaluation of AUB begins with a thorough history and physical examination including a careful pelvic exam and Pap smear. The diagnosis is made by excluding organic causes, specifically pregnancy, uterine or ovarian pathology, medications, or systemic disease. Based on the information gained, specific laboratory tests such as pregnancy test, liver and renal function tests, thyroid tests, coagulation studies, or prolactin levels may be indicated. Based on the woman's age and findings, other tests that may be indicated include transvaginal ultrasound, saline infusion sonography (SIS), hysteroscopy, magnetic resonance imaging (MRI), and endometrial biopsy. Endometrial biopsy to rule out endometrial cancer is indicated for all women over age 35 (Dodds & Sinert, 2009).

The goals of treatment are to control bleeding, prevent or treat anemia, prevent endometrial hyperplasia or cancer, and restore quality of life. Pharmacologic treatment for AUB varies depending on the woman's desire for pregnancy and whether she is premenopausal, perimenopausal, or postmenopausal. Combined oral contraceptives (COCs) are the most common treatment for women who are not actively trying to conceive. COCs help regulate cycles while also providing contraception. Other options include short-term, high-dose estrogen therapy, cyclic progesterone to regulate cycles in women with contraindications to estrogen therapy, danazol, gonadotropin-releasing hormone (GnRH) therapy, and the levonorgestrel intrauterine system (LNG-IUS) (see chapter 5 ∞). If conservative measures are not effective, the woman and her provider may consider surgical interventions, such as hysteroscope-assisted dilation and curettage (D&C), for the resection of fibroids or endometrial polyps, endometrial ablation, or hysterectomy (Dodds & Sinert, 2009).

Dysfunctional uterine bleeding (DUB) is characterized by anovulatory cycles with AUB that does not have a demonstrable organic cause. Oligomenorrhea, polymenorrhea, menorrhagia, metrorrhagia, menometrorrhagia, and intermenstrual bleeding are all forms of DUB (see chapter 4 ∞). DUB can occur at any age but is most common at either end of the reproductive age span. Adolescents account for 20% of DUB cases due to hypothalamic immaturity after menarche. Perimenopausal women account for 50% of cases due to waning ovarian function. The remaining cases occur among women of reproductive age, generally as a result of polycystic ovary syndrome, hyperprolactinemia, or hypothalamic dysfunction. It is typically treated medically. Surgical intervention is generally limited to cases in which medical therapy is contraindicated or has failed.

Ovarian (Adnexal) Masses

An *adnexal mass* most commonly refers to an ovarian abnormality but it can also refer to masses found in the fallopian tubes, broad ligament, or bowel, or even a lateral mass of the uterus. Between 70% and 80% of ovarian masses are benign. More than 50% are functional cysts (cysts that develop from ovarian follicles, from the corpus luteum, or from the theca luteum) occurring most commonly in women 20 to 40 years of age. Functional cysts are rare in women who take oral contraceptives.

Ovarian cysts usually represent physiologic variations in the menstrual cycle. Nearly all perimenopausal women have ovarian cysts, and about 15% of postmenopausal women have them. Dermoid cysts (cystic teratomas) comprise 10% of all benign ovarian masses. Cartilage, bone, teeth, skin, or hair can be observed in these cysts. Endometriomas, or "chocolate cysts," are another common type of ovarian mass.

No relationship exists between benign ovarian masses and ovarian cancer. Unfortunately, at present, no adequate techniques exist for ovarian cancer screening. Over 15,000 deaths in the United States occur each year as a result of ovarian cancer. Over 70% of all cases diagnosed are in advanced states. Five-year survival rates for women with advanced disease are 15% to 30%; however, if the disease is diagnosed early, those rates increase to 70% to 90% (Goff & Muntz, 2008). Risk factors for ovarian cancer are:

- Increased age (mean age is 56)
- Nulliparity (never having children)
- History of breast cancer
- Early menarche or late menopause

The risk of ovarian cancer is 5% to 10% for women with family members diagnosed with the disease (Helm & Edwards, 2009).

Family transmission and increased lifetime risk of ovarian cancer account for 5% to 10% of all cases of ovarian cancer. Some cases of ovarian cancer are associated with a mutation in specific genes (BRCA1 and BRCA2 genes). It is now possible to identify many of these mutations. If a mutation of BRCA1 is found, for example, estimates suggest that a woman's lifetime risk of ovarian cancer is between 15% and 45%. If the BRCA2 mutation is present, the lifetime risk of developing ovarian cancer is 10% to 20%. These two mutations are inherited in an autosomal dominant pattern, meaning the gene can come from either parent. Hereditary ovarian cancer tends to occur at a younger age, but the prognosis is generally better. The National Cancer Institute currently recommends that women who are considered high risk should have annual ultrasound examination and a CA 125 blood test (Helm & Edwards, 2009).

In reality, ovarian cancer is the most fatal of all cancers in women because it is difficult to diagnose and often has spread throughout the pelvis before it is detected. Symptoms are often vague and nonspecific and may include:

- Bloating
- Increased abdominal size
- Difficulty eating
- Abdominal or pelvic pain
- Urinary symptoms (urgency and frequency)

Women who have these symptoms daily for several weeks should see a gynecologist for prompt medical evaluation (Goff & Muntz, 2008). The risk of ovarian cancer is decreased significantly by bearing children, taking combined oral contraceptive pills for more than 5 years, or having a tubal ligation (Helm & Edwards, 2009).

A woman with an ovarian mass may be asymptomatic; the mass may be noted on a routine pelvic examination. She may experience a sensation of fullness or cramping in the lower abdomen (often unilateral), dyspareunia, irregular bleeding, or delayed menstruation.

Diagnosis is made on the basis of a palpable mass, with or without tenderness, and other related symptoms. Radiography or ultrasonography may be used to assist or confirm the diagnosis.

The woman is frequently kept under observation for a month or two because most cysts will resolve on their own and are harmless. Oral contraceptives may be prescribed for 1 to 2 months to suppress ovarian function. If this regimen is effective, a repeat pelvic examination should yield normal findings. If the mass is still present after 60 days of observation and oral contraceptive therapy, a diagnostic laparoscopy or laparotomy may be considered. Tubal or ovarian lesions, ectopic pregnancy, cancer, infection, or appendicitis also must be ruled out before a diagnosis can be confirmed.

Surgery is not always necessary but will be considered if the mass is larger than 6 to 7 cm in circumference; if the woman is over 40 years of age with an adnexal mass, a persistent mass, or continuous pain; or if the woman is taking oral contraceptives. Surgical exploration is also indicated when a palpable mass is found in an infant, a young girl, or a postmenopausal woman.

Women may need clear explanations about why the initial therapy is observation. A discussion of the origin and resolution of ovarian cysts may clarify this treatment plan. If a surgical treatment removes or impairs the function of one ovary, the woman needs to be assured that the remaining ovary can be expected to take over ovarian functioning and that pregnancy is still possible.

Uterine Masses

Endometrial polyps are pedunculated (growing on a stalk) overgrowths of the endometrium. They can occur as single or multiple growths. Polyps are common and are often accompanied by symptoms of midcycle bleeding or spotting, bleeding or spotting after intercourse, or prolonged bleeding or spotting with menstrual cycles. Polyps are generally benign, but they can coexist with carcinoma of the endometrium in about 10% of postmenopausal women. Treatment is dilation and curettage (D&C) using the hysteroscope for visualization.

Fibroid tumors, or *leiomyomas,* are among the most common benign disease entities in women. By the age of 50, 70% of Caucasian women and 80% of African American women have fibroids (Parker, 2008b). Fortunately, these tumors progress to a malignancy in fewer than 0.5% of all patients (Flowers, 2008).

Most uterine fibroids are asymptomatic and require no treatment. Treatment is indicated when the fibroids cause symptoms such as lower abdominal pain, fullness or pressure, menorrhagia, metrorrhagia, or increased dysmenorrhea, compelling the woman to seek medical advice. The majority of fibroids will shrink after menopause. In an older woman who experiences uterine growth, pain, or postmenopausal bleeding, a malignancy may be suspected (Parker, 2008b).

On pelvic examination the patient may have an irregular shaped, enlarged uterus. Tentative diagnosis is initially made through pelvic ultrasound for number, size, and location of the fibroid. Occasionally MRI or hysterosonography is used for further evaluation and planning for surgical interventions (Flowers, 2008).

Treatment for uterine fibroids varies from the use of oral contraceptives to control heavy menstrual bleeding to hysterectomy. Myomectomy is a surgical procedure to remove the fibroid without removing the uterus. This is a safe and effective alternative to hysterectomy, which carries more overall risk (Parker, 2008a). GnRH analogs such as Lupron are used off-label to reduce the size and subsequent bleeding due to these tumors. These medications carry with them symptoms of menopause such as hot flashes and reduced bone mineral density. Once discontinued, however, growth of the fibroid can reoccur. Treatment with GnRH analogs may be used before surgery to reduce the size of the fibroid and decrease complications (Flowers, 2008). Uterine artery embolization (UAE) is a relatively new procedure that allows women with symptomatic, moderate-sized (less than 10 cm) fibroids to avoid hysterectomy. It is a radiologic procedure in which a catheter is inserted into the femoral artery and advanced to the uterine arteries. The uterine arteries are then blocked by injecting polyvinyl alcohol particles. This results in diminished blood flow to the uterus and the necrosis of the fibroids (Bradley, 2009). Hysterectomy may be indicated for the treatment of uterine fibroids. This can be performed laparoscopically or abdominally depending on the size of the uterus. A laparoscopic-assisted hysterectomy is less invasive and has a

lower risk of surgical and postoperative complication (Parker, 2008a). Myomectomy can be performed to preserve fertility or improve fertility if the location of the fibroid distorts the uterine cavity and would prevent implantation (Parker, 2008a).

Endometrial cancer is the most common female genital tract cancer with over 40,000 new cases annually. It has a high rate of cure if detected early. Although the overall incidence is lower in black women than in white women, black women have a poorer survival rate. This disparity is multifactorial and may be due to barriers to receiving care in the early stages of disease. It may also be related to comorbid conditions such as obesity and diabetes as well as basic genetic differences found in tumors in black women (Allard & Maxwell, 2009).

Risk factors for endometrial cancer include (Gordon et al., 2007):

- White race
- Increased age (mean age is 60)
- Obesity
- Nulliparity
- History of infertility or menstrual irregularities
- History of diabetes
- Hypertension
- Thyroid or gallbladder disease
- Long-term use of unopposed estrogen
- Early menarche or late menopause
- Use of tamoxifen

The majority of endometrial cancer occurs in postmenopausal women. The hallmark sign is vaginal bleeding in postmenopausal women not treated with hormone therapy (HT). Women may present with this complaint or have an incidental finding on a Pap smear of atypical endometrial cells. Generally a pelvic ultrasound is done to evaluate the thickness of the endometrium, and subsequent endometrial biopsy is taken if the thickness is greater than 4 mm. The endometrial biopsy will confirm the suspicion of cancer and the grade of lesion will be reported with pathology. Hysterectomy with bilateral salpingo-oophorectomy (removal of both fallopian tubes and ovaries) is performed and staging of the cancer is done. Although controversy exists in the role of lymph node dissection for staging purposes, in the United States this is generally done in all women with endometrial growths (Fiorelli, Gerzog, & Wright, 2008).

Once staging of the cancer is completed, a plan of treatment is proposed. Hysterectomy may be adequate treatment for stage I disease without lymph node involvement. For more advanced disease, however, adjuvant therapy may be prescribed. Intermediate risk endometrial cancer is generally treated with whole pelvis radiation. Chemotherapy is used in conjunction with radiation for advanced endometrial cancer (Fiorelli et al., 2008).

NURSING CARE MANAGEMENT

Only nurses with special training perform pelvic examinations and Pap smears. In most cases, nursing assessment is directed toward evaluating the woman's understanding of the findings and their implications and her psychosocial response.

The woman needs accurate information on the etiology of the disorder, its symptoms, and treatment options. She should be encouraged to report symptoms and keep appointments for follow-up examination and evaluation. The woman needs realistic reassurance if her condition is benign; she may require counseling and effective emotional support if a malignancy is likely. If the management plan includes surgery, she may need the nurse's support in obtaining a second opinion and making her decision. The nurse can also provide information on available community resources, including support groups.

Care of the Woman with Toxic Shock Syndrome

Case Study: Toxic Shock Syndrome

Although **toxic shock syndrome (TSS)** has been reported in children, postmenopausal women, and men, it is primarily a disease of women in their reproductive years, especially women at or near menses or during the postpartum period. In most cases, the causative organism is a strain of *Staphylococcus aureus.* The use of superabsorbent tampons has been widely related to an increased incidence of TSS. However, occluding the cervical os with a contraceptive device such as a diaphragm or cervical cap, especially if it is left in place for more than 48 hours, may also increase the risk of TSS. The rates of staphylococcal TSS have declined since 1980 because of the decrease in the use of superabsorbent tampons (Totten, 2009).

Early diagnosis and treatment are important in preventing a fatal outcome. For a diagnosis of TSS to be made, certain criteria must be met. The woman must have fever (38.9°C), shock, rash, and multisystem involvement (Totten, 2009). The fever and rash on the trunk present initially, followed by desquamation of the skin, especially the palms and soles, which usually occurs 1 to 2 weeks after the onset of symptoms; hypotension; and dizziness. Systemic symptoms often include vomiting, watery diarrhea, severe myalgia, and inflamed mucous membranes (oropharyngeal, conjunctival, or vaginal). Disorders of the central nervous system, including alterations in consciousness, disorientation, and coma, may also occur. Evidence of renal, hepatic, and hematologic involvement can be seen in abnormal laboratory findings, which reveal elevated blood urea nitrogen (BUN), creatinine, aspartate aminotransferase (AST), alanine aminotransferase (ALT), and total bilirubin, while platelets are often less than $100{,}000/mm^3$.

Women with TSS are generally hospitalized and given supportive therapy, including oxygen, intravenous (IV) fluids to maintain blood pressure, and antibiotics. Severe cases may require administration of vasopressors and intubation. Close follow-up care is necessary because some patients may require dialysis and are also at a higher risk for further episodes. Recurrence rates can be as high as 40% to 50% (Totten, 2009).

> "Two years ago a friend died of toxic shock syndrome. It happened so quickly. Within days she was on life support until the family had it turned off. Until that happened, I was oblivious to the risk factors, especially leaving tampons in too long, one of my big offenses. I have changed that for myself, and I am making it a point to tell other women about toxic shock and ways to prevent it. Such a senseless death!"

NURSING CARE MANAGEMENT

Nurses play a major role in helping to educate women about ways to prevent the development of TSS. Women should understand the importance of avoiding prolonged use of tampons. They should change tampons every 3 to 6 hours, avoid using superabsorbent tampons, and never use more than one tampon at a time. Some women may choose to use other products, such as sanitary pads or minipads. The woman who chooses to continue using tampons may reduce her risk by alternating them with pads and avoiding overnight use of tampons.

Women who are postpartum should avoid the use of tampons for 6 to 8 weeks after childbirth. Women with a history of TSS should be advised of the risk of recurrence and should never use tampons. Women who use diaphragms or cervical caps should not leave them in place for prolonged periods and should not use them during the postpartum period or when they are menstruating. Nurses can also help make women aware of the signs and symptoms of TSS so that they can seek treatment promptly if symptoms occur.

Care of the Woman with Endometriosis

Endometriosis is a condition characterized by the presence of endometrial tissue outside the uterine cavity. The exact prevalence of endometriosis is unknown but it is found in 5% to 15% of reproductive-age women who undergo laparoscopy (Gordon et al., 2007). Endometriosis has been found almost everywhere in the body, including the vagina, lungs, cervix, central nervous system, and gastrointestinal tract. The most common location, however, is the pelvis. This tissue responds to the hormonal changes of the menstrual cycle and bleeds in a cyclic fashion. The bleeding results in inflammation, scarring of the peritoneum, and formation of adhesions.

Endometriosis may occur at any age after puberty, although it is most commonly diagnosed in women between ages 20 and 45 and is rare in postmenopausal women. There is a 20% to 50% prevalence rate of endometriosis in infertile women. A hereditary component also exists with a 10 times greater risk in women with a first-degree relative with endometriosis (Kapoor & Davila, 2008).

The exact cause of endometriosis is unknown. Proposed causative factors include retrograde menstrual flow of the endometrium through the fallopian tubes into the pelvis, lymphatic-vascular (through lymph or blood vessels spreading to lungs, brain, and pericardium), and decrease in cellular immunity (Gordon et al., 2007). Although endometriosis can be asymptomatic, its most common symptom is pelvic pain, which is often dull or cramping although it can be debilitating. It is generally related to the menstrual cycle; however, some women may experience chronic pelvic pain. Dyspareunia may be present due to scarring of the pelvic tissues and organs from the endometrial implants. The condition is often diagnosed when the woman seeks evaluation for infertility. Bimanual examination may reveal a fixed, tender, retroverted uterus and palpable nodules in the cul-de-sac. Diagnosis is confirmed by laparoscopy.

Treatment may be medical or surgical, or a combination of the two. In women with minimal disease and symptoms, treatment includes observation, analgesics, and nonsteroidal anti-inflammatory drugs (NSAIDs). Medical treatment of mild endometriosis does not seem to improve fertility; however, in cases of moderate to severe disease, surgical intervention is indicated (Kapoor & Davila, 2008). Medical therapies include the following:

- ***Combined oral contraceptives (COCs):*** COCs, which suppress menstruation, can be used in women who do not desire fertility.
- ***Progestins:*** Progestins such as medroxyprogesterone acetate (MPA) exert an antiendometriotic effect and ultimate atrophy. The medication is administered intramuscularly every 3 months, and the effectiveness of the treatment is evaluated every 3 to 6 months. Side effects may include nausea, weight gain, fluid retention, and breakthrough bleeding.
- ***Danazol:*** The antiprogestin danazol is sometimes used to treat endometriosis. It suppresses gonadotropin-releasing hormone (GnRH) and has high androgen and low estrogen effects that do not support the growth of the endometrium. It suppresses ovulation and causes amenorrhea. In effect, danazol and the other GnRH analogs (discussed next) induce a "pseudomenopausal" state. Danazol does have some significant side effects, including hirsutism, vaginal bleeding, acne, oily skin, weight gain, reduced libido, voice changes and hoarseness, clitoral enlargement, and decreased breast size.
- ***GnRH analogs:*** GnRH analogs such as nafarelin acetate (given as a metered nasal spray twice daily) and leuprolide acetate (Lupron, given once a month as an intramuscular injection), are gaining popularity because many women tolerate them better than danazol and their results in treating endometriosis are comparable. GnRH analogs suppress the menstrual cycle through estrogen antagonism. This may result in the hypoestrogen side effects of hot flashes, vaginal dryness, headache, breast reduction, and loss of bone density.

Surgical treatment may be conservative (laparoscopy) or definitive (hysterectomy). It is conservative when the uterus and as much of the ovaries as possible are preserved. During the laparoscopic examination, the physician may surgically resect any visible implants of endometrial tissue, taking care to avoid damaging any organs. Laser vaporization can be used for all but the deepest

implants. This allows for more exact removal of tissue, less damage of adjacent tissue, and decreased bleeding. There is a 19% recurrence rate for all techniques (Kapoor & Davila, 2008). If the woman is experiencing severe dyspareunia or dysmenorrhea, the surgeon may perform a presacral neurectomy. In advanced cases in which childbearing is not an issue, treatment may be a hysterectomy with bilateral salpingo-oophorectomy (removal of the uterus, fallopian tubes, and ovaries).

Complementary therapies may also play a role in the treatment of endometriosis. These include acupuncture to help with pain control; yoga for relaxation and stress reduction; massage; traditional Chinese herbal medicine for symptomatic relief; and "soul therapies" such as prayer, religious rituals, meditation, and support groups (Kaatz, Solari-Twadell, Cameron et al., 2010).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse should be aware of the common symptoms of endometriosis and elicit an accurate history if a woman mentions these symptoms. If a woman is being treated for endometriosis, the nurse should assess the woman's understanding of the condition, its implications, and the treatment alternatives.

Nursing diagnoses that may apply to a woman with endometriosis include the following:

- ***Acute pain*** related to peritoneal irritation secondary to endometriosis
- ***Compromised family coping*** related to depression secondary to infertility

Nursing Plan and Implementation

The nurse can be available to explain the condition, its symptoms, treatment alternatives, and prognosis. The nurse can help the woman evaluate treatment options and make appropriate choices. If the woman begins taking medication, the nurse can review the dosage, schedule, possible side effects, and any warning signs. Women are often advised to avoid delaying pregnancy because of the risk of infertility. The woman may wish to discuss the implications of this decision on her life choices, relationship with her partner, and personal preferences. The nurse can be a nonjudgmental listener and help the woman consider her options. In addition, the nurse can refer the woman to the Endometriosis Association. This group, founded in 1980, offers women support and education.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is able to discuss her condition, its implications for fertility, and her treatment options.
- After considering the alternatives, the woman chooses appropriate treatment options.

Care of the Woman with Polycystic Ovarian Syndrome

Many women struggle with the short-term and long-term effects of a condition known as **polycystic ovarian syndrome**, or **PCOS**. This complex syndrome, with no clear etiology, is the most common endocrine disorder affecting women of reproductive age, with a suggested incidence of 6.5% of women (Guzick & Hoeger, 2009).

As early as 1921, Achard and Thiers cited the link between insulin and elevated androgens in the medical literature in their description of a "bearded woman with diabetes." In 1935, Stein and Leventhal described a triad of symptoms in some women—obesity, hirsutism, and amenorrhea—and additionally, pathologic ovarian findings. As ultrasound techniques became more refined in the 1970s and 1980s, the ability to see polycystic ovaries more clearly further complicated the diagnostic process. Over time, it became evident that not all women with PCOS had polycystic ovaries, and it became recognized that many "normal" women did have polycystic ovaries noted by ultrasound. For these reasons, the term "polycystic ovarian syndrome" is a bit misleading because PCOS is a complex disorder with many confounding variables and multisystem effects.

Signs and Symptoms of PCOS

The most common clinical signs and symptoms of PCOS include menstrual dysfunction since the onset of menstruation, signs of androgen excess (hirsutism or acne), or infertility (Guzick & Hoeger, 2009). Insulin resistance also occurs in women with PCOS.

Menstrual Dysfunction

Irregular menses, including total absence of periods (amenorrhea) or intermittent or infrequent periods (oligomenorrhea), is the hallmark of PCOS (Guzick & Hoeger, 2009). In women of reproductive age, 85% to 90% of oligomenorrhea and 30% to 40% of amenorrhea are attributed to PCOS. Anovulation is usually a chronic problem with PCOS, but it often presents as a long history of menstrual irregularities. However, some women with PCOS can have regular periods and still be chronically anovulatory.

Hyperandrogenism

PCOS is the most common cause of androgen excess in women. Most often it is manifested as *hirsutism*, or an excess of hair growth, and acne. The hair is coarse and appears in a pattern typically seen in adult males. This pattern occurs on the face, chest, between the breasts and on the abdomen. Acne is less prevalent in PCOS than hirsutism; however, most women with severe acne have PCOS (Mason et al., 2008).

Obesity

About 50% of women with PCOS are clinically obese (Guzick & Hoeger, 2009). In women with PCOS who struggle with obesity, it is generally of the android type, with an increased hip-to-waist ratio. PCOS-related obesity is consistent with increased androgen levels, glucose intolerance, insulin resistance, and abnormal lipoprotein profiles. Unfortunately, women with PCOS

obesity have difficulty losing weight, which is probably related to hyperinsulinemia and carbohydrate cravings.

Infertility

The majority of women who have been diagnosed with PCOS struggle with some degree of infertility related to anovulation. (See chapter 12 ∞, Special Reproductive Concerns: Infertility and Genetics.)

Insulin Resistance and Diabetes Mellitus

Women with PCOS may be insulin resistant. This is an important long-term clinical manifestation of PCOS. Obese women with PCOS have a higher rate of type 2 diabetes mellitus (7.5%–10%) and glucose intolerance (31%–35%). The rates of glucose intolerance and type 2 diabetes are not as high in women with PCOS who are lean (Guzick & Hoeger, 2009). An estimated 20% of patients with PCOS are lean (ACOG, 2009c).

Diagnosis of PCOS

The National Institutes of Health Androgen Excess Society, the European Society of Human Reproduction and Embryology, and the American Society for Reproductive Medicine (ESHRE/ASRM) agreed in Rotterdam that the diagnosis of PCOS should be based on the presence of two out of three of the following criteria: oligo- or anovulation, clinical and/or biochemical hyperandrogenism, and the appearance of polycystic ovaries on ultrasound. This is known as the Rotterdam Criteria (Barth, Yasmin, & Balen, 2008). If a woman presents with complaints of hirsutism, menstrual irregularities, acne, difficulty conceiving, and unexplained weight gain, several other disorders must be ruled out. Important disorders to consider include hyperthyroidism or hypothyroidism, congenital adrenal hyperplasia, Cushing's syndrome, hyperprolactinemia, and androgen-producing tumors. The diagnostic process is fourfold: history, physical examination, laboratory studies, and imaging. See Table 7-3.

TABLE 7-3 Diagnostic Process for PCOS

History

- Medical history—onset, timing, duration of symptoms (acne, hirsutism, menstrual problems)
- Surgical history
- Menstrual history—frequency, duration, regularity of periods; perception of pain and amount of bleeding
- Medications history (some medications may cause hirsutism, acne, menstrual irregularities)
- Family history—close attention to diabetes, menstrual problems, hirsutism, infertility

Physical

- Blood pressure
- Body mass index (BMI) (weight in kg divided by height in m^2): 25–30 = overweight; over 30 = obese
- Waist circumference: over 35 is abnormal, indicating central fat distribution
- Presence of acne, hirsutism, acanthosis nigricans, androgenic alopecia

Laboratory

- Total testosterone and sex-hormone binding globulin or bioavailable and free testosterone
- Thyroid-stimulating hormone (rules out thyroid disorders)
- Prolactin (rules out hyperprolactinemia)
- 17-hydroxyprogesteron (congenital adrenal hyperplasia)
- 2-hour oral glucose tolerance test using 75 g oral glucose
  fasting glucose less than 110 mg = normal
  110 mg–125 mg = impaired
  greater than 126 mg = type 2 diabetes
  2-hour glucose less than 140 mg = normal
  140 mg–199 mg = impaired
  greater than 200 mg = type 2 diabetes

Ultrasound Examination

- Determination of polycystic ovaries in one or both ovaries
- Identification of endometrial abnormalities

Source: Adapted from American College of Obstetricians and Gynecologists (ACOG). (2009). Polycystic ovary syndrome *(ACOG Practice Bulletin No. 108). Washington, DC: Author.*

Clinical Therapy

Once the diagnosis of PCOS is made, several options are available to the clinician for management. First, the goals for treatment should be established. These include decreasing the effects of hyperandrogenism (hirsutism, acne, etc.); restoring reproductive functioning for women desiring pregnancy; protecting the endometrium (increased risk for uterine cancer); and reducing long-term risks, specifically type 2 diabetes and cardiovascular disease.

If pregnancy is not an immediate goal, menstrual irregularities can be treated with a combined oral contraceptive (COC) or cyclic progesterone. COCs help to regulate menstrual cycles; provide a balance between estrogen and progesterone, thereby protecting the endometrium and decreasing the risk of uterine cancer; and may improve acne by inhibiting ovarian androgen production (Guzick & Hoeger, 2009).

If pregnancy is the immediate goal for the woman and she is overweight or obese, the initiation of a weight loss diet and regular exercise should be the first approach to achieving ovulation. If weight loss does not occur or is not successful in inducing ovulation, the use of clomiphene citrate is the initial therapy of choice for ovulation induction. The starting dose is 50 mg per day usually given on days 5–9 of the menstrual cycle. Approximately 50% of women with PCOS will ovulate on this dose. Ultrasound is done on day 13 to confirm follicle development. If an adequate follicle is present, timed intercourse is then recommended for conception (Guzick & Hoeger, 2009). Although metformin has been used in the past in conjunction with clomiphene citrate, more recent studies show that the combination does not improve ovulatory outcomes and is reserved for women who do not ovulate on clomiphene citrate alone (Guzick & Hoeger, 2009).

Long-Term Implications

PCOS may increase a woman's risk for developing overt type 2 diabetes, dyslipidemia, hypertension, cardiovascular disease, endometrial cancer, breast cancer, and ovarian cancer. Additionally, and very importantly, the woman with PCOS may struggle with significant emotional responses to this chronic disorder. She will likely face, throughout her lifetime, issues related to body image, infertility, problematic menses, and depression.

NURSING CARE MANAGEMENT

The nurse plays a vital role in the identification, evaluation, management, and follow-up when caring for a woman with PCOS. Sometimes it is the nurse who puts the bigger picture together, especially in a community health setting where knowledge of PCOS may be lacking. Women with PCOS may present with complaints such as weight gain, excess hairiness, difficult periods, inability to get pregnant, depression, or expressing feelings like, "What is wrong with me? Why am I not normal like other women?"

Research suggests that the signs of PCOS, especially hirsutism, negatively impact women's feelings of femininity and lead them to invest considerable time and effort in hair removal treatments. Women with PCOS also feel a strong desire to "be normal," with regular menstrual cycles and a more feminine appearance, and struggle with a sense of guilt over their difficulty losing weight (Snyder, 2006). Nurses can help women recognize these feelings and find ways to develop a more positive body image. The nurse also has an important role in providing accurate information, education, and counseling for a woman diagnosed with PCOS. Finally, because the woman with PCOS is at great risk for developing long-term complications, the nurse can play a key role in follow-up and continuity of care throughout the life of a woman facing this challenging disorder.

Care of the Woman with Pelvic Relaxation

The muscles of the pelvic floor form a supportive layer that prevents the abdominal and pelvic organs from prolapsing or sagging downward into the genital tract. If these muscles are weakened or damaged, a variety of conditions may develop, including cystocele, rectocele, and uterine prolapse. Factors that may contribute to diminished pelvic floor muscle tone include damage to these structures related to childbirth; deterioration with age due to estrogen deficiency; metabolic diseases that affect muscle functioning; prolonged lifting; or even chronic coughing due to chronic pulmonary disease, chronic constipation, and obesity (Smith, 2007).

Cystocele

A **cystocele** is the downward displacement of the bladder, which appears as a bulge in the anterior vaginal wall. Arbitrary classifications of mild to severe are frequently given. Genetic predisposition, childbearing, obesity, and increased age are factors that may contribute to cystocele.

Women with a cystocele commonly show symptoms of stress incontinence including loss of urine with coughing, sneezing, laughing, or sudden exertion. The woman may present with complaints of the perception of something "falling out" of her vagina. She may also have urinary retention, problems with sexual dysfunction, or pelvic pressure. If pelvic relaxation is mild, Kegel exercises are helpful in restoring tone (see chapter 16 ∞). The exercises involve contracting and relaxing the pubococcygeal muscle. Women have found these exercises helpful before and after childbirth in maintaining vaginal muscle tone. Estrogen may improve the condition of vaginal mucous membranes—especially in menopausal women. The healthcare provider may refer the woman to a physical therapist who specializes in pelvic floor dysfunction to assist her in learning how to isolate and strengthen the pelvic floor muscles. The use of biofeedback, vaginal weights, electric stimulation, and bladder training may be implemented by the therapist (Rackley, Sandip, Ingber, & Firoozi, 2009). Vaginal pessaries or rings may be used if surgery is undesirable or impossible, or until surgery can be scheduled. Surgery may be considered for cystoceles considered moderate to severe.

The nurse can instruct the woman in the use of Kegel exercises. Providing information on causes and contributing factors and discussing possible alternative therapies greatly assists the woman.

Rectocele

A rectocele may develop if the posterior vaginal wall is weakened. The anterior wall of the rectum protrudes forward, ballooning into the vagina, pushing the weakened posterior wall of the vagina into the vaginal lumen. When the woman strains to have a bowel movement, a pocket of rectum develops that traps stool, and constipation results. The harder a woman with rectocele strains, the larger the pocket becomes. To defecate, women with a rectocele may find it necessary to press the tissue between the vagina and rectum, which elevates the rectocele.

Diagnosis is based on history and physical examination. Decisions about treatment are based on the size of the prolapse, the presence and severity of symptoms, and the woman's individual situation including her overall health status. Surgery is often indicated.

Uterine Prolapse

Because the vagina and the uterus are attached to one another, prolapse of the uterine cervix is associated with prolapse of the upper vagina. The extent of the prolapse is determined by the location of the cervix in the vagina. In severe cases the cervix may prolapse below the vaginal introitus. The woman may report a "dragging" sensation in her groin and a backache over the sacrum, which is caused by pulling on the uterosacral ligaments. Typically these sensations are relieved when the woman lies down. Furthermore, with pronounced prolapse, exposure of the moist vaginal walls may cause a sensation of perineal wetness that the woman might mistake for incontinence. As with cystocele, conservative treatment includes the use of topical or systemic estrogen and vaginal pessaries. Surgery for uterine prolapse often involves hysterectomy and repair of the prolapsed vaginal walls.

Care of the Woman Requiring Gynecologic Surgery

Gynecologic surgeries—particularly hysterectomies—are some of the most common surgical procedures being done in the United States. Many new techniques have been developed

for treating a variety of gynecologic and reproductive disorders, and controversy remains as to the high number of procedures being done annually. For these reasons, it is important for the woman considering medical or surgical management of a given gynecologic problem to be well informed.

There are many components to an informed decision to undergo reproductive tract surgery. Questions that should be addressed include, for example: What are the indications for having the surgery? What are the risks? What is the success rate? Are there other alternative therapies to try before proceeding to surgery? An explanation of the surgical procedure and the reasons it is recommended over other possible therapies should be given to the woman. Effects on childbearing ability and potential impact on sexual performance should be addressed as well as the effects on the general functioning of the body. A discussion of the risks and benefits should be presented, and the risks should include the common risks, the nonserious risks, the rare or unusual complications, and the risk of death.

The question of whether to seek a second opinion about the recommended treatment is somewhat controversial. In the case of elective surgery, different physicians may have very different opinions. A woman should be encouraged to consult other physicians when there is controversy about a treatment (as in the treatment of early cervical cancer) or when the surgeon is unknown to the woman. A specialist in gynecology is the preferred source for a second opinion. Some third-party payment plans require second opinions. The woman can analyze the information and discuss her concerns with the nurse or physician before signing a written consent acknowledging that the information has been given and authorizing the surgery.

Women's Surgery Group

Other concerns that may influence the decision to have reproductive surgery may be categorized as general concerns about surgery and specific concerns related to gynecologic surgery. General concerns may include:

- Fear of general anesthesia because of loss of control or fear of "not waking up"; fear of regional anesthesia because of possible postoperative problems and concern about being awake during surgery
- Fear of death or disability
- Concerns about limitation of normal functioning and dependency during recovery
- Financial coverage for hospitalization, and potential financial loss if it is necessary to take extensive time off from work
- Concerns about welfare of family members while undergoing surgery (such as child care, loss of wages, help with household work)

Specific concerns related to gynecologic surgery are related to the significance of the reproductive organs for the woman. Surgery to alter or remove reproductive organs may be perceived as a threat to self-concept.

Body image is affected whenever a body part is lost. The degree of mourning for that loss is related to the significance attached to it. Even though there is no outwardly apparent change with a hysterectomy and most other gynecologic procedures, the loss may be felt very strongly. Many women fear postoperative changes such as masculinization, weight gain, loss of sexuality, and permanent loss of the ability to have a child. Reproductive surgery may also be seen as a threat to femininity in any social or cultural group that emphasizes childbearing and motherhood.

Hysterectomy

Hysterectomy is the removal of the uterus. In the United States, approximately 600,000 hysterectomies are performed each year, making it the most common non–pregnancy-related surgical procedure that women in the United States undergo (Gor, 2008).

Removal of the uterus through an abdominal incision is called a *total abdominal hysterectomy (TAH)* and removal of both fallopian tubes and ovaries is called a *bilateral salpingo-oophorectomy (BSO);* when both procedures are done at the same time it is termed a TAH-BSO. When the uterus is removed through the vagina it is termed a *total vaginal hysterectomy (TVH).*

A common technique to perform this surgery is a laparoscopic-assisted vaginal hysterectomy (LAVH). In this technique, the surgeon inserts the laparoscope through an incision near the umbilicus and uses it to assist with visualization and dissection to facilitate vaginal removal of the uterus. The benefit is that the surgeon can achieve results similar to those of a TAH without a large abdominal incision. LAVH shortens the hospital stay, allows for shorter recovery time, and is associated with less postoperative pain. The disadvantage of LAVH is a higher risk of injury to adjacent organs (Domingo & Pellicer, 2009).

Hysterectomy is the usual treatment for several conditions, although there is no medical consensus about absolute indications. Abdominal hysterectomy is generally recommended for cancer of the cervix, endometrium, or ovary; large fibroids; severe endometriosis; chronic pelvic inflammatory disease (PID); and adenomyosis. TAH is preferred when malignancy is suspected or confirmed because the procedure allows exploration of the abdomen and pelvis to determine the degree and extent of involvement. This approach is also helpful when large uterine masses are present, requiring a larger incision. Disadvantages include more scarring, more postoperative pain, slower recovery, and more problems with bowel function.

Vaginal hysterectomy is generally done for pelvic relaxation, abnormal uterine bleeding, or small fibroids. An anterior and posterior repair of the vaginal walls may also be performed during TVH. Sometimes this repair is done when weakened pelvic supports have displaced one or more of the pelvic organs (such as the urethra, bladder, or rectum), sometimes causing urinary incontinence, constipation, or defecation problems. Advantages include earlier ambulation, less postoperative pain, less anesthesia and operative time, less blood loss, no visible scar, and a shorter hospital stay. This approach is preferred for the elderly, obese, or debilitated woman who is a poor risk for abdominal surgery. The major disadvantage is increased risk of trauma to the bladder.

Removal of the ovaries at the time of hysterectomy remains controversial. In premenopausal women, without evidence of ovarian pathology, the ovaries are generally left to avoid forced surgical menopause. Because of the risk of ovarian cancer, some physicians recommend removal of ovaries in all women over 40 years old who undergo hysterectomy. Still others rec-

ommend removal of the ovaries in any woman with a family history of ovarian cancer. In any case, removal of the ovaries is not considered routine, and when a BSO is performed in a premenopausal woman, supplemental estrogen replacement therapy is recommended.

Dilation and Curettage

In the United States, dilation and curettage (D&C) is the most frequently performed minor gynecologic procedure. Indications for a D&C may be diagnostic or therapeutic. Diagnostic indications include evaluation for uterine malignancy, infertility evaluation, and investigation of dysfunctional uterine bleeding (DUB). Therapeutic indications include elective abortion, treatment of heavy bleeding, incomplete abortion, dysmenorrhea, and removal of polyps. Sometimes D&C is done after hysteroscopy, which is a procedure that allows visualization of the endometrial cavity and minor surgical procedures. Another procedure that can be done at the time of hysteroscopy is an endometrial ablation, which cauterizes endometrial tissue, preventing regeneration and further bleeding. This procedure is not recommended for women who desire pregnancy, and so a simple D&C may be more appropriate. All of these procedures can be done under general anesthesia, intravenous sedation, and/or regional anesthesia, and most are done as an outpatient procedure.

Uterine Ablation

Several newer techniques and instruments have been developed to treat DUB. One form of therapy gaining wider acceptance is *uterine ablation,* which is a procedure using a variety of specialized instruments to destroy the innermost layer of the endometrium. The instruments often involve some type of heat source, such as cautery or a balloon filled with hot water. In most cases, this procedure is done in a day-surgery setting, and it will often immediately follow a hysteroscopy/D&C, if these procedures confirm the diagnosis of simple endometrial hyperplasia. The success rate varies, depending on the device used and the experience of the operator of the device, but some manufacturers quote as high as a 75% success rate with uterine ablation.

Salpingectomy

The unilateral or bilateral removal of the fallopian tube is called a *salpingectomy*. Indications include diseases of the tubes, sepsis, malignancy, and ectopic pregnancy of the fallopian tube. Salpingectomy for an ectopic pregnancy is generally an emergency procedure. The developing placental tissue erodes the fallopian tube and can cause rupture and hemorrhage once the tube is completely eroded. This procedure can be done via laparoscopy or via an open abdominal approach.

Oophorectomy

Oophorectomy is the unilateral or bilateral removal of the ovary. Indications include severe PID, malignancy, ectopic pregnancy, and symptomatic ovarian cysts. When both ovaries are removed in a premenopausal woman, abrupt surgical menopause occurs. In this case the woman will experience the same symptoms she might in natural menopause: decreased libido, decreased vaginal lubrication, hot flashes and/or night sweats, and decreased sensation in the lower vaginal tract. These symptoms can be treated with estrogen replacement.

Vulvectomy

A *simple vulvectomy* is the removal of the labia majora, labia minora, and clitoris. *Radical vulvectomy* is the removal of the entire vulva, including the skin and the fat of the femoral triangle, and the pelvic lymph nodes. Skin grafts may be necessary. A simple vulvectomy is performed for leukoplakia and intractable pruritus, whereas a radical procedure is done for malignant disease.

This disfiguring procedure is associated with marked psychosexual disturbances. Most women report decreased sexual arousal levels and low self-image. Sexual activity can be resumed within 3 months; however, significant adjustments will be necessary owing to the loss of sensory perception for foreplay. Stimulation of breasts, thighs, buttocks, or anterior abdominal wall can be suggested.

Pelvic Exenteration

A pelvic exenteration is performed for recurrence of cervical cancer. Only about 5% of women with recurrence are candidates for this procedure, which is not performed if there is any evidence of tumor outside the pelvis, if the cancer has metastasized to the lymph nodes, or if all of the tumor cannot be removed.

Exenteration can be of the anterior or posterior pelvis, or of the total pelvis. Anterior exenteration is the removal of the uterus, ovaries, fallopian tubes, vagina, bladder, urethra, and pelvic lymph nodes. Urine is diverted through an ileal conduit. Posterior exenteration is the removal of the uterus, fallopian tubes, ovaries, descending colon, rectum, and anal canal. A colostomy is created. A total exenteration is a combination of the anterior and posterior procedures. A vagina can be reconstructed from split-thickness skin grafts or a segment of small bowel.

Complications associated with exenteration include intestinal and urinary obstruction, thrombophlebitis, pulmonary embolism, pyelonephritis, hypovolemia, peritonitis, pneumonia, and wound infection.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Nursing assessment for all of these surgical procedures includes identifying the woman's physiologic, psychosocial, and sexual needs as she approaches her surgery. Additionally, it is important to understand her learning needs about the procedure and its effects. Some factors to consider are the age of the woman, her cultural background and educational level, the attitude of her partner and family, her preoperative status (physically and emotionally), and whether or not this involves a cancer diagnosis. The significance of her reproductive health to her self-image will be reflected in her attitudes about menstruation, childbearing, body image, and sexuality. Many of these procedures have the potential to involve loss, so grieving, anger, sadness, and loss of control are just a few of the feelings the woman may experience.

Nursing diagnoses that may apply to a woman facing gynecologic surgery include the following:

- ***Deficient knowledge*** related to lack of information about preoperative routines, postoperative activities, and expected postoperative changes
- ***Fear*** related to the unknown outcome and long-term implications of the surgery

Nursing Plan and Implementation

Preoperative teaching may be brief in the instance of a simple D&C, or quite extensive in the instances of hysterectomy or pelvic exenteration. In any case, preoperative teaching should include information about the procedure, expected preparation, type of anesthesia to be used, possible risks and complications, postoperative care routines, and expected recovery time. See Figure 7-5 ■.

Routine postoperative care includes monitoring of physiologic responses, emotional responses, and nursing interventions to facilitate physical and emotional well-being specific to the procedure performed. The woman should be aware of potential postoperative complications and when to follow up with her surgeon. Additionally, it is important to discuss those psychosocial issues identified preoperatively, such as support at home, potential for sadness or depression related to the loss she has experienced, and expected sexual and self-image fears. In some instances, it may be necessary to refer the woman to a professional therapist who can help her adjust to these dramatic changes.

Figure 7-5 ■ The nurse provides information for the woman during preoperative teaching.

Source: Michal Heron/Pearson Education.

Evaluation

Expected outcomes of nursing care include:

- The woman can discuss the reasons for her surgery, the alternatives, and the aspects of self-care after surgery.
- The woman has an uneventful recovery without complications.
- The woman feels she is able to ask questions and obtain support.
- The woman participates in decision making about her care.
- The woman is aware of available resources if she has physical or emotional concerns in the postoperative period.

FOCUS YOUR STUDY

- With fibrocystic breast changes, the cysts tend to be round, mobile, and well delineated. The woman generally experiences increased discomfort premenstrually.
- Because of the increased risk of breast cancer, women with fibrocystic changes should understand the importance of monthly breast self-examination (BSE).
- Galactorrhea (nipple discharge not associated with lactation) should be evaluated with cytologic testing.
- Breast cancer affects one in eight women in the United States. Biopsy is essential for a diagnosis, and prompt treatment is critical.
- Vulvitis is an inflammation of the vulva often caused by external irritants such as tight clothing, feminine hygiene products, and some harsh soaps.
- Vulvar lesions range from slight irritation to vulvar cancer. A common vulvar lesion found in postmenopausal women is atrophic vaginitis. All vulvar lesions should be closely evaluated because cancer of the vulva can have various presentations.
- Pap smear screening is recommended for all women 21 years of age and older. Several factors put a woman at high risk for an abnormal Pap: intercourse at a young age,

multiple partners, history of immunotherapy, long-term combined oral contraceptive (COC) use, smoking, and previous history of dysplasia. Human papilloma virus (HPV) is highly associated with abnormal Pap smears.

- Abnormal uterine bleeding can occur with or without organic pathology. Treatment is geared toward controlling bleeding, preventing anemia, and detecting pathology.
- Toxic shock syndrome, a rare but potentially fatal disease, is usually caused by a toxin of *Staphylococcus aureus* and is most common in women of childbearing age. There is an increased incidence in women who use superabsorbent tampons or barrier methods of contraception, such as the diaphragm and cervical cap, especially if the woman leaves them in place for extended periods of time.
- Endometriosis is a condition in which endometrial tissue occurs outside the endometrial cavity. This tissue bleeds in a cyclic fashion in response to the menstrual cycle. The bleeding leads to inflammation, scarring, and adhesions. The prime symptoms include dysmenorrhea, dyspareunia, and infertility.
- Treatment of endometriosis may be medical or surgical, or a combination of both. For the woman not desiring pregnancy at present, oral contraceptives are used. Women desiring pregnancy are treated with danazol or the gonadotropin-releasing hormone (GnRH) analogs.
- Polycystic ovary syndrome (PCOS) is a disorder of unknown etiology characterized by ovulatory dysfunction, hyperandrogenism, and polycystic ovaries. Women with PCOS often experience infertility, hirsutism, and difficulty controlling their weight. They are at increased risk for type 2 diabetes and cardiovascular disease.
- There are three common forms of pelvic relaxation: A cystocele is a downward displacement of the bladder into the vagina. Often it is accompanied by stress incontinence. Kegel exercises may help restore tone in mild cases. A rectocele is displacement of the rectum into the vagina. Prolapse of the uterus is displacement of the uterine cervix into the vagina.
- Gynecologic surgeries are some of the most common surgical procedures performed in the United States. It is important for the nurse to understand the purpose of the procedure, to know the alternatives to surgery, and to assess the woman's emotional response.

CRITICAL THINKING IN ACTION

Mercedes de Martini is a 32-year-old gravida 2, para 2 who has a well-documented history of fibrocystic breast changes. Mercedes's breast symptoms typically increase premenstrually, when her breasts become markedly nodular and dense. She is being seen today because she has a palpable "lump" in her left breast that she describes as painful and easily movable. Mercedes reports that her menses is due in 5 days. Based on history and physical examination, the physician suspects that Mercedes has developed a cyst and decides to complete a fine-needle aspiration.

1. Identify findings on examination that might help distinguish a cyst from breast cancer.
2. Why is a fine-needle aspiration done?
3. What steps can Mercedes take to help decrease the discomfort associated with her fibrocystic breast changes?

See www.nursing.pearsonhighered.com for possible responses.

Women's Care: Social Issues

CHAPTER 8

There has never been a more exciting time for women. Although we face many challenges—work, wage, and role issues; safety in pregnancy and childbearing; and conflict over women's rights—we have never been more active and involved in issues that affect us. Moreover, the men who care about us, and recognize the importance of fairness for all, are beginning to join us in speaking out. Together, men and women of integrity and vision are making a difference in women's lives.

LEARNING OUTCOMES

1. Define the phrase *feminization of poverty.*
2. Identify factors that contribute to the wage gap between women and men.
3. Discuss poverty's effect on women's health care.
4. Describe the impact of the Family and Medical Leave Act (FMLA) of 1993 on maternity and paternity leave.
5. Identify environmental hazards that may be present in the workplace or home of a woman of childbearing age.
6. Specify the factors that contribute to older women's economic vulnerability.
7. Identify four different categories of elder abuse.
8. Discuss the implications of aging on women's health and health care.
9. Summarize the five main types of disability.
10. Discuss ways in which a woman's disability may affect her health care.
11. Explain the implications of homophobia for lesbian and bisexual women's health care.
12. Identify types of discrimination commonly faced by lesbian and bisexual women.
13. Discuss the cultural implications of female genital mutilation.

KEY TERMS

Civil unions *160*
Comparable worth *150*
Disability *158*
Domestic partnership *160*
Elder abuse *156*
Environmental toxins *153*
Female genital mutilation (FGM) *161*
Feminization of later life *155*
Feminization of poverty *146*
Polypharmacy *157*

In the 21st century, many women in developed nations are creating and experiencing new opportunities for personal and professional growth. Despite these unparalleled opportunities, other women still struggle daily to overcome poverty, age discrimination, abuse, the economic and interpersonal effects of disability, and unequal treatment because of sexual orientation. Even the most successful and satisfied working women face wage discrimination, lack of safe and nurturing day care for their children, and failure of their governments to support paid maternity and paternity leave.

Every day in their clinical practices, nurses working with women are confronted with these issues and their impact on women's health and well-being. To help nurses better understand their patients' concerns and problems, this chapter addresses some of the serious social issues facing women today.

Social Issues Affecting Women Living in Poverty

For impoverished women, life is a day-by-day struggle fraught with anxiety and hardship.

> "I never thought this would happen to me. Two months after I became pregnant with our second child, it was over. My husband left us. Suddenly, I am the sole support of myself and my children. Since he left I haven't been able to get a job, so I don't have medical insurance or any benefits to help with this pregnancy. Applying for Medicaid has to be one of the most humiliating experiences I have ever had. I'm an intelligent woman with a college degree, and yet I couldn't figure out the forms. I felt so dumb. The lines and the impersonal treatment that you hear about are real. I felt like a number, shuttled from one place to the next. I know they don't do it on purpose; they've heard so many awful stories. Still, it hurt. It will take 6 weeks to qualify for assistance, and by then I will be more than halfway through my pregnancy. What's more, only two doctors here accept Medicaid, and they are clear across town—that means three bus transfers with a 2-year-old in tow. I'm thankful that I can get some help, but it is so hard. I never dreamed I'd be in this position. I just never dreamed."

The Feminization of Poverty

The fact that many more women than men live below the poverty level is reflected in the phrase **feminization of poverty**, which was coined by Diana Pearce in 1993. Increasing numbers of U.S. women and their children are attempting to live on $22,050 or less, which is the current income that defines the poverty level for a family of four. In 2008, the number of women living in poverty totaled 14.1 million, or more than 12% of all women 18 years of age or older (Department of Health and Human Services [DHHS], 2009).

Women raising children alone are especially likely to be impoverished. In 2007, only 8.5% of families headed by a married couple lived in poverty, but among households headed by single mothers the percentage was 28.3% (DHHS, 2009). With a divorce rate of approximately 40%, an out-of-wedlock birth rate of about 38.5%, and the median age at first marriage rising for men and women, the reality is that many children will spend at least a portion of their lives in a single-parent family (Centers for Disease Control and Prevention [CDC], 2009b).

The number of children in the United States living in poverty is disturbing. Eighteen percent live below the poverty level. No other age group, not even the elderly, has a higher poverty rate. The two demographic factors most strongly associated with children's poverty are female-headed family and race. Parental gender is important because men earn more money overall than women; women working full time year round earn 78% of what men earn. In 2007, men earned an average of $45,113 per year, whereas women earned $35,102 (U.S. Census Bureau, 2008). More than 43% of impoverished children live in female-headed homes (U.S Census Bureau, 2008). Parental race is related to poverty in children because ethnic minority parents tend to have less education and lower incomes, on average, than Caucasian parents. Twenty-four percent of black children and 21% of Hispanic children live in poverty, but only 12% of Caucasian children do. Currently, two thirds of all poor people in the United States are women and children; in other words, women and children account for most of the people living in poverty (Figure 8-1 ■).

The feminization of poverty is also evident in the rising trend for women to declare bankruptcy. In 2005, new bankruptcy laws were passed that reduced consumer protection and gave lenders more leverage to push for repayment. These new laws have hurt women who are divorced, separated, or widowed, particularly single mothers. Single mothers often work in low-wage jobs and have been shown to be more likely to file for bankruptcy than married parents and 3 times more likely than childless couples. Estimates indicate that 30% of those filing for bankruptcy are single women. In 2008, bankruptcy filings increased 43% in response to an economic recession and heightened unemployment rates (Bankruptcy Action Coalition, 2009).

The feminization of poverty extends beyond the United States. Although there are many scales used to measure global poverty, the Purchasing Power Parity (PPP) scale uses calculations based on money available for purchasing. It is estimated that 1.4 billion people in the world live on less than $1 per day, an additional 2.5 billion live on less than $2 per day, and 80% of the world's population lives on less than $10 per day (UNICEF, 2009; World Bank, 2009). Globally, women must cope with some unique challenges. They typically work more hours than men but are paid less for the same work; they are often expected to bear and raise many children, sometimes in addition to performing a job outside the home; they are frequently abused and beaten in their own homes; and often they have few legal rights.

Both globally and in the United States, poverty has been directly linked to a lack of literacy and educational attainment. In many countries, the literacy rate for females is lower than that for males, and education—when available—is more frequently

Figure 8-1 ■ Two thirds of Americans living in poverty are women and children.

provided for men even though economic returns on investment in women's education are found to exceed those for men. Also, women who use their skills to increase their income typically invest more in their children's health and education.

Economic Effects of Divorce

The increase in the number of female-headed families is closely associated with divorce. Almost one out of every two marriages ends in divorce. As a result of divorce, a woman's standard of living generally decreases significantly, whereas a man's increases. This dramatic change in the standard of living is usually associated with the lower earning capacity of women, the fact that women receive custody of the children in 75% of cases, and that women often accept lower support payments in exchange for a guarantee of custody (McIntosh & Chisholm, 2008). Although only about one half of divorced women receive the full amount of promised child support payments, tightened enforcement policies at the national level have increased the percentage of men who meet their obligations, either partially or in full, through improved rates of paternity establishment, support order initiation, and support collection. The United States Department of Justice actively investigates and prosecutes individuals who cross state lines to avoid paying child support, and the federal government now intercepts delinquent parents' income tax refunds. To make it easier to track delinquent parents across state lines, employers are required to report all newly hired employees to state agencies, which then transmit the information to the national directory. Moreover, states are required to establish central registries of child support orders and centralized collection and disbursement units. States are permitted to implement tough collection techniques, including garnishing wages, seizing assets, revoking driver's and professional licenses, and, in some cases, requiring mandatory community service of individuals who are delinquent in making child support payment. Information about the enforcement program may be found on the DHHS Office of Child Support Enforcement's Internet home page.

Factors Contributing to Poverty in Working Women

Women have steadily increased their participation in the labor force. In the United States, the number of working women has risen from 5.1 million in 1900, to 18.4 million in 1950, to nearly 68 million in 2008 (U.S. Department of Labor, 2009).

Along with their participation in the labor market, women have steadily increased their earnings; however, a significant wage discrepancy still exists. In 2008, women employed full time earned only about 80% of men's median weekly wages, and for women of color, the gap was wider: African American women earned 63.3%, and Latina women 51.7%, of men's weekly earnings. Although Asian Pacific American women do better, they still earn only 83.5% as much as men (United States Committee on Pay Equality, 2008). The disparity between men's and women's wages may be attributed to several factors:

- About one third of women work in a cluster of "pink collar" occupations, which tend to be poorly paid when compared with male-dominated positions requiring comparable levels of responsibility, skill, and education. When men are employed in these occupations, however, they tend to make more than their female counterparts (Dey & Hill, 2008).
- Women are paid less than men for comparable work in virtually all occupations: In 2008, professional and technical women earned almost 27% less than their male counterparts, whereas women in office and administrative support occupations earned over 12% less. Even women in female-dominated fields (teaching, office work, clerical work) are outearned by male peers (Dey & Hill, 2008).
- Because women are paid less when they work, they receive smaller pensions and social security benefits when they retire. More older women rely on social security payments as their primary source of income than do men. More retired men receive private pensions than do women because, until recent times, fewer women worked in their younger years and thus did not accrue the years of service necessary to participate in a pension program (Employee Benefit Research Institute, 2010). Only 16.4% of older women derive their earnings from employment-based finances compared to 30.5% of older men (Employee Benefit Research Institute, 2007). Part-time workers, who make up 20% of the U.S. workforce, many of whom are women, often have no benefits such as sick leave and health insurance (Shulman, 2009).

For working divorced or single women with children, the issue of child care is especially difficult. Child care is expensive and places a tremendous burden on the single parent's household budget. Moreover, with no partner to bear the burden, divorced or single mothers without social support must miss work when their children become ill, causing employers to view them as unreliable or uncommitted. Currently, more enlightened employers are beginning to recognize and accommodate the needs of mothers in the workforce. Like other areas of reform, however, this trend tends to benefit women in better paying, more secure positions far more than it benefits women who are poor and in low-paying positions.

Public Assistance

The U.S. welfare system was originally designed to provide assistance to those in need, frequently single female heads of households and their children. Unfortunately, the system often failed to provide adequate assistance to raise families above poverty levels and, in many cases, actually provided disincentives for women to work.

In 1996, growing national concern over the failure of the system led to welfare reform via the passage of the Personal Responsibility and Work Opportunity Reconciliation Act. As part of the act, a block grant known as the Temporary Assistance for Needy Families (TANF) was created. The TANF grant replaced the Aid to Families with Dependent Children (AFDC) program, which had provided cash welfare to poor families with children since 1935. The TANF program became the TANF Bureau within the Office of Family Assistance in 2006 and administers all its programs.

TANF is implemented through block grants to the states. States use these funds to operate their own programs in whatever fashion they choose, provided they are congruent with the four TANF purposes set out in federal law:

- Provide assistance to needy families so that children may be cared for in their own homes or in the homes of relatives.
- End the dependence of needy parents on government benefits by promoting job preparation, work, and marriage.
- Prevent and reduce the incidence of out-of-wedlock pregnancies and establish annual numerical goals for preventing and reducing the incidence of these pregnancies.
- Encourage the formation and maintenance of two-parent families.

Under TANF, states are granted unprecedented flexibility in designing welfare programs to meet the needs of their recipients, but they must demonstrate measurable results in moving families toward self-sufficiency and work. With few exceptions, recipients are required to find employment after they have received assistance for 2 years. Work requirements may be met through participation in subsidized or unsubsidized employment, community service, on-the-job training, or 12 months of vocational education. Recipients can also meet the requirement by providing child care services to others who are involved in community service. After 5 cumulative years of assistance, families become ineligible for cash aid, although states can exempt up to 20% of their cases from the time limit provision. States can also choose to use state funds or social security block grant dollars to provide additional noncash assistance and vouchers for families who have reached the time limit. TANF provides $17 billion, which includes child care funding, to enable mothers to provide for adequate child care as they move into jobs. Women on welfare are guaranteed continued healthcare coverage for their families, including at least 1 year of transitional Medicaid as they leave the welfare rolls for work.

The law also mandates that unmarried teenage parents live at home (or in an adult-supervised setting) and stay in school in order to receive assistance (The Urban Institute, 2010). As discussed previously, the act also contains several provisions designed to crack down on noncustodial parents who fail to pay child support.

Several trends have emerged as a result of the welfare reform efforts. A comparison of welfare recipients' pre-TANF status in 1996 to their post-TANF status in 2008 reveals the following: more single women on welfare are living with partners, a decrease in the poverty rate, a decrease in the poverty gap (the amount of income necessary to lift poor families out of poverty), and an increase in the number of families that include at least one working parent (Falk, 2006). Although results appear favorable, it is too early to judge more long-term effects of welfare reform; many parents who have entered the workforce have not yet escaped poverty.

Homelessness

For many people the thought of a homeless person conjures up a vision of an older man curled in a doorway or making a home under a bridge. However, this vision is less accurate today than in the past; today's homeless people have very different characteristics. It is estimated that 3.5 million people, including 1.35 million children, are likely to experience homelessness within a given year. That equates to 6.3% of the population of those living in poverty (National Law Center on Homelessness & Poverty, 2010). Homeless families with children represent the fastest growing group of homeless, having increased to 33% of the homeless population. Children account for 39% of the homeless population and 42% of these children were under the age of 5. Many of these families are composed of single mothers and their children. In addition, single childless women make up 17% of the homeless population (National Coalition for the Homeless, 2008).

Factors Contributing to Homelessness

Because of the nature of homelessness, it is very difficult to come up with a number that reliably reflects the number of people who experience homelessness. Data collected by various local jurisdictions indicates that the homeless population is continuing to increase each year. Approximately 90% of homeless families are headed by a single mother. A major factor contributing to the incidence of homelessness is a lack of housing that low-income people can afford. During the past 20 years, housing costs have increased far more than wages or other income sources, especially for women. In many communities, low-income housing has waiting lists of several hundred families. In addition, federal support for low-income housing has fallen by 49% since 1980 (National Coalition for the Homeless, 2008).

Another factor contributing to homelessness is domestic violence. Research suggests that as many as 22% of homeless women and their children are fleeing from an abusive situation (National Coalition for the Homeless, 2008). Domestic violence and lack of affordable housing are interrelated factors contributing to women's homelessness. Women often return to abusive living situations following unsuccessful attempts to find adequate affordable housing. Many women who have been victims of domestic violence lack rental and employment histories or have poor credit; all are barriers to finding adequate housing and can lead to homelessness.

Other factors that contribute to homelessness include job loss, eroding work opportunities, mortgage foreclosure, low-paying jobs, substance abuse, untreated mental illnesses, domestic violence, poverty, prison release, and changes and cuts in public assistance programs (National Coalition for the Homeless, 2008). Race, education, and the number of children a woman has borne also influence the likelihood that she will experience homelessness. The homeless population consists of 49% African American, 35% Caucasian, 13% Hispanic, 2% Native American, and 1% Asian (National Coalition for Homelessness, 2008). Years of education varied inversely with episodes of homelessness, and women who had given birth to more children experienced homelessness more often than women who had fewer children. The incidence of homelessness is also related to the extent of a woman's social support system. Because middle-class women typically have relatives and friends with more living space and resources, they are able to avoid becoming homeless to a greater extent than poorer women.

A rising concern exists that the nation's weakening economy, bankruptcies of large and small commercial companies, and associated job losses are also having a negative impact on the incidence of homelessness. In 2008, a record number of 3.1 million home foreclosures occurred. In 2009, it was estimated that more than 350,000 foreclosures were occurring monthly (Christy, 2009). These foreclosures dramatically increased the number of homeless families living in the United States. Many of the foreclosures were the result of adjustable rate low-interest or interest-only loans that had adjusted to higher interest rates and thus higher monthly mortgage payments that the borrowers could no longer afford to pay. In addition, the unemployment rate rose during the same period to 8.9%, the highest rate since 1983 (U.S. Bureau of Labor Statistics, 2009). Job losses combined with losses of homes led to a significant increase in homelessness. The demand for shelters and subsidized housing increased rapidly.

Health Risks of Homeless Women and Children

Homeless women and children experience greater health risks and problems than do people in the general population. Malnutrition predisposes homeless people to a variety of respiratory and nutritional disorders. Moreover, a disproportionately high number of homeless women and children have not received preventive healthcare services, such as screening tests and immunizations.

Homeless women who are pregnant are a special challenge for healthcare providers. Inadequate prenatal care, limited access to general health care, poor nutrition, and inadequate housing lead to poor birth outcomes, including an increased incidence of low-birth-weight newborns and a higher rate of infant mortality. In addition, as a group they are at risk for many illnesses that could negatively affect their pregnancies, including substance abuse; sexually transmitted infections; and hepatitis A, B, and C (Bloom et al., 2006).

Even when prenatal care services are available in the community, 75% of homeless pregnant women feel there are barriers to services, including costs, fears, inconvenience, site-related factors, and issues with the provider-patient relationship (Bloom et al., 2006).

Effects of Poverty on Women's Health Care

The effects of poverty on women's health care are extensive. Since 1981, many funding cuts have reduced or eliminated programs that used to help families in poverty access health care. Funding has not been restored, even though adequate nutrition and prenatal care have been proven to yield significant healthcare benefits.

Medicaid is the major U.S. program providing health care to low-income people in four categories: children, adults in families, the elderly, and blind and disabled people. Traditionally Medicaid has played an important role in financing maternity care, covering the costs of about 40% of births in the United States. Because welfare reform measures eliminate the automatic connection between TANF and Medicaid and mandate that women apply for Medicaid separately, the number of women that Medicaid serves may be shown to have decreased over the years since the inception of TANF. Although such an outcome would certainly be undesirable, the overall effect of welfare reform on women's health is not yet clear. Some research suggests that because women on Medicaid are served in managed care programs that typically stress preventive care, poor women's health will improve. TANF recipients are eligible for programs including WIC (Women, Infants and Children nutrition program), nonmedical home visiting for families, and youth development programs aimed at reducing out-of-wedlock births (State Health Department of Minnesota, 2008). A study showed that women enrolled in the Florida Medicaid program had a 2.5% less chance of delivering a small-for-gestational-age infant compared to those not enrolled in Medicaid (Morse, Zheng, Tang, et al., 2009). Investigators in another study found that women enrolled in Medicaid for family-planning services saved over $5.7 billion in pregnancy-related expenditures by not becoming pregnant and attending family planning clinics instead (Frost, Finer, & Tapales, 2008).

Lack of health insurance is also a major problem for the poor. In 2007, 45.7 million people were without health insurance coverage of any kind. The number of people covered by government programs such as Medicaid and The State Children's Health Insurance Program increased from 80.3 million in 2006 to 83 million in 2007. Lack of employment and eligibility for publicly funded programs are responsible for these trends: The percentage of people covered by private health insurance decreased from 67.9% in 2006 to 67.5% in 2007 (Reinberg, 2008). Decreases in health insurance coverage have led to declines in preventive health care that are costing dollars and even lives. Women who do not receive prenatal care are 3 times more likely to have low-birth-weight babies, and the incidence of low-birth-weight babies is increasing. Women who receive adequate prenatal care are less likely to develop severe complications, such as preterm labor. Moreover, lack of prenatal care is a risk factor for infant morbidity and mortality.

The issue of women and poverty is critical, and the implications for childbearing care are very real. A pregnant woman who is suffering economically may also suffer physically and psychologically. In the end, it is often the children who suffer

the most, bearing the physical and psychologic scars of their mothers' struggles. As healthcare professionals, nurses should be concerned about the issue of women and poverty. The limited resources available to impoverished women often frustrate nurses' efforts to provide quality care. Nurses need to explore their own beliefs about poverty and public assistance programs and inform others about the barriers poor women face.

Assessing women's financial status is a nursing responsibility, because some women may not have the economic resources to buy infant supplies or other medical supplies that may be needed in the home setting. The nurse asks questions in a sensitive manner and refers women with insufficient resources to social workers or appropriate agencies. A nurse who is knowledgeable about community resources and who can provide the woman with follow-up contacts and phone numbers provides an immeasurable service to impoverished patients.

PROFESSIONALISM IN PRACTICE

Assisting Impoverished Women

Nurses can assist impoverished women by working with community groups and organizations and becoming actively involved in the political process. Nurses can use their work experience to present their views to legislators, support various childbearing programs, and alert legislators to legislation that would benefit mothers and families. Nurse researchers can explore medical and social issues related to the impact of poverty on families.

Social Issues Affecting Women in the Workplace

In 2008, women workers totaled more than 68 million within the U.S. workforce (U.S. Department of Labor, Bureau of Labor Statistics, 2008). Seventy-five percent worked full time, whereas 25% worked part time (U.S. Department of Labor, 2009). As a result of political and social changes that began in the early 1970s, women's career options have expanded dramatically. Although many women still choose careers traditionally entered into by women (office work, nursing, etc.), or choose to stay home full time to raise children, others are entering occupations that until recently were reserved for men. More women than ever have joined the ranks of lawyers and judges, authors and artists, managers and corporate heads, scientists, engineers, legislators, construction workers, plumbers, and electricians, and thus are sharing in the benefits that come with these positions.

Progress has its costs, however. For example, the woman with both a career and a family may experience tremendous day-to-day stress in attempting to fulfill both her professional and mothering roles. The woman who would like nothing more than to be a stay-at-home mother may be forced by financial pressures to work outside the home and entrust the care of her children to others. Women who do stay at home to raise their children sacrifice earnings, retirement savings, and social security benefits, and have decreased opportunities for social contact and intellectual stimulation. In contrast, the woman who has devoted her prime childbearing years to establishing a career rather than a family may feel a deep sense of loss as she ages.

Several social issues affect women in the workplace. Key among these are wage discrepancy, maternity/paternity leave issues, child care, and environmental hazards.

Wage Discrepancy

In 2008, the male-to-female earnings ratio was approximately 79.9%. This means that in that year, women, on average, earned about 79.9 cents for every dollar earned by men (Institute for Women's Policy Research, 2009). To keep this percentage in perspective, however, bear in mind that 40 years ago the wage discrepancy between men and women was much greater. Over the past four decades, women have entered the labor market in great numbers and have also substantially increased their level of educational attainment. For example, in 1970, only 8% of workers classified as professionals (physicians, executives, lawyers, etc.) were women, but by 2008, the percentage had soared to 39%. At the same time, the wage gap between professional workers and blue-collar workers (laborers, service workers, etc.) widened considerably. Consequently, the overall wage discrepancy between men and women declined as women's educational attainment grew and their workforce participation increased. Nevertheless, a wage gap remains, and, ironically, it is widest between well-educated women and men.

Wage disparities begin early in professional women's careers. A study by the American Association of University Women (2009) found that these wage gaps kick in as early as 1 year after college graduation, when female counterparts are making 80% of their male peers' earnings. Within 10 years after college graduation, the percentage drops to 69%. The decreasing, but tenacious, discrepancy between men's and women's wages is thought to be related to a number of factors: deliberate wage discrimination against women, undervaluing of women's work, and women's socialization.

In the past, deliberate and blatant wage discrimination against women was ubiquitous and generally accepted. Women's wages were purposely set lower than men's because it was assumed that men needed substantial funds to support families whereas women did not. In the 1960s and 1970s, women's groups and unions pushed for legislation that would end wage discrimination by mandating that compensation for various types of work be based on **comparable worth**, which means equal pay for work that is of comparable value and requires comparable skills, responsibility, education, and experience. Comparable worth legislation was opposed by business leaders, who argued that wage disparities were rooted not in discrimination against women, but in differences in educational level and seniority, and that basing wages on comparable worth would decrease U.S. manufacturers' ability to compete with foreign manufacturers and reallocate limited salary resources away from lower-class, minority men to middle-class, Caucasian women. Such arguments prevailed, and comparable worth legislation proposed during the Carter administration (1977–1981) was never implemented. Comparable worth has not been raised as a serious issue in recent years, even though research has demonstrated that neither worker nor job characteristics fully account for the wage differences between men and women and that the gender of individuals performing a given job

is the best single predictor of the salary associated with that job. Surveys of wage trends show that when the proportion of women in a given occupational field increases, the average weekly salary level decreases. Women commonly are clustered in low-wage jobs such as child care, in which 87% of the workers are women (American Association of University Women, 2009).

Labor classified as "women's work" has been historically undervalued, and that pattern continues and contributes to the wage gap. In 2008 the mean hourly wage for occupations classified under construction and extraction (e.g., brick masons, construction laborers, paving equipment operators), in which male workers predominate, was $20.91. In contrast, the mean hourly wage for the largely female workers in healthcare support occupations (e.g., home health aides, medical assistants, and nursing aides) was $11.68 (U.S. Department of Labor, Bureau of Labor Statistics, 2009). Whether wage discrimination favoring males exists in the nursing profession is not clear. Although it is known that overall, male nurses outearn female nurses, some attribute that phenomenon to the fact that male nurses are overrepresented in high-paying nursing specialties such as anesthesiology. The small numbers of men in the profession make it difficult to determine whether men working in the less well-compensated areas of nursing practice are also better compensated, overall, than women.

Women can combat wage discrimination in several ways. First, they can refuse to contribute to the secrecy about wages that allows some employers to get away with paying women less than men for doing the same job. Women can also actively push for wage equity by making community leaders and legislators aware of wage discrepancies and by urging legislators to support legislation that enhances equal employment and wages for women.

Women's socialization has long been thought to contribute to the wage gap. Although most boys are encouraged to develop a competitive spirit, first in sports and then in other areas of their lives, girls may lack this early introduction to healthy competition, because the willingness and ability to compete has not been seen as an important or desirable trait for a girl to have. Also, some girls learn from their parents, the media, their peers, and others that physical attractiveness, rather than intelligence and hard work, is the key to popularity and success. And, until relatively recently, another significant factor was women's tendency to settle for lower levels of education than men and then choose to work in poorly compensated "women's fields." Since 1982, however, more American women than men have earned bachelor's degrees, and parents, educators, and other concerned citizens have lobbied successfully for programs that encourage girls to explore a wide range of academic pursuits and career options, especially in fields not traditionally seen as welcoming to women. For example, the Department of Labor has developed a mentoring program that encourages schoolgirls to seek nontraditional, higher paying careers.

PROFESSIONALISM IN PRACTICE

Speaking in Public

Speaking out about issues that affect women, children, and families is an integral part of maternal-child nursing. It is difficult for many nurses to do this, so you should practice with friends and family frequently. Be prepared with accurate information, and try various techniques for presenting the information. A friendly, supportive audience helps you get started.

Maternal and Paternal Leave Issues

Combining full-time employment with motherhood has always been challenging. In the past, women who took official or unofficial maternity leave to bear a child often lost benefits, missed out on promotions, or lost their jobs completely. Paternity leave for fathers was unheard of, and remains rare, even in developed countries.

Parenthood and employment became a bit more compatible in 1993 when President Clinton signed the Family and Medical Leave Act (FMLA) into law. FMLA permits employees to take up to 12 weeks of unpaid leave from work following the birth or adoption of a child or the placement of a foster child. Employees may also take leave if faced with serious illness or the illness of a spouse, child, or parent. Health insurance benefits must be continued during the leave, and employees are entitled to return to their former position or one considered comparable. Because the FMLA applies only to companies with 50 or more employees, however, the vast majority of companies are not subject to the law. Moreover, coverage is not mandated for employees who work fewer than 25 hours per week or who have been employed less than 1 year. Thus about 25 million employees are not covered by FMLA and must rely on whatever policies their employers have established. Even though FMLA applies to men as well as women, U.S. fathers often fail to take advantage of it. Studies have shown that American men often forgo paternity leave because they fear that taking it will hinder their careers and that men who do take it feel stigmatized. Companies often send out subtle messages to men that paternity leave exists only on paper; men who do take paternity leave are often seen as pioneers even though the law has been in effect since 1993.

Despite the advances made in this country by the FMLA, parental leave benefits in the United States are meager in comparison with benefits provided in other countries. In other parts of the world, paid parental leave is the rule rather than the exception, and the funding source is often public rather than the private employer. Paid maternity leave, and often paternity leave as well, are standard in most European countries and Canada. The United States remains one of the few countries that have no legislation requiring a national *paid* maternity leave program.

Discrimination Against Pregnant Women

Discrimination against pregnant women by employers who cling to false stereotypes about them (that they cannot do their jobs, that they take more sick leave than other employees, that they fail to return to work after having given birth) remains an issue in some areas. Each year, the Equal Employment Opportunity Commission receives complaints from pregnant women who were turned down for jobs, denied transfers to positions for which they were qualified, or fired unjustly (U.S. Equal Employment Opportunity Commission, 2006). Thus it is important that pregnant women be aware of their

legal rights. The Pregnancy Discrimination Act of 1978 guarantees the following:

- A pregnant woman cannot be denied a job if she is able to perform major job functions.
- The same procedure for using sick leave pay or disability benefits must be used for the pregnant woman as for other employees.
- Employee medical coverage must include pregnancy benefits.
- The mother can use all her maternity benefits without penalty.

When a woman is planning a pregnancy, she should acquire information about pregnancy benefits in her work setting. The state in which she lives also has guidelines or regulations about pregnancy.

> "I was thrilled when I found out I was pregnant! Although I had a high-stress job and worked long hours, I rejoiced in the thought of being a mother. As my pregnancy became apparent, my boss started "worrying about me." He feared I could not keep up with my demanding schedule and that the "emotional strain" would be hard on the baby. By the time I reached 28 weeks, I learned that a coworker would be taking over some of my responsibilities and 2 weeks later I was laid off. My boss felt that my current workload would be too difficult for a "very pregnant woman or a new mother." I immediately started fighting for my right to keep my position. I was the perfect employee previously with flawless evaluations. Sure there may be legal protection in place, but right now I have no income, am paying high insurance premiums to maintain my health insurance, and am rapidly depleting my savings. I am angry and cry all of the time. I have been diagnosed with depression and am now taking antidepressants. I never missed a minute of work, my performance remained flawless . . . their only complaint, I was pregnant! This should be the happiest time of my life but instead I'm in counseling and taking Prozac; it's so unfair!"

Child Care

In 1947, only 12% of mothers with small children were employed. By 2008 that percentage had jumped to 81.5%. The number of families with stay-at-home dads rose to 6.9% in 2008 (U.S. Bureau of Labor Statistics, 2009). Although some fathers are actively involved in meshing work and family responsibilities, child care remains predominantly a woman's issue, both because of the traditional belief that child care is "women's work," and because of the high percentage of single-parent households headed by a woman (Figure 8-2 ■). In 1970, there were approximately 3 million single mothers heading families. In 2009, there are over 10 million single mothers heading households. Finding high-quality, affordable child care is a critical issue for many American women (National Association of Child Care Resource & Referral [NACCRRA], 2009).

Figure 8-2 ■ Some women rely on the father to provide full-time child care at home while they pursue their career. Stay-at-home fathers provide only 1.5% of care to children under the age of 5 in the United States.

Source: Corbis RF.

> "In contemplating starting a family, I never dreamed that child care would top my list of primary stressors. The decision to work is hard enough, but then you are faced with the inability to find safe, nurturing child care. The turnover is constant, the settings never ideal. I used to think the trick was to pay more. I was wrong there. It doesn't seem to matter how much you pay or how much you investigate, it is an unending struggle. It leaves you wishing away your children's preschool years, just so you can get past the point in their lives when you are constantly dealing with child care!"

Child care costs in the United States range from $4388 to $14,647 per child per year, with an average of $8150 per year per child (BabyCenter.com, 2009). Families with multiple children can quickly consume a large amount of their income on child care costs. These costs hit low-income families especially hard because they are spending a high percentage of their earnings on providing child care.

Numerous studies have demonstrated the benefits of early, high-quality child care that features frequent, positive staff-child

Figure 8-3 ■ Childhood education centers provide preschoolers with advanced skills for early education and provide care while parents work outside of the home.

Source: Tom and Dee Ann McCarthy/CORBIS-NY.

interactions and a strong educational component (Figure 8-3 ■). Children who receive such care tend to do better in school and are more likely to graduate, and they have lower rates of juvenile crime and adolescent pregnancy when they are older. In contrast, low-quality child care is associated with strained maternal-child relationships; higher incidence of insecurity; more problem behaviors; and lower scores on cognitive, language, and school readiness scales (National Institute for Early Education Research, 2009).

Mothers who have a college education and work outside of the home are more likely to enroll their children in education-based child care programs. Currently some employers provide support for employees' child care needs through such mechanisms as referral programs, on-site or near-site centers, or financial assistance programs. Other creative approaches to handling child care are also gaining in popularity: flex-time scheduling, part-time work, job sharing, and telecommuting (working at home via e-mail, phone, and fax) (Figure 8-4 ■). Some parents choose to work alternate shifts to eliminate the need for day care or other forms of nonparental care. Although this option has its advantages, it can be stressful for the family because the parent who is at home may not get enough sleep.

Figure 8-4 ■ Some mothers are able to combine professional careers with motherhood by telecommuting from a home office.

Source: Andrew Errington/Getty Images Inc.—Stone Allstock.

Grandparents can be an invaluable source of child care assistance to working families. In the United States about 8% of grandparents, usually grandmothers, provide extensive care (more than 30 hours per week, or more than 90 nights per year) to their grandchildren. Approximately 4.6 million children live with grandparents who function in the parenting role full time. Grandmothers who take on such daunting responsibility are at risk for neglecting their own health and feeling greater stress than grandmothers who do not act as primary care providers for their grandchildren (Stitof & Stitof, 2009).

Until recently, grandparents and other relatives who assume responsibility for one or more children whose parents are unable to care for them have not been eligible for the financial aid routinely provided to nonrelated foster parents. As of 2004, however, 35 states and the District of Columbia had instituted *Subsidized Guardianship,* a mechanism by which custodial relatives may receive funds through a variety of local, state, and federal programs (National Resource Center for Family-Centered Practice & Permanency Planning, 2009).

Advocacy for Working Women

All women, including nurses, who must balance work and family responsibilities should inquire about maternity and paternity leave; child care benefits; the possibility of working flexible hours; and whether on-site, discounted day care is provided before accepting employment. Women should also inquire about the flexibility of break periods to express their milk for nursing infants. Many employers now have special areas specifically designed for women who need to express milk throughout the workday. Nurses, and women in general, must support other women who are fighting for their rights in the workplace and must demand that legislators pass family- and woman-friendly employment laws. Solidarity and the willingness to actively oppose unfair or discriminatory practices are twin keys to equal rights and treatment for working women.

PROFESSIONALISM IN PRACTICE

Advocating for Working Women

Nurses can act as advocates for working women by serving as role models, providing positive reinforcement and support, and working actively to establish woman-friendly workplace policies.

Environmental Hazards in the Workplace and at Home

Women in developed countries such as the United States are increasingly exposed to **environmental toxins**, chemical compounds found in air, food, and water, whose bioaccumulation can lead to adverse health effects. These substances can affect their reproductive and general health and the health of their children. Toxins of greatest concern include gases that may contaminate indoor air; toxic chemicals to which women may be exposed at work and at home; and various poisonous or otherwise harmful

substances that contaminate produce, fish, and meats. Women who are nurses are also exposed to potentially harmful chemical and biologic agents associated with the healthcare industry.

Air pollution is an environmental hazard caused by the release of toxins into the air. Both indoor and outdoor air pollution can cause minor problems such as eye, nose, and throat irritation and headaches as well as serious problems such as lung and heart disease. Indoor air pollution, however, poses the more serious threat to women's health, because most Americans spend 90% of their time indoors. Most indoor air pollution is caused by gases (fumes) released from lit cigarettes, burning candles (especially those scented with synthetic chemicals), wood-burning stoves, kerosene lamps, oil-burning furnaces, cleaning products, paint, varnish, and carpets made from synthetic materials. Pressed-wood products, such as fiberboard, used in flooring, shelving, and paneling, may release a colorless, odorless gas known as *formaldehyde gas,* which is known to cause cancer in animals and may eventually be shown to cause it in humans. *Radon,* a naturally occurring radioactive gas, may seep into homes from certain types of bedrock beneath the foundation and is the second leading cause of lung cancer (smoking is the first), which kills more women than any other type of cancer, including breast cancer. Special kits for detecting radon gas are available, as are devices for removing it from homes. Other common sources of indoor air pollution are cat dander, molds and mildew, dust mites, and cockroaches. Asthma, an increasingly common and serious problem in children, is worsened by most forms of indoor air pollution (MedlinePlus, 2009).

Women may be exposed to potentially harmful chemicals and other toxic substances at work and at home. Of the approximately 80,000 chemicals used today in industry and found in various consumer products, only about 1500 have been tested to find out whether they are likely to cause cancer or have toxic effects on the immune and/or reproductive systems or on children's pre- and postnatal growth and development. Even when testing is done, chemicals are tested individually, not in combination. The interactive and cumulative effects of the thousands of chemicals to which adults and children may be exposed are unknown.

Some types of employment expose women to chemical toxins that may harm them or their unborn children. Women who work around paints, varnishes, sealants, dry cleaning chemicals, synthetic perfumes, hair or clothing dyes, and organic solvents (such as benzene and acetone) are at increased risk.

Women may be exposed to toxic chemicals in their homes as well. Some plastics, such as polyvinyl chloride (PVC), release harmful chemicals (e.g., dioxin and phthalates) when heated. *Dioxin* is a highly toxic compound that occurs as impurities in petroleum-containing pesticides and has been linked to cancer, birth defects, and neurologic disorders. *Phthalates*, salt compounds with known toxic qualities, have been linked to a number of adverse effects on health; they are known carcinogens and sufficient levels of exposure can cause male fetuses to be born with undescended testicles and other abnormalities of the sex organs. They can also lower estrogen and testosterone levels in men (Eco Child's Play, 2009).

Beauty products may also contain harmful chemicals. Studies funded by the nonprofit organization Environmental Working Group have revealed that many brands of nail polish, fragrances, deodorants, lotions, hair spray, and other hair care products contain phthalates. The Food and Drug Administration (FDA) maintains that phthalate levels in cosmetic products are too low to be of concern and does not regulate them, nor does it mandate safety testing of personal care products before they are marketed. Some companies voluntarily submit some or all of their products to the Cosmetic Ingredient Review (CIR) panel for testing. CIR is an industry-established and policed body that has no direct ties to the FDA. According to a study done by the Environmental Working Group, 89% of the nearly 42,000 ingredients used in personal care products have never been tested by the CIR or the FDA (Skin Deep Cosmetic Safety Database, 2009).

Many *pesticides,* chemicals used to kill unwanted pests, are commonly used on public and private lawns and gardens and are potentially dangerous to women and their children. Currently, there are over 1200 such chemicals registered for use in the United States. These chemicals, in various combinations, make up the hundreds of products used by the public to control insects. Of the 30 most frequently used pesticide chemicals, 26 have been found to cause liver or kidney damage; 21 have been linked to various reproductive problems in men or women, or both; 19 have been found to be carcinogenic; 15 are known to be toxic to the nervous system; 13 have been linked with birth defects; and 11 disrupt the hormone systems of human beings (National Coalition for Pesticide-Free Lawns, 2009). Few of us escape exposure to these dangerous chemicals. We may breathe them in if we are downwind when insecticide sprays are being applied to crops or golf courses or along highways, or we may inadvertently consume them when we eat nonorganic fruits and vegetables. We may track them from our lawns into our homes, where they degrade more slowly in the absence of rain and sunlight, and where children who play on the floor will come into contact with them. Pesticide exposure can result in a variety of physical symptoms including headache, elevated body temperature, dizziness, irritability, nausea, vomiting, epigastric pain, myalgia, pain in the limbs and joints, skin irritation, and sweating (Titlic, Josipovic-Jelic, & Punda, 2008). One pesticide chemical subtype, the *organochlorines* (a combination of dioxin, malathion, chlorpyrifos, and lindane) degrade very slowly and remain in the environment for many decades. Thus even if these dangerous pesticides were banned today, exposures would not cease entirely.

The fact that organochlorines persist in the environment has implications for women of childbearing age, because organochlorines can be passed from mothers to babies in the womb and through breast milk. It is imperative that women not increase their own and their children's exposure to pesticides by applying them to their own lawns and gardens. Infants' and children's rapid rates of growth from conception through adolescence make them particularly susceptible to the effects of toxic chemicals. Moreover, children's organ systems are not fully developed and are, therefore, more susceptible to damage from exposures to toxins. The National Coalition for Pesticide-Free Lawns provides information about effective alternatives to the use of dangerous pesticides and herbicides. The plethora of dangerous pesticides sold and used in this country is a problem women should take very seri-

ously. Pesticides and polychlorinated biphenyls are associated with decreased fetal growth and shorter gestations. Exposure to certain pesticides can also increase the risk of developmental delays in children and chronic illness and reduced reproductive capabilities in adults (Stillerman, Mattison, Giudice, et al., 2008).

Produce, fish, and meats can also be contaminated with substances that are not good for women and their children. Nonorganic fruits and vegetables carry *pesticide residue* (trace amounts of pesticides left on produce after washing) on their surfaces. Some fruits and vegetables typically carry more residue than others. Bananas, canned peaches, grape juice, and broccoli tend to have low levels. Organic produce has been shown to have much lower levels of pesticide residue than nonorganic produce; however, it is important to wash all produce before ingesting it.

Nearly all fish and shellfish contain some amount of *mercury,* a silvery white metallic element that can cause birth defects when consumed in large quantities. Most fish do not contain enough mercury to be of concern. Because larger amounts of mercury can harm the nervous systems of fetuses and small children, however, pregnant women and toddlers should not eat the flesh of large, predator fish that can have a large buildup of mercury in their fat; for example, shark, tilefish (white or golden snapper), swordfish, and king mackerel. Because tuna are also large, predator fish, pregnant women should not eat more than 6 ounces of white, albacore tuna per week or more than 12 ounces per week of "light" tuna. Salmon is typically low in mercury, but it may be contaminated with industrial chemicals known as *polychlorinated biphenyls (PCBs).* PCBs are different types of compounds that are used to replace hydrogen atoms in biphenyls with chlorine. These industrial chemicals were banned 30 years ago, but they still linger in the environment. PCBs are known carcinogens, at least in animals. Farmed salmon contains much higher PCB levels than wild salmon, but wild salmon is available only at certain times of the year and is expensive. The farmed fish industry is being pressured by environmental and consumer groups to lower the PCB levels in its products. Meanwhile, there are still quite a few varieties of tasty, uncontaminated fish; for example, cod, mahi-mahi, ocean perch, whitefish, pollock, halibut, haddock, flounder, sole, tilapia, and striped bass (Gabbe et al., 2008).

Meat animals, such as cattle, hogs, and chicken, are dosed with antibiotics to prevent diseases from spreading because of the generally overcrowded conditions in which these animals are kept. The antibiotics given to farm animals are the same ones used to control disease in human beings—sulfa drugs, penicillin, and others. Because the flesh of commercially raised meat animals contains antibiotic residues, humans who eat meat may develop antibiotic-resistant bacterial strains in their bodies. Organic meats are free of antibiotic residues.

The exposure to various biologic and chemical toxins inherent in providing care for sick people constitutes an occupational hazard for nurses. Exposure to toxoplasmosis, rubella, cytomegalovirus, herpes simplex, and hepatitis B may adversely affect pregnancy and fetal outcome. The risk of exposure to HIV infection via needle sticks and contact with blood and other body fluids also exists. Latex allergy is rapidly becoming a significant problem among healthcare workers, with 5% to 15% demonstrating hypersensitivity symptoms ranging from mild contact dermatitis to severe systemic reactions and anaphylactic shock (American Academy of Allergy, Asthma and Immunology, 2009).

Two governmental agencies have primary responsibility for addressing workplace safety. The Occupational Safety and Health Administration (OSHA), part of the Department of Labor, is responsible for creating and enforcing workplace health and safety regulations. The National Institute for Occupational Safety and Health (NIOSH), which is part of the Department of Health and Human Services, is primarily a research agency. However, it also disseminates information on preventing workplace injury and illness, provides training to occupational safety and health professionals, and investigates potentially hazardous working situations when requested by employers or employees.

PROFESSIONALISM IN PRACTICE

Environmental Risks

Nurses need to educate women and childbearing families about the risks that they face in their environment. Nurses can encourage women to investigate potential hazards in their environment. The Internet can provide information and resources on specific hazards and preventive strategies to decrease risk of exposure. Nurses can also lobby community leaders and legislators to support positions that protect childbearing women from environmental toxins. Nurse researchers can investigate workforce and environmental hazards, recording, analyzing, and publishing findings.

Social Issues Affecting Older Women

In the United States and other developed nations, women tend to outlive men. Thus women are overrepresented in the ranks of older people. This phenomenon is referred to as the **feminization of later life**. As of 2007, there were over 37 million people aged 65 or older living in the United States, 58% of whom are women. Among people aged 80 or older, 65% are female (U.S. Census Bureau, 2007).

Economic Vulnerability of Older Women

The feminization of later life means that older women are more likely than their male counterparts to be widowed, to live alone, to be disabled, and to be poor. However, of all the elderly in the United States, women of color have the highest poverty rates. Factors that contribute to the increased economic vulnerability of women include the following:

- Women must stretch their financial resources further than men because of their longer life expectancy.
- Older women tend to have less educational preparation than older men.
- Historically women have been economically dependent on men and may have intermittent or nonexistent employment histories.
- Women typically earn less than men and often work in jobs without pension benefits or have only limited benefits.

- Intermittent employment is more common in women, which decreases their social security and retirement benefits.
- Women generally have more family caregiving responsibilities than men.
- Historically, public pension systems have been designed with an expectation that men would be the primary economic providers. Older women who worked outside their homes may have only meager pensions.

Middle-class women too face the risk of "cycling into poverty" should they become widows. The current economic difficulties and reductions in stock market holdings have threatened many retirees' incomes that have been saved for their later years. A drastic decline in financial circumstances is particularly likely if a woman's husband had a long, costly illness or if his pension is decreased or discontinued following his death. To help keep elderly women from spending their final years in poverty, it is necessary for governments to develop solutions to the economic concerns caused by a fixed income, to deal with problems of pension inequity, and to address the potentially disastrous effects of staggering healthcare costs for the uninsured or underinsured. Because women are living longer than men and the average age has continued to climb, the need for additional income sources is imperative (Table 8-1).

Elder Abuse

Elder abuse includes any deliberate action, or lack of action, that causes harm to an elderly person. It is difficult to determine how many elderly women in the United States are victims of abuse, because perpetrators are usually careful to conceal their behavior, but elderly women are believed to be more at risk than elderly men. Currently in the United States, it is estimated that 3% to 5% of the total elderly population, or approximately 500,000 individuals, are abused annually. Experts anticipate that the problem will continue to grow as the population ages and as illness and financial burdens strain family relationships (National Center on Elder Abuse [NCEA], 2009).

Five different categories of elder abuse have been recognized: psychologic abuse, physical abuse (including sexual abuse), neglect (by self or caregiver), financial abuse, and abandonment (Table 8-2). Multiple forms of abuse may occur simultaneously and tend to intensify with time unless intervention occurs.

The prototypic victim of elder abuse is a white woman over 80 years old who lives in her own home or the home of a family member. The abuser is most often a spouse, followed by family members and then primary caregivers. Elder abuse by staff in nursing homes and long-term care facilities is also well documented. On average, elderly black Americans are more at risk for abandonment than older white Americans. Abandonment statistics are much lower for Asians and Hispanics. Factors that increase the risk of elder abuse include shared living arrangements, family history of violence, lack of financial resources, dependence, isolation, poor health, and cognitive impairment. Substance abuse and stressful events in the life of the abuser may also contribute to the risk (NCEA, 2009).

A full discussion of this growing problem, its identification, and treatment is beyond the scope of this textbook. It is imperative, however, that nurses who care for the elderly be alert for signs of abuse and take steps to address the problem when it is identified.

Application: Elder Abuse

National Center for Prevention of Elder Abuse

TABLE 8-2 Definitions of Elder Abuse

Physical abuse: Any physical pain or injury that is intentionally inflicted upon an elderly person by a caregiver or individual who has custody of, or stands in a position of trust with, that elder. Sexual assault, physical attacks, unreasonable physical restraint, and prolonged deprivation of food and water all constitute physical abuse.

Financial abuse: Any theft or misuse of an elderly person's money or property by a caregiver or person in a position of trust.

Neglect: Failure on the part of a caregiver, or any person having custody of an elder, to provide reasonable care, which is the degree of care that a reasonable person would provide. Reasonable care includes, but is not limited to, assistance with personal hygiene; protection from health and safety hazards; and provision of shelter, food, clothing, health needs, and medical care except in instances when the elder refuses treatment.

Self-neglect: Failure to provide adequate self-care because of inability or inattention.

Psychologic abuse: The intentional infliction of mental suffering on an elder by a caregiver or person in a position of trust. Psychologic abuse includes, but is not limited to, verbal assaults, threats, humiliation, intimidation, or isolation of the elder.

Abandonment: The desertion of an elder by any person responsible for the care and custody of that elder, under circumstances in which a reasonable person would continue to provide care.

PROFESSIONALISM IN PRACTICE

Elder Abuse

If you suspect elder abuse is occurring, you should immediately report the case to the county social services office of adult protective services.

Implications of Aging for Women's Health and Health Care

Older women often face health problems that become more common as people age: hypertension, coronary artery disease, arthritis, diabetes, osteoporosis, dementia, and depression. Heart disease, cancer, and stroke are the leading causes of death for all women age 65 or older. Among white women, lung disease is the fourth leading cause of death, but for minority women it is diabetes. By age 65, half of all women have developed two or more chronic diseases. Minority and low-income women are more likely than white, higher income women, to have serious health problems.

Unfortunately, older women, particularly those who are poor, face multiple barriers in obtaining adequate healthcare services. For some, lack of transportation to healthcare facilities is an issue. Many older women are no longer able to drive because of failing eyesight or diminished reflexes. Although public transportation may be available in larger cities, many rural areas have no bus, train, or cab service, and even if public transportation is available, poorer women may not be able to afford the costs involved.

Lack of private health insurance coverage or excessive medical costs not covered by Medicare are major problems for many older women. Too often, women on limited incomes must choose between paying rent and purchasing food and paying for needed medicines or other forms of health care. Thus nurses must remain aware of the possibility that a patient's noncompliance may be economically driven.

Another problem common in older women with multiple health problems is a phenomenon known as **polypharmacy**, which means "multiple medicines." A woman who sees two or more specialists for the treatment of multiple medical conditions may well be taking a half-dozen or more powerful drugs, each with its own array of side effects and with the potential for dangerous interactions with one or more of the others, and perhaps several over-the-counter drugs as well. Sometimes polypharmacy is justified by the woman's medical needs, but often it is inadvertent; nurse practitioners and physicians are sometimes unaware that a woman is taking medications prescribed by one or more different providers. Elderly people may not remember what medications they are taking or may not think to keep caregivers informed about them. Also, many people assume that herbs and various other products classified as *nutritional supplements* are safe because they are sold without a prescription. Although such products are generally much less potent than prescription drugs, many can and do interact with drugs elderly people commonly take. For example, the herbal supplement St. John's wort, often taken to relieve mild depression, can increase or decrease the effects of oral contraceptives, blood thinners, and some prescription antidepressants (Barnes, Bloom, & Nahin, 2008).

Figure 8-5 ■ Older women are more likely to have multiple medical conditions that require medication. Careful instructions should be given to prevent medication interactions.

Source: Dann Tardif/CORBIS-NY.

Sometimes, symptoms in an elderly person are related to drug effects or interactions rather than to disease or illness. Nurses must advise elderly patients to keep a list of the medications they take and provide each of their providers with a copy and to fill all their prescriptions at the same pharmacy. Pharmacists are increasingly alert, aided by computerized systems, to the potential risks posed by multiple drug prescriptions and will warn patients and providers of likely negative effects and interactions (Figure 8-5 ■).

Some drugs have known potential for causing cognitive impairment in elderly persons who have diminished kidney and liver function. Drugs that alter the central nervous system (anticholinergics, antihistamines, antidepressants, anxiolytics, antipsychotics, and antiepileptics) may cause such symptoms as forgetfulness, confusion, disorientation, and inability to concentrate (Waldman, 2008). Nurses can play a key role in identifying older women's concerns as well as the onset of new symptoms. In collaboration with other providers, they can improve an older woman's chances of receiving optimal health care.

Social Issues Affecting Women with Disabilities

Approximately 19.1 million U.S. women and girls have some type of mental or physical disability, and of these, 15.4% are unable to perform basic self-care activities. It is estimated that 11.4% to 25.8% of all Americans have some type of disability (CDC, 2009a). Women are more likely than men to be disabled because of longer life expectancy rates, and disabilities are most prevalent in women over the age of 85. The majority of women with disabilities (56%) are in this age group, whereas another 44% are over the age of 65 (National Center on Birth Defects and Developmental Disabilities [NCBDDD], 2009). It is estimated that there are 19.9 to 28.6 million women living in the United States who have some type of a disability (CDC, 2010).

Care Plan Activity: Pregnancy in a Patient Who Is Disabled

CLINICAL JUDGMENT

Case Study: Tanesia Ford

Tanesia Ford is a 24-year-old with an intellectual disability who recently gave birth to a baby girl named Ruby Rose. Tanesia finished high school and has experience in the church nursery caring for infants during church services. Her husband, Ben, also has a mild intellectual disability but has several younger siblings and has some experience with newborns and toddlers. Tanesia's parents live 1.5 miles away from the young family and are willing to provide assistance as needed. Ben works full time for a large grocery store and Tanesia will be staying at home with Ruby to care for her. Tanesia states "I love taking care of Ruby, I don't even mind changing her diapers or breastfeeding her."

Critical Thinking

Discuss what resources you would recommend for this young family based on the parents' intellectual disability and family circumstances.

See www.nursing.pearsonhighered.com for possible responses.

Definitions of Disability

A **disability** is a chronic physical or mental health problem or impairment that restricts an individual's ability to perform one or more major activities. Whether a given activity is considered major depends on the circumstances and responsibilities of the woman in question. For example, if a middle-aged woman cannot care for her home and children because of a disability, that disability would be considered major. If an elderly woman's disability makes independent self-care impossible, that disability would be considered major. Disabilities may also be categorized as "work" and "severe." *Work disabilities* restrict individuals from employment; a nurse who sustains a back injury that becomes chronic and prevents her from returning to her position as a staff nurse has a work disability. *Severe disabilities* prohibit individuals from performing basic activities of daily living without assistance.

Types of Disabilities

Disabilities are categorized as physical, developmental, learning, neurologic, psychiatric, and sensory. *Developmental disabilities* such as autism, cerebral palsy, epilepsy, and spina bifida are ongoing and manifest before the age of 22. They create severe limitations in three or more of the following areas: self-care, receptive and expressive language, learning, mobility, self-direction, ability to live alone, and financial independence. More than 4 million individuals are affected with some type of developmental disability, and *intellectual disability* (formerly referred to as mental retardation) is the most common (Figure 8-6 ■) (NCBDDD, 2009).

In the early- to mid-20th century, women with intellectual disabilities were often faced with mandatory sterilization at the request of family members or caregivers as a means to prevent pregnancy and thus contamination of the gene pool. This mentality led to the involuntary sterilization of many individuals without their consent. In recent years, the need for sexual health choices have become a norm as the human rights movement has evolved (Eastgate, 2008). While some women with intellectual disability may find themselves with an unplanned pregnancy, others are now choosing pregnancy and parenting as a basic human right.

Figure 8-6 ■ Intellectual disability is the most common developmental disability.

Source: Stephanie Maze/CORBIS-NY.

Women with intellectual disability may pursue prenatal care services later than other women. It is also common for women with intellectual disability to request termination services after the gestational age limit due to significant barriers with reproductive choices (Burgen, 2010). Among women with intellectual disability who do give birth, one quarter of those will become involved with Child Protective Services (Burgen, 2010). Those who choose to parent need additional social support and parenting education offerings. Peer support often provides an effective means of learning and educating these mothers (Australian Family & Disability Studies Research Collaboration, 2007). Caregivers should give concise easy to understand directions at multiple times to ensure information is understood clearly and accurately.

Learning disabilities, such as dyslexia and attention-deficit hyperactivity disorder, can inhibit educational attainment and employment. *Common neurologic disabilities* include spina bifida, cerebral palsy, multiple sclerosis, and Alzheimer's disease. Spina bifida, or congenital malformation of the spinal cord, can cause partial paralysis. Multiple sclerosis, which affects a disproportionately high number of women in comparison with men, can cause severe mental and physical disability through degeneration of nerve fibers in the brain and spinal cord. Alzheimer's disease causes ongoing, incurable dementia that culminates in death. *Psychiatric disabilities* can cause significant impairment and significantly alter an individual's quality of life. Women's rates of depression, anxiety, panic disorders, and phobic disorders are 50% higher than men's. *Sensory disabilities* such as hearing loss and visual impairments can dramatically impair a woman's ability to interact socially and to live independently (CDC, 2009c).

Economic Vulnerability of Women with Disabilities

Only about 31% of women with disabilities are employed, in contrast with 62% of men with disabilities. Many women with

disabilities can only manage part-time employment, which severely restricts their income potential. An additional problem is that people with disabilities face formidable barriers to employment: Some cannot drive or easily access public transportation. Many buildings are still without ramps and wide door openings that facilitate wheelchair access, and employers are sometimes reluctant to hire persons with disabilities. The Americans with Disabilities Act (ADA) of 1990 was intended to reduce such barriers by mandating modest improvements in building accessibility and forbidding unjustified hiring discrimination against persons with disabilities (Waldman, 2008). Although the ADA has brought about some improvements, many barriers to employment still exist.

Even when women with disabilities are able to work and find work, they typically do not earn as much as women who are not disabled. A greater number of women who are disabled live in poverty than men who are disabled or women without a disability. Many women who are disabled live in less expensive rural areas where unemployment rates are also higher (Waldman, 2008). When women with disabilities cannot work, or cannot find a job, they often lose the ability to care for themselves and their families financially. Although many people assume that social security benefits keep individuals with disabilities out of poverty, this is simply not the case. More than a fourth of all women with disabilities live in poverty (Waldman, 2008).

Violence Against People with Disabilities

Both men and women with developmental disabilities are 4 to 10 times more likely to be victims of crime than people without disabilities. Women who have intellectual disabilities are 50% more likely to be sexually assaulted in their lifetime than women of normal intelligence. Women with intellectual disabilities are sexually assaulted by caregivers, family members, residential care staff, or transportation personnel in 97% to 99% of all cases of sexual abuse (Association of Retarded Citizens [ARC], 2010). Women who are disabled may have difficulties escaping from or fighting off an attacker, may be unable to communicate well enough to report crimes, and/or may be unable to positively identify an attacker because of sensory or cognitive limitations (National Women's Health Information Center, 2009a).

Effects of Disability on Women's Health Care

Women with disabilities need routine gynecologic care and preventive health education, as do all women, but healthcare services for women who are disabled are often suboptimal. Many women with disabilities report that various barriers prevent them from obtaining routine healthcare services. Overall, women who are disabled receive less preventive care than women without disabilities but have 2.5 times the yearly health expenditures of women without disabilities (Waldman, 2008).

An additional problem is that many healthcare providers assume incorrectly that women with severe disabilities are not sexually active. Because of these false assumptions, many women who are disabled are not offered screening for sexually transmitted infections (STIs), education regarding STI prevention, contraceptive counseling, or preconception counseling. Women with intellectual disabilities are more likely to develop osteoporosis and need appropriate screening (Wilkinson & Cerrato, 2008).

Social Issues Affecting Lesbian and Bisexual Women

Various social issues can detract from lesbian and bisexual women's quality of life. These include employment and housing discrimination, discrimination involving domestic life and parenting issues, and general social discrimination based on the stigma associated with homosexuality. In addition, lesbian and bisexual women face perceived and actual discrimination on the part of healthcare providers that negatively affects both access to and quality of health care.

Employment Discrimination

Employment discrimination is the most frequent complaint the American Civil Liberties Union (ACLU) receives from gay and lesbian individuals. An act that would have prohibited termination of employment on the basis of sexual orientation, the 1997 Employment Non-Discrimination Act, was defeated by one vote. An updated version of the bill was introduced in 2007 but has yet to be passed. Table 8-3 lists those states that do provide legal protection for homosexual employees. In addition, Indiana, Kansas, Michigan, Ohio and Arizona, Delaware, Montana, Virginia, and Pennsylvania have executive orders prohibiting public employers from discrimination based on sexual orientation (Lambda Legal Defense Fund, 2009).

Discrimination exists not only in the private sector, but also in the military. The battle over homosexuals in the military has raged on since President Clinton enacted the "don't ask, don't tell" policy in 1994. Although this legislation removed sexual orientation as a contraindication to military service, it has been far from successful in protecting gay and lesbian service members from expulsion; homosexual conduct is still grounds for terminating their service. Homosexual conduct includes not only homosexual acts, but also statements that demonstrate a

TABLE 8-3 States with Legislation Protecting Homosexual Workers Against Discrimination by Public and Private Employers

Maryland	Washington
Massachusetts	Wisconsin
Minnesota	

propensity or intent to engage in homosexual acts. In short, lesbian women can serve in the military, but if their sexual orientation becomes known, they can be asked to resign. In 2006, the number of military discharges based on sexual orientation was lower (612) than at any time since 1996, comprising a small fraction of total unplanned discharges (Tyson, 2007).

Spousal Benefits

Lesbians face additional discrimination in the area of spousal benefits. Under federal statutory laws, civil marriage grants 1138 federal provisions designed to support and protect family life, therefore excluding most lesbian couples (American College of Obstetricians and Gynecologists [ACOG], 2009). Although individuals who are legally married can receive health insurance coverage, life insurance benefits, retirement pensions, and disability coverage for their partners, lesbian partners who are not legally married (the vast majority) cannot. Currently, only six states—Massachusetts, Vermont, Maine, New Hampshire, Iowa, and Connecticut, plus the District of Columbia—recognize marriage between same-sex individuals. In May 2008, California passed a law allowing same-sex marriage that was later repealed in the November 2008 elections. In August 2010, however, a federal district court struck down the ban on California same-sex marriage, and the issue is currently being debated anew.

New Jersey permits **civil unions**, which are legally recognized partnerships that involve rights and responsibilities comparable with those enjoyed by married couples. Other states offer limited recognition to same-sex couples, including Hawaii, Maryland, and Washington state. Couples who enter into civil unions are generally subject to the same laws and processes regarding inheritance, property rights, child custody, and medical decision making as married couples. Same-sex couples who wish to enter into a civil union must obtain a special license and have a solemnization ceremony. Civil union dissolution proceedings are handled in much the same manner as divorces (Lambda Legal Defense Fund, 2009).

Domestic partnership recognition is another mechanism by which public and private employers can provide insurance coverage and pension rights benefits to the partners of gay and lesbian employees. Both California and Oregon provide such benefits to employees, as do increasing numbers of city and county governments and private employers (Lambda Legal Defense Fund, 2009).

Housing Discrimination

Lesbians also face housing discrimination. Although *Fair Housing laws* protect members of various groups (minorities, pregnant women, and families with children) from being denied housing, they do not generally apply to homosexuals. Except in the few states and municipalities in which antidiscrimination-in-housing laws cover sexual orientation, landlords can refuse to rent, and homeowners can refuse to sell, to gay and lesbian people. The mechanisms by which housing discrimination on the basis of sexual orientation work are often subtle; leases may forbid "immoral" (code for homosexual) activities and/or restrict occupancy to those "related by blood or marriage." Some homeowner association boards reserve the right to refuse prospective purchasers on the basis of "inappropriate lifestyle." In one study of gay and lesbian couples, 34% had been turned away from either renting or purchasing a home due to their sexual orientation (Lamda Legal Defense Fund, 2009). Another housing-related problem gay and lesbian couples face is that, unlike married couples, they may not be able to use their combined income to determine their eligibility for a mortgage and may have to settle for cheaper housing than they can actually afford. Ironically, gay and lesbian couples who are not well off often wind up at the bottom of eligibility lists for public housing because they are not considered to constitute a "family."

Parenting Issues

Many lesbian women wish to become adoptive parents. Both single women and couples often desire the presence of children in their lives, and women who are coparenting their partner's child may want to formally adopt that child. Gay and lesbian people who wish to adopt, however, often face formidable barriers. Some child placement agencies have policies restricting adoption to married couples and in a few states (Florida, Virginia, Mississippi, Nebraska, Oklahoma, and Utah), legislation specifically bars homosexuals from adopting. Even in the absence of such policies or statutes, however, prejudice on the part of judges, social workers, and others who make decisions about child placement often makes it almost impossible for gay and lesbian people to adopt children or even become foster parents. Foreign adoptions may be no easier, because some agencies that facilitate them refuse gay and lesbian applicants; other countries ban single women from adopting. A small number of states, however, have laws prohibiting child custody or adoption discrimination against homosexuals, and some states make what is known as *second parent adoption* available to lesbian women who are coparenting the biologic children of their partners. This option allows coparents to adopt children legally, thus ensuring stability for them, should the biologic parent become incapacitated or die (ACOG, 2009).

Although there are societal concerns about children who are being raised by same-sex parents, there is no objective evidence supporting such concern. The American Academy of Pediatrics (AAP) reviewed decades of research data on children raised by heterosexual parents and children raised by lesbian or gay parents, and in 2002 it issued a policy statement stating that no differences were observed (AAP, 2009) (Figure 8-7 ■).

Although sexual orientation per se has no effect on the quality of parenting, discriminatory tax laws can adversely affect lesbian couples' ability to provide for their children. If one of the partners is employed and the other remains at home to care for the children, the working partner may not be able to claim either her partner or their children as dependents because the partners are not legally married. Lesbian couples are typically not eligible to access the family Medical Leave Act to care for their partner or their partner's children (ACOG, 2009).

Social Barriers

Lesbian and gay individuals and couples often face discrimination—and even danger. They may be treated rudely in stores; motels; restaurants; and other public facilities and ostracized by business networks, churches, neighbors, and even families. There

Figure 8-7 ■ Lesbian families face discrimination that more traditional families do not commonly encounter.

Source: Vanessa Vick/Photo Researchers, Inc.

are reports of newspapers having refused to accept advertisements from gay people or gay organizations. When homosexual people are made to feel uncomfortable in establishments that cater to the general public, they are forced to congregate in gay bars or other venues, where they may become inviting targets for violently homophobic individuals. In 2006, 1415 hate crimes based solely on sexual orientation (16.4% of total hate crimes) were reported to the Federal Bureau of Investigation (Johnson, 2008). Although those numbers may seem relatively small, it must be kept in mind that hate crime reporting by law enforcement officials is voluntary, and hate crimes motivated by homophobia are considered to be significantly underreported. Many lesbian women are reluctant to be open about their lifestyle because of social discrimination and the possibility of violence.

Although the goal of equality for all women is still unmet and the burden of discrimination is even greater for lesbian than heterosexual women, there is reason for optimism. Acceptance of gay men and lesbian women is on the rise with sympathetic portrayals in the media. Ongoing research by CNN Politics indicates that 44% of Americans now believe homosexual people should be allowed to marry (CNN Politics, 2009).

Effects of Discrimination on Lesbian and Bisexual Women's Health Care

In its *Healthy People 2010* action plan, the U.S. Department of Health and Human Services acknowledged sexual orientation as a risk factor for inferior health care, citing reasons such as lack of insurance, fear of discrimination on the part of providers, and provider ignorance of gay and lesbian people's healthcare needs. The first two factors limit access to health care, and the third has a negative effect on healthcare quality.

Lesbian and bisexual women are less likely than heterosexual women to have health insurance because, unlike heterosexual women, they are usually not eligible for insurance benefits based on a partner's employment. Lack of coverage can cause women to forgo health screening procedures such as Pap smears and mammography, and delay treatment until illnesses have become serious. The fear that providers may harbor antigay sentiments, or be uncomfortable around gay people, is common, despite position statements from multiple healthcare organizations advocating for lesbian rights. The assumption of heterosexuality, revealed daily in questions such as *What kind of birth control do you use?* and intake forms that list only *single, married, widowed, or divorced* as lifestyle options, can alienate lesbian women and may cause them to conceal their sexual orientation. Lesbian women's reluctance to disclose their sexual orientation can lower the quality of health care they receive. For example, women who do not admit that they live with a partner will not be screened for domestic violence, which is a routine screening for women in heterosexual relationships.

An additional problem that lesbian women face is that providers tend to not be knowledgeable about lesbian women's healthcare needs. Providers may not realize, for example, that lesbians are thought (but not yet proven) to be at increased risk for breast cancer because they are more likely than heterosexual women to have never given birth, to be overweight, to be stressed, and to smoke and drink alcohol. Many providers also believe that lesbian women are not at risk for sexually transmitted infections (STIs) and cervical cancer, both of which are untrue. Lesbian sexual contact can transmit a number of STIs and the virus that causes cervical cancer, because it involves exposure to vaginal secretions.

Female Genital Mutilation (FGM)

Female genital mutilation (FGM), also known as *female genital cutting, female circumcision,* and *genital circumcision,* refers to the practice of removing all or parts of a girl's or woman's genitalia for cultural reasons. It is a phenomenon with which nurses who provide health care to women, especially immigrant women from certain parts of the world, must be familiar. The damage done to a woman's anatomy in the more severe versions of the practice can cause a variety of health problems, including bleeding, infection, infertility, painful intercourse, and difficulties related to childbearing.

Origin and Demographics of FGM

FGM is a very old practice; evidence of it is present in the female mummies of Egyptian royalty. It survives in at least 28 countries in Northern Africa, parts of the Middle East (Oman, Yemen, United Arab Emirates), and Asia (Indonesia, Malaysia, Sri Lanka, India). In 18 African countries, more than 50% of women undergo the procedure (Turner, 2007). In other countries, a high percentage of women undergo the procedure, and in others only a minority does. FGM is not associated with any particular religion and is found among Christians, Muslims, Animists, and one Jewish sect. FGM is practiced in male-dominated societies in which patriarchal authority and control of women's bodies and fertility are taken for granted. In such societies, girls receive little education and are valued primarily as sources of labor and for their future role as producers of children. Fathers in many such societies sell their daughters into marriage, the payment being known as the *brideprice.*

The original reason for FGM is thought to have been the prevention of sexual intercourse before or outside of marriage, thus ensuring men that the children their wives bear are theirs. In societies in which genital mutilation has become the norm, the procedure has become heavily enculturated and is supported by both men and women. It is women, in fact, who actively promote and carry out FGM. Myths about the clitoris (that it will grow very long if not amputated; that if it touches a baby during childbirth, the baby will die) are widely believed, and uncircumcised women are seen as impure, unclean, and ugly. They are generally cut off from marriage, motherhood, and full female identity and may be ostracized. Because FGM is so closely associated with female identity, even the educated women in a given society may support it. The age at which FGM procedures are performed varies from culture to culture, with the most common range being from 5 to 12 years. A few societies carry out the procedure on infants or on teenagers just before marriage (Turner, 2007).

Nature of the Procedure(s)

In the most extreme form of FGM, known as *infibulation,* the clitoris, the labia minora, and most of the labia majora are removed and the raw surfaces of the remaining stumps of the labia majora are sewn together over the vaginal opening, leaving only a small hole for the passage of urine and menstrual blood. The opening is widened (deinfibulated) somewhat at the time of marriage, either rapidly, with a knife, or gradually, to permit sexual intercourse. Infibulation accounts for 15% of women with FGM (Shah, Susan, & Furcroy, 2009). Further deinfibulation is done to permit childbirth, and women are sewn up again afterward. Of all circumcised women in Djibouti, the Sudan, and Somalia, 80% to 90% are infibulated. The least extreme form of FGM is *partial clitoridectomy,* in which the tip of the clitoris is removed. The most common procedure (80% to 85% of all procedures) involves complete removal of the clitoris with partial or complete removal of the labia minora (Shah et al., 2009).

FGM procedures are generally carried out in villages, by a female birth attendant or elder, as part of an elaborate ritual. Very primitive instruments may be used and no anesthesia is provided. The procedure lasts approximately 20 to 30 minutes, depending on its nature and the skill of the person carrying it out. Girls are restrained by female relatives, usually including their mothers. Young girls generally do not realize what is about to happen to them; older girls may undergo the procedure willingly to conform to societal expectations.

Health Implications

Data on the number of deaths from shock and infection that occur following FGM are hard to come by, because mortality is often attributed to some other cause. Hemorrhage is the most common immediate complication of all procedures, followed by pain, infection, and urinary retention related to swelling. In developing countries, HIV transmission can occur from the use of unsterilized instruments (O'Connor, 2008). Infibulation causes the most severe long-term complications, most of which are related to the urinary tract and childbirth. Chronic urinary infections caused by inadequate emptying of the bladder are common; although a woman with intact genitalia can usually empty her bladder in 5 to 10 seconds, it may take an infibulated woman as long as 5 minutes to do so. Many women have meatal obstruction or urinary strictures. Some women develop chronic reproductive tract infections related to retained vaginal fluid and blood. Such infections can lead to infertility, which is thought to affect 25% to 30% of infibulated women. Urinary incontinence in the form of dribbling is another common problem, as is genital pain. Many infibulated women experience pain during sexual intercourse (dyspareunia), some because they have developed a neuroma in their scar tissue and introital and vaginal stenosis (Turner, 2007). Infibulation-related complications associated with childbirth include obstructed labor, nonreassuring fetal status, postpartum hemorrhage, and postpartum sepsis. The psychologic trauma caused by FGM may persist throughout a woman's life. It is related not only to personal suffering, but also to knowing that daughters and granddaughters will undergo the procedure too (Turner, 2007).

Efforts to Eradicate FGM

FGM has been denounced as a form of child abuse by the World Health Organization and by many other international and national organizations. Healthcare-related organizations, including the American Medical Association and the American Nurses Association, have denounced it as well. FGM has been outlawed in 14 African countries and some Arab countries in which it has traditionally been practiced. It is illegal in many North American and European countries that have sizable immigrant populations. The United States and Great Britain have laws forbidding parents from taking girls to another country for the purpose of having an FGM procedure performed. Grassroots organizations in many countries combat FGM by providing education about its dangers to parents and village elders. Nevertheless, FGM persists, even in countries in which it is illegal. Entrenched cultural values and practices are exceedingly difficult to change and can only be changed from within a given society. In time, FGM will no doubt go the way of foot-binding in China, but until it does, nurses must respond appropriately and professionally to women who have been subjected to it (Turner, 2007).

Responding Appropriately to Circumcised Women

It is estimated that as many as 140,000 women worldwide have had an FGM procedure (Shah et al., 2009). Given the increasingly multicultural nature of American society, it is likely that nurses who provide physical care to female patients will encounter women and/or girls whose genitalia have been surgically altered. Nurses must be prepared for this eventuality and refrain from behavior that may insult or alienate the patient. Exhibiting shock, revulsion, or pity at the sight of altered genitalia, for example, is inappropriate. Nurses must also understand that women brought up in cultures in which FGM is a fact of life may not consider themselves to have been mutilated or victimized. In fact, such a woman may be offended if her nurse uses the term *mutilation* or expresses disapproval of genital alteration. If a woman shares her indecision regarding some aspect of FGM, for example, whether to be sewn up again after delivery, the nurse should listen nonjudgmentally.

FOCUS YOUR STUDY

- The number of women living in poverty is increasing. Childbearing women seem to be at particular risk because of current trends in the divorce rate, the frequency with which the mother gains custody of children, and factors in the work environment that make it difficult for women to earn an adequate wage.
- The number of homeless families is increasing.
- Women's wages have always been lower than men's because of demand, education, skills, discrimination, and underlying philosophies that deem women's work less valuable. Many people are working to change the wage system by pushing for comparable worth legislation.
- Employee benefits that affect women include maternity leave, paternity leave, and child care. The Family and Medical Leave Act mandates parental leave for childbirth or adoption but applies only to companies with 50 or more employees. Insurance coverage for childbirth varies by company.
- Elder abuse includes physical abuse, financial abuse, neglect, self-neglect, psychologic abuse, and abandonment.
- Older women may face multiple barriers when obtaining health care, including transportation difficulties; lack of health coverage; lack of research regarding chronic conditions affecting women; and symptom-specific, rather than holistic, care.
- There are multiple types of disabilities. All have the potential for limiting a woman's quality of life, her ability to care for herself, and the quality of her health care.
- Lesbian and bisexual women face various forms of discrimination, some of which can negatively affect their health and health care.
- Nurses must provide culturally sensitive care to women who have undergone procedures involving genital mutilation.

CRITICAL THINKING IN ACTION

DOMESTIC VIOLENCE IN THE ELDERLY

Grace Abbey, an 83-year-old woman, presents for irregular bleeding to the gynecologist. Mrs. Abbey, a widow, has been living with her son, a 54-year-old unemployed retail manager, for the last 2 years since her husband died. Her son accompanies her to the visit and is reluctant to leave his mother's side. You ask the son to wait in the waiting room and begin your assessment of Mrs. Abbey. When you roll up her sleeve to take her blood pressure, you note bruises on her wrist and forearm. When you question her about the etiology of the bruises, she looks down at the floor and avoids making eye contact. She then states she cannot remember how the bruises occurred. After obtaining her vital signs, you escort her into the exam room and note additional bruises on her back as you assist her with her gown. When you question her about those bruises, she breaks down sobbing, saying. "Don't say anything. Don't tell my son you saw them."

1. Discuss how you would assess Mrs. Abbey for other forms of elder abuse.
2. Mrs. Abbey describes physical violence that started occurring after her son lost his job and his wife left him. She admits. "I have been more trouble with my health problems lately." What factors can increase the risk of elder abuse?
3. Mrs. Abbey begins crying and says, "I know this has never happened to anyone else. I don't understand why this is happening." What is your reply?

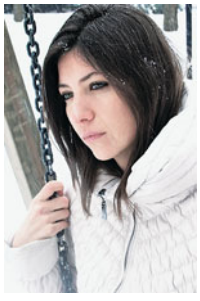
Violence Against Women

CHAPTER 9



My friends believe I'm living the American dream. My husband has a great job in his company and our life looks ideal. Even if I told them about the occasional slap, the shove, the forced sex, and the angry words, they would probably think it was worth it. Sometimes I think about leaving, but it would mean admitting I failed. I know it doesn't make sense—he does the hitting, but I feel ashamed. I'm not a battered wife; I can't be. My husband just has a quick temper.

LEARNING OUTCOMES

1. Describe the social, psychologic, political, and cultural factors that contribute to the occurrence of domestic violence and sexual assault.
2. Identify factors that contribute to domestic violence.
3. Identify the phases of the cycle of violence.
4. Summarize the characteristics of batterers and perpetrators of sexual assault.
5. Delineate the role of the nurse in caring for women who have experienced partner abuse.
6. Specify physical and psychologic signs that may indicate a woman is in an abusive relationship.
7. Describe the needs that women with abusive partners and their children may have beyond the healthcare setting.
8. Identify the phases of the rape trauma syndrome.
9. Discuss the nurse's role as patient advocate with domestic violence and sexual assault survivors.
10. Summarize the procedures for collecting and preserving physical evidence of sexual assault.
11. Discuss the legal responsibilities of the community to prevent and address violence against women.

KEY TERMS

Acquaintance rape *178*
Cycle of violence *169*
Date rape *178*
Domestic violence *166*
Post-traumatic stress disorder (PTSD) *179*
Rape *176*
Rape trauma syndrome *178*
Sexual assault *176*

Violence against women has become endemic in society today. Experts suggest that as many as one in three women will be abused at some time in their lives. Violence affects women of all ages, races, ethnic backgrounds, and religions, from all socioeconomic levels, all educational levels, and all walks of life. Two of the most common forms of societal violence are domestic violence (also called *intimate partner violence (IPV)* or *relationship violence*) and sexual assault, the topics of this chapter. Perhaps surprisingly, these two types of violence are primarily perpetrated by intimate partners or persons known to the victim. Further, evidence indicates that a significant proportion of all female homicide victims are killed by their intimate partners. For example, national statistics indicate that in 2007 24% of female homicide victims were murdered by a spouse or ex-spouse and an additional 21% were killed by a boyfriend or girlfriend. Specifically, 1640 females were killed by an intimate partner. It is somewhat encouraging to note that between 1993 and 2007 the total number of female homicide victims killed by an intimate partner decreased by 26% (Figure 9-1 ■) (Catalano, Smith, Snyder, et al., 2009).

Between 1993 and 2008 nonfatal violence against a female by an intimate partner declined 53% from a rate of 9.4 per 1000 females age 12 or older to 4.3 per 1000. Specifically, in 2008 nonfatal violence against women by an intimate partner resulted in 552,000 victimizations. Nevertheless, estimates suggest that fewer than half (49%) of acts of intimate partner violence against females are reported to police (Catalano et al., 2009). In addition to injuries sustained during violent episodes, physical, sexual, and psychologic violence are linked to a number of adverse physical and mental health outcomes. The estimated health-related costs of violence against women exceed $8.3 billion *annually* in the United States. This cost includes medical care, mental health services, and lost productivity (e.g., time away from work) (Centers for Disease Control and Prevention [CDC], 2006).

Individuals who are controlling of their partners are much more likely to be physically assaultive, sending partners for visits to emergency departments and often leading to future homicides (Felson & Outlaw, 2007). Healthcare providers can play a critical role in identifying and reducing violence, even in homicide prevention efforts.

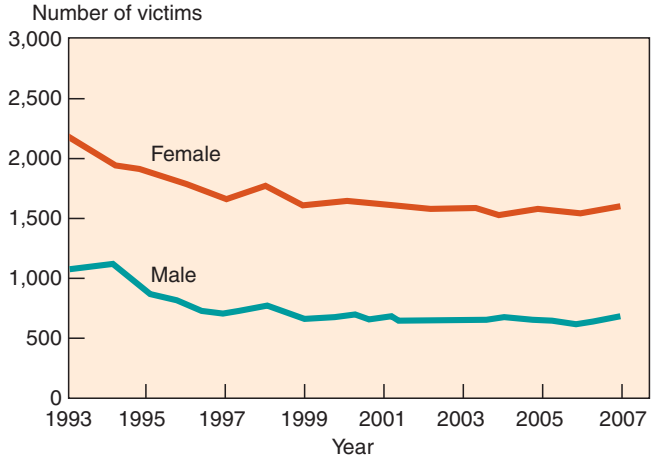


Figure 9-1 ■ Homicides of intimate partners by gender of victim, 1993–2007.

Source: Catalano, S., Smith, E., Snyder, H., & Rand, M. (2009). Female victims of violence. Bureau of Justice statistics: Selected findings. *Retrieved from http://bjs.ojp.usdoj.gov/content/pub/pdf/fw.pdf*

Since the early 1980s healthcare providers and organizations have recognized the importance of their role and have worked to address this issue. Over the past three decades there have been a number of notable changes in healthcare policy and practices aimed at responding to violence against women. In 1985 the U.S. Surgeon General identified intimate partner violence as a public health problem of epidemic proportions. In 1990 the Joint Commission on Accreditation of Healthcare Organizations mandated the development of protocols for the identification and treatment of women who have been abused by their intimate partners. *Healthy People 2010*, a national health promotion and disease prevention project, identifies IPV as a problem crossing racial/ethnic boundaries and socioeconomic strata and cites intervention and prevention for violent behavior as a national priority.

Significantly, nursing has played and continues to play a key role in developing and evaluating innovative healthcare practices aimed at identifying and reducing violence against women. In 1991 the American Nurses Association (ANA) authored a position statement, which was revised in 2000, advocating education for all nurses in identifying and preventing violence against women, assessment of women for evidence of violence in community settings and healthcare institutions, and research on violence against women (ANA, 2002).

Historic Factors Contributing to Violence Against Women

Violence against women is not new. Throughout history, for thousands of years in patriarchal societies, women have been victims of violence. Within the institution of marriage, wives were considered the property of husbands, subject to their wishes and demands. A husband had the right—even the duty—to "keep her in line," to have sex on demand, even to kill her. Outsiders were expected to "keep out of it"; battering and sexual assault were family matters. The legal status of women has improved over the years in many cultures. However, many people still hold to the traditional views of male dominance in marriage or any intimate relationship, which can contribute to the occurrence of domestic violence and sexual assault.

Traditionally, rape outside of marriage was not viewed as an act of a man against a woman, but as an act of aggression against another man—the woman's husband, father, or brother, whoever was considered her "owner."

Worldwide, women today are at great risk. Violence against women and girls is increasingly being used as a weapon of war, stigmatizing, humiliating, and terrifying women and their families. And yet, according to the United Nations, it has been the least condemned war crime (Plan UK, 2007).

Domestic Violence

Domestic violence is defined as a pattern of coercive behaviors and methods used to gain and maintain power and control

by one individual over another in an adult intimate relationship. This chapter focuses on domestic violence experienced by women in heterosexual relationships, although gay and lesbian individuals do experience domestic violence in their relationships as well. Among heterosexual couples, estimates indicate that in at least 95% of all domestic violence cases the perpetrators are men. Domestic violence occurs in relationships in which the partners are dating, living together, married, separated, or divorced.

Domestic violence is staggeringly common in the United States. In the United States, one in four women will experience domestic violence (CDC, 2008a). Forms of abuse vary but are typically described as falling into the following categories, which the batterer uses to maintain control over his partner's behavior and the relationship: psychologic abuse, physical abuse, sexual abuse, and threats of physical or sexual violence. In addition, stalking, a course of conduct directed at a specific person that would cause a reasonable person to feel fear, is another way that women with abusive partners are threatened.

Psychologic abuse includes a range of behaviors such as:

- ***Emotional abuse:*** putting her down, making her feel bad about herself, calling her names, negatively comparing her to other women, making unreasonable demands, using things that matter to her against her.
- ***Isolation:*** controlling who she sees and where she goes, using jealousy to justify restricting her actions, interfering with her job, forbidding her to see family and friends, limiting her outside involvement.
- ***Obfuscation:*** denying responsibility for his actions, blaming her, minimizing her concerns, distorting the truth, lying to her.
- ***Using others:*** using the children against her, using visitation to harass her, threatening to take the children away from her, using religion to control her.
- ***Male privilege:*** treating her like a servant, defining rigid men's and women's roles, making all of the decisions or rules in the household.
- ***Economic abuse:*** preventing her from getting or keeping a job, making her ask for money, controlling her money, destroying her property, making all the financial decisions.
- ***Coercion threats:*** making and/or carrying out threats to harm her or her family and friends, threatening to commit suicide, pressuring her to drop charges, threatening negative consequences if she does not cooperate with his wishes, pressuring her with gifts/promises/apologies.
- ***Intimidation:*** making her afraid through looks and gestures, smashing things, harming pets, displaying weapons, yelling, stalking her, driving recklessly.

Often, in addition to psychologic abuse, the batterer will use physical and sexual abuse to maintain power and control within the relationship. Physical abuse can include acts such as pushing, shoving, slapping, hitting the woman with a fist or object, kicking, choking, threatening with a gun or knife, or using a gun or knife against her. Sexual abuse occurs any time the batterer forces or tries to force sex (including vaginal, oral, or anal intercourse). It also includes the forced use of objects, or forcing a woman to have sex with someone else against her will. Figure 9-2 ■, the power and control wheel, illustrates how batterers use these tactics in relationships.

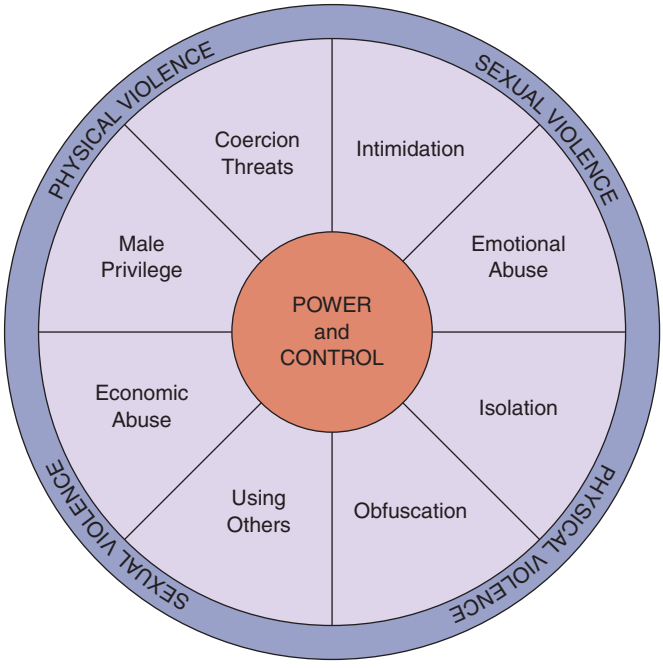

Figure 9-2 ■ The power and control wheel.

Source: Adapted from the Domestic Abuse Intervention Project, Duluth, Minnesota.

Typically these forms of abuse begin slowly and subtly after some form of commitment, such as engagement, onset of a sexual relationship, marriage, pregnancy, first childbirth, or first statement of commitment. Sometimes the woman will not recognize that she is in an abusive relationship.

The consequences of the abuse can be profound. In addition to the physical consequences, which are outlined later in this chapter, a woman may experience adverse psychologic consequences, such as symptoms of post-traumatic stress disorder, depression, antisocial behavior, anxiety, suicidal behavior, low self-esteem, and fear of intimacy. Women sometimes face social consequences as well, including restricted access to services, isolation from social networks, and strained relationships with health providers and employers (CDC, 2008a). Clearly it is important to understand the factors that contribute to domestic violence and the role of the nurse in caring for women who have experienced battering.

Contributing Factors

Domestic violence is a result of the complex and dynamic interaction of social, cultural, political, and psychologic factors. Although none of these factors alone is sufficient to explain why domestic violence occurs, there is substantial research to suggest that the following factors are significantly related to experiences of domestic violence.

- ***Childhood experiences:*** Children who witness or experience abuse and battering are more likely to become batterers (men) or to be abused (women) in their own relationships.

Exposure to domestic violence, however, is not a prerequisite for future abuse. Perhaps more importantly, not all children who witness violence in the home as children find themselves in abusive relationships as adults.

- ***Male dominance in the family:*** Worldwide, male economic and decision-making authority in the family is one of the strongest predictors of societies that demonstrate high violence against women, including domestic violence. This notion is also supported by research that demonstrates that men raised in patriarchal families (those that encourage traditional gender roles) are more likely to engage in domestic violence.
- ***Marital conflict:*** Relationships that are characterized by high levels of conflict, including verbal disagreements, are more likely to include the use of violence than are those relationships with lower levels of marital conflict.
- ***Unemployment/low socioeconomic status:*** Domestic violence occurs in all socioeconomic classes; however, it is more common in families with low incomes and unemployed men. The reasons for this have not yet been determined. It may not be a lack of income, but some other variable related to living in poverty—stress, frustration, feelings of inadequacy in filling the male role of provider, overcrowding, or a lack of community institutions and norms that would create quality community social interactions—that explains this relationship.
- ***Traditional definitions of masculinity/hypermasculinity:*** Cultures that link definitions of manhood to dominance, toughness, or male honor are more likely to demonstrate violence against women. This may result because socialization into traditional male norms includes telling young boys to be tough, not to shy away from violence, and to hide their feelings, particularly those that are associated with traditional notions of femininity.

Often healthcare providers view domestic violence as primarily a problem of younger women and believe that the violence decreases with age. Research indicates, however, that domestic violence does exist in older couples and that it will become an ever-increasing health problem as the population of baby boomers ages (Straka, 2006).

Common Myths About Battering and Women with Abusive Partners

Both professionals and the public believe numerous myths about battering and about women with abusive partners. These myths often reinforce misunderstanding of battering, furthering a woman's sense of victimization. Nurses need to recognize and counteract these myths. Some commonly accepted myths are discussed here.

- ***Battering occurs in a small percentage of the population:*** The statistics on reported cases underrepresent the true incidence. As many as 1 in 3 women may be the victim of assault by her partner in her lifetime; however, it is estimated that only 1 in 10 women will report battering assaults.
- ***Women who are abused provoke men to beat them; women push men beyond the breaking point and incite physical violence:*** It is important to recognize that people are individually responsible for their own behavior. Batterers become violent because of their own internal inadequacies, not because of what their partners did or did not do.
- ***Alcohol and drug abuse cause battering:*** Studies do show a relationship between battering incidents and alcohol or drug use by batterers, and many batterers have a history of alcoholism or drug addiction. However, claims that substance abuse *causes* domestic violence are false and only serve to shift the responsibility away from the batterer. Some researchers suggest that batterers use alcohol as an excuse to carry out a violent act and shift the blame from themselves to the alcohol. Others suggest that alcohol or drugs reduce the batterer's inhibitions, increasing the likelihood of violent acts. Battered women sometimes think that the abuse will stop if their partners stop drinking or using drugs. Unfortunately, this usually does not happen.
- ***Battered women can easily leave the situation:*** Leaving is easier said than done. Society encourages women to take greater responsibility for their marriages and children. In addition, battered women may still love their partners or husbands and believe the promises of change, rely on them for financial support, and feel their children need a father. Women with physically abusive partners nearly always experience psychologic abuse as well and have been told repeatedly by their batterers that the family's problems are their fault. They often are isolated by their abuser from family, friends, and agencies that could assist them. Women may also experience a lack of support from family members, friends, and their religious community. Others may not believe the woman's accounts or blame her for the violence she experiences. Many women with children have no place to go, and shelters sometimes have long waiting lists. Moreover, battered women are at greatest risk for injury or domestic homicide when they leave the abuser. A woman may fear for her safety, her children's safety, and the safety of those who help her.
- ***Domestic violence is a low-income or minority issue:*** Domestic violence occurs among all sectors of society. It happens to women of all socioeconomic statuses, races, ethnicities, and religious faiths. It is true that lower income women are more likely to seek assistance from public agencies, such as hospitals and emergency departments, because they have fewer private resources than women with greater incomes do. Therefore, they are more likely to be counted in various reporting statistics.
- ***Battered women will be safer when they are pregnant:*** Battering may occur for the first time during pregnancy or may escalate in intensity if the woman is already being abused. The injury is frequently aimed at the breasts, abdomen, or vagina. Many researchers and advocates believe that batterers are threatened by a pregnancy because the fetus interferes with the abuser's ability to maintain power and control within the relationship. Pregnancy is often a time during which a woman receives extra attention from family, friends, and healthcare providers. The intensified violence that some women experience merits serious attention.

> "Miles hit me for the first time when I was 5 months pregnant. I was stunned. My father never laid a hand on my mother or any of us. Women who stayed in abusive situations had always appalled me but suddenly I found myself making excuses for him and rationalizing that he hadn't meant it, that he would never do it again. Three months later he shoved me so hard I fell against an end table. I was pretty bruised, but I didn't go into labor. Somehow I found the courage to call my dad. He came and got me that night. My baby is 3 months old now and Miles keeps calling, telling me how sorry he is and that he loves me. Oh, how I want to believe him when he says he is changed, but I just can't take the chance."

Cycle of Violence

Walker (1984), in an effort to better explain the experience of battered women, developed the theory of the **cycle of violence**, which postulates that battering takes place in a cyclic fashion through three phases.

1. In the *tension-building phase,* the batterer demonstrates power and control. This phase is characterized by anger, arguing, blaming the woman for external problems, and possibly minor battering incidents. As the stress builds and communications break down, the woman often senses growing danger. She may also blame herself for the battering and believe she can prevent the escalation of the batterer's anger by her own actions, hoping that the relationship will somehow change for the better. The length of this phase varies considerably across individual cases, ranging from weeks to years.
2. The *acute battering incident* is typically triggered by some external event or internal state of the batterer. It is an episode of acute violence distinguished by lack of predictability and major destructiveness. The batterer blames the woman for the abuse, and the woman may accommodate him in order to survive, believe that escape is futile, or escape and return when the crisis is over. This is generally the briefest of the three phases, lasting from a few hours to a few days.
3. The *tranquil phase* is also sometimes called the *honeymoon period.* This phase may be characterized by extremely loving, kind, and contrite behaviors by the batterer as he tries to make up with the woman, or it may simply be manifested by an absence of tension and violence. The couple or family is often relieved that the crisis is past, and the woman may accept the batterer's promises and gifts because she is worn down and wants to believe that the violence will not happen again. Without intervention this phase will end at some point, and the cycle of violence will repeat. Over time, the cycle of violence often increases in severity and frequency.

Characteristics of Batterers

Batterers come from all racial, ethnic, and religious groups and all professions, occupations, and socioeconomic strata. They may have only a sixth-grade education or hold a doctorate. What they have in common are feelings of insecurity, inferiority, powerlessness, and helplessness that conflict with their assumptions of male supremacy. Because they tend to be emotionally immature and aggressive, they have a tendency to express their overwhelming feelings of inadequacy through violence.

Many batterers feel undeserving of their partners, yet they blame and punish the very person they value. Extreme jealousy and possessiveness are the hallmarks of abusers. They characteristically express their ambivalence by alternating episodes of unmerciful beatings with periods of remorse and loving attention. Extremes in behavior and overreacting are typical patterns.

Batterers may be very calculating and select a partner they feel may be vulnerable. Over time they slowly and purposefully isolate the woman, creating a situation of increased dependence.

Women often describe their abusive husbands or partners as lacking respect toward women in general, having come from homes where they have witnessed abuse of their mothers or were themselves abused as children, and having a hidden rage that erupts occasionally. Batterers accept conventional "macho" values, yet when they are not angry or aggressive, they may appear childlike, dependent, seductive, manipulative, and in need of nurturing. They may be well respected in the community. This is important because it is one of the reasons why women are sometimes not believed or taken seriously when they seek support and assistance from friends, family members, and other resources. This dual personality of batterers reflects the conflict between their belief that they must live up to their macho image and their feelings of inadequacy and insecurity in the role of husband or provider. Combined with low tolerance for frustration and poor impulse control, the batterers' pervasive sense of powerlessness leads them to strike out at life's inequities by abusing women.

Care Plan Activity: Suspicious Injury and Bruises

NURSING CARE MANAGEMENT

Increased publicity, public sensitivity, and heightened awareness of domestic violence are encouraging women with abusive partners to seek resources and community assistance. In the past decade, many communities have developed domestic violence programs, shelters, and resources for women with abusive partners. However, the needs of women who have been abused and their children are still insufficiently met.

Women in abusive relationships enter the healthcare system in many different settings. Nurses may see them in the physician's office with minor trauma or in the emergency department with multiple severe injuries. They are frequently seen in obstetric services because battering often begins or escalates during pregnancy. Nurses in psychiatric-mental health services frequently counsel women who have been battered, and community health nurses may find women reporting abuse during home visits. Universal screening is advocated as an effective approach to identify women in such situations, and nurses must recognize that being so identified requires both caring concern and follow-up practices.

Nurses in many different healthcare settings often come in contact with women who have experienced abuse but fail to recognize them, especially if they have no visible injuries.

Nurses who wish to help battered women need advanced knowledge of the dynamics of battering; assessment skills for recognizing and documenting abuse; and appropriate intervention skills in counseling, safety planning, and referral.

Working with women who have been abused is sometimes frustrating, and many healthcare providers feel puzzled when women return to their abusive situations. Nurses must realize that they cannot rescue women with abusive partners; women must decide on their own how to handle the situation, which is often incredibly complex and dangerous. Research has shown that women's risk for homicide and additional violence are greatest during separation or attempts at separation. The effective nurse provides women who have been abused with information that empowers them in decision making and provides critical assistance in safety planning for women and their children.

Nursing Assessment and Diagnosis

Domestic violence is very prevalent and yet frequently remains unidentified by healthcare providers. Though experts and caregivers now advocate universal screening of all female patients at every healthcare encounter, impediments to universal screening range from a lack of institutional or organizational support to the attitudes of individual nurses.

A majority of the reasons cited by nurses indicate a lack of education about domestic violence in general and a lack of confidence in their own skills specific to domestic violence intervention. This fact underscores the importance of and need for comprehensive domestic violence education and training for healthcare providers, a policy recommendation that was affirmed by the 2000 National Violence Against Women (NVAW) Survey and the ANA Position Statement on Physical Violence Against Women (ANA, 2000). In addition to factual information about domestic violence and its impact on women's physical, psychologic, and sexual health, comprehensive education and training should include opportunities to practice skill development (e.g., in screening, assessment, empathic listening, diagnosis, planning, and communication across diverse age and ethnic/cultural groups) as well as opportunities to explore one's personal responses, attitudes, and values related to abuse.

Nurses may also be hesitant to ask because they presume the woman may be offended by the questions. However, women are rarely offended by questions about abuse, particularly if prefaced by a statement such as, "Because violence is so common in many people's lives, I've begun routinely asking all the women I care for about it." Showing knowledge about and familiarity with the issue of domestic violence not only increases a nurse's effectiveness in identifying women who have experienced abuse, but also fulfills an important health education function for women who have not experienced abuse.

Four basic screening questions, identified in Figure 9-3 ■, are useful in identifying women who are experiencing abuse. If a woman responds affirmatively to the questions, she is asked to mark the area(s) of injury on the body map. Screening for women experiencing domestic violence must be done privately, with only the nurse and patient present, in a safe and quiet place (Figure 9-4 ■). The nurse needs to reassure the woman that her responses will be kept confidential. The nurse should also strive for a calm and reassuring tone. Although tone, body language, and other nonverbal signs are important in establishing trusting relationships with all women, nurses should be especially aware of these issues in interventions with women from cultural and linguistic minority groups. Women from cultural and linguistic minority groups are often sensitized to these cues because they have used them as a survival strategy against discrimination and prejudice.

A number of signs that may not be related to a woman's presenting injuries can indicate the possibility that a woman is in a violent relationship. Although no single one of these signs necessarily indicates abuse, the occurrence of several of these signs certainly merits an at-risk diagnosis. Nurses must exercise their professional judgment and communicate their conclusions to their patients. Signs that may indicate a woman is in an abusive relationship include the following:

- ***Neurologic signs:*** Headaches, including headache following trauma or concussion, tension headache, and migraines; dizziness; paresthesias; unexplained stroke from strangulation; hearing loss; detached retina
- ***Gynecologic signs:*** Dyspareunia (painful intercourse), sexually transmitted infections (STIs), frequent vaginal infections, sexual dysfunction, menstrual disorders, pelvic pain
- ***Obstetric signs:*** Late onset of prenatal care, premature labor, low-birth-weight infant, excessive concern over fetal well-being, recurrent therapeutic abortion, recurrent spontaneous abortion
- ***Gastrointestinal signs:*** Dyspepsia, irritable bowel syndrome, globus (sensation of a lump in the throat)
- ***Musculoskeletal signs:*** Arthralgias (painful joints), chronic pain, osteoarthritis, fibromyalgia
- ***Psychiatric signs:*** Anxiety, panic, post-traumatic stress disorder, mood disorders, depression, suicide attempts, somatization, eating disorders, substance abuse, child abuse and neglect
- ***Constitutional signs:*** Fatigue, weight loss, weight gain, multiple somatic complaints, contusions, abrasions, sleep and appetite disturbances, decreased concentration, frequent use of pain medication or tranquilizers
- ***Trauma:*** Any injury to the female organs, extensive accident history, old fractures, sexual trauma
- ***Other signs:*** History of missed appointments or frequently changed appointments; low self-esteem, as seen in the woman's dress, her appearance, and the way she relates to healthcare providers

When a woman seeks care for an injury, the nurse should be alert to the following cues of abuse:

- Hesitation in providing detailed information about the injury and how it occurred
- Inappropriate affect for the situation
- Defensive injuries
- Delayed reporting of symptoms or of seeking care for injuries
- Pattern of injury consistent with abuse, including multiple injury sites involving bruises, abrasions, or contusions to the head (eyes and back of neck), throat, chest, breast, abdomen, or genitals (Nonbattered women's injuries are usually lo-

Abuse Assessment Screen

Universal Screening is recommended for all women during ED visits, Hospital admission, Prenatal visits, Routine PE and GYN screening, and Well Child visits of children to their pediatricians.

Note: Some agencies have nurses and/or physicians verbally ask questions, others include them in a written health questionnaire given to all patients, and others do both.

INTRODUCTION AND QUESTIONS:

Because violence is so common in many people's lives, I've begun to ask all my patients about it routinely:

1. **WITHIN THE LAST YEAR**, have you been hit, slapped, kicked, or otherwise physically hurt by someone? YES NO

   If YES, by whom? _____

   Total number of times _____

2. **SINCE YOU'VE BEEN PREGNANT**, have you been hit, slapped, kicked, or otherwise physically hurt by someone? YES NO

   If YES, by whom? _____

   Total number of times _____

MARK THE AREA OF INJURY ON THE BODY MAP
SCORE EACH INCIDENT ACCORDING TO THE FOLLOWING SCALE

SCORE

1 = Threats of abuse including use of a weapon _____
2 = Slapping, pushing; no injuries and/or lasting pain _____
3 = Punching, kicking, bruises, cuts, and/or continuing pain _____
4 = Beating up, severe contusions, burns, broken bones _____
5 = Head injury, internal injury, permanent injury _____
6 = Use of weapon; wound from weapon _____

If any of the descriptions for the higher number apply, use the higher number.

3. **WITHIN THE LAST YEAR**, has anyone forced you to have sexual activities? YES NO

   If YES, by whom? _____

   Total number of times _____

4. Are you afraid of anyone at home or an ex-partner? YES NO

cated at one or two sites and on the extremities, such as sprains and strains. Women in abusive relationships may have scars and evidence of old injuries that have healed.)

- Inappropriate explanation for the injuries, such as being "accident prone"
- Vague complaints without accompanying pathology
- Lack of eye contact
- Signs of increased anxiety in the presence of the possible batterer, who frequently does most of the talking or hovers around the woman

Figure 9-4 ■ Screening for domestic violence should be done privately.

Source: Al Dodge, Photographer.

As with the universal screening, if the nurse observes these potential cues, then the nurse should arrange for a private place in which the woman can feel safe. If a man is with the woman, the nurse should tell him to remain in the waiting room while the woman is examined. It is good practice to ask the same of family members or friends because it can be difficult for women in abusive relationships to talk candidly about their situation with others present. The nurse can encourage the woman to talk about her injuries and home situation by asking, "How did this happen to you?" or by saying, "We often see injuries like yours when a woman has been beaten. Has this happened to you?" Directly confronting the injuries and possible abuse may provide an opening for the woman who is trying to cope in private. A woman may continue to deny her battering. The nurse should encourage her to talk but should avoid badgering her. When culturally appropriate, it is important to maintain eye contact and avoid excessive note taking. The nurse should assure the woman that her privacy will be respected. It is essential that the nurse remains nonjudgmental; creates a warm, caring climate conducive to sharing; and demonstrates a willingness to talk about violence. A woman will often interpret the nurse's willingness to discuss violence as permission for her to discuss it as well.

> "No one had ever asked me about my 'injuries' until I was in the ER one night and the nurse asked me right out if I had been beaten. It gave me real hope to think that people might see what was happening to me."

Assessment is a complex process. It is important for the nurse to gather information about the woman's history of abuse. Getting a sense of the pattern of abuse is key to determining the degree of danger she might face. The nurse can help the woman assess whether or not the cycle of violence is becoming more frequent or severe. Determining whether or not there are weapons in the home, and whether or not her batterer has used or threatened to use weapons might also be warranted. In cases of severe abuse, it is important for the nurse to address the connection between homicide and domestic violence. Finally, the nurse should ask about the presence of sexual abuse within the relationship, another factor that indicates severe abuse.

Equally important, however, the assessment of the woman who may be experiencing abuse should include information about her strengths and her support system. Strengths may include education, employment history, activities in the home, community involvement, and her ability to cope with past problems. The woman's support system may include her family, friends, neighbors, and community agencies or organizations. It is helpful to consider assessing a woman's strengths in a cultural context. If the nurse is aware of strong values that a particular cultural group holds, then he or she should look for opportunities to recognize and affirm those strengths as valuable.

CLINICAL TIP

In seeking ways to help a woman feel less helpless, consider actually recording a woman's strengths in her medical record and showing her that they are an official part of the record. This action lets her know that you believe that her strengths are as significant as any problems that were noted.

During the assessment phase, the nurse begins building a relationship with the woman based on trust, understanding, and advocacy. A woman may feel ashamed and embarrassed about her injuries and her situation. It is important to tell her the purpose of the assessment and to communicate what level of confidentiality she can expect. Clearly, nurses need to be informed about the confidentiality policies of the organization where they work and aware of any mandatory reporting policies that exist. Trust begins as the nurse conveys an attitude of unconditional acceptance, empathy, and positive regard for the woman's worth and dignity. Nurses should show that they recognize the woman's feelings and accept her right to feel as she does.

In cases in which the woman states she has been beaten, kicked, punched, or attacked but does not identify the assailant, the nurse should record the extent of injuries (e.g., size, shape, color, where they are located on her body), note the woman's exact words, and describe the incident with a diagnosis of probable battering. Full documentation of specific information is critical, because the nurse might be called to testify in court or the medical records might be subpoenaed as evidence in legal proceedings such as custody disputes, stay-away/restraining orders, or other civil or criminal proceedings. Moreover, documenting the abuse works to ensure a woman's continuity of care. Those cases in which the woman states she was beaten by a husband or partner may be diagnosed as battering with all evidence recorded, including the woman's statements. In both cases, taking photographs of the injuries can be of great value. However, to further protect the woman's confidentiality and safety, it is critical that the nurse or other medical personnel do not refer to domestic violence or abuse on any discharge papers.

When abuse or battering is suspected or determined, the nurse should formulate nursing diagnoses based on the assessment findings. Nursing diagnoses related to nonphysical components of abuse or battering may include the following:

- ***Risk for powerlessness*** related to feelings of worthlessness secondary to ongoing psychologic partner abuse.
- ***Readiness for enhanced knowledge:*** Information about community resources to assist battered women related to an expressed desire to learn about alternatives to remaining in an abusive situation.

Nursing Plan and Implementation

A woman who is experiencing abuse needs to reestablish a feeling of control over her world. She needs to regain a sense of predictability by knowing what to expect from her disclosure. The nurse should provide sufficient information about what to expect in terms the woman can understand. Simple explanations about how long she will stay, whom she will see, and what will be done are important. Giving the woman control can be accomplished by asking her permission before any activities or procedures and by providing her with choices whenever possible.

Supportive counseling and reassurance are professional skills nurses use throughout each phase of the nursing process with a battered woman. The nurse should do the following:

- Acknowledge and support the woman for discussing her situation. Reporting abuse is a risk.
- Let the woman work through her story, problems, and situation at her own pace.
- Let the woman know that she is believed and that her feelings are reasonable and normal.
- Anticipate her ambivalence in the love-hate relationship with the batterer. She knows he may be loving and contrite after the incident if she has been through the cycle of violence before.
- Respect the woman's capacity to change and grow when she is ready.
- Assist her in identifying specific problems, and support realistic ideas for reducing or eliminating those problems.
- Help clarify the woman's beliefs and myths; provide information to change her false beliefs.
- Stress that no one should be abused and that the abuse is not her fault.

The appropriate intervention is not to tell an abused woman what to do but to explore options and resources with her, allowing her to make her own decisions. Even advising or encouraging a woman to leave an abusive situation is not always in the woman's best interest; leaving the home is a major decision with long-lasting consequences. The woman may be economically unable to leave the situation, especially if she has young children. If the woman leaves and then later returns home, both husband and wife may become more frustrated, increasing the possibility of further beatings and even homicide. The most acceptable course of action is one that the woman freely chooses. It often takes many interventions before a woman gains enough courage and skill to leave an abusive situation.

DEVELOPING CULTURAL COMPETENCE

Cultural Factors Influencing Survivors of Violence

Providing nursing care to women who are from a different cultural community, who speak a different language, or who are immigrants can be challenging. This is especially true when providing care to women who are in abusive relationships. When assisting survivors from different cultural or linguistic backgrounds, consider the following:

- It is often difficult for women in certain cultural communities to seek help outside their families for a variety of reasons, ranging from cultural notions about the role of women, to fear of being ostracized within or isolated from her community, to a loss of social respect that includes her entire family (Tahirih Justice Center, 2009).
- Language can be a powerful barrier to effective communication. Patients with comparable needs require comparable service. Thus it is important to have bilingual nurses and personnel available and to translate assessment tools, such as those found in Figure 9-2 (The Joint Commission, 2008).
- Have information available about language-specific and culturally appropriate community resources, including legal services that specialize in family and immigration law, individual and family counseling services, and shelters with bilingual and bicultural staff.
- Immigrant women may have inaccurate perceptions of law enforcement and the legal system, either because of negative experiences with law enforcement in their country of origin or because of misinformation about the U.S. legal system from their abusers (Tahirih Justice Center, 2009).
- Abusers may threaten women with deportation if they seek help for the abuse. Women may be fearful of jeopardizing their financial or immigration status and that of their children, their family, or their abuser. For a more complete list of tactics used to control immigrant women experiencing domestic violence, see Table 9-1.
- Women in some cultures may have deeply held religious beliefs that conflict with standard legal remedies. It is vital to find creative remedies that do not ask a woman to choose between religious and spiritual convictions and much needed legal remedies (Tahirih Justice Center, 2009).
- Avoid cultural stereotyping—there are many subcultures and traditions within any cultural community. Create a safe space for the woman to share her needs, fears, and any cultural barriers that she must overcome.
- Educate yourself. Become aware of your own biases and stereotypes and make a commitment to learn about the practices of others from various minority communities.

Health Promotion Education

If the woman returns to an abusive situation, the nurse should encourage her to develop an exit, or safety, plan for herself and her children, if she has any. As part of the plan, she should pack a change of clothes for herself and the children, including toilet articles and an extra set of car and house keys. She should store these away from the house with a friend or neighbor and ask a neighbor to call the police if violence begins. If possible,

Going Back?

TABLE 9-1 Tactics Used to Control Immigrant Women in Abusive Relationships

Isolation	Keeping her isolated from family, friends, community and religious leaders, or people who speak her native language; not allowing her to learn English.
Threats	Threatening to report the victim to the U.S. Immigration and Naturalization Service (INS) or threatening to withdraw a petition to legalize immigration status. The abuser often threatens to seek sole custody of the children if the woman reports the abuse or attempts to leave.
Intimidation	Hiding or destroying important papers such as passports and green cards, documentation for the children; destroying her only property from the country of origin such as mementos or photographs.
Citizenship or Residency Privilege	Failing to file papers to legalize immigration status and/or withdrawing such papers altogether; lying to the woman that her immigration is legal.
Economic Abuse	Not letting her obtain job training, work, or schooling; threatening to report the victim for working "under the table"; taking money she wants to send abroad to family; forcing the woman to work illegally.
Emotional Abuse	Lying about immigration status; threatening to harm the children or other family members; calling her racist or abusive names.
Spiritual Abuse	Misusing religious teachings and/or personal beliefs and values.

she should have money, identification papers (driver's license, social security cards), checkbook, bank account information, other financial records (such as mortgage papers, rent and utility receipts, automobile title, insurance policies and numbers), and information about the children to help her enroll them in school. She should also plan where she will go, regardless of the day or time. It is also helpful to identify friends and family who know about the situation and will help her. Ask that she establish a code word for danger with those family and friends. The nurse should ensure that the woman has a planned escape route and emergency telephone numbers she can call, including personal numbers, the local police, a phone hotline, and a women's shelter if one is available in the community.

Community-Based Nursing Care

Besides offering emotional support, medical treatment, and counseling, the nurse should inform any woman who may be in an abusive situation of the services available in the hospital, through agencies, and in the community. The nurse can also provide the woman with the phone number of any local resources, as well as the number for the National Domestic Violence Hotline (1-800-799-SAFE).

Specifically, a woman who has been abused may need:

- Medical treatment for injuries
- Temporary shelter to provide a safe environment for herself and her children
- Legal assistance for protection or prosecution of the batterer
- Financial assistance to provide shelter, food, and clothing
- Job training or employment counseling
- Counseling to raise her self-esteem and help her understand the dynamics of domestic violence, or an ongoing support group for herself and her children

A network of community agencies can meet the numerous, varied needs of women, children, and batterers. It is important that employees in these agencies understand the complex dynamics of domestic violence as well as how their services and those of other agencies can assist women and their children. An overview of resources available to women with abusive partners and their children is presented in the following sections.

Emergency Department Services

Many women who are experiencing abuse are first seen and diagnosed in the emergency departments (EDs) of their neighborhood hospitals. ED nurses and personnel need to be alert to symptoms of battering, recognize these cues, and encourage women to seek assistance from community agencies. The most innovative and effective domestic violence programs in hospitals and urgent care facilities work collaboratively with domestic violence service agencies, develop a comprehensive community referral network, and work with multidisciplinary intervention teams. Some states require that suspected cases of abuse and battering be reported to the legal authorities or social service agencies. Domestic violence forensic examinations are now available at many large community hospitals, allowing for needed forensic gathering of evidence for possible future legal use by the survivor.

Shelter

Because domestic violence has been recognized as a major social problem, many community agencies have sought federal and state funds to provide shelters. These shelters differ in the services they provide, depending on the governing body, financial resources and funding agencies, organizational structure, staff qualifications, and range of available community services. Typical shelters provide women in abusive relationships and their children with a room, beds, food, clothing, and other basic necessities. If professional staff is available, the shelter may offer crisis counseling; individual and group counseling; and information about community agencies such as legal aid, welfare, job training, financial and employment agencies, and women's counseling or support groups.

For safety reasons, the location of most shelters is undisclosed, but they can be contacted through a community crisis line. Admission requirements vary from shelter to shelter, so it is wise for nurses to become familiar with all local shelters and other resources available in case one or more shelters are full and the woman and her children are in need of a safe place to stay.

Legal Services and Options

During incidents of domestic violence, the woman or her neighbors may summon the police. Domestic violence often occurs on the weekend or in late evening, when most social service agencies are closed; therefore, the police department is one of the first major agencies involved, in addition to those that provide medical services.

National Coalition Against Domestic Violence

RESEARCH EVIDENCE IN PRACTICE

Advocacy Interventions to Reduce Intimate Partner Violence Against Women

CLINICAL QUESTION

Are either brief or intensive advocacy interventions effective in reducing or stopping intimate partner abuse or its associated morbidity?

RESEARCH EVIDENCE

The World Health Organization estimates that between 10% and 50% of women worldwide report having been assaulted physically or sexually by an intimate partner at some time in their lives. This number escalates when emotional and financial abuse are included. Domestic violence affects the physical and mental well-being of its victims and often continues throughout pregnancy. Intimate partner abuse is one of the most common causes of non–fatal injury in women and makes up between a third and a half of all murders of women in the United States and Canada.

A variety of interventions have been proposed to prevent or alleviate intimate partner abuse. Advocacy interventions are considered secondary interventions, in that these efforts seek to prevent further abuse once it has begun. Advocacy interventions vary, but in general they aim to empower women and link them to community resources that might assist them in avoiding abuse. The core activities of advocacy are provision of legal, housing, and financial advice; facilitation of access to community resources such as refuges or shelters; and the provision of safety planning advice. Advocacy may be brief, such as that delivered in an emergency department, or more intensive, involving group and/or individual therapies over time. Advocacy interventions are based on the concept of empowerment and seek to help women make decisions and find solutions rather than directing or prescribing certain actions.

Trials involving more than 1500 women demonstrated evidence that intensive advocacy for women recruited into domestic violence shelters has a beneficial effect on the women's physical and psychosocial well-being. However, it does not appear that even intensive advocacy services are effective for women who continue to live with abusive partners. Brief advocacy may have a positive effect on reducing minor physical abuse in women in emergency settings or who present for antenatal care, but there is no evidence to suggest that brief interventions result in a reduction of more severe abuse. Neither appears to affect the long-term rate of depression or post-traumatic stress disorder, two common conditions that accompany intimate partner abuse.

WHAT QUESTIONS REMAIN UNANSWERED?

What interventions can be offered to the abusive partner that might alleviate the pattern of abuse? What advocacy interventions will help a woman take the step of leaving an abusive relationship?

WHAT IS BEST PRACTICE?

Intensive interventions to empower women to take advantage of community services such as refuges and shelters hold the most promise for ending a pattern of domestic violence. In the absence of intensive interventions, brief interventions in emergency settings can help reduce the effects of minor injuries.

CRITICAL THINKING

How are the effects of intimate partner violence detected in the clinic or emergency setting? How can intensive interventions be initiated in these settings?

PROFESSIONALISM IN PRACTICE

Legislative Advocacy

Patient advocacy is a nursing responsibility that extends beyond individual nurse-patient relationships. Nurses can follow and become involved in legislative advocacy for issues related to domestic violence and other issues related to women's health through participation in their local and state chapters of the American Nurses Association, by being aware of current issues, by following the progress of specific bills online, by writing to their legislators, and by exercising their right to vote.

Legal options for women with abusive partners vary according to state laws and services. In some states a woman may seek a restraining (or protective) order from the family court or a domestic relations court to protect herself from the batterer. This restraining/protective order specifies the type of contact, if any, allowed between the batterer and the victim. Unfortunately, many abusive men violate the restraining/protective order and continue to stalk, harass, intimidate, and abuse their female partners. The case then becomes a criminal matter. If the woman decides to prosecute, and if her case meets the legal requirements for an indictment, the case is usually heard in criminal court, which handles crimes of assault, harassment, and battery. Criminal court hearings may result in a fine, probation, or a jail sentence if the batterer is convicted, giving the man a criminal record. The prosecution process is often lengthy and may last more than a year. Some state judicial systems are introducing other options, such as mandatory counseling in a Batterer Intervention Program (BIP) in lieu of prosecution. Unfortunately, this counseling does not show great promise for permanent change. Divorce is another legal recourse a woman may choose, but divorce takes time and may cause added financial burdens for the woman.

Many women who are abused are unaware of their legal options. They fear further beatings if they prosecute the batterer. Limited financial resources may also keep them from seeking legal assistance. Some women report lack of sensitivity or awareness about domestic violence on the part of some members of the legal and criminal justice systems, further limiting their ability or willingness to seek help. Currently, some communities provide legal advocacy services to help women understand the

judicial process, their options within that system, and the possible consequences for the woman, her children, and the batterer.

Financial Services

Once women who have been in battering relationships leave their homes or seek legal assistance, they usually receive no financial support from their batterers. Without funds, women and their children are at the mercy of community social service agencies, and it usually takes weeks for papers to be processed before any money is forthcoming. Agencies that may provide financial assistance include their county welfare department; federal programs (e.g., Temporary Assistance for Needy Families); the United Way; women's support groups; religious organizations; and, possibly, the Salvation Army. There may be other local groups who assist abused women in other ways, such as by providing food or clothing.

Employment Training or Placement

Some women who experience abuse are full-time mothers who may lack advanced education, training, and job experience. Minimal or out-of-date skills and inadequate transportation often make it difficult for these women to obtain employment with an adequate salary. Women who have children must consider where to place them during working hours as well as the added cost of child care. Often, the woman's choice is restricted to accepting welfare or taking a low-paying job. Either choice usually means lowering the standard of living to mere subsistence.

Some women do seek job training if the opportunities are available, but training provides no guarantee of future job placement. A woman may still have to arrange for financial support and child care while obtaining advanced employment skills or an education.

Counseling or Advocacy

Women who have experienced domestic violence may be offered a variety of counseling and advocacy services, such as crisis intervention, short-term individual therapy, group therapy, or peer support groups, over an extended period. Specially trained nurses, social workers, psychologists, mental health specialists, or clergy may provide counseling and therapy.

Evaluation

Expected outcomes of nursing care include the following:

- The woman receives compassionate, respectful, and individualized medical attention.
- The woman recovers from the physical effects of physical and sexual abuse.
- The woman has the information she needs to make a decision about her future based on thoughtful consideration of alternatives.
- The woman is able to identify culturally appropriate community resources available to her and develops strategies for keeping herself, her children, and her family as safe as possible.
- If the woman chooses to apply for a restraining order or to prosecute her assailant, all necessary documentation is recorded in her medical records, leading to a more successful prosecution.

Sexual Assault

Sexual assault is a broad term that refers to a variety of types of unwanted sexual touching or penetration without consent, from unwanted sexual contact or touching of an intimate part of another person to forced anal, oral, or genital penetration. Rape is, therefore, one type of sexual assault. Although the specific definition of rape varies from state to state, the Bureau of Justice Statistics (2009) defines it as follows: **Rape** is "forced sexual intercourse including both psychologic coercion as well as physical force. Forced sexual intercourse means vaginal, anal or oral penetration by the offender(s). This category also includes incidents where the penetration is from a foreign object such as a bottle" (p. 2). The rapist may be a stranger, acquaintance, spouse or other relative, or an employer. Rape is an act of violence expressed sexually—most commonly, a man's need for power and control acted out against a woman (Tjaden & Thoennes, 2006).

Sexual assault remains one of the most underreported violent crimes in the United States. The Rape, Abuse, and Incest National Network (RAINN) (2009) estimates that someone is sexually assaulted in the United States every 2 minutes. Research indicates that one in six American women over age 12 will be the victim of an attempted or completed sexual assault or rape in her lifetime (Tjaden & Thoennes, 2006). In 2008, 551,590 women were the victims of a reported rape or sexual assault; however, only an estimated 47% of incidents were reported to the police, making the actual number significantly higher (Catalano et al., 2009).

Reporting varies by the type of rape or sexual assault. Rapes and sexual assaults committed by strangers are more likely to be reported to the police than rapes and sexual assaults committed by "nonstrangers," including intimate partners, other relatives, and friends or acquaintances. Women injured during a rape incident are also much more likely to report it to the police. Much research suggests that only 2% to 20% of sexually victimized women report the incidents to the police (Thompson, Sitterle, Clay, et al., 2007; RAINN, 2009).

Although both men and women can be sexually assaulted, the National Crime Victimization Survey reported that 9 out of every 10 rape victims were female (RAINN, 2009). Sexual violence often occurs early in life. Over half (60.4%) of all female victims were first raped before age 18; of these, 25.5% occur before age 12 (CDC, 2008a). No woman of any age, cultural or ethnic background, or socioeconomic status is immune, but statistics indicate that young, unmarried women; women who are unemployed or have low family income; and students have the highest incidence of sexual assault or attempted assault.

Common Myths About Rape

As with domestic violence, many myths about rape exist. These myths can have a negative impact on women who are assaulted and can hinder their ability to receive optimum health care following their attack. Some of the most commonly cited myths include the following:

- ***Only certain types of women are raped:*** No woman is safe from a rape attempt. Women of all ages, races, ethnicities, classes, religious backgrounds, occupations, ability levels,

sexual and gender identities, or appearances are raped; rape is a very "democratic" form of violence.

- ***Men rape women because that is men's nature and biologic role:*** Rape is not universal to all societies and not all men rape women. This suggests that rape is an act that can be encouraged or discouraged. Generally, violent societies that encourage aggression in boys and men tend to have more reports of sexual violence.
- ***Women who party hard, drink, and do drugs are setting themselves up to be sexually assaulted:*** No one asks for or deliberately "sets herself up" to be sexually violated. The misunderstanding that rape is about sex perpetrates this myth. Rape is sexual violence and a crime of power. Blaming the victim for the crime is not only inappropriate, it serves to excuse the behavior of the perpetrator. Because alcohol and drugs may affect judgment, feelings, and perceptions, as well as lower inhibitions, a woman may be in a more vulnerable position when she engages in these activities. However, it is not a crime to wear particular clothes, show naivete, use poor judgment, or even engage in reckless behavior. The victim's behavior before the crime is irrelevant.
- ***If a woman just relaxes, it will all be over with soon. She might even find it isn't so bad after all:*** Rape is an act of violence in which the perpetrator uses sex as a weapon to control, intimidate, and violate the victim. Rape involves persistent pressure, taking advantage of a person's inability to say "no"; calculated drugging with alcohol or other substances; and/or threats, sometimes against the woman's life, her livelihood, her academic career, even her family members and friends. Many survivors recall being in fear for their lives, even if a weapon was not present.
- ***Most rapes are interracial:*** The overwhelming majority of rapes and other sexual assaults involve people of the same racial background. Unfortunately, media reports and the entertainment industry tend to emphasize incidents that are interracial, which may encourage racist misconceptions in our society.
- ***A rapist is easy to spot in a crowd:*** There is no way to distinguish men who commit sexual assault from men who do not on the basis of race, ethnicity, socioeconomic status, educational level, or religious background. They can be large or small, able-bodied or disabled, married or single.
- ***Women lie about rape as an act of revenge or guilt:*** False rape charges are infrequent. According to the Federal Bureau of Investigation (FBI), false charges are reported at the same rate for rape as for other felonies; that is, about 2% to 6% of all rape reports. Furthermore, it is important to remember that simply because there is not enough evidence to prosecute, it *does not* mean the woman was lying.
- ***Fighting back incites a rapist to violence:*** Most assailants pick out potential victims they believe may be good targets without a fight. They may even test women nonverbally or verbally before determining whether or not to assault. Both verbal and physical resistance may actually lessen the severity of injury in some instances. Women who recognize that they have options for responding to their assailant are less likely to be paralyzed by fear and more likely to resist. Each incident is unique. Only the targeted person knows her abilities and can assess the assailant's behavior. Evaluating her options realistically may help the survivor understand that submission is also a viable form of self-protection.

Characteristics of Perpetrators

Like their victims, rapists come from all ethnic, racial, and religious backgrounds; socioeconomic statuses; educational levels; and professions. Clinicians and researchers who work with rapists, both convicted and not convicted, report that many rapists are married and engage in regular sexual relationships, both inside and outside of marriage. A substantial number of perpetrators are quite young. Most research studies indicate that sex offenders are often under the age of 18, while the largest number is between 18 and 25 years of age. Unfortunately, so few perpetrators are arrested and convicted that clear characterizations of assailants are not available.

Attitudes toward women do seem to influence who is likely to be a rapist and who is not, especially when it comes to believing that men have a right to sexual access of women. Perpetrators tend to be impulsive and have antisocial tendencies. They may prefer impersonal sex and feel hostility toward women. Additional individual risk factors for perpetration include being male, alcohol and drug use, having friends who are sexually aggressive, an emotionally unsupportive family environment, childhood history of witnessing or experiencing violence, and a belief in societal norms or shared beliefs that support male entitlement and sexual violence (CDC, 2009).

Types of Rape

Rape has been categorized in different ways, which are not mutually exclusive. Specifically, rape may be categorized according to the rapist's possible motives or purposes for the assault, according to the relationship between the victim and perpetrator, or according to the number of assailants.

- In *power rape,* the purpose of the assault is control or mastery. The assailant uses sexual intercourse to place a woman in a powerless position so that he can feel dominant, potent, and strong. He often believes that his victim enjoys the assault, and he exerts only the amount of force necessary to subdue his victim. Often power rape is a planned stranger attack, but most acquaintance rapes are also power rapes. The vast majority of all rapes are motivated by this need for power and control.
- In *anger rape,* the sexual assault is used to express feelings of rage and to retaliate for what the attacker perceives as wrongs against him. These perceived wrongs most often have nothing to do with the rape victim. Considerable brutality and degradation can characterize this type of rape. Attacks on older women often are a form of anger rape.
- In *sadistic rape,* the assailant has an antisocial personality and delights in torture and mutilation. In this type of rape, the victim and assailant are generally strangers, and the assault is planned. Sadistic rapes cause the most injuries, including homicide.

- In *stranger rape,* the assailant and victim are strangers, and the rape is often a blitz-style attack—sudden and unexpected. The rapist is more likely to use a weapon and threaten violence or murder.
- In **acquaintance rape** *or nonstranger rape,* the assailant is someone with whom the victim has had previous nonviolent interaction. The attacker uses deception and trust to gain access to the victim and then betrays that trust. Marital rape and date rape are included in this category. In **date rape**, the male has usually planned to have sex and will do what he feels is necessary if denied. Between 70% and 80% of rapes are committed by someone the victim knows—an acquaintance, a friend, a relative, a coworker, or an intimate partner (Victim Rights Law Center, 2009).
- In *gang rape,* the rape is used as a reinforcing mechanism for membership in a particular group of men (such as a street gang, fraternity, athletic team, or other known group). Often responding to peer pressure from the group leader, participation in the rape provides a means for individuals to demonstrate their power by forcing sex on a woman, thus proving their status in the group. Often gang rape can escalate to severe violence as the young men resort to mob mentality.

> "I always knew that rape was a terrifying experience physically but I never really thought about the horror that comes from being helpless and in someone else's control."

Role of Substances in Sexual Assault

Application: Rohypnol

In some cases, a perpetrator uses alcohol or other drugs to sedate his intended victim—*alcohol or drug-facilitated sexual assault*. While alcohol is the most common and most easily obtained drug, flunitrazepam (Rohypnol), a potent sedative-hypnotic that is legal in 80 countries worldwide but illegal in the United States, has received considerable attention as the "date rape drug of choice" since the late 1990s. Typically Rohypnol, which dissolves easily and is odorless, is slipped into the drink of an unsuspecting woman. Gamma hydroxybutyrate (GHB), ketamine, MDMA (Ecstasy), clonazepam, and scopolamine have also been identified as date rape drugs that are used to incapacitate a woman. More recently, prescription drugs have been used in combination with alcohol to facilitate many sexual assaults. Because these drugs frequently produce amnesia, the woman may be unable to remember details of her assault, thereby making prosecution more difficult. She may be left uncertain about the perpetrator's identity, the events of the assault, the presence of birth control or a condom, and possible injury or risk for contracting sexually transmitted infections (STIs). See Table 9-2 for indicators of possible drug-facilitated sexual assault.

TABLE 9-2 Indicators of Possible Drug-Facilitated Sexual Assault

- Becoming intoxicated very rapidly, especially after accepting a drink from someone else or drinking a drink she left unattended.
- Having just one or two drinks, and then suddenly feeling "very drunk"; feeling more intoxicated than usual after drinking an amount of alcohol she is used to consuming.
- Feeling drowsy, dizzy, agitated, weak, confused, or nauseous; experiencing an increased heart rate or blood pressure, slurred speech, or a lack of motor coordination.
- Waking up suspecting she may have been raped because of vaginal soreness, finding herself in an unfamiliar place, or other indicators.
- Being told that she suddenly appeared drunk; drowsy; dizzy; or confused with impaired motor skills, judgment, and amnesia or partial amnesia.

Rape Trauma Syndrome

Rape is viewed as a situational crisis; that is, an unanticipated traumatic event that the victim generally is unprepared to handle because it is unforeseen. Following rape, the survivor may experience a cluster of symptoms originally described by Burgess and Holmstrom (1979) as the **rape trauma syndrome**. Burgess and Holmstrom described this syndrome as having two phases: the acute phase and the adjustment, or reorganization, phase. Other authors added a third phase: an intermediate, outward adjustment phase. A fourth phase—integration and recovery—has also been suggested, which serves to complete the syndrome (Holmes, 1998). Although the phases of response are discussed individually in the following sections, they often overlap, as do individual responses and their duration.

Acute Phase (Disorganization)

The acute phase of rape trauma syndrome begins during the rape and may last for a few days or up to 3 weeks. The woman may experience fear; shock; disbelief; and, sometimes, denial. The woman may feel humiliated, guilty, and unclean; her wish to cleanse herself by bathing or douching may be overpowering, even if she knows that by doing so she is destroying evidence. She may feel angry or anxious, powerless or helpless.

The rape survivor may suppress her emotions or may reveal them by crying, sobbing, or acting tense and restless. Survivors who control or mask their emotions may appear calm, composed, or subdued. Many rape survivors also experience alterations in sleep patterns, such as insomnia, nightmares, or crying out at night.

Outward Adjustment Phase (Denial)

Once the acute stage has passed, the survivor may appear adjusted. She returns to work or school and resumes her usual roles. But although she appears composed, she is actually coping by denial and suppression. The survivor needs the outward adjustment phase to cope with the experience of rape; it is a means of regaining control of her life. During this time, she may move to a different residence or may institute security measures, such as installing extra locks or requesting an unlisted telephone number. She may buy a weapon or take a course in self-defense. These activities do not resolve her emotional trauma; they simply push it further into her subconscious. In addition she may get less support from others who perceive her as being "over it."

Reorganization

Denial and suppression cannot sustain the survivor for long. As these coping mechanisms deteriorate, she becomes depressed and anxious and feels a strong urge to talk about the rape. At

this point, the woman enters the reorganization phase of the rape trauma syndrome. She must alter her self-concept and resolve her feelings about the rape.

During this phase, the rape survivor may develop phobias. Fears of being indoors or outdoors or of being attacked from behind—depending on how the attack took place—are common. Because of these fears, the woman may alter her lifestyle. If she is afraid of crowds, of being out after dark, or of returning to an empty house, she may become a virtual recluse.

Rape survivors frequently report menstrual or other gynecologic disorders as well as sexual dysfunction. Some women become totally averse to sexual activity. Those who do try to engage in sex often report a decrease in vaginal lubrication, an inability to be aroused, unusual sensations in the genital area, and an inability to achieve orgasm.

There are a number of long-term physical and psychologic health consequences of sexual assault. Long-term physical consequences include pregnancy, chronic pain, gastrointestinal disorders, headaches, and sexually transmitted infections. Chronic psychologic consequences include depression, fear and anxiety, difficulty trusting others, eating disorders, attempted or completed suicide, post-traumatic stress disorder, and/or unhealthy behaviors (e.g., smoking, alcohol abuse, use of drugs, and risky sexual behavior) (National Center for Injury Prevention and Control [NCIPC], 2007). Sleep disorders persist. Survivors report repeated nightmares in which they either relive the rape or thwart the rapist's attempt. In either case the dream contains disturbing violence. The woman repeatedly replays the role of victim until she comes to terms with the experience.

Integration and Recovery

This final phase brings resolution for the woman. She is able to recognize that the blame for her assault lies with her assailant. She begins to trust others again and begins to feel safe in her life and day-to-day activities. She may be filled with a sense of righteous anger and become an advocate for other women (Holmes, 1998).

Silent Reaction

Women who do not report the rape go through the phases of the rape trauma syndrome without using available support systems. Their reasons for keeping silent vary. A woman may be embarrassed, she may accept society's "temptress view" and blame herself, or she may fear retaliation. Her experience may be discovered much later, perhaps when she seeks professional help in resolving a different crisis.

Some women seek medical help for their physical injuries without disclosing that a rape was the cause. The nurse who suspects that a woman has been raped should seek validation through sympathetic questioning.

Sexual Assault as a Cause of Post-Traumatic Stress Disorder

Sexual assault survivors may exhibit high levels of **post-traumatic stress disorder (PTSD)**, the same disorder that developed in many of the veterans of the Vietnam War. To be diagnosed as having PTSD, a person must:

- Have been exposed to a traumatic event that triggered feelings of intense fear, horror, or helplessness.
- Reexperience the event in recurrent, intrusive thoughts, images, perceptions, and flashbacks.
- Persistently avoid stimuli associated with the trauma and demonstrate a generalized "numbing" of responsiveness.
- Demonstrate persistent signs of increased arousal, such as exaggerated startle response, difficulty falling asleep, hypervigilance or outbursts of anger, emotional detachment, and sleep disturbances that were not present before the trauma occurred.

PTSD is marked by varying degrees of intensity depending on prior mental health issues and the woman's own resiliency. Sexual assault victims with PTSD are 13 times more likely than nonvictims to have alcohol-related problems and 26 times more likely to have two or more serious drug abuse problems. Compared to victims of other types of traumatic events, sexual assault victims are the largest single group of PTSD sufferers (Victim Rights Law Center, 2009).

PTSD is difficult to treat. Because the symptoms keep an individual from addressing the problem, she cannot integrate the event into her life and healing is blocked. Recovery depends on empowering the woman to seek to regain control of her life within the context of healing relationships and professional counseling.

Physical Care of the Sexual Assault Survivor

Following a sexual assault, a primary purpose of care is to meet the needs of the survivor. This is accomplished by evaluating and treating injuries; conducting prompt examinations; providing support, crisis intervention, and advocacy; providing prophylaxis against STIs; assessing for pregnancy risk and discussing treatment options; and providing follow-up care for medical and emotional needs. As many as 31.5% of women who are sexually assaulted sustain injuries although often the injuries are minor; more severe physical consequences may also occur (CDC, 2008b; Tjaden & Thoennes, 2006).

Sexual assault victims tend to have more medical complaints and to access healthcare services more than those who have not been victimized. Both emotional and physical symptoms manifest themselves in the aftermath of an assault, sometimes immediately and sometimes for a lengthy period postassault. Research indicates that between 45% and 77% of women who were actual victims of rape did not define their experience as rape. Even without such an acknowledgment, these women experience physical health concerns, including headaches, stomachaches, distress, menstrual difficulties, and sexual functioning difficulties (Conoscenti & McNally, 2006). All healthcare settings must be alert to this phenomenon and assess patients carefully.

Because sexual assault is a crime as well as a traumatic emergency, however, the other purpose of health care is to collect and preserve legal evidence for use in prosecuting the assailant. It is important to note that even though evidence is collected, it does not necessarily mean that the survivor has to prosecute; the

survivor always has the right to reconsider her decisions. In collecting legal evidence, healthcare providers must respect the rights of the survivor. Sexual assault survivors have the right to immediate, compassionate, and comprehensive medical-legal examination and treatment by a trained professional who has the experience to anticipate their needs during this time of crisis.

As a result of the reauthorization and new provisions of the Violence Against Women Act of 2005, additional services have been available to all victims of sexual assault. Beginning in January 2009 all victims of rape, sodomy, and other penetrating types of sexual assault have been able to receive a forensic examination at specially equipped medical settings without the requirement to first participate in the criminal justice system or cooperate with law enforcement. This new law has given greater freedom to victims to access forensic care whether or not they choose to report to police. Specific procedures have been created in all jurisdictions to accomplish this new right and provide expert, timely medical services to victims who otherwise may not have chosen to access services. With the passage of this law, there is a hope that more victims will eventually report their crimes to the police since they no longer must do so within those first few hours following the incident, while at the same time obtaining needed services for future prosecutorial efforts.

Unfortunately, in many communities the treatment of a woman immediately following a sexual assault has been almost as traumatic as the assault itself. Often referred to as "the second rape" or as "secondary victimization," it is reflected in victim blaming and insensitive and prying care. To address this concern, many emergency departments use multidisciplinary teams to provide effective care to sexual assault survivors and their families. Sexual assault nurse examiner (SANE) programs and sexual assault response teams (SART) (composed of law enforcement and prosecution professionals, forensic examiners and/or healthcare providers, and victim advocates) are two examples of successful multidisciplinary community programs that coordinate teams of medical, legal, and social service professionals with effective advocacy on behalf of sexual assault survivors.

Other communities provide rape victim advocates, who help survivors in hospital emergency departments (EDs) and in dealing with the police. Research suggests that rape survivors who have the assistance of an advocate in the ED report less emotional distress from the experience, have fewer negative interactions with hospital staff, and receive more medical services such as prophylaxis against STIs and emergency contraception (Campbell, 2006).

Detailed History

Obtaining a detailed history is an essential first step in acquiring necessary medical and forensic data, but it can also be a therapeutic tool if done in a sensitive, caring way. Because a sexual assault survivor may appear relaxed and normal when first seen, caregivers may underestimate her needs, but it is essential that she receive immediate attention. Immediately after the woman has received any necessary emergency care, the nurse takes an explicit history of the event in the woman's own words to aid in evidence collection and examination of injuries. Many agencies use a standardized forensic chart containing a history flow sheet to record information obtained. The caregiver should use a nonjudgmental approach and must avoid leading or coaching the woman.

Collection of Evidence

The collection of evidence may, in itself, be traumatic for the woman. It is valuable to have someone available to provide support and act as an advocate. This person may be a family member or close friend, but often it is a nurse. An interpreter should also be provided as necessary.

The woman should receive a thorough explanation of the procedures to be carried out and should sign an informed consent form. An important legal concept when dealing with rape survivors is the need to preserve the *chain of evidence,* meaning that all physical evidence and specimens must remain in the hands of a professional until they are turned over to a police officer. The evidence that the nurse or forensic examiner collects has four primary uses (Ledray, 1999): (1) to confirm recent sexual contact; (2) to show that force or coercion was used; (3) to identify the assailant; and (4) to corroborate the survivor's story. Most agencies have special sexual assault kits that contain all necessary supplies for collecting and labeling evidence.

A careful examination of the entire body is necessary. Vaginal and rectal examinations are performed, along with a complete physical examination for trauma. Any lacerations of the vaginal wall are repaired and noted. A colposcope with photographic capability can be used to document injuries to the genitalia.

CLOTHING Each piece of clothing and foreign material dislodged from clothing is marked, placed in an individual paper bag, sealed, and labeled.

SWABS OF STAINS AND SECRETIONS Swabs of body stains and secretions are analyzed for semen or sperm. The absence of sperm, however, does not signify that no sexual assault has occurred. Many assailants do not ejaculate because of sexual dysfunction, or they may use a condom. Because victims are often forced to commit fellatio, oral swabs are also examined for semen. Gonorrhea and chlamydia cultures also are taken from vaginal, rectal, and oral cavities.

HAIR AND SCRAPINGS Clippings or scrapings of the woman's fingernails are examined for blood or tissue from the assailant. Approximately 20 to 25 hairs are pulled from her head and pubic area to analyze the root structure and identify foreign hairs. Her pubic hair is also combed to check for loose hairs that may have been transferred from the rapist.

BLOOD SAMPLES Blood is drawn to test for syphilis and to determine the woman's blood type. Additional blood may be drawn for a pregnancy test if the woman indicates that she wants to take emergency contraception (see discussion in chapter 5 ∞) to prevent pregnancy. She has to have a negative pregnancy test to receive the medication.

URINE SAMPLES Urine should be collected in cases in which a drug-facilitated sexual assault is suspected and the drug was ingested within 96 hours of the evidentiary exam. It is important to document in the record the time the survivor believes that the drug was ingested and the number of urinations between the ingestion

and the exam. A forensic laboratory with the capability of conducting toxicology tests should be identified because not all crime laboratories have the specialized equipment needed to test for rape drugs. Moreover, because of the increased sensitivity of deoxyribonucleic acid (DNA) tests, many jurisdictions are extending the standard cutoff time for evidence collection in their jurisdictions (U.S. Department of Justice, 2004).

PHOTOGRAPHS Photographs should be taken of injured areas if possible. Before taking any photos, the healthcare provider should ask the woman to sign an informed consent form.

Prevention of Sexually Transmitted Infections

Among women who have been sexually assaulted, trichomoniasis, bacterial vaginosis, gonorrhea, and chlamydia are the most frequently diagnosed infections. Thus, during the initial examination, cultures for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* should be obtained from any body sites of penetration or attempted penetration. However, because these infections are fairly prevalent among sexually active women, the diagnosis of one or more of these infections following an assault does not necessarily indicate that it was acquired during the assault. If any STI is diagnosed, it is treated (CDC, 2007). Most clinicians recommend routine preventive therapy after a sexual assault with follow-up referral to a clinic specializing in the treatment of STIs to evaluate the effectiveness of the therapy. The CDC (2007) recommends a prophylaxis regimen that includes a single dose of ceftriaxone intramuscularly plus a single oral dose of metronidazole and a single oral dose of azithromycin. If the survivor chooses not to receive prophylactic antibiotic treatment, the nurse should instruct her to be seen by her caregiver in 2 weeks for assessment for any STIs. In addition, because hepatitis B is a risk, the woman who has never been immunized should be given hepatitis B immune globulin; she should also begin the hepatitis B 3-dose immunization series immediately (CDC, 2007).

If the assailant's HIV status is not known, consideration should be given to offer postexposure prophylaxis with HIV antiviral medications. If postexposure HIV prophylaxis is considered, consultation with an HIV specialist is advised (CDC, 2007).

Prevention of Pregnancy

The woman is questioned about her menstrual cycle and contraceptive practices. If she is at risk for pregnancy and a pregnancy test is negative, she should receive information about her treatment options. Women of different ages, social, cultural, and religious/spiritual backgrounds will have diverse feelings about acceptable treatment options. The nurse needs to be sensitive and nonjudgmental when discussing various reproductive health services. If the woman wishes, emergency postcoital contraception is provided. (See chapter 5 ∞ for further discussion.)

NURSING CARE MANAGEMENT

Sexual assault survivors frequently enter the healthcare system by way of the ED; thus nurses are often the first to provide services to them. Because the caregiver's values, attitudes, and beliefs will necessarily affect the competence and focus of the care, nurses who work with survivors must understand their own attitudes and beliefs about sexual assault and sexual assault survivors and resolve any conflicts that may exist, ensuring nonjudgmental patient support.

In addition to examining their own attitudes and beliefs, nurses must be mindful of the potential for increased complexity of treatment with sexual assault survivors who are members of different ethnic or cultural backgrounds. For example, a woman's membership in a particular ethnic or cultural group could affect her willingness to disclose all the details of an assault, her willingness to follow up with community resources or to seek counseling, and her willingness to prosecute. Being aware of potential cultural differences is important when discussing future courses of action available.

Nursing Assessment and Diagnosis

Policies for admitting and examining sexual assault survivors vary among institutions, but clinical guidelines and protocols for the health care of sexual assault victims have been issued by many national medical agencies to create consistency in treatment in healthcare facilities across the United States. A woman who has been assaulted is under great stress and needs the sensitive care of professionals who are aware of her special needs. The first priority is creating a safe, secure environment. Professionals should gather admission information from the victim in a quiet, private room and reassure the woman that she is not alone, will not be abandoned, and is safe from a second attack.

A full mental status examination should be performed, both for the purpose of planning care and as possible courtroom evidence. Scrupulous documentation is essential because the victim's medical record is often used in the courtroom to verify her testimony if the rapist is prosecuted.

Examples of nursing diagnoses that may apply to the sexual assault victim include the following:

- ***Fear*** related to invasion of personal space secondary to assault
- ***Powerlessness*** related to inability to regain sense of control secondary to assault

Nursing Plan and Implementation

Table 9-3 outlines the general nursing actions that are appropriate during each of the phases of recovery. It is imperative that control be returned to the woman as quickly as possible. When feasible, the woman should decide on the sequence of forensic events, such as pulling her own hair (head and pubic), having blood drawn after clothes are collected rather than before, and so forth. In this way the nurse helps her deal with her crisis in small, manageable increments. The nurse should encourage the woman to express her feelings and reassure her that anger and fear are normal, appropriate responses. The nurse can also address expressed or unexpressed guilt by assuring the woman that the sexual assault was not her fault.

By explaining the general health or forensic examination and the sequence of events in the ED, the nurse can alleviate the patient's anxiety related to fear of the unknown. The woman should know what is going to happen and why and how she can assist in each phase of the examination. Throughout the experience, the

Case Study: Teenage Rape Victim

TABLE 9-3 Nursing Actions Appropriate to Phases of Recovery Following Rape

Acute Phase	Create a safe environment.
	Explain the sequence of events in the healthcare facility.
	Allow the woman to grieve and express her feelings.
	Provide care for significant others.
Outward Adjustment Phase	Provide advocacy and support at the level requested by the woman.
	Provide assistance to significant others.
Reorganizational Phase	Establish a trusting relationship.
	Assist the woman to understand her role in the assault.
	Clarify and enhance the woman's feelings.
	Assist the woman in planning for her future.
Integration and Recovery	Acknowledge the victim's success in overcoming trauma; support advocacy efforts.

nurse acts as the survivor's advocate, providing support without usurping decision making. The nurse need not agree with all the survivor's decisions but should respect and defend her right to make them. A victim also has the right to have a victim advocate, family member, or friend with her throughout the examination process.

The family members or friends on whom the survivor calls also need nursing care. Like those of the victim, the reactions of the family will depend on the values to which they ascribe. Some family members or partners may blame the survivor for the sexual assault and feel angry with her for not having been more careful. They may also incorrectly view the assault as a sexual act rather than as an act of violence. They may feel personally wronged or attacked and see the survivor as being devalued or unclean. Their reactions may compound the victim's crisis. By spending some time with family members before their first interaction with the survivor, the nurse can reduce their anxiety and help them examine and reconcile their feelings, sparing the woman further trauma. In most cases, the nurse should contact and/or refer them to a sexual assault advocate who can help them address their needs. Hospital-based advocates, if available, should be called to the ED to provide support services. Community victim advocates are on call in most areas of the United States to respond 24 hours a day and be of assistance throughout the medical and/or forensic examinations as well as providing crisis intervention and advocacy in future criminal justice process involvement.

PROFESSIONALISM IN PRACTICE

Remaining Nonjudgmental

Strive to listen and respond nonjudgmentally. Allowing your own beliefs to interfere with care can make the difference in a victim's readiness to disclose the full details of her assault and to begin the recovery process. Hindering that ability is detrimental to the mental health of the woman and can decrease the possibility of identifying a sex offender.

Community-Based Nursing Care

As the woman enters the reorganization phase, she usually feels a strong urge to discuss and resolve her feelings about herself and her assailant. During this phase, the victim may benefit from talking with a specially trained sexual assault advocate or counselor. The nurse offers the services of the responding sexual assault advocate to the patient and introduces the advocate as soon as is possible, preferably prior to any physical examination. If she is not certain that she wants added support, or denies any need for counseling or advocacy, it is appropriate to respect her current wishes and to provide her with referral information for possible future use.

Information and support, provided by qualified nurses or other service providers, is a valuable tool in helping the sexual assault victim come to terms with her attack and its impact on her life. The woman should be encouraged to explore and identify her feelings and determine appropriate actions to resolve her problems and concerns. It is important for the provider to assist the woman to realize that the sexual assault was not her fault. The fault always lies with the perpetrator. With the provider/advocate, the woman explores her thoughts and feelings about self-care and celebrates her victories. It is important to emphasize that the loss of control that occurred during the assault was temporary and that she *does* have control over other aspects of her life.

Health Promotion Education

Local high schools, colleges, or rape awareness groups may offer courses in preventive strategies. Some classes focus on increasing women's awareness of situations in which they are at risk, whereas others are concerned with changing societal and men's attitudes about sexual assault and sexual assault survivors. Because sexual assault is a considerable risk for any woman, courses in what to do during and after an attack and how family members and friends can support a survivor are also helpful. Table 9-4 provides general guidelines for helping victims of sexual assault. Nurses who have completed addi-

TABLE 9-4 General Guidelines for Helping Victims of Sexual Assault

- Believe the victim—one of the greatest fears of sexual assault survivors is that they will not be believed.
- Listen and be patient—let the person talk and tell the story at her/his own pace.
- Reinforce the fact that the sexual assault was not the victim's fault.
- For recent assaults, encourage the victim to report the assault and preserve evidence.
- Encourage the person to seek medical attention.
- Suggest seeking counseling and other support services.
- Help the victim to organize her/his thoughts, but let the survivor make her/his own decision on how to proceed.
- Take care of yourself—assisting a friend or family member can be stressful. Set aside time for yourself so that you don't feel overwhelmed by the survivor's problems.
- Acknowledge your limits and realistically identify your abilities to assist the survivor.

tional education and are thoroughly prepared are well qualified to initiate or participate in preventive instruction.

Sexual Assault Advocacy and Information

Most sexual assault crisis centers operate 24 hours a day, 7 days a week. Their services are invaluable. Properly trained advocates and counselors can help the victim regain control early in the crisis. Many sexual assault crisis centers offer free services to victims or can refer them to qualified counselors within the community. Information on STIs and pregnancy alternatives may also be obtained from these centers. In addition, there are many Internet resources that provide information for survivors and their family members and friends as well as for professionals seeking information about how to better assist victims of sexual assault. See www.nursing.pearsonhighered.com for a list of hotline information and Internet-based resources about sexual assault.

Evaluation

Expected outcomes of quality nursing care include the following:

- The woman receives prompt, compassionate, respectful, and individualized medical attention.
- The woman recovers from the physical effects of the sexual assault.
- The woman is able to verbalize her recognition that sexual assault is a crime of violence expressed sexually.
- The woman is able to identify culturally appropriate community resources available to her as she works to adjust psychologically to the assault.
- The woman makes a decision about whether to prosecute her assailant.

CLINICAL JUDGMENT

Case Study: Sally Smith

Sally is a 19-year-old college student who has just transferred to her university. In order to make some new friends, Sally decided to go to an off-campus party that was advertised on a poster hanging in her residence hall lobby. She accepted a ride to the party with one of her new schoolmates. Once there, she became separated from her new friend and became isolated in the basement by a few males she had just met. She began drinking some of the punch the party-givers had made and soon felt very disoriented. Someone escorted her to a bedroom on the third floor to "sleep it off." The next thing Sally remembers is awaking to an unknown male on top of her having sex with her. Her slacks and panties were around her ankles. She tried to push him away but before she could get him off her body, he ejaculated inside of her. He then left the room, and she went downstairs to wait for her ride back to the residence hall. When she got back to her room, she told her roommate what happened, and the roommate drove her to the nearest hospital to get an exam.

Critical Thinking

As the nurse responding to this young woman, what are the presenting issues that must be addressed before an examination should begin?

What will be important for you to include in the history of this patient?

See www.nursing.pearsonhighered.com for possible responses.

- If a victim decides to prosecute her assailant, all necessary forensic evidence will have been collected, leading to a more successful investigation and prosecution.

Prosecution of the Assailant

Legally, sexual assault, like any criminal action, is considered a crime against the state rather than against the victim. Therefore, prosecution of the assailant is a community responsibility in which the prosecuting attorney will act on the victim's behalf. The victim, however, must initiate the process by reporting the crime and pressing charges against her assailant. Once authorities have apprehended the alleged attacker, the judicial system is set into motion.

Procedures vary from state to state. A judge or magistrate generally conducts a hearing to determine whether there is sufficient evidence to hold the defendant over for a trial. If indicted, a defendant must stand trial unless he waives this right. Either a judge or a jury will find the defendant guilty or not guilty, and he will be retained or set free accordingly.

Many sexual assault survivors who have gone through the judicial process refer to it as a second rape—and sometimes a more damaging one. The victim must identify the assailant and repeat the details of the assault. Delays can further frustrate the victim and increase her fear. Publicity may intensify her feelings of humiliation, and if the perpetrator is released on bail pending trial, she may fear retaliation.

During the trial itself, cross-examination by the defendant's attorney can be a severely degrading and intimidating experience for the victim. The defense attorney may try to discredit her testimony, causing a second victimization. Fortunately, rape shield laws are quite common, and nearly every state prohibits the publicizing of a victim's sexual history. Moreover, despite the difficulties of prosecution, many victims feel a sense of justice in taking their case to court.

The nurse involved with any sexual assault victim needs to be aware of the judicial sequence to anticipate rising tension and frustration in the victim and her support system. They will need consistent, effective support at this crucial time.

Responding to Violence Against Women: Vicarious Trauma

Vicarious trauma, or secondary trauma effect, can occur as a result of working with people who are trauma victims. It refers to a gradual internal transformation that can negatively affect commitment to one's work, reduce any sense of accomplishment, and lead to a questioning of personal belief systems. Nurses who treat and assist domestic violence and sexual assault survivors should be aware of this phenomenon so that they are able to periodically assess the effect of their work on their lives. When the lives of nurses—and indeed of all healthcare professionals—are balanced and there is equal time for self, family, friends, work, play, and rest, then they are better able to provide compassionate and sensitive health care.

FOCUS YOUR STUDY

- Domestic violence is very common. One in three to one in four women will experience violence at the hands of an intimate partner during their lifetime.
- Batterers use psychologic, physical, and sexual abuse to maintain power and control in abusive relationships.
- Battering occurs in a cyclic pattern called the cycle of violence, which increases in frequency and severity over time.
- Women in abusive relationships who belong to cultural and linguistic minority communities and immigrant women face additional barriers when attempting to access services. The nurse must work to provide culturally aware and competent care.
- Nurses are in an excellent position to intervene and assist women with abusive partners by recognizing their cues, diagnosing their problems appropriately, and understanding the complex dynamics of the battering family. The nurse provides information about available culturally appropriate community resources, medical attention, and emotional support.
- Estimates suggest that the majority of sexual assaults are not reported to the police. Rapes and sexual assaults committed by strangers are more likely to be reported to the police than rapes or sexual assaults committed by nonstrangers, including intimate partners, other relatives, and friends or acquaintances.
- Rape is an act of violence acted out sexually. Most sexual assaults are expressions of a need for power and control.
- Following sexual assault, the victim will usually experience an assortment of symptoms known as rape trauma syndrome. Recent research also links the effects of rape to post-traumatic stress disorder. Nursing actions to assist rape victims are encompassed in the roles of healthcare provider, advocate, and educator.
- Nurses inform the woman of the sequence of events involved in providing her care and developing the chain of evidence, and support the victim's decisions.
- Widespread education is needed to abolish societal myths surrounding domestic violence and sexual assault.

CRITICAL THINKING IN ACTION

Marishka Devonowski, a 28-year-old G2P2, has a 9-year-old daughter and a 3-month-old daughter at home. Mrs. Devonowski has been seen at the emergency department several times for a variety of problems including a broken arm, sprained ankle, and multiple contusions from reportedly "walking into a door" when she got up during the night but did not turn on a light. She describes herself as clumsy and accident-prone. At each visit her husband, a computer analyst, who appears thoughtful and protective of his wife, accompanies her.

Today she is being seen for a severe laceration of her cheek and a mild concussion.You observe that she also has a black eye and bruising of her upper arm and chest. At each previous visit the nurse had managed to spend time alone with Mrs. Devonowski and had asked specifically about domestic violence. However, Marishka denied it vehemently each time. Today, when you are alone with her you ask about abuse. This time she admits that her husband caused her injuries. She states, "His job is so stressful and sometimes he just loses his temper. But he seems to get more angry no matter what I do. I hate it but I can't leave him. I don't know how I would manage alone."

1. In talking with Marishka, what information would you focus on initially?
2. What specific information should you share about preparing an exit or safety plan?

The Reproductive System 187

CHAPTER 11
Conception and Fetal Development 216

CHAPTER 12
Special Reproductive Concerns: Infertility and Genetics 242

The Reproductive System

CHAPTER 10

I always thought it was so boring to study anatomy and physiology. Who cares how many bones there are in the pelvis or the muscles involved. But now I'm with mothers having babies, and now it all makes sense.

—A Nursing Student

LEARNING OUTCOMES

1. Describe the differentiation of the male and female reproductive organs during embryonic development.
2. Summarize the major changes in the reproductive system that occur during puberty.
3. Identify the structures and functions of the female reproductive system.
4. Identify the structures and functions of the male reproductive system.
5. Discuss the significance of specific female reproductive structures during pregnancy and childbirth.
6. Summarize the actions of the hormones that affect reproductive functioning.
7. Identify the two phases of the ovarian cycle and the changes that occur in each phase.
8. Describe the phases of the menstrual cycle, their dominant hormones, and the changes that occur in each phase.

KEY TERMS

Ampulla *197*
Areola *204*
Breasts *203*
Broad ligament *196*
Cardinal ligaments *196*
Cervix *195*
Conjugate vera *201*
Cornua *194*
Corpus *194*
Corpus luteum *207*
Diagonal conjugate *201*
Endometrium *195*
Estrogens *206*
Fallopian tubes *197*
False pelvis *200*
Female reproductive cycle (FRC) *205*
Fimbria *197*
Follicle-stimulating hormone (FSH) *190*
Fundus *194*
Gonadotropin-releasing hormone (GnRH) *190*
Graafian follicle *207*
Human chorionic gonadotropin (hCG) *207*
Infundibulopelvic ligament *197*
Ischial spines *198*
Isthmus *197*
Luteinizing hormone (LH) *190*
Myometrium *195*
Nidation *195*
Nipple *204*

True pelvis *200*
Uterosacral ligaments *197*
Uterus *193*
Vagina *192*
Vulva *190*

Understanding childbearing requires more than understanding sexual intercourse or the process by which the female and male sex cells unite. The nurse must also become familiar with the structures and functions that make childbearing possible and the phenomena that initiate it. This chapter considers the anatomic, physiologic, and sexual aspects of the female and male reproductive systems. It also provides information regarding basic embryonic development of the reproductive structures.

The female and male reproductive organs are *homologous;* that is, they are fundamentally similar in function and structure. The primary functions of both the female and male reproductive systems are to produce sex cells and transport them to locations where their union can occur. The sex cells, called *gametes,* are produced by specialized organs called *gonads.* A series of ducts and glands within both the male and female reproductive systems contributes to the production and transport of the gametes.

Embryonic Development of Reproductive Structures and Processes

Although the genetic sex of an embryo is determined at fertilization, the male and female reproductive systems are undifferentiated for about the first 8 weeks of gestation. This undifferentiated period is followed by a period of rapid, dramatic changes as the reproductive organs differentiate into recognizable structures.

Ovaries and Testes

During the 5th week of gestation, a primitive gonad arises from the intermediate mesoderm tissue known as gonadal ridges (Figure 10-1 ■ top image). The gonad develops a medulla (inner part of the organ) and cortex (outer part of the organ), which appear in the underlying mesenchyme (embryonic tissue from which connective and muscle tissue arises; see Table 11-2 on page 224). In genetic males during the 7th and 8th weeks, the medulla develops into a testis, and the cortex regresses. In genetic females by about the 10th week, the cortex develops into an ovary, and the medulla regresses.

Every egg available for maturation in a woman's reproductive life is present at her birth. During fetal life the ovary produces oogonia, cells that become primitive eggs called *oocytes,* by the process of **oogenesis** (see chapter 11 ∞). No oocytes are formed after fetal development. About 150,000 oocytes are contained in the ovaries at birth.

Each testis produces the male gametes, called *spermatozoa* or *sperm,* by a process called **spermatogenesis**. This process is described in chapter 11 ∞. Spermatogenesis of mature sperm does not occur until the onset of puberty. Figure 10-1 illustrates the embryologic development of the gonads and other internal reproductive organs.

Other Internal Structures

During the undifferentiated period—the first 7 weeks—two pairs of genital ducts develop: the mesonephric and paramesonephric ducts (Cunningham et al., 2010).

In genetic females the fallopian tubes are formed from the unfused portions of the paramesonephric ducts, and the fused portions give rise to the epithelium and uterine glands. The endometrial stroma and the myometrium (thick layer of smooth muscle in the wall of the uterus) develop from the adjacent mesenchyme.

The vagina is derived from more than one embryologic structure. The vaginal epithelium develops from the endoderm of the urogenital sinus, and the musculature develops from the uterovaginal primordium.

The urethral and paraurethral glands develop from outgrowths of the urethra into the surrounding mesenchyme. Bartholin's glands arise from similar structures.

In genetic males the fetal testes secrete two hormones. The first hormone, testosterone, stimulates the mesonephric ducts to develop into the male genital tract. The other hormone, Müllerian regression factor, suppresses the development of the paramesonephric ducts, which would otherwise develop into the female genital tract.

From the mesonephric ducts comes development of the efferent ductule, vas deferens, epididymis, seminal vesicle, and ejaculatory duct. Both the prostate and the bulbourethral glands develop from endodermal outgrowths of the urethra.

External Structures

Genetic males and females possess the same external genitals until the end of the 9th week. By the 12th week, differentiation of the external genitals is complete.

If fetal testosterone is not present, the undifferentiated external genitals are feminized. The phallus becomes the clitoris, and the urogenital folds remain open, forming the labia minora. The labioscrotal folds form the labia majora.

If fetal testosterone is present, the undifferentiated external genitals become masculine. The phallus elongates, forming the penis. The fusion of the urogenital folds on the ventral surface of the penis forms the penile urethra with the urethral meatus moving forward toward the glans penis.

Puberty

The term **puberty** refers to the developmental period between childhood and attainment of adult sexual characteristics and functioning. Generally, boys mature physically about 2 years later than girls. Puberty lasts from 1.5 to 5 years and involves profound physical, psychologic, and emotional changes. These changes include an altered body image, changing roles, and changing societal expectations and responses as the child matures into an adult.

Major Physical Changes

In both girls and boys, puberty is preceded by an accelerated growth rate called adolescent spurt. Widespread body system changes occur, including maturation of the reproductive organs.

Girls experience a broadening of the hips, then budding of the breasts, the appearance of pubic and axillary hair, and the onset of menstruation, called menarche. The average time between breast development and menarche is 2.3 years.

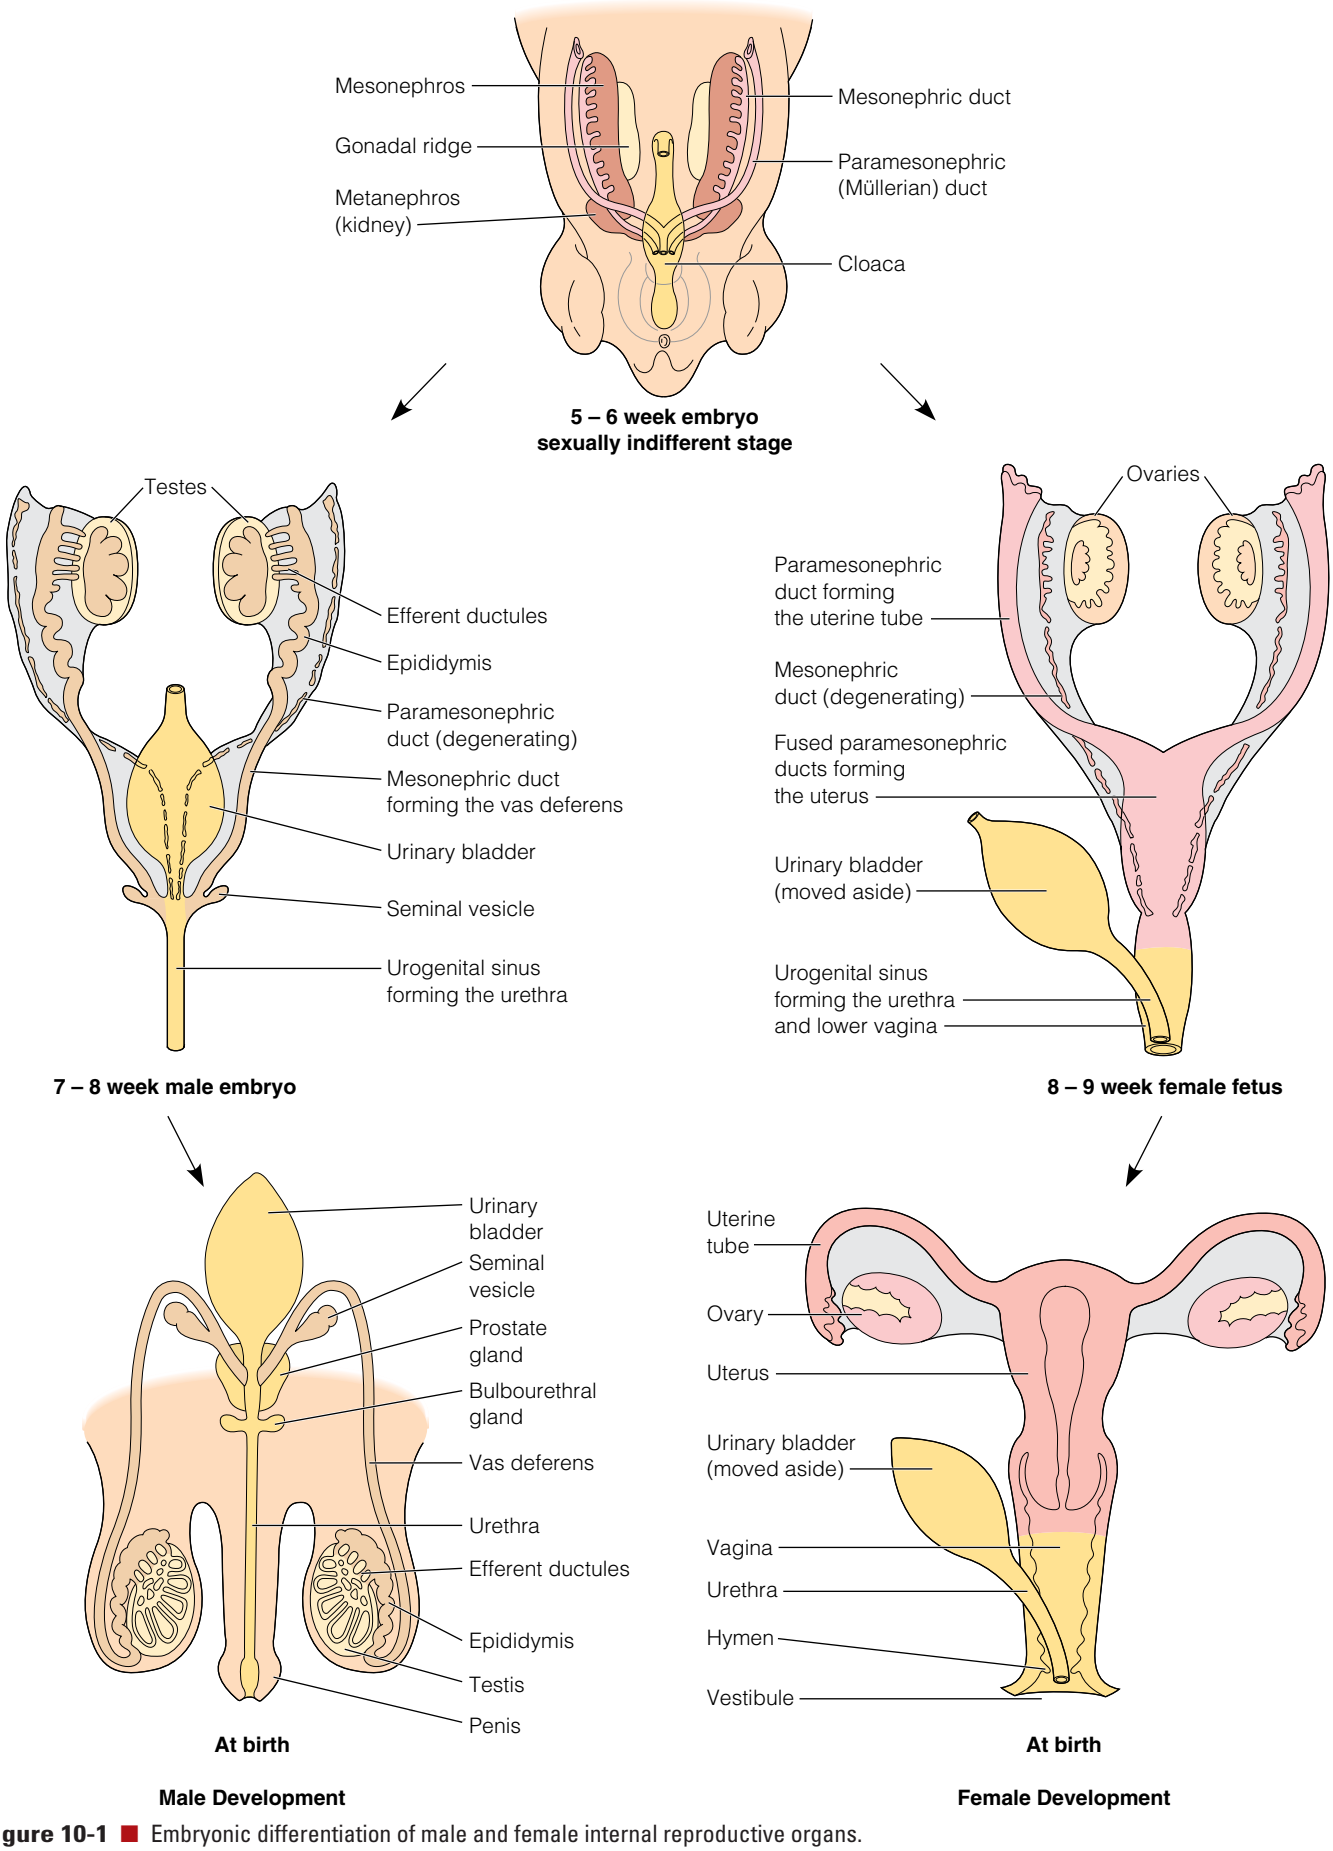

Figure 10-1 ■ Embryonic differentiation of male and female internal reproductive organs.

Boys experience linear growth spurts; an increase in the size of the external genitals; the appearance of pubic, axillary, and facial hair; deepening of the voice; and nocturnal seminal emissions (called wet dreams) without sexual stimulation. These early seminal emissions do not usually contain mature sperm.

The physical changes of puberty present themselves differently in each person. The age at onset and progress of puberty vary widely, physical changes overlap, and the sequence of events can vary from person to person. This diversity results from each individual's response to hormonal stimulation.

Physiology of Onset

Puberty is initiated by the maturation of the hypothalamic-pituitary-gonad complex (the *gonadostat*) and input from the central nervous system. The process, which begins during fetal life, is sequential and complex.

The central nervous system releases a neurotransmitter that stimulates the hypothalamus to synthesize and release **gonadotropin-releasing hormone (GnRH)**. GnRH is transmitted to the anterior pituitary, where it causes the synthesis and secretion of the gonadotropins **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)** (Figure 10-2 ■).

Although the gonads do produce small amounts of *androgens* (male sex hormones) and *estrogens* (female sex hormones) before the onset of puberty, FSH and LH stimulate increased secretion of these hormones. Androgens and estrogens influence the development of secondary sex characteristics. FSH and LH stimulate the processes of spermatogenesis and maturation of ova.

Other hormones are involved in the onset of puberty; although less direct, their action is essential. Abnormally high or low levels of adrenocorticotropic hormone (ACTH), thyroid hormone, or growth hormone (GH) can disrupt the onset of normal puberty. The maturation process that begins during fetal life continues through puberty and childbearing years. The external and internal female reproductive organs develop and mature in response to estrogen and progesterone.

Female Reproductive System

The female reproductive system consists of the external and internal genitals and accessory organs of the breasts. The structure of the bony pelvis is also discussed in this section because of its importance in childbearing.

External Genitals

All the external reproductive organs, except the glandular structures, can be directly inspected. The appearance of the external genitalia varies greatly among women. Heredity, age, race, and the number of children a woman has borne influence the size, color, and shape of her external organs.

The female external genitals, called the **vulva**, include the following structures (Figure 10-3 ■):

- Mons pubis
- Labia majora
- Labia minora
- Clitoris
- Urethral meatus and opening of the paraurethral (Skene's) glands
- Vaginal vestibule (vaginal orifice, vulvovaginal glands, hymen, and fossa navicularis)
- Perineal body

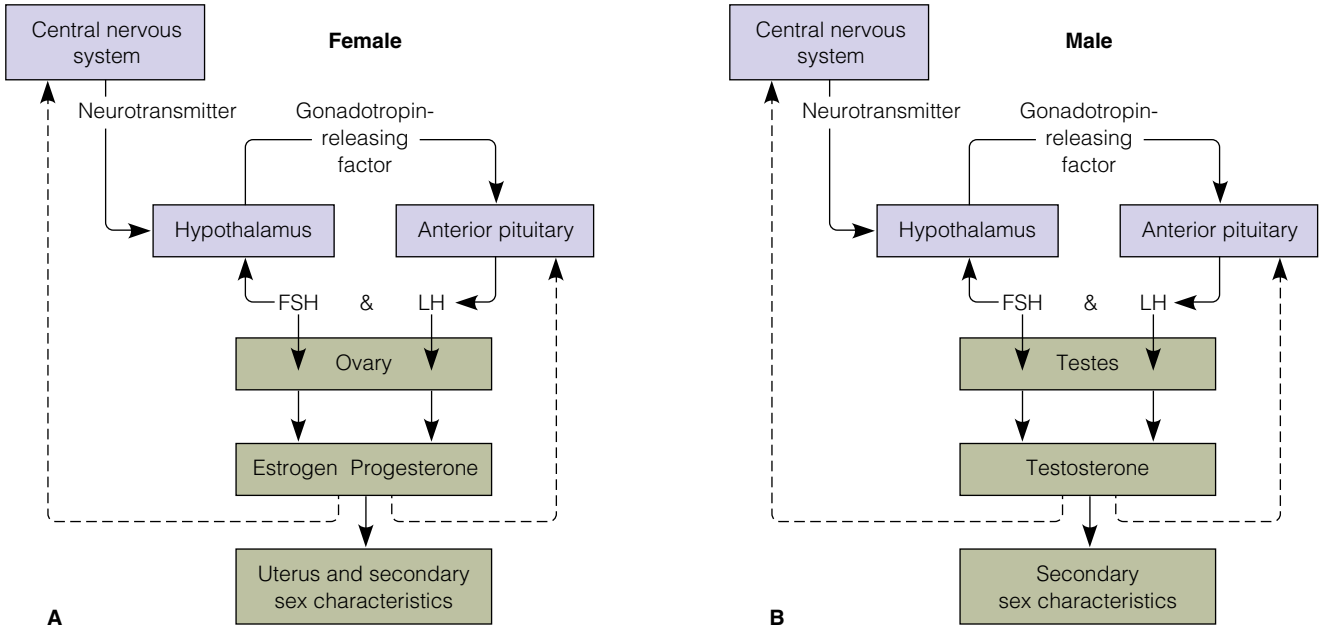

Figure 10-2 ■ Physiologic changes leading to onset of puberty. A. In females; and B. in males. Solid lines illustrate stimulation of hormone production, and broken lines illustrate inhibition. Through a neurotransmitter the central nervous system (CNS) stimulates the hypothalamus, which in turn produces a gonadotropin-releasing factor that causes the anterior pituitary to produce gonadotropins (FSH or LH). These hormones stimulate specific structures in the gonads to secrete steroid hormones (estrogen, progesterone, or testosterone). The rise in pituitary hormone production increases hypothalamus activity. Elevated steroid hormone levels stimulate the CNS and pituitary gland to inhibit hormone production.

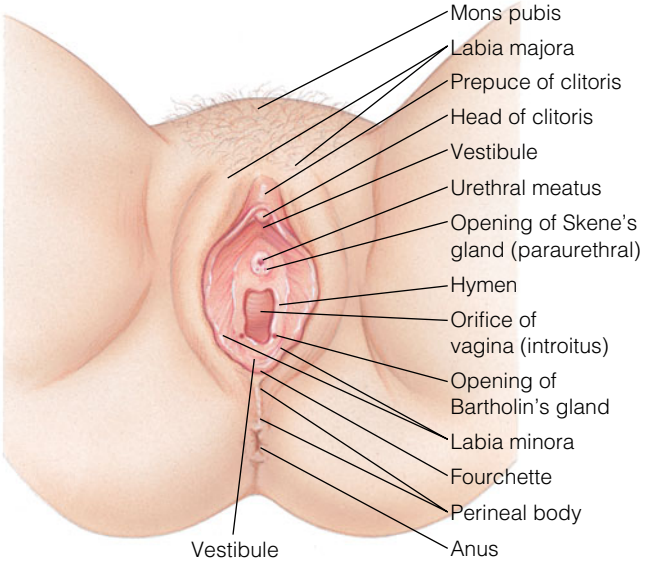

Figure 10-3 ■ Female external genitals, longitudinal view.

Although they are not true parts of the female reproductive system, the urethral meatus and perineal body are considered here because of their proximity and relationship to the vulva. The vulva has a generous supply of blood and nerves. As a woman ages, estrogen secretions decrease, causing the vulvar organs to atrophy.

Mons Pubis

The *mons pubis* is a softly rounded mound of subcutaneous fatty tissue beginning at the lowest portion of the anterior abdominal wall (see Figure 10-3). Also known as the mons veneris, this structure covers the anterior portion of the symphysis pubis. The mons pubis is covered with pubic hair, typically with the hairline forming a transverse line across the lower abdomen. The hair is short in all women. It can vary from sparse and fine in Asian women to heavy, coarse, and curly in women of African descent. The mons pubis protects the pelvic bones, especially during coitus.

Labia Majora

The *labia majora* are longitudinal, raised folds of pigmented skin, one on either side of the vulvar cleft (see Figure 10-3). As the pair descends, they narrow, enclosing the vulvar cleft, and merge to form the posterior junction of the perineal skin. Their chief function is to protect the structures lying between them. The labia majora are covered by stratified squamous epithelium containing hair follicles and sebaceous glands with underlying adipose and muscle tissue. The dartos muscle sheath is responsible for the wrinkled appearance of the labia majora as well as for their sensitivity to heat and cold. The inner surface of the labia majora in women who have not had children is moist and looks like mucous membrane, whereas after many births it is more skinlike. With each pregnancy the labia majora become less prominent.

Because of the extensive venous network in the labia majora, varicosities may occur during pregnancy, and birth trauma or sexual trauma may cause hematomas. The labia majora share an extensive lymphatic supply with the other structures of the vulva, which can facilitate the spread of cancer in the female reproductive organs. Because nerves from the first lumbar and third sacral segment of the spinal cord supply the labia majora, certain regional anesthesia blocks will affect them and cause numbness.

Labia Minora

The *labia minora* are soft folds of skin within the labia majora that converge near the anus, forming the *fourchette* (see Figure 10-3). Each labium minus has the appearance of a shiny mucous membrane, moist and devoid of hair follicles. The labia minora are rich in sebaceous glands, which lubricate and waterproof the vulvar skin and provide bactericidal secretions. Because sebaceous glands do not open into hair follicles but directly onto the surface of the skin, sebaceous cysts commonly occur in this area. The labia minora are composed of erectile tissue and involuntary muscle tissue. Vulvovaginitis in this area is very irritating because the labia minora have many tactile nerve endings. The labia minora increase in size at puberty and decrease after menopause because of changes in estrogen levels.

Clitoris

The *clitoris,* located between the labia minora, is about 5 to 6 mm long and 6 to 8 mm across. Its tissue is essentially erectile (see Figure 10-3). The glans of the clitoris is partly covered by a fold of skin called the *prepuce,* or clitoral hood (an extension of the labia minora). This area resembles an opening to an orifice and may be confused with the urethral meatus. Accidental attempts to insert a catheter in this area produce extreme discomfort. The clitoris has very rich blood and nerve supplies and is the primary erogenous organ of women. It secretes *smegma,* which, along with other vulval secretions, has a unique odor that may be sexually stimulating to the male. In some cultures, the clitoris is removed (see discussion in chapter 8 ∞).

Urethral Meatus and Paraurethral Glands

The *urethral meatus* is located 1 to 2.5 cm beneath the clitoris in the midline of the vestibule; it often appears as a puckered, slitlike opening (see Figure 10-3). At times the meatus is difficult to visualize because of the presence of blind dimples, small mucosal folds, or wide variations in location.

The paraurethral glands, or *Skene's glands,* open into the posterior wall of the urethra close to its opening (see Figure 10-3). Their secretions help lubricate the vaginal vestibule, facilitating sexual intercourse.

Vaginal Vestibule

The vaginal vestibule is a boat-shaped depression enclosed by the labia majora and visible when they are separated (see Figure 10-3). The vestibule contains the vaginal opening, or *introitus,* which is the border between the external and internal genitals.

The *hymen* is a thin, elastic collar or semicollar of tissue that surrounds the vaginal opening. The appearance of the hymen changes during the woman's lifetime. The hymen is essentially avascular. For thousands of years, some societies have perpetuated the belief that the hymen covers the vaginal opening and thus that an intact hymen is a sign of virginity. However, modern

studies of female genital anatomy have revealed that the hymen surrounds rather than entirely covers the vaginal opening, and can be torn not only through sexual intercourse, but also through strenuous physical activity, masturbation, menstruation, or the use of tampons, thus dispelling old beliefs. For discussion of the nurse's role in discussing these topics see chapter 4 ∞.

External to the hymen at the base of the vestibule are two small papular elevations containing the openings of the ducts of the *vulvovaginal (Bartholin's) glands.* They lie under the constrictor muscle of the vagina. These glands secrete a clear, thick, alkaline mucus that enhances the viability and motility of sperm deposited in the vaginal vestibule. These gland ducts can harbor *Neisseria gonorrhoeae* and other bacteria, which can cause suppuration and abscesses in the Bartholin's glands.

The vestibular area is innervated mainly by the perineal nerve from the sacral plexus. The area is not sensitive to touch generally; however, the hymen contains numerous free nerve endings as receptors to pain.

Perineal Body

The **perineal body** is a wedge-shaped mass of fibromuscular tissue measuring about 4 × 4 × 4 cm, found between the lower part of the vagina and the anus (see Figure 10-3). The superficial area between the anus and the vagina is referred to as the *perineum.*

The muscles that meet at the perineal body are the external sphincter ani, both levator ani (the superficial and deep transverse perineal), and the bulbocavernosus. These muscles mingle with elastic fibers and connective tissue in an arrangement that allows a remarkable amount of stretching. During the last part of labor, the perineal body thins out until it is just a few centimeters thick. This tissue is often the site of an episiotomy or lacerations during childbirth (see chapter 28 ∞).

Female Internal Reproductive Organs

The female internal reproductive organs—the vagina, uterus, fallopian tubes, and ovaries—are target organs for estrogenic hormones, and they play a unique part in the reproductive cycle (Figure 10-4 ■). Certain internal reproductive organs can be palpated during vaginal examination and assessed with various instruments.

Vagina

The **vagina** is a muscular and membranous tube that connects the external genitals with the uterus (see Figure 10-4). It extends from the vulva to the uterus in a position nearly parallel to the plane of the pelvic brim. The vagina is often referred to as the *birth canal* because it forms the lower part of the axis through which the fetus must pass during birth.

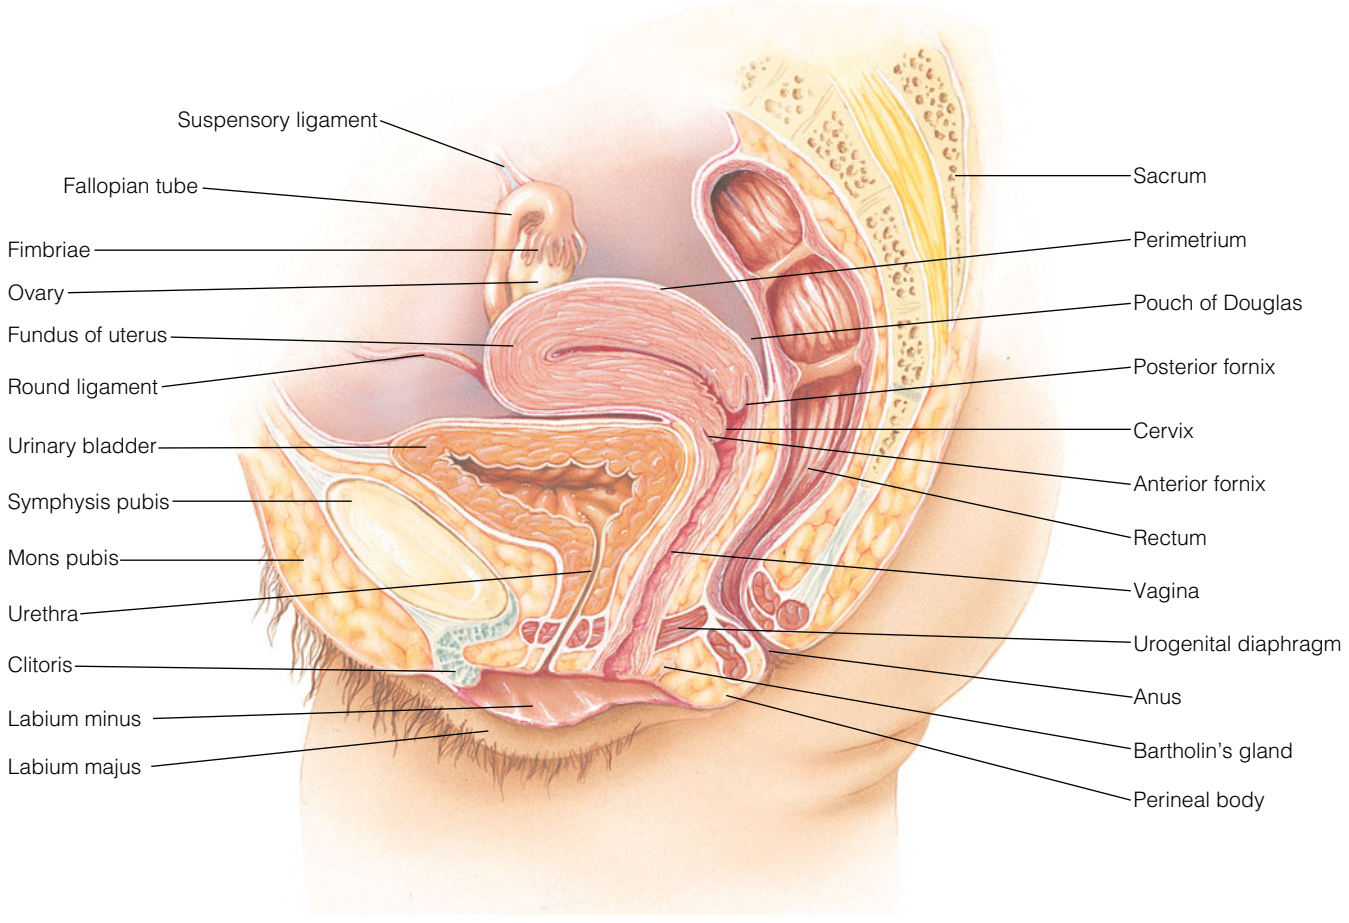

Figure 10-4 ■ Female internal reproductive organs.

Because the cervix of the uterus projects into the upper part of the anterior wall of the vagina, the anterior wall is approximately 2.5 cm shorter than the posterior wall. Measurements range from 6 to 8 cm for the anterior wall and 7 to 10 cm for the posterior wall.

In the upper part of the vagina, which is called the *vaginal vault*, there is a recess or hollow around the cervix. This area is called the vaginal fornix. Because the walls of the vaginal vault are very thin, various structures can be palpated through them, including the uterus, a distended bladder, the ovaries, appendix, cecum, colon, and the ureters. The upper fourth of the vagina is separated from the rectum by the pouch of Douglas (sometimes referred to as the cul-de-sac of Douglas). This deep pouch or recess is posterior to the cervix.

When a woman lies on her back after intercourse, the space in the fornix permits the pooling of semen. The collection of a large number of sperm near the cervix at or near the time of ovulation in the woman increases the chances of pregnancy.

The walls of the vagina are covered with ridges, or *rugae*, crisscrossing each other. These rugae allow the vaginal tissues to stretch enough for the fetus to pass through during childbirth as well as stretch for accommodation during coitus. A rich blood supply is needed to maintain a high glycogen content in the epithelial cells as well as to nourish the underlying musculofascial layer, through which the vaginal vault has strong attachments to the cervix. These muscle layers are continuous with the superficial muscle fibers of the uterus. A thin band of striated muscle, the sphincter vaginae, is found at the lowest extremity of the vagina. However, the levator ani is the principal muscle that closes the vagina.

During a woman's reproductive life, the vaginal environment is normally acidic (pH 4 to 5). Secretion from the vaginal epithelium provides a moist environment. The acidic environment is maintained by a symbiotic relationship between lactic acid-producing bacilli (Döderlein's bacillus or lactobacillus) and the vaginal epithelial cells. These cells contain glycogen, which is broken down by the bacilli into lactic acid. The amount of glycogen is regulated by the ovarian hormones. Any interruption of this process can destroy the normal self-cleansing action of the vagina. Such interruption may be caused by antibiotic therapy, douching, or use of vaginal sprays or deodorants. For further discussion, see chapter 4 ∞. The acidic vaginal environment is normal only during the mature reproductive years and in the first days of life, when maternal hormones are operating in the infant. A relatively neutral pH of 7.5 is normal from infancy until puberty and after menopause.

Each third of the vagina is supplied by a distinct vascular and lymphatic pattern. Although one would expect venous drainage to go directly to the heart and then the lungs, anastomoses of veins are present and make it possible for a pelvic embolism or carcinoma to bypass the heart and lungs and lodge in the brain, spine, or other remote part of the body.

Vaginal lymphatics drain into the external and internal iliac nodes, the hypogastric nodes, and the inguinal glands. The posterior wall drains into nodes lying in the rectovaginal septum. Any vaginal infection follows these routes.

The pudendal nerve supplies what relatively little somatic innervation there is to the lower third of the vagina. Thus vaginal sensation during sexual excitement and coitus is minimal, as is vaginal pain during the second stage of labor.

The vagina has the following functions:

- To serve as the passageway for sperm during coitus and for the fetus during birth
- To provide passage for the menstrual blood flow from the uterine endometrium to the outside of the body
- To protect against trauma from sexual intercourse and infection of the uterus, ovaries, and pelvis from pathogenic organisms

Uterus

As the core of reproduction and hence continuation of the human race, the uterus, or womb, has been endowed with a mystical aura. Numerous customs, taboos, mores, and values have evolved about women and their reproductive function. Although scientific knowledge has replaced much of this folklore, remnants of old ideas and superstitions persist. To provide effective care, nurses must be cognizant of their own attitudes and beliefs as well as those of their patients.

The **uterus** is a hollow, muscular, thick-walled organ shaped like an upside-down pear (Figure 10-5 ■). It lies in the center of the pelvic cavity between the base of the bladder and the rectum and above the vagina (see Figure 10-4). It is level with or slightly below the brim of the pelvis with the external opening of the cervix (the external os) about the level of the ischial spines. The uterus of the mature women weighs about 40 to 70 g and is 6 to 8 cm long (Cunningham et al., 2010).

Many uterine anomalies are thought to be congenital. A normal uterus requires two symmetric, parallel, equal-sized paramesonephric ducts to meet in the midline. Their ultimate midline fusion gives rise to the fallopian tubes, uterine fundus, cervix, and upper vagina. Anomalies represent the absence of either one

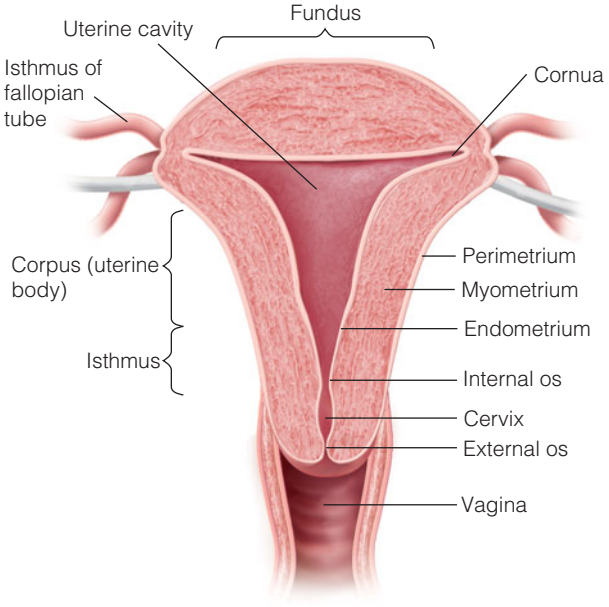

Figure 10-5 ■ Structures of the uterus.

or both of the ducts, degrees of failure to fuse, or canalization defects. Uterine malformations such as the uterus bicornuate ("two-horned") and uterus didelphys ("double uterus") are associated with habitual abortion. Because both the urinary and reproductive systems develop from the common urogenital fold in the embryo, anomalies in one system are frequently accompanied by anomalies in the other. Problems of infertility and premature labor and birth are common.

About a fourth of women exposed to diethylstilbestrol (DES) in utero have structural variations of the cervix, uterus, and vagina (Cunningham et al., 2010). These women have increased incidence of miscarriage, ectopic pregnancy, cervical incompetency, and preterm births.

The body of the uterus can move freely forward or backward. Only the cervix is anchored laterally. Thus the position of the uterus can vary, depending on a woman's posture, number of children borne, bladder and rectal fullness, and even normal respiratory patterns. Generally, the uterus bends forward, forming a sharp angle with the vagina. If there is a bend in the area of the isthmus of the uterus, and from there the cervix points downward, the uterus is said to be anteverted or anteflexed. Four pairs of ligaments (i.e., cardinal, uterosacral, round, and broad) support the uterus. Single anterior and posterior ligaments also support the uterus.

The uterus is divided into two major parts: an upper triangular portion called the **corpus**, or uterine body, and a lower cylindric portion called the cervix (see Figure 10-5). The corpus comprises the upper two thirds of the uterus and is composed mainly of a smooth muscle layer (myometrium). The lower third is the cervix, or neck. The rounded uppermost portion of the corpus that extends above the points of attachment of the fallopian tubes is called the **fundus**. The elongated portion of the uterus where the fallopian tubes enter is called the **cornua**.

The *isthmus* is that portion of the uterus between the internal cervical os and the endometrial cavity. The isthmus is about 6 mm above the uterine opening of the cervix (the internal os), and it is in this area that the uterine lining changes into the mucous membrane of the cervix; it joins the corpus to the cervix. The isthmus takes on importance in pregnancy because it becomes the lower uterine segment. At birth, this thin lower segment, situated behind the bladder, is the site for lower-segment cesarean births (see chapter 28 ∞).

The blood and lymphatic supplies to the uterus are extensive (Figure 10-6 ■). The uterus is innervated entirely by the autonomic nervous system. Efferent sympathetic motor nerves arise from the ganglia of the 5th to 10th thoracic vertebrae, come together over the sacrum, and reach the uterus through ganglia that lie near the base of the uterosacral ligaments. These sympathetic motor nerves are believed to cause vasoconstriction and muscular contraction. Even without an intact nerve supply, the uterus can contract adequately for birth. Thus, for example, hemiplegic women have adequate uterine contractions.

Pain of uterine contractions is carried to the central nervous system by the 11th and 12th thoracic nerve roots. Pain from the cervix and upper vagina passes through the ilioinguinal and pudendal nerves. The motor fibers to the uterus arise from the 7th and 8th thoracic vertebrae. Because the sen-

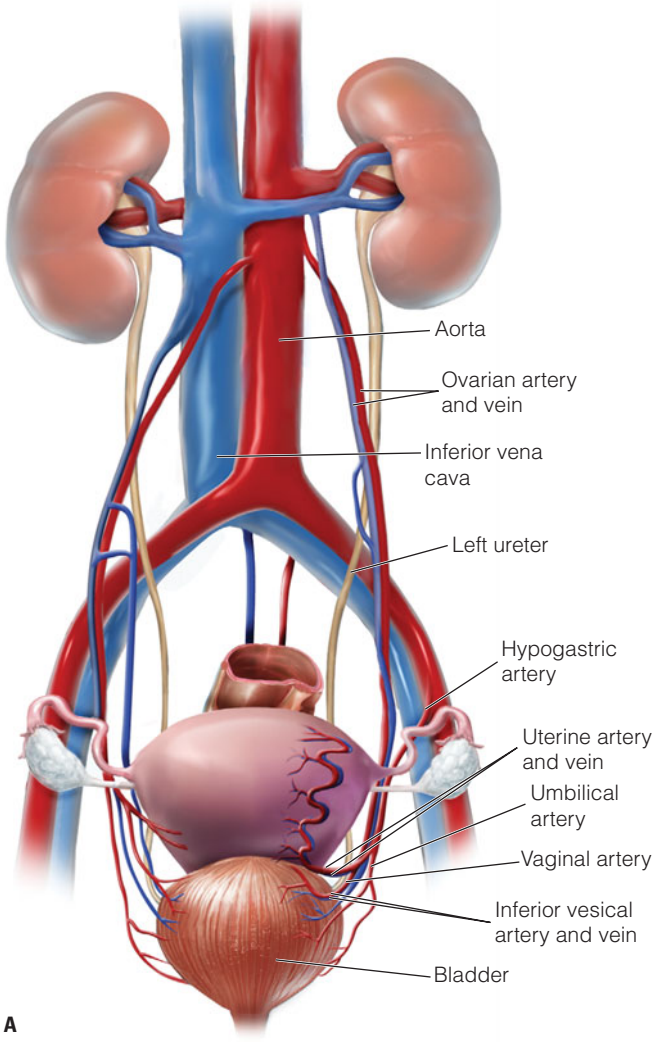

Figure 10-6 ■ Blood supply to internal reproductive organs: A. Pelvic blood supply. B. Blood supply to the vagina, ovary, uterus, and fallopian tube.

sory and motor levels are separate, epidural anesthesia can be used during labor and birth.

The function of the uterus is to provide a safe environment for fetal development. The uterine lining is cyclically prepared by steroid hormones for implantation of the embryo, a process known as **nidation**. Once the embryo is implanted, the developing fetus is protected until it is expelled.

Both the body of the uterus and the cervix are changed permanently by pregnancy. The body never returns to its prepregnant size, and the external os changes from a circular opening of about 3 mm to a transverse slit with irregular edges.

UTERINE CORPUS The uterine corpus is made up of three layers. The outermost layer is the *serosal layer,* or **perimetrium**, which is composed of peritoneum. The middle layer is the *muscular uterine layer,* or **myometrium**. This muscular uterine layer is continuous with the muscle layer of the fallopian tubes and with that of the vagina. This characteristic helps the organs present a unified reaction to various stimuli—ovulation, orgasm, or the deposit of sperm in the vagina. These muscle fibers also extend into the ovarian, round, and cardinal ligaments and minimally into the uterosacral ligaments, which helps explain the vague but disturbing pelvic "aches and pains" reported by many pregnant women.

The myometrium has three distinct layers of uterine (smooth) involuntary muscles (Figure 10-7 ■). The outer layer, found mainly over the fundus, is made up of longitudinal muscles that cause the descent of the fetus, which places pressure on the cervical fibers leading to cervical effacement and delivery of the fetus. The thick middle layer is made up of interlacing muscle fibers in figure-eight patterns that assist the longitudinal fibers in expelling the fetus. These muscle fibers surround large blood vessels, and their contraction produces a hemostatic action (a tourniquet-like action on blood vessels to stop bleeding after birth). The inner muscle layer consists of circular fibers that form sphincters at the fallopian tube attachment sites and at the internal os. The internal os sphincter inhibits the expulsion of the uterine contents during pregnancy but relaxes in labor as cervical dilatation occurs. An incompetent cervical os can be caused by a torn, weak, or absent sphincter at the internal os. The sphincters at the fallopian tubes prevent menstrual blood from flowing backward into the fallopian tubes from the uterus.

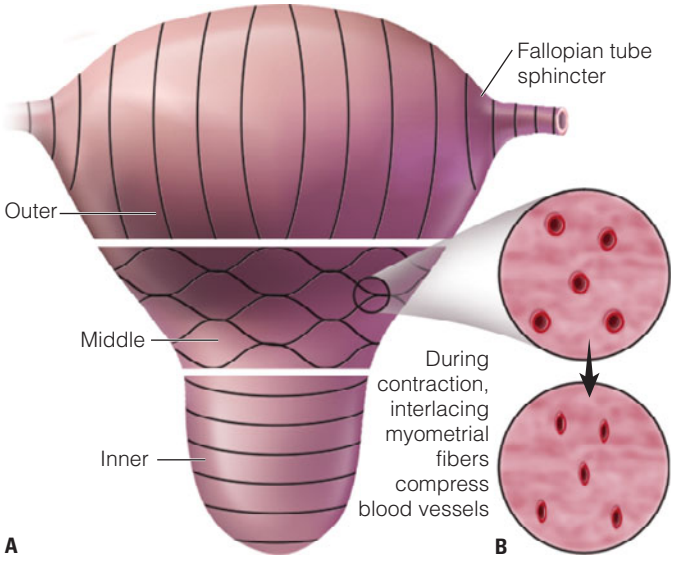

Figure 10-7 ■ Myometrium uterine muscle layers placement and function. A. Outer layer (longitudinal muscles) suited to expel fetus. B. Middle layer (interlacing muscle fibers in figure-eight pattern) surround and constrict blood vessels to stop bleeding, C. Inner layer (circular muscle fibers form sphincters at fallopian tubes and internal os) to prevent backflow menstrual blood into fallopian tubes and cervical dilatation during labor/delivery.

Although each layer of muscle has been discussed as having a unique function, it must be remembered that the uterine musculature works as a whole. The uterine contractions of labor are responsible for the dilatation of the cervix and provide the major force for the passage of the fetus through the pelvic and vaginal canal at birth.

The innermost layer of the uterine corpus is the *mucosal layer,* or **endometrium**, which is composed of a single layer of columnar epithelium, glands, and stroma. From menarche to menopause, the endometrium undergoes monthly renewal and degeneration in the absence of pregnancy. As it responds to a governing hormonal cycle and prostaglandin influence as well, the endometrium varies in thickness from 0.5 to 5 mm.

The glands of the endometrium produce a thin, watery, alkaline secretion that keeps the uterine cavity moist. This endometrial milk not only helps sperm travel to the fallopian tubes but also nourishes the developing embryo before it implants in the endometrium (see chapter 11 ∞).

The blood supply to the endometrium is unique. In the myometrium, the radial arteries branch off from the arcuate arteries at right angles. Once inside the endometrium, they become the basal arteries supplying the zona basalis (a layer of the endometrium) and ultimately become the coiled arteries supplying the zona functionalis (also part of the endometrium). The basal arteries are not sensitive to cyclic hormonal control; hence, the zona basalis portion remains intact and is the site of new endometrial tissue generation. The coiled arteries are extremely sensitive to cyclic hormonal control. Their response is alternate relaxation and constriction during the ischemic, or terminal, phase of the menstrual cycle. These differing responses allow for part of the endometrial tissue to remain intact while other endometrial tissue is shed during menstruation.

When pregnancy occurs and the endometrium is not shed, the reticular stromal cells surrounding the endometrial glands become the decidual cells of pregnancy. The stromal cells are highly vascular, channeling a rich blood supply to the endometrial surface.

CERVIX The distal end of the uterus is the **cervix**. It meets the body of the uterus at the internal os and descends about 2.5 cm to connect with the vagina at the external os (see Figure 10-5). Thus it provides a protective portal for the body of the uterus. The cervix is divided by its line of attachment into the vaginal and supravaginal areas. The vaginal cervix projects into the vagina at an angle from 45 to 90 degrees. The *supravaginal* cervix is surrounded by the attachments that give the uterus its

main support: the uterosacral ligaments, the transverse ligaments of the cervix (Mackenrodt's ligaments), and the pubocervical ligaments.

The vaginal cervix appears pink and ends at the external os. The cervical canal appears rosy red and is lined with columnar ciliated epithelium, which contains mucus-secreting glands. Most cervical cancer begins at this *squamocolumnar junction.* The specific location of the junction varies with age and number of pregnancies. Figure 10-8 ■ shows this junction at various stages of a woman's life.

Elasticity is the chief characteristic of the cervix. Its ability to stretch is due to the high fibrous and collagenous content of the supportive tissues and also to the vast number of folds in the cervical lining.

The cervical mucosa has three functions:

- To provide lubrication for the vaginal canal
- To act as a bacteriostatic agent
- To provide an alkaline environment to shelter deposited sperm from the acidic vaginal secretions

At ovulation, cervical mucus is clearer, thinner, and more alkaline than at other times.

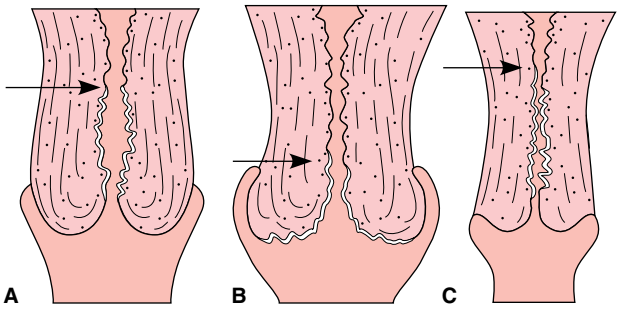

Figure 10-8 ■ Changes in squamocolumnar junction (arrows) at various stages of life: A. Childhood. B. Reproductive years. C. Postmenopausal years.

Uterine Ligaments

The uterine ligaments support and stabilize the various reproductive organs. The ligaments shown in Figure 10-9 ■ are described in this section.

- The **broad ligament** keeps the uterus centrally placed and provides stability within the pelvic cavity. It is a double layer that is continuous with the abdominal peritoneum. The broad ligament covers the uterus anteriorly and posteriorly and extends outward from the uterus to enfold and stabilize the fallopian tubes. The round and ovarian ligaments are at the upper border of the broad ligament. At its lower border, the broad ligament forms the cardinal ligaments. Between the folds of the broad ligament are connective tissue, involuntary muscle, blood and lymph vessels, and nerves.
- The **round ligaments** keep the uterus in place. The round ligaments arise from the sides of the uterus near the fallopian tube insertions. They extend outward between the folds of the broad ligament, passing through the inguinal ring and canals and eventually fusing with the connective tissue of the labia majora. The round ligaments are made up of longitudinal muscle and enlarge during pregnancy. During labor the round ligaments steady the uterus, pulling downward and forward, so that the presenting part of the fetus is forced into the cervix.
- The **ovarian ligaments** anchor the lower pole of the ovary to the cornua of the uterus. They are composed of muscle fibers, which allow the ligaments to contract. This contractile ability influences the position of the ovary to some extent, thus helping the fimbriae of the fallopian tubes to "catch" the ovum as it is released each month.
- The **cardinal ligaments** are the chief uterine supports, suspending the uterus from the side walls of the true pelvis. These ligaments, also known as Mackenrodt's ligaments or

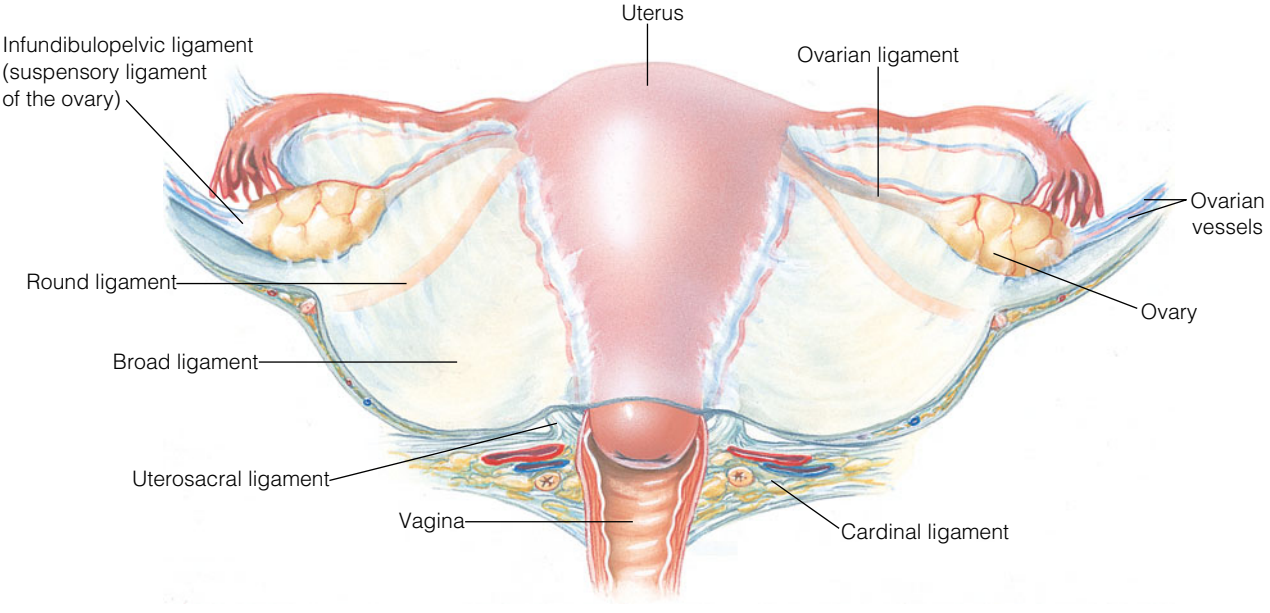

Figure 10-9 ■ Uterine ligaments.

transverse cervical ligaments, arise from the sides of the pelvic walls and attach to the cervix in the upper vagina. These ligaments prevent uterine prolapse and also support the upper vagina.

- The **infundibulopelvic ligament** suspends and supports the ovaries. Arising from the outer third of the broad ligament, the infundibulopelvic ligament contains the ovarian vessels and nerves.
- The **uterosacral ligaments** provide support for the uterus and cervix at the level of the ischial spines. Arising on each side of the pelvis from the posterior wall of the uterus, the uterosacral ligaments sweep back around the rectum and insert on the sides of the first and second sacral vertebrae. The uterosacral ligaments contain smooth muscle fibers, connective tissue, blood and lymph vessels, and nerves. They also contain sensory nerve fibers that contribute to dysmenorrhea (painful menstruation; see chapter 4 ∞).

Fallopian Tubes

The two **fallopian tubes**, also known as *oviducts* or *uterine tubes,* arise from each side of the uterus and reach almost to the side of the pelvis, where they turn toward the ovaries (Figure 10-10 ■). Each tube is approximately 8 to 13.5 cm long. A short section of each fallopian tube is inside the uterus; its opening into the uterus is 1 mm in diameter. The fallopian tubes link the peritoneal cavity with the uterus and vagina. This linkage increases a woman's vulnerability to disease processes.

Each fallopian tube may be divided into three parts: the isthmus, the ampulla, and the infundibulum or fimbria. The fallopian tube **isthmus** is straight and narrow, with a thick muscular wall and an opening (lumen) 2 to 3 mm in diameter. It is the site of tubal ligation (a surgical procedure to prevent pregnancy; see chapter 5 ∞).

Next to the isthmus is the curved **ampulla**, which comprises the outer two thirds of the tube. Fertilization of the secondary oocyte by a spermatozoon usually occurs here. The ampulla ends at the **fimbria**, which is a funnel-like enlargement with many moving fingerlike projections (fimbriae) reaching out to the ovary. The longest of these, the *fimbria ovarica,* is attached to the ovary to increase the chances of intercepting the ovum as it is released.

The wall of the fallopian tube is made up of four layers: peritoneal (serous), subserous (adventitial), muscular, and mucous tissues. The peritoneum covers the tubes. The subserous layer contains the blood and nerve supply, and the muscular layer is responsible for the peristaltic movement of the tube. The mucosal layer, immediately next to the muscular layer, is composed of ciliated and nonciliated cells with the number of ciliated cells more abundant at the fimbria. Nonciliated cells secrete a protein-rich, serous fluid that nourishes the ovum. The constantly moving tubal cilia propel the ovum toward the uterus. Because the ovum is a large cell, this ciliary action is needed to assist the tube's muscular layer peristalsis. Any malformation or malfunction of the tubes could result in infertility, ectopic pregnancy, or even sterility.

A well-functioning tubal transport system involves active fimbriae close to the ovary, peristalsis of the tube created by the muscular layer, ciliated currents beating toward the uterus, and the proximal contraction and distal relaxation of the tube caused by different types of prostaglandins.

A rich blood and lymph supply serves each fallopian tube. Thus the fallopian tubes have an unusual ability to recover from any inflammatory process.

The fallopian tubes have three functions:

- To provide transport for the ovum from the ovary to the uterus (transport through the fallopian tubes varies from 3 to 4 days)
- To provide a site for fertilization
- To serve as a warm, moist, nourishing environment for the ovum or zygote (a fertilized egg; see also chapter 11 ∞)

Ovaries

The **ovaries** are two almond-shaped glandular structures just below the pelvic brim. One ovary is located on each side of the pelvic cavity. Their size varies among women and according to the stage of the menstrual cycle. Each ovary weighs 6 to 10 g and is 1.5 to 3 cm wide, 2 to 5 cm long, and 1 to 1.5 cm thick.

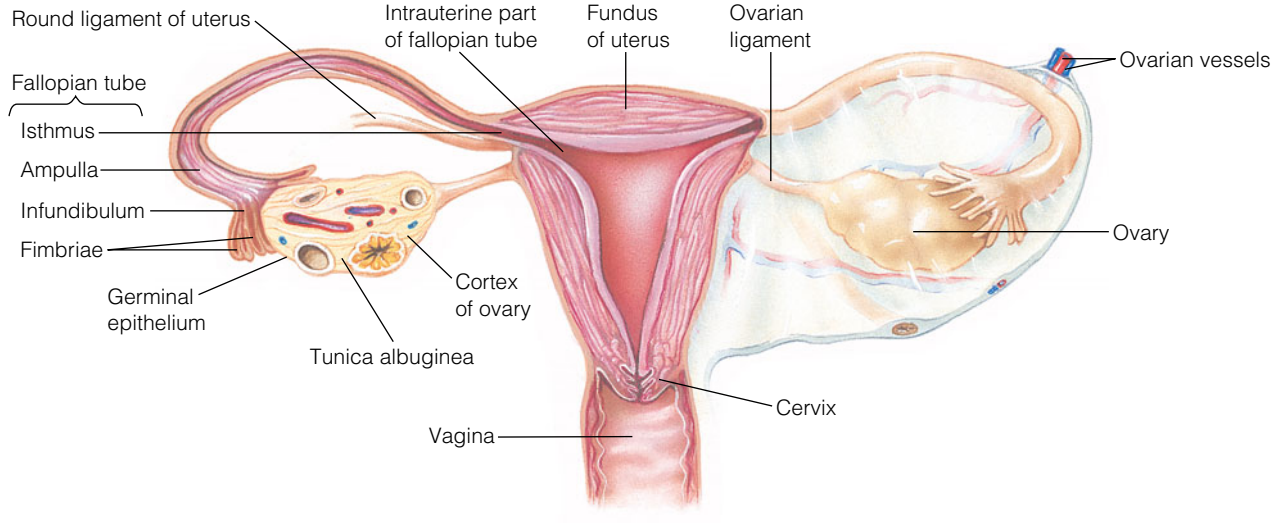

Figure 10-10 ■ Fallopian tube and ovaries.

The ovaries of girls are small, but they become larger after puberty and then decrease in size following menopause. They also change in appearance from smooth-surfaced, dull white organs to pitted gray organs as the woman ages. The pitting appearance on their surface is the result of scarring after ovulation. It is rare for both ovaries to be at the same level in the pelvic cavity. The ovary is held in place by the ovarian, broad, and infundibulopelvic ligaments (see Figure 10-9), discussed earlier in the chapter.

There is no peritoneal covering for the ovaries. Although this lack of covering assists the mature ovum to erupt, it also allows easier spread of malignant cells from cancer of the ovaries. A single layer of cuboidal epithelial cells, called the germinal epithelium, covers the ovaries. The ovaries are composed of three layers: the tunica albuginea, the cortex, and the medulla. The *tunica albuginea* is dense and dull white and serves as a protective layer. The *cortex* is the main functional part, containing ova, graafian follicles, corpora lutea, degenerated corpora lutea (corpora albicantia), and degenerated follicles. The *medulla* is completely surrounded by the cortex and contains the nerves and the blood and lymphatic vessels.

The ovaries are the primary source of two important hormones: the estrogens and progesterone. *Estrogens* are associated with characteristics contributing to femaleness, including breast alveolar lobule growth and duct development. The ovaries secrete large amounts of estrogens; the adrenal cortex (extraglandular sites) produces minute amounts of estrogens in nonpregnant women and the fat cells produce a secondary estrogen.

Progesterone is often called the *hormone of pregnancy* because it inhibits uterine contractions and relaxes smooth muscle to cause vasodilation, allowing pregnancy to be maintained. The placenta is the primary source of progesterone during pregnancy. This hormone also inhibits the action of prolactin in α-lactalbumin synthesis, thereby preventing lactation during pregnancy (Lawrence & Lawrence, 2009).

The interplay between the ovarian hormones and other hormones such as follicle-stimulating hormone (FSH) and luteinizing hormone (LH) is responsible for the cyclic changes that allow pregnancy to occur. The hormonal and physical changes that occur during the female reproductive cycle are discussed later in this chapter. Between the ages of 45 and 55 years, the woman's ovaries secrete decreasing amounts of estrogen. Eventually ovulatory activity ceases, and menopause occurs.

Bony Pelvis

The female bony pelvis has two unique functions:

- To support and protect the pelvic contents
- To form the relatively fixed axis of the birth passage

Because the pelvis is so important to childbearing, its structures should be understood clearly.

Bony Structure

The pelvis is made up of four bones: two innominate bones, the sacrum, and the coccyx (or tailbone) (Figure 10-11 ■). The pelvis resembles a bowl or basin; its sides are the innominate bones, and its back is composed of the sacrum and coccyx. Lined with fibrocartilage and held tightly together by ligaments, the four bones join at the symphysis pubis, the two sacroiliac joints, and the sacrococcygeal joints.

The *innominate* bones, also known as the hip bones or os coxae, are made up of three separate bones: the ilium, the ischium, and the pubis. These bones fuse to form a circular cavity, the *acetabulum,* which articulates with the femur.

The *ilium* is the broad, upper prominence of the hip. The *iliac crest* is the margin of the ilium. The ischial spines, the foremost projections nearest the groin, are the site of attachment for ligaments and muscles.

The *ischium,* the strongest bone, lies under the ilium and below the acetabulum. The L-shaped ischium ends in a marked protuberance, the *ischial tuberosity,* on which the weight of a seated body rests. The **ischial spines** arise near the junction of the ilium and ischium and jut into the pelvic cavity. The shortest diameter of the pelvic cavity is located between the ischial spines. The ischial spines can serve as a reference point during labor to evaluate the descent of the fetal head into the birth canal. (See chapter 22 ∞ and Figure 22-7 on page 535).

The **pubis** forms the slightly bowed front portion of the innominate bone. Extending medially from the acetabulum to the midpoint of the bony pelvis, the two pubic bones meet to form a joint, the **symphysis pubis**. The triangular space below this junction is known as the pubic arch. The fetal head passes under this arch during birth. The symphysis pubis is formed by heavy fibrocartilage and the superior and inferior pubic ligaments. The mobility of the inferior ligament increases during the first pregnancy and to a greater extent in subsequent pregnancies.

The sacroiliac joints also have a degree of mobility that increases near the end of pregnancy and results in an upward gliding movement. The pelvic outlet may be increased by 1.5 to 2 cm in the squatting and sitting positions. Relaxation of the pelvic joints is induced by relaxin, one of the hormones of pregnancy.

The *sacrum* is a wedge-shaped bone formed by the fusion of five vertebrae. On the anterior upper portion of the sacrum is a projection into the pelvic cavity known as the **sacral promontory**. This projection is another obstetric guide in determining pelvic measurements. (For discussion of pelvic measurements, see chapter 15 ∞).

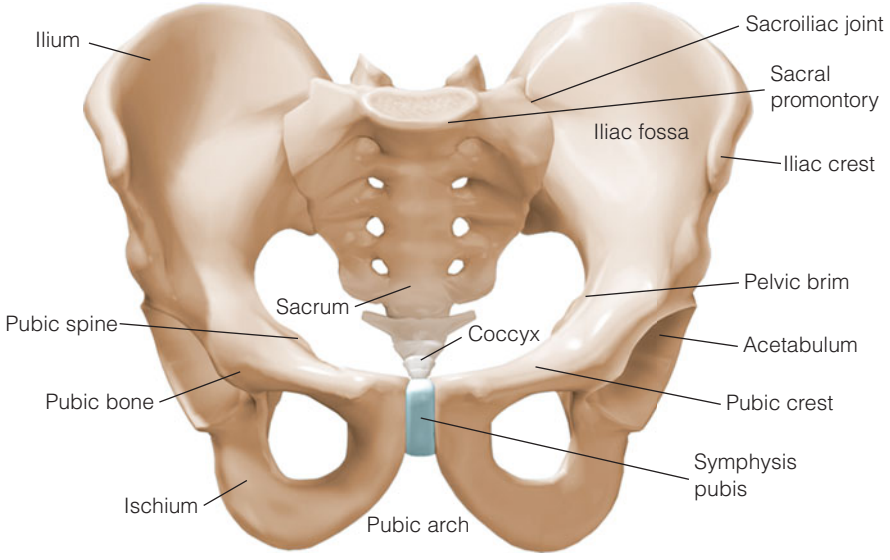
The small triangular bone last on the vertebral column is the coccyx. It articulates with the sacrum at the sacrococcygeal joint. The coccyx usually moves backward during labor to provide more room for the fetus.

Pelvic Floor

The muscular *pelvic floor* of the bony pelvis is designed to overcome the force of gravity exerted on the pelvic organs. It acts as a supporting structure to the irregularly shaped pelvic outlet, thereby providing stability and support for surrounding structures.

Deep fascia and the levator ani and coccygeal muscles form the part of the pelvic floor known as the **pelvic diaphragm**. The components of the pelvic diaphragm function as a whole, yet they are able to move over one another. This feature provides an exceptional capacity for dilatation during birth and re-

Application: Pelvic Structures



A

B

Figure 10-11 ■ Pelvis: A. Pelvic bones. B. Midsagittal view in supine position with uterosacral ligament attachment.

turn to prepregnancy condition following birth. Above the pelvic diaphragm is the **pelvic cavity**; below and behind it is the perineum. The sacrum is located posteriorly.

The levator ani muscle makes up the major portion of the pelvic diaphragm. It consists of four muscles: the iliococcygeus, pubococcygeus, puborectalis, and pubovaginalis muscles. The iliococcygeal muscle, a thin muscular sheet underlying the sacrospinous ligament, helps the levator ani support the pelvic organs. Muscles of the pelvic floor are shown in Figure 10-12 ■ and discussed in Table 10-1.

Endopelvic fascia covers the pelvic diaphragm and allows the pelvic diaphragm components to function as a whole, yet allows them to move over one another. This feature provides the pelvic diaphragm with the exceptional capacity for dilatation during birth and facilitates the return to prepregnant condition following birth.

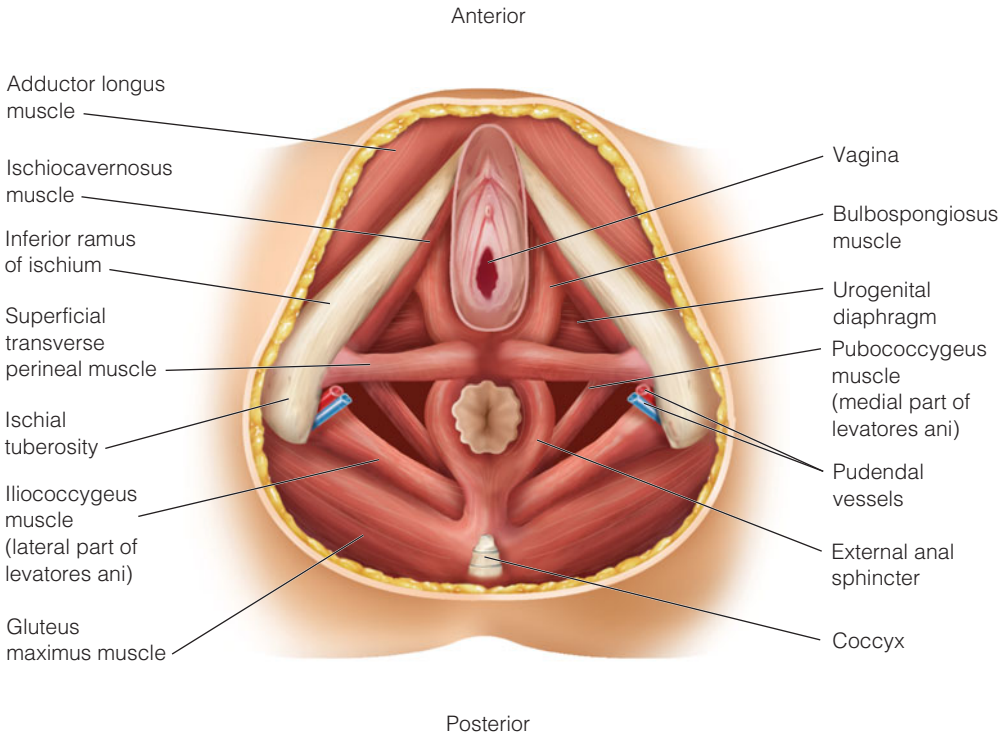


Figure 10-12 ■ Muscles of the pelvic floor. (The puborectalis, pubovaginalis, and coccygeal muscles cannot be seen from this view.)

TABLE 10-1 Muscles of the Pelvic Floor

MUSCLE	ORIGIN	INSERTION	INNERVATION	ACTION
Levator ani	Pubis, lateral pelvic wall, and ischial spine	Blends with organs in pelvic cavity	Inferior rectal, second and third sacral nerves, plus anterior rami of third and fourth sacral nerves	Supports pelvic viscera; helps form pelvic diaphragm
Iliococcygeus	Pelvic surface of ischial spine and pelvic fascia	Central point of perineum, coccygeal raphe, and coccyx		Assists in supporting abdominal and pelvic viscera
Pubococcygeus	Pubis and pelvic fascia	Coccyx		
Puborectalis	Pubis	Blends with rectum; meets similar fibers from opposite side		Forms sling for rectum, just posterior to it; raises anus
Pubovaginalis	Pubis	Blends into vagina		Supports vagina
Coccygeus	Ischial spine and sacrospinous ligament	Lateral border of lower sacrum and upper coccyx	Third and fourth sacral nerves	Supports pelvic viscera; helps form pelvic diaphragm; flexes and abducts coccyx

The urogenital triangle (diaphragm) is external to the pelvic diaphragm, in the triangular area between the ischial tuberosities and the hollow of the pubic arch. The most important muscles in this region are the deep transverse perineal muscles, which are flat bands of muscle arising from the ischiopubic rami and intertwining in the midline to form a seam, or raphe. These muscles are modified to encircle both the urinary meatus and the vaginal orifice, forming the urethral and vaginal sphincters.

Pelvic Division

The pelvic cavity is divided into the false pelvis and the true pelvis (Figure 10-13 ■). The **false pelvis** is the portion above the pelvic brim, or linea terminalis, and serves to support the weight of the enlarged pregnant uterus and direct the presenting fetal part into the true pelvis below.

The **true pelvis** is the portion that lies below the pelvic brim. The bony circumference of the true pelvis is made up of the sacrum, coccyx, and innominate bones and represents the bony limits of the birth canal. It measures about 5 cm at its anterior wall at the symphysis pubis and about 10 cm at its posterior wall. When a woman is standing upright, the upper portion of the pelvic cavity or canal is directed downward and backward; its lower portion, downward and forward. This forms a curved canal through which the presenting part of the baby must pass during birth (see Figure 10-13). The inclina-

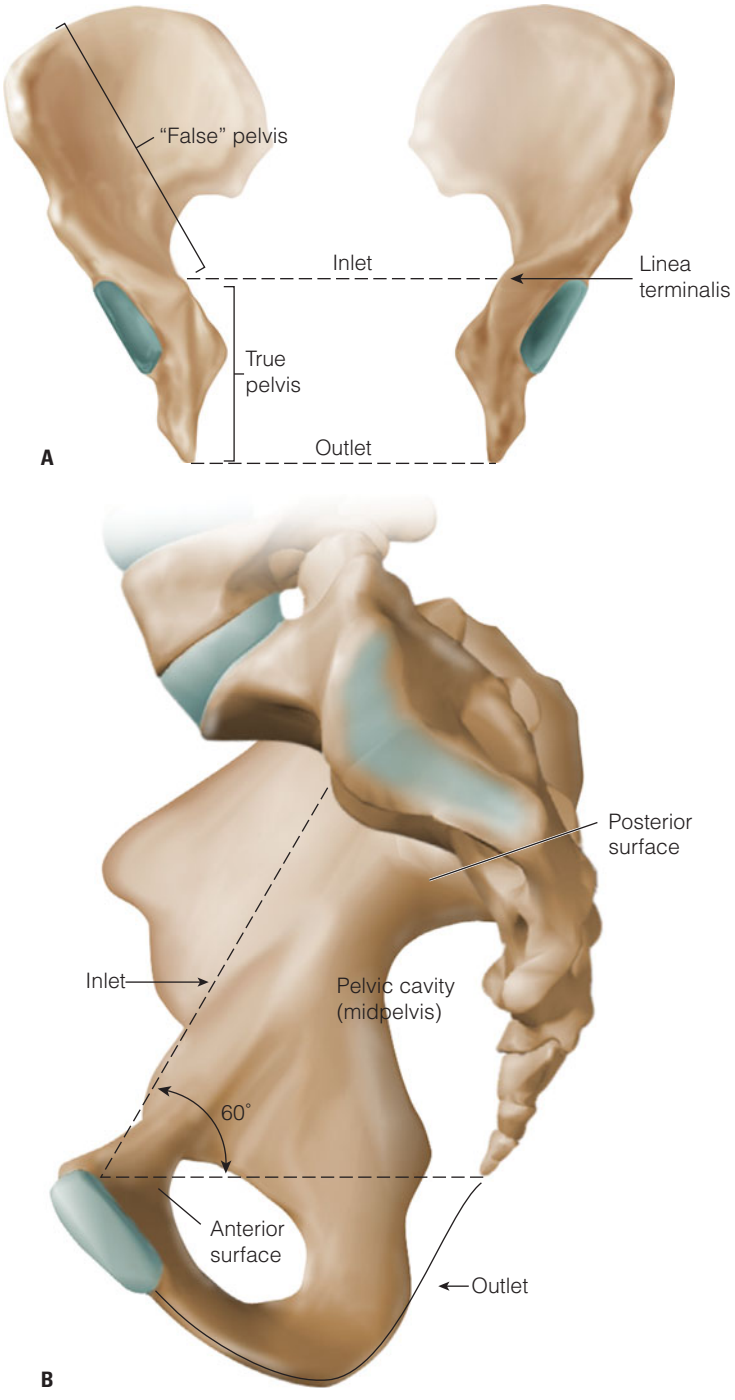

Figure 10-13 ■ Female pelvis: A. The false pelvis is the shallow cavity above the inlet; the true pelvis is the deeper portion of the cavity below the inlet. B. The true pelvis consists of the inlet, cavity (midpelvis), outlet, and pelvic angle of inclination when the woman is standing.

tion of the pelvis is the angle formed by two planes: a horizontal plane passing through the tip of the coccyx and the superior border of the symphysis pubis, and an inclined plane passing through the sacral promontory and the superior border of the symphysis pubis. This pelvic angle of inclination usually measures 50 to 60 degrees.

The relationship of the fetal head to the true pelvic cavity is of paramount importance. The size and shape of the true pelvis must be adequate for normal fetal passage during labor and at birth. The true pelvis consists of three parts: the inlet, the pelvic cavity, and the outlet. Each part has distinct measurements that aid in evaluating the adequacy of the pelvis for childbirth. Measurement techniques are discussed in chapter 15 ∞. The effects of inadequate or abnormal pelvic diameters on labor and birth are considered in chapter 27 ∞.

The **pelvic inlet** is the upper border of the true pelvis and typically is round in the female. The size and shape of the pelvic inlet are determined by assessing three anteroposterior diameters: the diagonal conjugate, obstetric conjugate, and conjugate vera (Figure 10-14 ■). (For an in-depth discussion, see chapter 15 ∞). The **diagonal conjugate** extends from the subpubic angle to the middle of the sacral promontory and is typically 12.5 cm. The diagonal conjugate can be measured manually during a pelvic examination. The **obstetric conjugate** extends from the middle of the sacral promontory to an area approximately 1 cm below the pubic crest. Its length is estimated by subtracting 1.5 cm from the diagonal conjugate. The fetus passes through the obstetric conjugate, and the size of this diameter determines whether the fetus can move down into the birth canal in order for engagement to occur. The true (anatomic) conjugate, or **conjugate vera**, extends from the middle of the sacral promontory to the middle of the pubic crest (superior surface of the symphysis). One additional measurement, the transverse diameter, helps determine the shape of the inlet. The **transverse diameter** is the largest diameter of the inlet and is measured by using the linea terminalis as the point of reference.

The *pelvic cavity* (canal) is a curved canal with a longer posterior than anterior wall. A change in the lumbar curve can increase or decrease the pelvic inclination and can influence the progress of labor, because the fetus has to adjust itself to this curved path as well as to the different diameters of the true pelvis.

The **pelvic outlet** is at the lower border of the true pelvis. The size of the pelvic outlet can be determined by assessing the *transverse diameter.* The anteroposterior diameter of the pelvic outlet increases during birth as the presenting part pushes the coccyx posteriorly at the mobile sacrococcygeal joint. Decreased mobility, a large fetal head, and/or a forceful birth can cause the coccyx to break. As the infant's head emerges, the long diameter of the head (occipital frontal) parallels the long diameter of the outlet (anteroposterior).

The transverse diameter *(bi-ischial or intertuberous)* extends from the inner surface of one ischial tuberosity to the other. It is the shortest diameter of the pelvic outlet and becomes even shorter if the woman has a narrowed pubic arch. The pubic arch has great importance because the baby must pass under it during birth. If it is narrow, the baby's head may be pushed backward toward the coccyx, making the extension of the head difficult. This situation, known as *outlet dystocia,* may require the use of forceps or a cesarean birth. The shoulders of a large baby may also get stuck under the pubic arch, making birth more difficult. The clinical assessment of each of these obstetric diameters is discussed further in chapter 15 ∞.

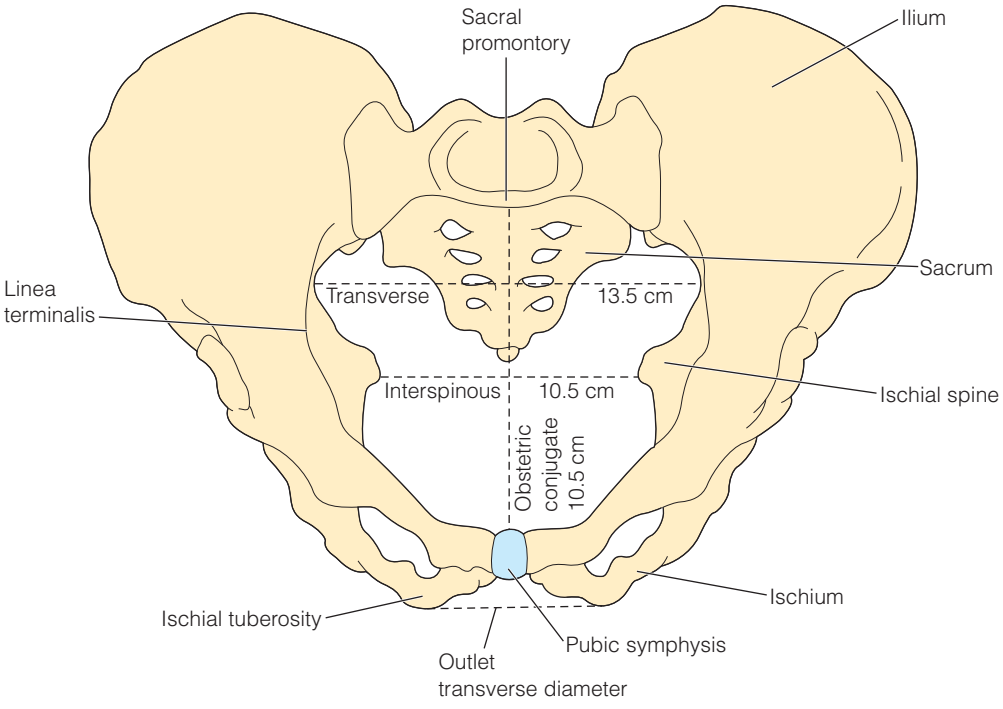

Figure 10-14 ■ Pelvic planes: coronal section and diameters of the bony pelvis.

Pelvic Types

The Caldwell-Moloy classification of pelves (Figure 10-15 ■) is widely used to differentiate types of bony pelves (Caldwell & Moloy, 1933). *Gynecoid, android, anthropoid,* and *platypelloid* are the four basic types. However, variations in the female pelvis are so great that classic types are not usual. Each type of pelvis has a characteristic shape, and each shape has implications for labor and birth. The types are described briefly here, and their implications for labor and birth are discussed in detail in chapter 22 ∞.

GYNECOID PELVIS The most common female pelvis is the gynecoid type. The inlet is rounded with the anteroposterior diameter a little shorter than the transverse diameter. All of the inlet diameters are at least adequate. The posterior segment is broad, deep, and roomy, and the anterior segment is well rounded. The gynecoid midpelvis has nonprominent ischial spines; straight and parallel side walls; and a wide, deep sacral curve. The sacrum is short and slopes backward. All of the midpelvic diameters are at least adequate. The gynecoid pelvic outlet has a wide and round pubic arch; the inferior pubic rami are short and concave. The anteroposterior diameter is long; the transverse diameter, adequate. The capacity of the outlet is adequate. The bones are of medium structure and weight. Approximately 50% of female pelves are classified as gynecoid.

ANDROID PELVIS The normal male pelvis is the android type; however, it occasionally is seen in females. The inlet is heart shaped. The anteroposterior and transverse diameters are adequate for birth, but the posterior sagittal diameter is too short, and the anterior sagittal diameter is long. The posterior segment is shallow because the sacral promontory is indented, resulting in a reduced capacity. The anterior segment is narrow, and the forepelvis is sharply angled. The android midpelvis has prominent ischial spines; convergent sidewalls; and a long, heavy sacrum inclining forward. All of the midpelvic diameters are reduced. The distance from the linea terminalis to the ischial tuberosities is long, yet the overall capacity of the midpelvis is reduced. The android outlet has a narrow, sharp, and deep pubic arch; the inferior pubic rami are straight and long. The anteroposterior diameter is short, and the transverse diameter is narrow. The capacity of the outlet is reduced. The bones are of medium to heavy structure and weight.

Approximately 20% of female pelves are classified as android. The influence of an android pelvis on labor is not favorable. Descent into the pelvis is slow. The fetal head usually engages in the transverse or occipital posterior diameter in asynclitism (oblique presentation) with extreme molding. Arrest of labor is frequent, requiring difficult forceps manipulation (rotation and extraction), and the deep, narrow pubic arch may lead to extensive perineal lacerations. Cesarean birth may be required.

ANTHROPOID PELVIS The inlet of an anthropoid pelvis is oval, with a long anteroposterior diameter and an adequate but rather short transverse diameter. Both the posterior and anterior segments are deep; the posterior sagittal diameter is extremely long, as is the anterior sagittal diameter. The anthropoid midpelvis has variable ischial spines, straight side walls, and a narrow and long sacrum that inclines backward. The midpelvic diameters are at least adequate, making its capacity adequate. The anthropoid outlet has a normal or moderately narrow pubic arch; the interior pubic rami are long and narrow. The outlet capacity is adequate, and the bones are of medium weight

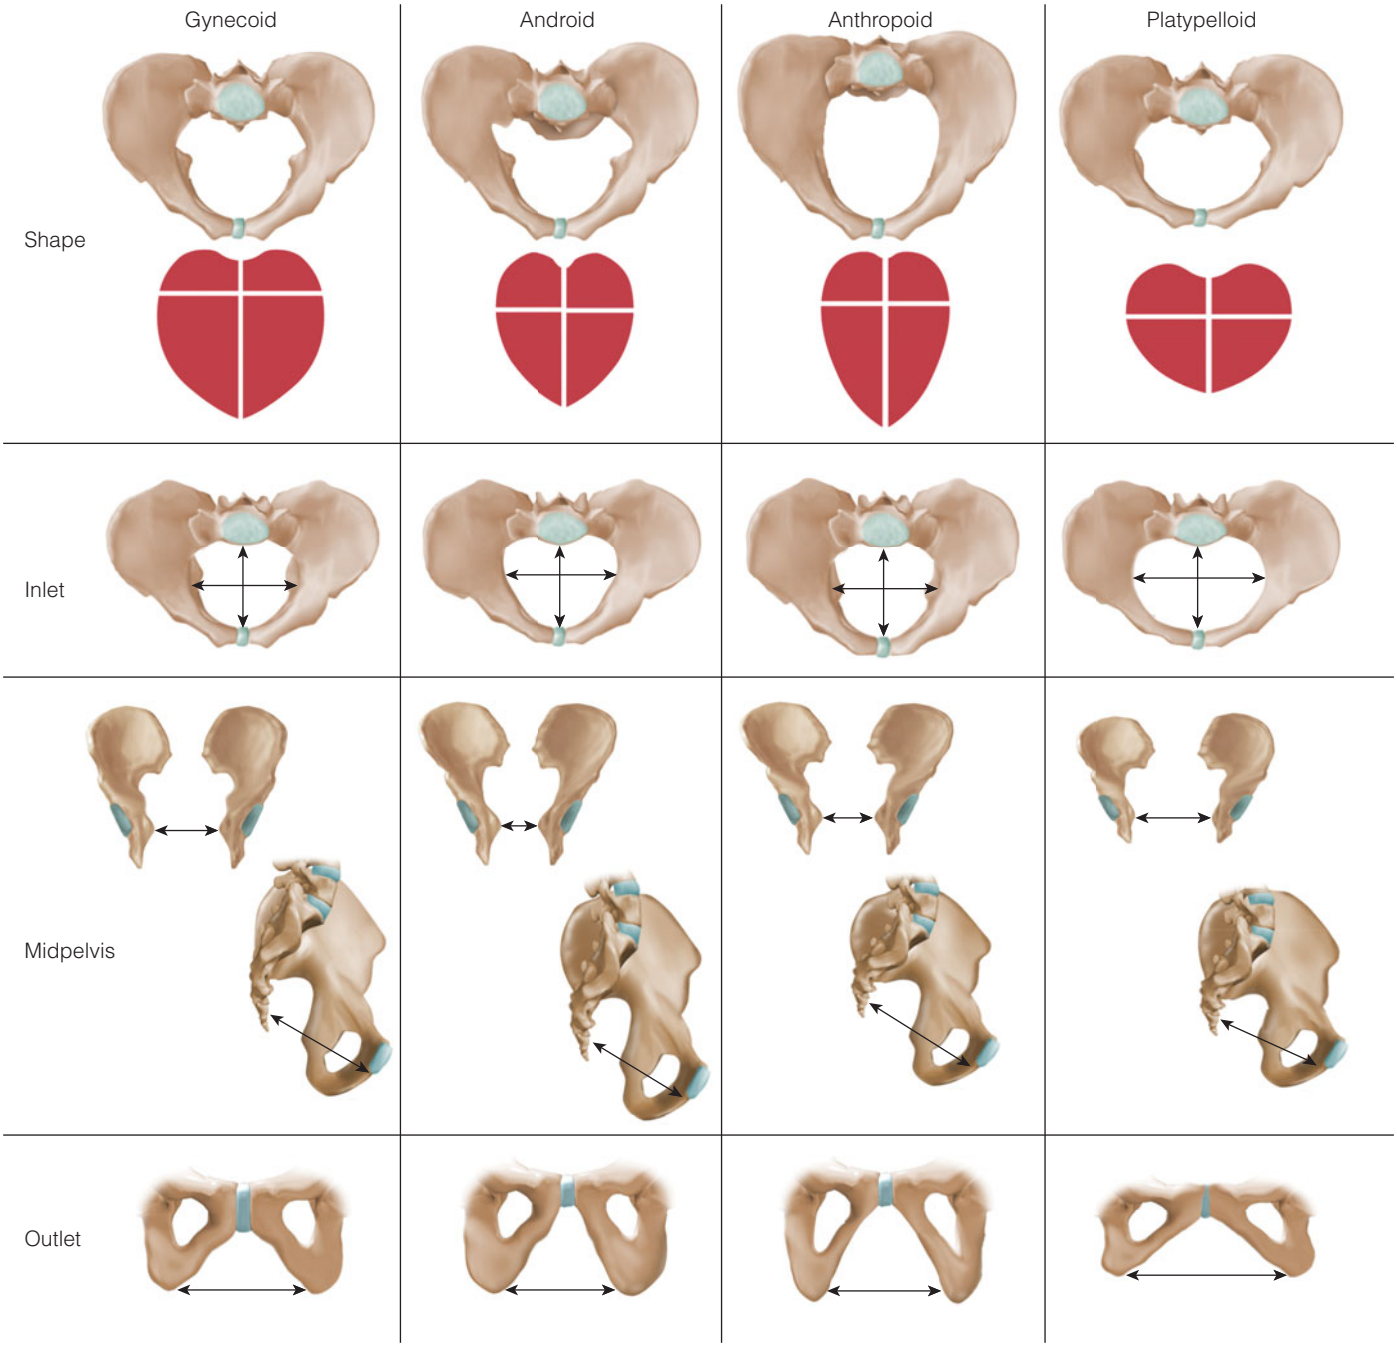

Figure 10-15 ■ Comparison of Caldwell-Moloy pelvic types.

and structure. Approximately 25% of female pelves are classified as anthropoid.

PLATYPELLOID PELVIS The platypelloid type refers to the flat female pelvis. The inlet is a distinctly transverse oval with a short anteroposterior and extremely short transverse diameter. The posterior sagittal and anterior sagittal diameters are short. Both the anterior and posterior segments are shallow. The platypelloid midpelvis has variable ischial spines, parallel side walls, and a wide sacrum with a deep curve inward. Only the transverse diameter is adequate; thus the midpelvic capacity is reduced. The platypelloid outlet has an extremely wide pubic arch; the inferior pubic rami are straight and short. The transverse diameter is wide, but the anteroposterior diameter is short. The outlet capacity may be inadequate. The platypelloid bones are similar to the gynecoid type. Only 5% of female pelves are classified as platypelloid.

Breasts

The **breasts**, or *mammary glands,* considered accessories of the reproductive system, are specialized sebaceous glands. They are conical and symmetrically placed on the sides of the chest. The greater pectoral and anterior serratus muscles underlie each breast. Suspending the breasts are fibrous tissues,

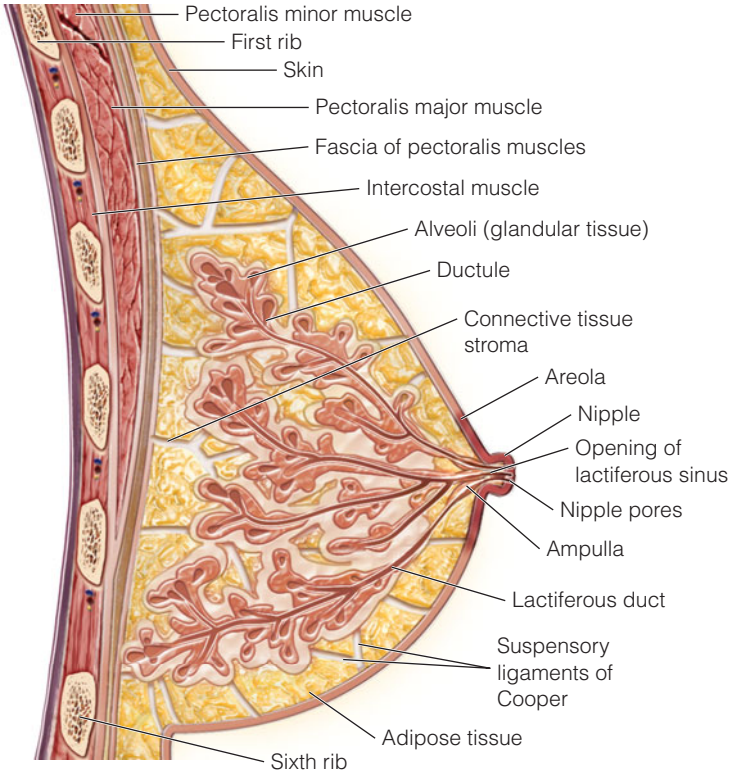

Figure 10-16 ■ Anatomy of the breast.

called *Cooper's ligaments,* which extend from the deep fascia in the chest outward to just under the skin covering the breast. The left breast is frequently larger than the right. In different racial groups breasts develop at slightly different levels in the pectoral region of the chest.

In the center of each mature breast is the **nipple**, a protrusion about 0.5 to 1.3 cm in diameter. The nipple is composed mainly of erectile tissue, which becomes more rigid and prominent during the menstrual cycle, sexual excitement, pregnancy, and lactation. The nipple is surrounded by the heavily pigmented **areola**, 2.5 to 10 cm in diameter. Both the nipple and areola are roughened by small papillae called *tubercles of Montgomery.* As an infant suckles, these tubercles secrete a fatty substance that helps lubricate and protect the breasts.

The breasts are composed of glandular, fibrous, and adipose tissue. The glandular tissue consists of acini, or alveoli (Figure 10-16 ■), which are arranged in a series of 15 to 24 lobes separated from each other by adipose and fibrous tissue.

Each lobe is made up of several lobules, which are made up of many grapelike clusters of alveoli around tiny ducts. They are lined with a single layer of cuboidal epithelium, which secretes the various components of milk. The ducts from several lobules combine to form larger lactiferous ducts and then join to form the lactiferous sinuses, which serve as reservoirs for milk collection and open on the surface of the nipple. The smooth muscle of the nipple causes erection of the nipple on contraction.

Cyclic hormonal control of the mature breast is complex. Essentially, estrogenic hormones stimulate the growth and development of the ductal epithelium. Progesterone, in association with estrogen, is responsible for the acinar and lobular development during the luteal phase of menstruation. Adrenal corticosteroids, prolactin, somatotropin (growth hormone), and thyroxine are also necessary for estrogen and progesterone to act.

The arterial, venous, and lymphatic systems communicate medially with the internal mammary vessels and laterally with the axillary vessels. Therefore, in cancer of the breast, metastasis follows the vascular supply both medially and laterally (Figure 10-17 ■).

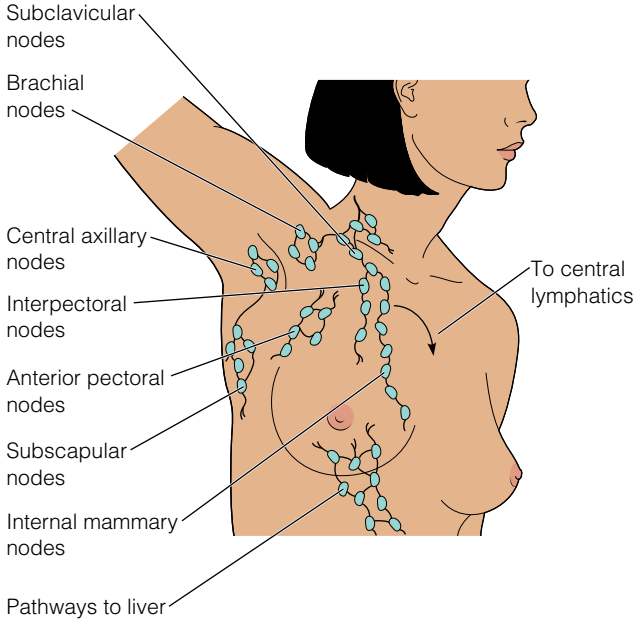

Figure 10-17 ■ Lymphatic vessels draining the breast.

The biologic function of the breasts is to provide nourishment and protective maternal antibodies to infants through the lactation process. They are also a source of pleasurable sexual sensation.

Female Reproductive Cycle

The **female reproductive cycle (FRC)** is composed of the ovarian cycle, during which ovulation occurs, and the menstrual cycle, during which menstruation occurs. These two cycles take place simultaneously (Figure 10-18 ■).

Effects of Female Hormones

After menarche, a woman undergoes a cyclic pattern of ovulation and menstruation for a period of 30 to 40 years. An orderly process under neurohormonal control, this cyclic pattern

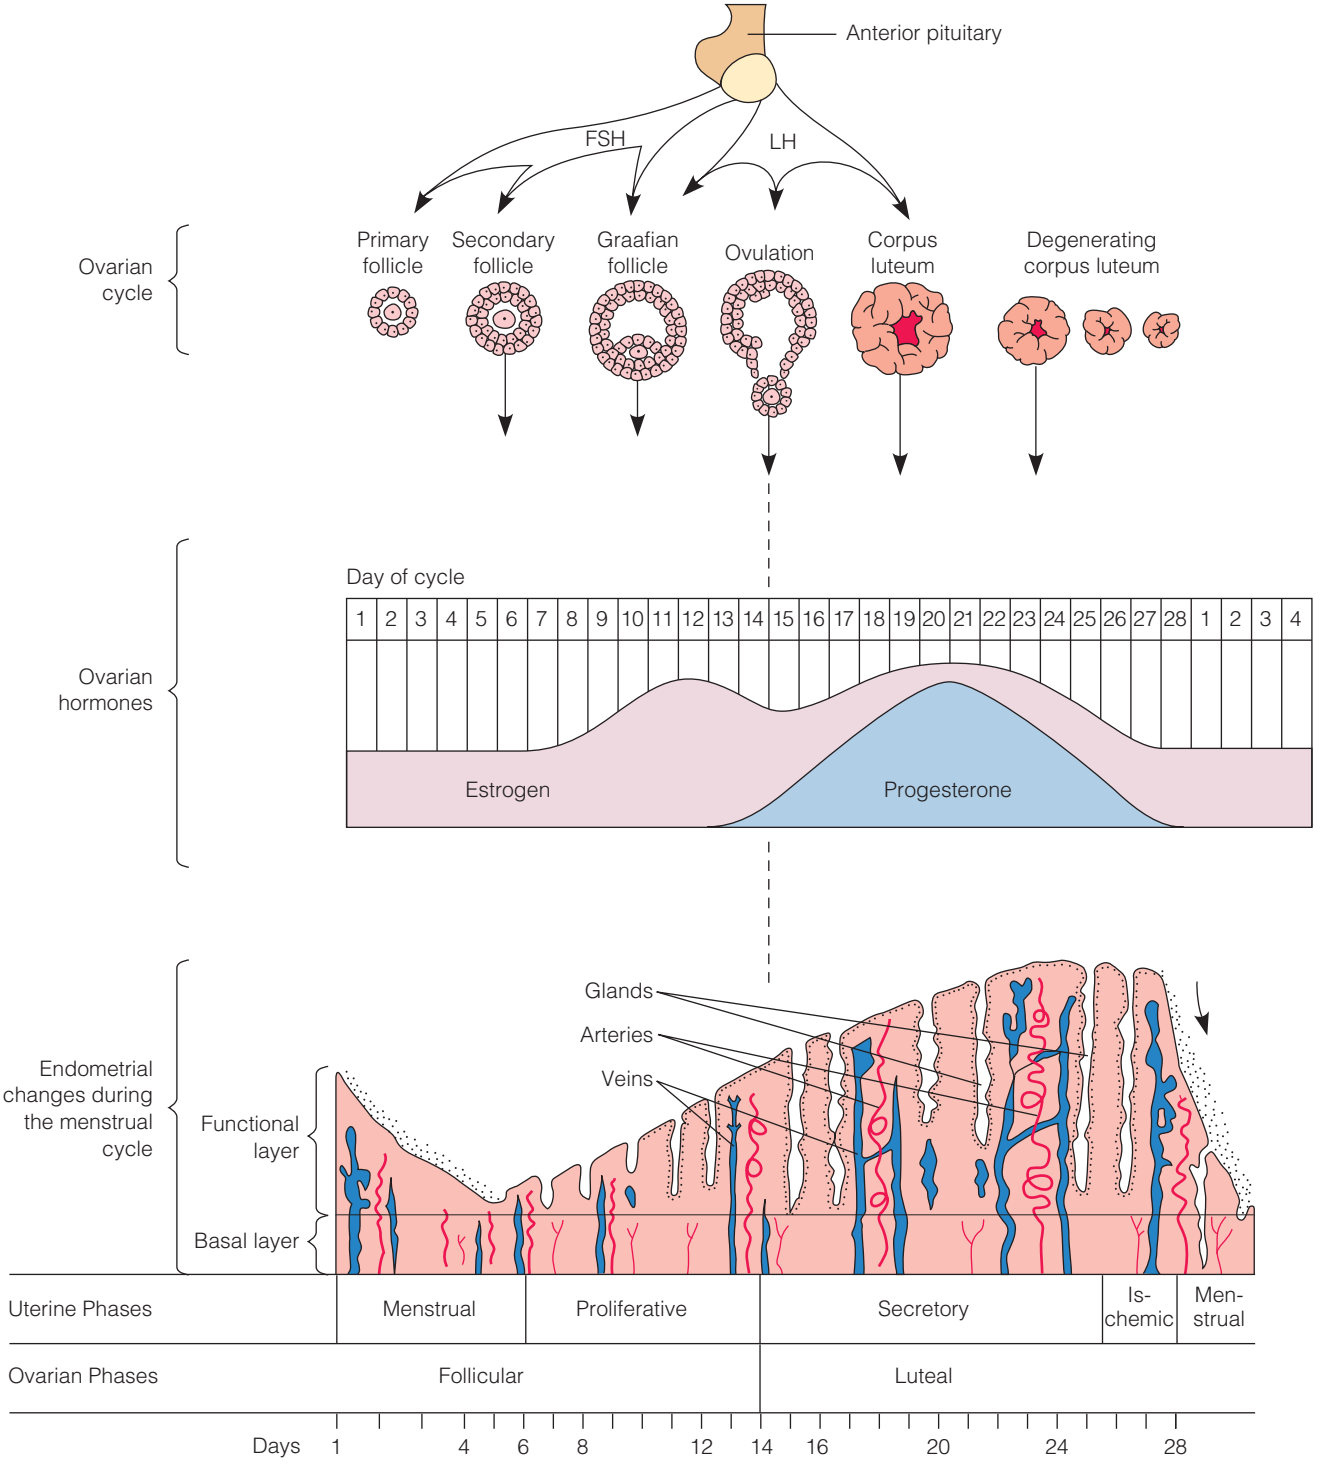

Figure 10-18 ■ Female reproductive cycle: interrelationships of hormones, the four phases of the uterine cycle, and the two phases of the ovarian cycle.

is disrupted only by pregnancy. Each month, multiple oocytes mature, with one rupturing from the ovary and entering the fallopian tube. The ovary, vagina, uterus, and fallopian tubes are major target organs for female hormones.

The ovaries produce mature gametes (see discussion in chapter 11 ∞) and secrete hormones. Ovarian hormones include the estrogens, progesterone, and testosterone. The ovary is sensitive to follicle-stimulating hormone (FSH) and luteinizing hormone (LH). The uterus is sensitive to estrogen and progesterone. The relative proportions of these hormones control the events of both ovarian and menstrual cycles.

Estrogens

Estrogens are hormones that are associated with those characteristics contributing to "femaleness." The major estrogenic effects are due primarily to three estrogens: estrone, β-estradiol, and estriol. β-Estradiol is the major estrogen.

Estrogens control the development of the female secondary sex characteristics: breast development, growth of body hair, widening of the hips, and deposits of tissue (fat) in the buttocks and mons pubis. In addition, estrogens assist in the maturation of the ovarian follicles and cause the endometrial mucosa to proliferate following menstruation. The amount of estrogens is greatest during the proliferative (follicular or estrogenic) phase of the menstrual cycle. Estrogens cause the uterus to increase in size and weight because of increased glycogen, amino acids, electrolytes, and water. Blood supply is expanded as well. The endometrial mucosa is in a ready state as a result of estrogenic influence. Under the influence of estrogens, myometrial contractility increases in both the uterus and the fallopian tubes, and uterine sensitivity to oxytocin increases. Estrogens inhibit FSH production and stimulate LH production.

Activity: Ovulation

Estrogens have effects on many hormones and other carrier proteins, such as contributing to the increased amount of protein-bound iodine in pregnant women and women who use oral contraceptives containing estrogen. Estrogens may increase libidinal feelings in humans. They decrease the excitability of the hypothalamus, which may cause an increase in sexual desire.

Progesterone

Progesterone is secreted by the corpus luteum and is found in greatest amounts during the secretory (luteal or progestational) phase of the menstrual cycle. It decreases uterine motility and contractility caused by estrogens, thereby preparing the uterus for implantation after the ovum is fertilized.

This hormone is often called the *hormone of pregnancy* because its effects on the uterus allow pregnancy to be maintained. Under the influence of progesterone, the vaginal epithelium proliferates, and the cervix secretes thick, viscous mucus. In the breast progesterone stimulates development of lobules and alveoli and supports secretory function of the breast during lactation (Cunningham et al., 2010).

The temperature rise of about 0.3°C to 0.6°C (0.5°F to 1°F) that accompanies ovulation and persists throughout the secretory phase of the menstrual cycle is due to progesterone.

Prostaglandins

Prostaglandins (PGs) are oxygenated fatty acids that are produced by the cells of the endometrium and are also classified as hormones. Prostaglandins have varied actions in the body. The two primary types of prostaglandins are groups E and F. Generally, PGE relaxes smooth muscles and is a potent vasodilator; PGF is a potent vasoconstrictor and increases the contractility of muscles and arteries. Although their primary actions seem antagonistic, their basic regulatory functions in cells are achieved through an intricate pattern of reciprocal events.

Prostaglandin production increases during follicular maturation, is dependent on gonadotropins, and seems to be critical to follicular rupture (Cunningham et al., 2010). Extrusion of the ovum, resulting from follicular swelling and increased contractility of the smooth muscle in the theca layer of the mature follicle, is thought to be caused by $PGF_{2\alpha}$. Significant amounts of PGs are found in and around the follicle at the time of ovulation.

During the late secretory phase, the level of $PGF_{2\alpha}$ is higher than that of PGE (Blackburn, 2007). This event increases vasoconstriction and contractility of the myometrium, which contributes to the ischemia preceding menstruation. A high concentration of PGs may also account for the vasoconstriction of the endometrium venous lacunae, allowing for platelet aggregation at vascular rupture points, thereby preventing a rapid blood loss during menstruation. The menstrual flow's high concentration of PGs may also facilitate the process of tissue digestion, which allows for an orderly shedding of the endometrium during menstruation.

Neurohormonal Basis of the Female Reproductive Cycle

The female reproductive cycle is controlled by complex interactions between the nervous and endocrine systems and their target tissues. These interactions involve the hypothalamus, anterior pituitary, and ovaries.

The hypothalamus secretes *gonadotropin-releasing hormone (GnRH)* to the pituitary gland in response to signals received from the central nervous system. This releasing hormone is often called follicle-stimulating hormone-releasing hormone (FSHRH) or luteinizing hormone-releasing hormone (LHRH) (Blackburn, 2007). In response to GnRH, the anterior pituitary secretes the gonadotropic hormones *FSH* and *LH*.

FSH is primarily responsible for the maturation of the ovarian follicle. As the follicle matures, it secretes increasing amounts of estrogen, which enhance the development of the follicle (Cunningham et al., 2010). (This estrogen also is responsible for the rebuilding/proliferation phase of the endometrium after it is shed during menstruation.)

Final maturation of the follicle will not come about without the action of LH. The anterior pituitary's production of LH increases 6-fold to 10-fold as the follicle matures. The peak production of LH can precede ovulation by as much as 12 hours (Cunningham et al., 2010).

LH is also responsible for "luteinizing" the increase in production of progesterone by the granulosa cells of the follicle.

As a result, estrogen production declines and progesterone secretion continues. Thus, estrogen levels fall a day before ovulation; tiny amounts of progesterone are in evidence. **Ovulation** takes place following the very rapid growth of the follicle—as the sustained high level of estrogen diminishes and progesterone secretion begins.

The ruptured follicle undergoes rapid change, complete luteinization is accomplished, and the mass of cells becomes the **corpus luteum**. The lutein cells secrete large amounts of progesterone with smaller amounts of estrogen. (Concurrently, the excessive amounts of progesterone are responsible for the secretory phase of the uterine cycle.) On day 7 or 8 following ovulation, the corpus luteum begins to involute, losing its secretory function. The production of both progesterone and estrogen is severely diminished. The anterior pituitary responds with increasingly large amounts of FSH; a few days later, LH production begins. New follicles become responsive to another ovarian cycle and begin maturing.

Ovarian Cycle

The ovarian cycle has two phases: the *follicular phase* (days 1 to 14) and the *luteal phase* (days 15 to 28 in a 28-day cycle). Figure 10-19 ■ depicts the changes that the follicle undergoes during the ovarian cycle. In women whose menstrual cycles vary, usually it is only the length of the follicular phase that varies, because the luteal phase is of fixed length. During the follicular phase, the immature follicle matures as a result of FSH. Within the follicle, the oocyte grows.

A mature **graafian follicle** appears about the 14th day under dual control of FSH and LH. It is a large structure, measuring about 5 to 10 mm, and produces increasing amounts of estrogen. In the mature graafian follicle, the cells surrounding the fluid-filled antral cavity are called granulosa cells. The mass of granulosa cells surrounding the oocyte and follicular fluid is called the *cumulus oophorus*. In the fully mature graafian follicle, the zona pellucida, a thick elastic capsule, develops around the oocyte. Just before ovulation, the mature oocyte completes its first meiotic division (see chapter 11 ∞ for a description of meiosis). As a result of this division, two cells are formed: a small cell called a *polar body,* and a larger cell called the *secondary oocyte.* The secondary oocyte matures into the ovum.

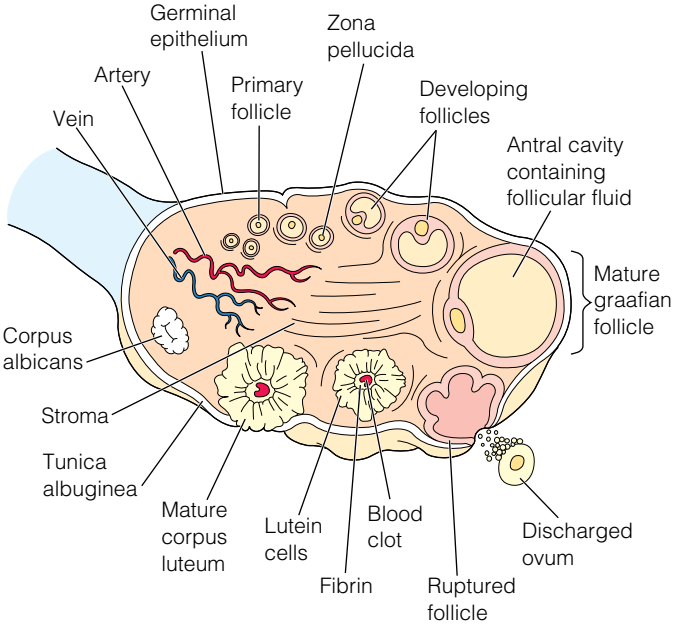

Figure 10-19 ■ Various stages of development of the ovarian follicles.

As the graafian follicle matures and enlarges, its walls thin and it travels outward to the surface of the ovary. This surface has a blisterlike protrusion 10 to 15 mm in diameter, where the secondary oocyte, polar body, and follicular fluid are pushed out. The ovum is discharged near the fimbria of the fallopian tube and is pulled into the tube to begin its journey toward the uterus. (See Figure 11-5 on page 223.)

In some women, ovulation is accompanied by midcycle pain, known as *mittelschmerz.* This pain may be caused by a thick tunica albuginea or by a local peritoneal reaction to the expelling of the follicular contents. Vaginal discharge may increase during ovulation, and a small amount of blood (midcycle spotting) may be discharged as well.

The body temperature increases about 0.3°C to 0.6°C (0.5°F to 1°F) 24 to 48 hours after the time of ovulation. It remains elevated until the day before menstruation begins. There may be an accompanying sharp basal body temperature drop just before the increase. These temperature changes are useful clinically to determine the approximate time ovulation occurs (Blackburn 2007).

Generally the ovum takes several minutes to travel through the ruptured follicle to the fallopian tube opening. The contractions of the tube's smooth muscle and its ciliary action propel the ovum through the tube. The ovum remains in the ampulla, where, if it is fertilized, cleavage can begin. The ovum is thought to be fertile for only 6 to 24 hours. It reaches the uterus 72 to 96 hours after its release from the ovary.

The luteal phase begins when the ovum leaves its follicle. Under the influence of LH, the corpus luteum develops from the ruptured follicle. Within 2 or 3 days the corpus luteum becomes yellowish and spherical and increases in vascularity. If the ovum is fertilized and implants in the endometrium, the fertilized egg begins to secrete **human chorionic gonadotropin (hCG)**, which is needed to maintain the corpus luteum. If fertilization does not occur, within about a week after ovulation, the corpus luteum begins to degenerate, eventually becoming a connective tissue scar called the *corpus albicans.* With degeneration comes a decrease in estrogen and progesterone. This allows for an increase in LH and FSH, which triggers the hypothalamus.

Application: Ovarian Cycle

Uterine (Menstrual) Cycle

Menstruation is cyclic uterine bleeding in response to cyclic hormonal changes. Menstruation occurs when the ovum is not fertilized and begins about 14 days after ovulation (in an ideal 28-day cycle), in the absence of pregnancy. The menstrual discharge, also referred to as the *menses* or *menstrual flow,* is composed of blood mixed with cervical and vaginal secretions, bacteria, mucus, leukocytes, and other cellular debris. The menstrual discharge is dark red and has a distinctive odor.

Menstrual Cycle Central

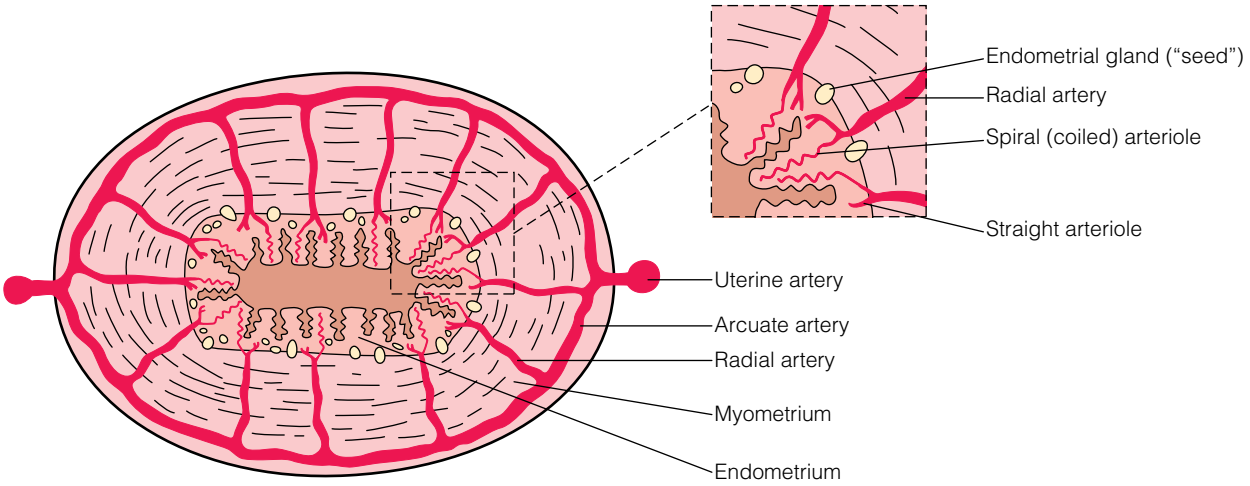

Figure 10-20 ■ Blood supply to the endometrium (cross-sectional view of the uterus).

Care Plan Activity: Irregular Menses in a Patient with Anxiety

Frequently, ovulation does not occur in early menstrual cycles; these are called anovulatory cycles. Early cycles also are often irregular in frequency, amount of flow, and duration. Within several months to 2 to 3 years, a regular cycle becomes established.

Menstrual parameters vary greatly among individuals. Generally, menstruation occurs every 29 days but varies from 21 to 35 days. Some women normally have longer cycles, which can skew standard calculations of the estimated date of birth (EDB) when they become pregnant. Emotional and physical factors such as illness, excessive fatigue, stress or anxiety, and rigorous exercise programs can alter the cycle interval. Certain environmental factors such as temperature and altitude may also affect the cycle. The duration of menses is from 2 to 8 days, with the blood loss averaging 25 to 60 ml and the loss of iron averaging 0.5 to 1 mg daily.

A review of the endometrium and its arterial blood supply will provide further understanding of the menstrual process (Figure 10-20 ■). Blood flow from the spiral arterioles in the superficial endometrium is reduced, leading to a lack of blood and oxygen, which in turn produces tissue death (necrosis) and discharge of the superficial endometrium (menses). At the same time, the straight arterioles provide the basal endometrium with sufficient blood flow to maintain this layer of the endometrium and the endometrial glands (or seeds) that are responsible for the generation of the endometrium in the next female reproductive or menstrual cycle (see Figure 10-18). Bleeding is controlled by vasospasm of the straight basal arterioles, resulting in coagulative necrosis at the vessel tips.

The uterine (menstrual) cycle has four phases: the menstrual phase, proliferative phase, secretory phase, and ischemic phase (Table 10-2). Menstruation occurs during the *menstrual phase.*

TABLE 10-2 Characteristics of Menstrual Cycle and Ovulation

Menstrual phase (days 1–6)	Estrogen levels are low.
	Cervical mucus is scanty, viscous, and opaque.
	Endometrium is shed.
Proliferative phase (days 7–14)	Endometrium and myometrium thickness increases.
	Estrogen peaks just before ovulation.
	Cervical mucus at ovulation: Is clear, thin, watery, and alkaline Is more favorable to sperm Has elasticity (spinnbarkheit) greater than 5 cm Shows ferning pattern on microscopic exam
	Just prior to ovulation body temperature drops; then at ovulation basal body temperature increases 0.3°C to 0.6°C, and mittelschmerz and/or midcycle spotting may occur.
Secretory phase (days 15–26)	Estrogen drops sharply, and progesterone dominates.
	Vascularity of entire uterus increases.
	Tissue glycogen increases, and the uterus is made ready for implantation.
Ischemic phase (days 27–28)	Both estrogen and progesterone levels fall.
	Spiral arteries undergo vasoconstriction.
	Endometrium becomes pale.
	Blood vessels rupture.
	Blood escapes into uterine stromal cells.

Some endometrial areas are shed, whereas others remain. Some of the remaining tips of the endometrial glands begin to regenerate. The endometrium is in a resting state following menstruation. Estrogen levels are low, and the endometrium is 1 to 2 mm deep. During this part of the cycle the cervical mucus is scanty, viscous, and opaque.

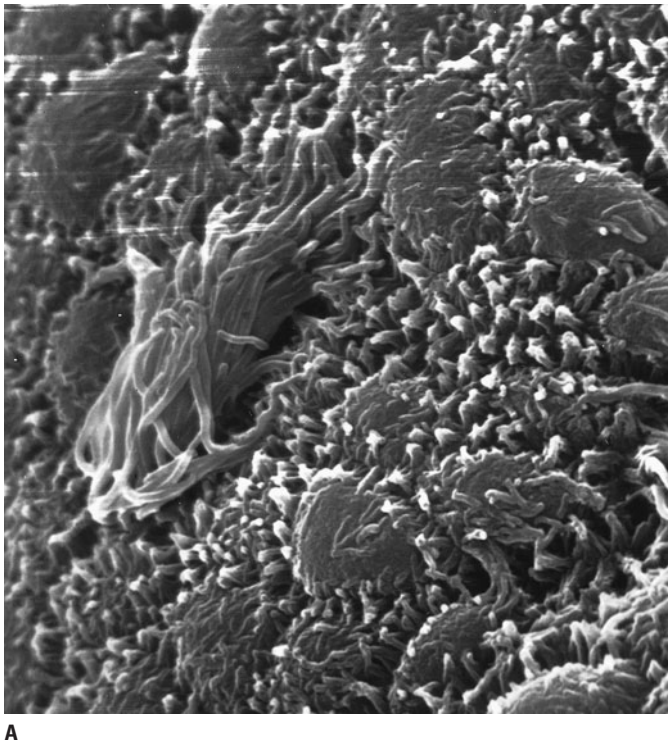
The *proliferative phase* begins when the endometrial glands enlarge, becoming twisted and longer, in response to increasing amounts of estrogen. The blood vessels become prominent and dilated, and the endometrium increases in thickness sixfold to eightfold. This gradual process reaches its peak just before ovulation. The cervical mucus becomes thin, clear, watery, and more alkaline, making the mucus more favorable to spermatozoa. As ovulation nears, the cervical mucus shows increased elasticity, called *spinnbarkheit.* At ovulation, the mucus will stretch more than 5 cm. The cervical mucosa pH increases from below 7 to 7.5 at the time of ovulation. On microscopic examination, the mucus shows a characteristic fern pattern (see Figure 12-4B on page 249). This fern pattern is a useful aid in assessment of ovulation time (Table 10-2). For an in-depth discussion, see chapter 12 ∞.

The *secretory phase* follows ovulation. The endometrium, under estrogenic influence, undergoes slight cellular growth. Progesterone, however, causes such marked swelling and growth that the epithelium is warped into folds (Figure 10-21 ■). The amount of tissue glycogen increases. The glandular epithelial cells begin to fill with cellular debris, and the glands become tortuous and dilate. The glands secrete small quantities of endometrial fluid in preparation for a fertilized ovum. The vascularity of the entire uterus increases greatly, providing a nourishing bed for implantation. If implantation occurs, the endometrium, under the influence of progesterone, continues to develop and becomes even thicker (Figure 10-22 ■). See chapter 11 ∞ for an in-depth discussion of implantation.

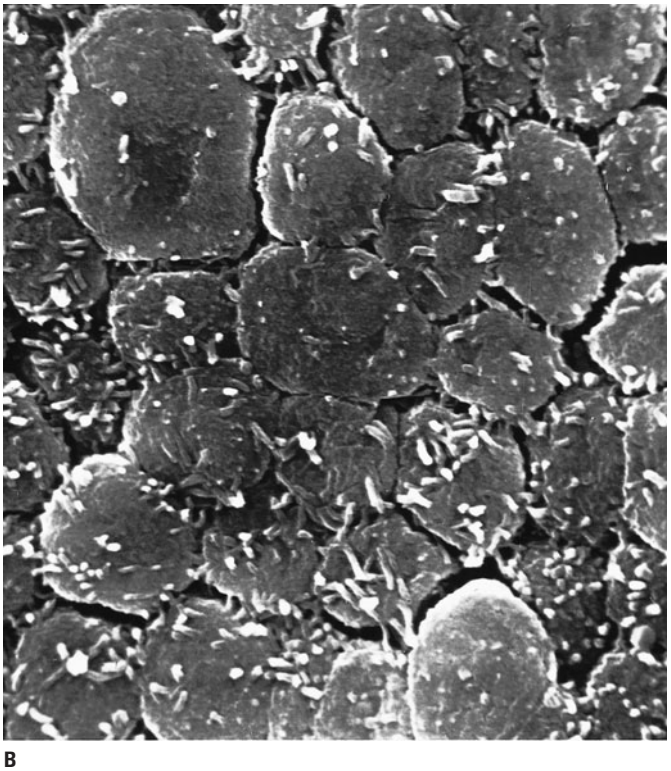
If fertilization does not occur, the *ischemic phase* begins. The corpus luteum begins to degenerate, and as a result both estrogen and progesterone levels fall. Areas of necrosis appear under the epithelial lining. Extensive vascular changes also occur. Small blood vessels rupture, and the spiral arteries constrict and retract, causing a deficiency of blood in the endometrium, which becomes pale. This ischemic phase is characterized by the escape of blood into the stromal cells of the uterus. The menstrual flow begins, thus beginning the menstrual cycle again. After menstruation, the basal layer remains so that the tips of the glands can regenerate the new functional endometrial layer. See Table 10-3 for a summary of the female reproductive cycle.

Male Reproductive System

The primary reproductive functions of the male genitals are to produce and transport the male sex cells (sperm) through and eventually out of the genital tract into the female genital tract. The male reproductive system consists of the external and internal genitals (Figure 10-23 ■).



A



B

Figure 10-21 ■ Scanning electron micrographs of the uterine lining during different phases of the uterine cycle. A. During the luteal phase, some of the cells have cilia, and some are secreting droplets. The secreting cells are covered with microvilli. B. In the secretory phase, microvilli are still present on the surface of the secreting cells, but the general surface of the lining has a lumpier appearance than during the proliferative phase, and the cilia appear shorter and less numerous. The named phases refer to the uterine condition at the time the photographs were taken.

TABLE 10-3 Summary of Female Reproductive Cycle

Ovarian Cycle

Follicular phase (days 1–14): Primordial follicle matures under influence of FSH and LH up to the time of ovulation.

Luteal phase (days 15–28): Ovum leaves follicle, corpus luteum develops under LH influence and produces high levels of progesterone and low levels of estrogen.

Menstrual Cycle

Menstrual phase (days 1–6): Estrogen levels are low, cervical mucus is scant, viscous, and opaque.

Proliferative phase (days 7–14): Estrogen peaks just prior to ovulation. Cervical mucus at ovulation is clear, thin, watery, alkaline, and more favorable to sperm; shows fern pattern; and has spinnbarkheit greater than 5 cm. At ovulation body temperature drops, then rises sharply and remains elevated under influence of progesterone.

Secretory phase (days 15–26): Estrogen drops sharply, and progesterone dominates.

Ischemic phase (days 27–28): Both estrogen and progesterone levels drop.

External Genitals

The two external reproductive organs are the penis and the scrotum.

Penis

The *penis* is an elongated, cylindrical structure consisting of a body, termed the *shaft,* and a cone-shaped end called the *glans.* The penis lies in front of the scrotum. The shaft of the penis is made up of three longitudinal columns of erectile tissue: the paired *corpora cavernosa* and a third, the *corpus spongiosum.* These columns are covered by a dense, fibrous connective tissue and then enclosed by an elastic tissue. The penis is covered by a thin outer layer of skin.

The corpus spongiosum contains the urethra and becomes the glans at the distal end of the penis. The urethra widens within the glans and ends in a slitlike orifice, located in the tip of the glans, called the *urethral meatus.* A circular fold of skin arises just behind the glans and covers it. Known as the *prepuce,* or *foreskin,* it is frequently removed by the surgical procedure of circumcision (see chapter 31 ∞). If the corpus spongiosum does not surround the urethra completely, the urethral meatus may occur on the ventral aspect of the penile shaft (hypospadias) or on the dorsal aspect (epispadias).

The penis is innervated by the pudendal nerve. Sexual stimulation causes the penis to elongate, thicken, and stiffen, a process called *erection.* The penis becomes erect when its blood vessels become engorged, a consequence of parasympathetic nerve stimulation. If sexual stimulation is intense enough, the forceful and sudden expulsion of semen occurs

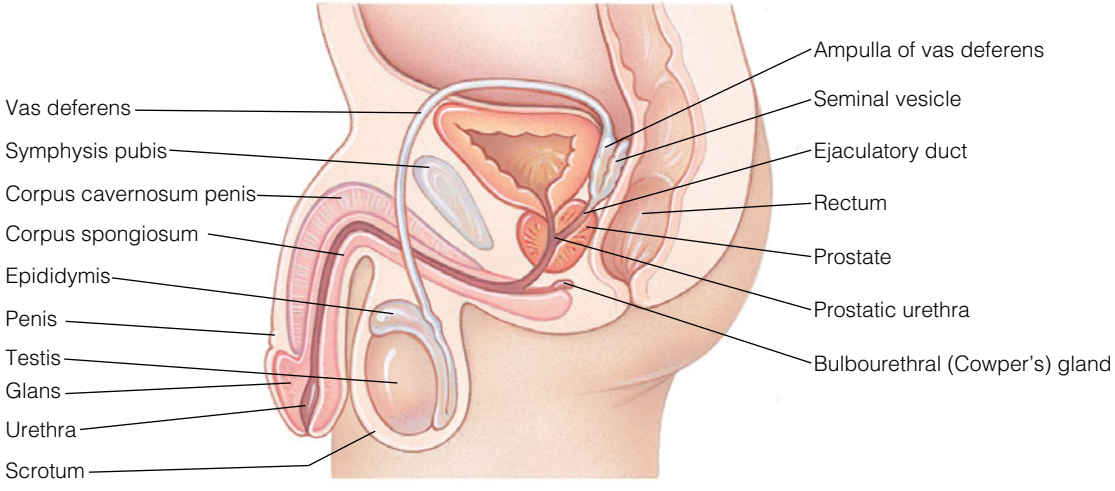

Figure 10-23 ■ Male reproductive system, sagittal view.

through the rhythmic contractions of the penile muscles. This phenomenon is called *ejaculation.*

The penis serves both the urinary and reproductive systems. Urine is expelled through the urethral meatus. The primary reproductive function of the penis is to deposit sperm in the female vagina during sexual intercourse so that fertilization of the ovum can occur.

Scrotum

The *scrotum* is a pouchlike structure that hangs in front of the anus and behind the penis. Composed of skin and the *dartos muscle,* the scrotum shows increased pigmentation and scattered hairs. The sebaceous glands open directly onto the scrotal surface; their secretion has a distinctive odor. Contraction of the dartos and cremasteric muscles shortens the scrotum and draws it closer to the body, thus wrinkling its outer surface. The degree of wrinkling is greatest in young men and at cold temperatures and is least in older men and at warm temperatures.

Inside the scrotum are two lateral compartments. Each compartment contains a testis with its related structures. Because the left spermatic cord grows longer, the left testis and its scrotal sac hang lower than the right. A ridge (raphe) on the external scrotal surface marks the position of the medial septum and continues anteriorly on the urethral surface of the penis but disappears in the perineal area.

The function of the scrotum is to protect the testes and the sperm by maintaining a temperature lower than that of the body. Spermatogenesis will not occur if the testes fail to descend and thus remain at body temperature. Because it is sensitive to touch, pressure, temperature, and pain, the scrotum defends against potential harm to the testes.

Male Internal Reproductive Organs

The male internal reproductive organs include the gonads (testes or testicles), a system of ducts (epididymis, vas deferens, ejaculatory duct, and urethra), and accessory glands (seminal vesicles, prostate gland, bulbourethral glands, and urethral glands). See Table 10-4 for a summary of male reproductive organ functions.

Testes

The *testes* are a pair of oval compound glandular organs contained in the scrotum (Figure 10-24 ■). In the sexually mature male, they are the site of spermatozoa (male gamete) production and the secretion of several male sex hormones.

Each testis is 4 to 6 cm long, 2 to 3 cm wide, and 3 to 4 cm deep and weighs 10 to 15 g. Each testis is covered by a serous membrane and an inner capsule that is tough, white, and fibrous. The connective tissue sends projections inward to form septa, dividing the testis into 250 to 400 lobules. Each lobule contains one to three tightly packed, convoluted *seminiferous tubules* containing sperm cells in all stages of development.

The seminiferous tubules are surrounded by loose connective tissue, which houses abundant blood and lymph vessels and the *interstitial (Leydig's) cells.* The interstitial cells produce testosterone, the primary male sex hormone. The tubules also contain Sertoli's cells, which nourish and protect the spermatocytes. The seminiferous tubules come together to form the 20 or 30 straight tubules, which in turn form an anastomosing network of thin-walled spaces, the rete testis. The rete testis forms 10 to 15 efferent ducts that empty into the duct of the epididymis.

TABLE 10-4 Summary of Male Reproductive Organ Functions

- The testes house seminiferous tubules and the gonads.
- Seminiferous tubules contain sperm cells in various stages of development and undergoing meiosis.
- Sertoli's cells nourish and protect spermatocytes (phase between spermatids and spermatozoa).
- Leydig's cells are the main source of testosterone.
- Epididymides provide an area for maturation of sperm and a reservoir for mature spermatozoa.
- The vas deferens connects the epididymis with the prostate gland and then connects with ducts from the seminal vesicle to become an ejaculatory duct.
- Ejaculatory ducts provide a passageway for semen and seminal fluid into the urethra.
- Seminal vesicles secrete yellowish fluid rich in fructose, prostaglandins, and fibrinogen. This provides nutrition that increases motility and fertilizing ability of sperm. Prostaglandins also aid fertilization by making the cervical mucus more receptive to sperm.
- The prostate gland secretes thin, alkaline fluid containing calcium, citric acid, and other substances. Alkalinity counteracts acidity of ductus and seminal vesicle secretions.
- Bulbourethral (Cowper's) glands secrete alkaline, viscous fluid into semen, aiding in neutralization of acidic vaginal secretions.

WebMD Anatomy

Most of the cells lining the seminiferous tubules undergo *spermatogenesis,* a process of maturation in which spermatocytes become spermatozoa. (See chapter 11 ∞ for further discussion of spermatogenesis.) Sperm production varies among and within the tubules, with cells in different areas of the same tubule undergoing different stages of spermatogenesis. The sperm are eventually released from the tubules into the epididymis, where they mature further.

Like the female reproductive cycle, the process of spermatogenesis and other functions of the testes are the result of complex neural and hormonal controls. The hypothalamus secretes releasing factors, which stimulate the anterior pituitary to release the gonadotropins—follicle-stimulating hormone (FSH) and luteinizing hormone (LH). These hormones cause the testes to produce testosterone, which maintains spermatogenesis, increases sperm production by the seminiferous tubules, and stimulates production of seminal fluid.

Testosterone is the most prevalent and potent of the testicular hormones. It is also responsible for the development of secondary male characteristics and certain behavioral patterns. The effects of testosterone include structural and functional development of the male genital tract, emission and ejaculation of seminal fluid, distribution of body hair, promotion of growth and strength of long bones, increased muscle mass, and enlargement of the vocal cords. The action of testosterone on the central nervous system is thought to produce aggressiveness and sexual drive. The action of testosterone is constant, not cyclic like that of the female hormones.

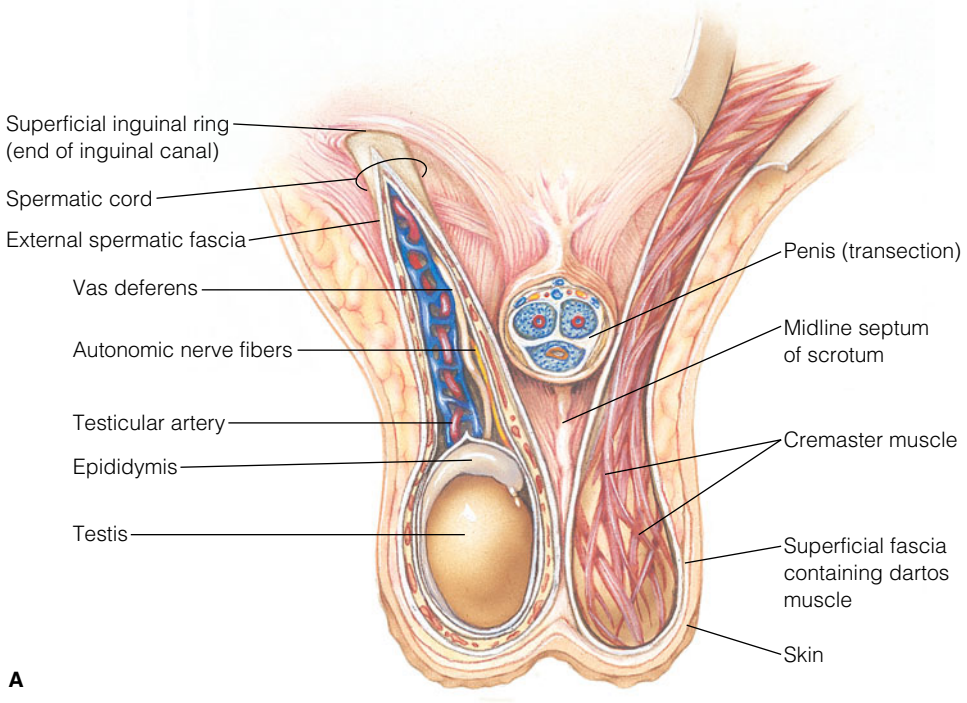

Figure 10-24 ■ The testes: A. External view. B. Sagittal view showing interior anatomy.

Its production is not limited to a certain number of years but is thought to decrease with age.

The testes have two primary functions:

- To serve as the site of spermatogenesis
- To produce testosterone

Epididymis

The *epididymis* (plural, *epididymides*) is a duct about 5.6 m long although it is convoluted into a compact structure about 3.75 cm long. An epididymis lies behind each testis. It arises from the top of the testis, extends downward, and then passes upward, where it becomes the vas deferens.

The epididymis provides a reservoir where spermatozoa can survive for a long period. When discharged from the seminiferous tubules into the epididymis, the sperm are immobile and incapable of fertilizing an ovum. The spermatozoa usually remain in the epididymis for 2 to 10 days but can be stored in the body for up to 42 days. As the sperm are transported along the tortuous course of the epididymis, they become both motile and fertile.

Vas Deferens and Ejaculatory Ducts

The *vas deferens,* also known as the *ductus deferens,* is about 40 cm long and connects the epididymis with the prostate (see Figure 10-23). One vas deferens arises from the posterior border of each testis. It joins the spermatic cord and weaves over and between several pelvic structures until it meets the vas deferens from the opposite side. Each vas deferens terminus expands to form the *terminal ampulla.* It then unites with the seminal vesicle duct (a gland) to form the ejaculatory duct, which enters the prostate gland and ends in the prostatic urethra. The ejaculatory ducts serve as a passageway for semen and fluid secreted by the seminal vesicles. The main function of the vas deferens is to rapidly squeeze the sperm from their storage sites (the epididymis and distal part of the vas deferens) into the urethra.

Men who choose to take total responsibility for birth control may elect to have a vasectomy. In this procedure, the scrotal portion of the vas deferens is surgically incised or cauterized. Although sperm continue to be produced for the next several years, they can no longer reach the outside of the body. Eventually, the sperm deteriorate and are reabsorbed.

Activities: Male Reproductive System

Urethra

The *male urethra* is a passageway for urine and semen. The urethra begins in the bladder and passes through the prostate gland, where it is called the *prostatic urethra.* The urethra emerges from the prostate gland to become the *membranous urethra.* It terminates in the penis, where it is called the *penile urethra.* In the penile urethra, goblet secretory cells are present, and smooth muscle is replaced by erectile tissue.

Accessory Glands

The male accessory glands secrete a unique and essential component of the total seminal fluid in an ordered sequence.

The *seminal vesicles* are two glands composed of many lobes. Each vesicle is about 7.5 cm long. They are situated between the bladder and rectum and immediately above the base of the prostate. The epithelium lining the seminal vesicles secretes an alkaline, viscous, clear fluid rich in high-energy fructose, prostaglandins, fibrinogen, and amino acids. During ejaculation this fluid mixes with sperm in the ejaculatory ducts. This fluid helps provide an environment favorable to sperm motility and metabolism.

The prostate gland encircles the upper part of the urethra and lies below the neck of the bladder. Made up of several lobes, it measures about 4 cm in diameter and weighs 20 to 30 g. The prostate is made up of both glandular and muscular tissue. It secretes a thin, milky, alkaline fluid containing high levels of zinc, calcium, citric acid, and acid phosphatase. This fluid protects the sperm from the acidic environment of the vagina and the male urethra, which could be spermicidal.

The *bulbourethral glands (Cowper's glands)* are a pair of small round structures on either side of the membranous urethra. The glands secrete a clear, thick, alkaline fluid rich in mucoproteins that becomes part of the semen. This secretion also lubricates the penile urethra during sexual excitement and neutralizes the acid in the male urethra and the vagina, thereby enhancing sperm motility.

The *urethral glands (Littre's glands)* are tiny mucus-secreting glands found throughout the membranous lining of the penile urethra. Their secretions add to those of the bulbourethral glands.

Semen

The male ejaculate, *semen* or *seminal fluid,* is made up of spermatozoa and the secretions of all the accessory glands. The seminal fluid transports viable and motile sperm to the female reproductive tract. Effective transportation of sperm requires adequate nutrients, an adequate pH (about 7.5), a specific concentration of sperm to fluid, and an optimal osmolarity.

A spermatozoon is made up of a head and a tail (Figure 10-25 ■). The head's main components are the acrosome and the nucleus. The head carries the male's haploid number of chromosomes (23), and it is the part that enters the ovum at fertilization (see chapter 11 ∞). The tail, or *flagellum,* is specialized for motility. The tail is divided into the middle and end piece.

Sperm may be stored in the male genital system up to 42 days, depending primarily on the frequency of ejaculations. The average volume of ejaculate following abstinence for several days is 2 to 5 ml but may vary from 1 to 10 ml. Repeated ejaculation results in decreased volume. Once ejaculated, sperm can live only 2 or 3 days in the female genital tract.

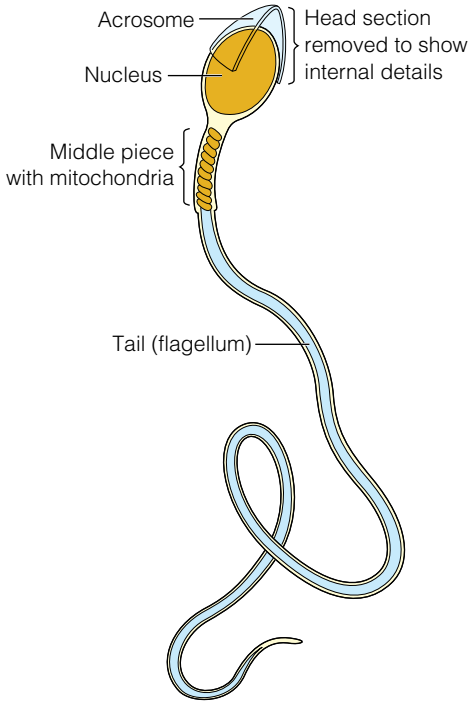

Figure 10-25 ■ Schematic illustration of a mature spermatozoon.

FOCUS YOUR STUDY

- The genetic sex of an embryo is determined at fertilization. The male and female reproductive systems are undifferentiated initially. By the 12th week the external genitals are fully differentiated.
- Reproductive activities require complex interactions between the reproductive structures; the central nervous system; and such endocrine glands as the pituitary, hypothalamus, testes, and ovaries.
- At puberty, an alteration in brain sensitivity leads to an increased release of gonadotropin-releasing hormone (GnRH), which stimulates luteinizing hormone (LH) and follicle-stimulating hormone (FSH), leading in the male to an increase in testosterone and in the female to an increase in estrogen and progesterone.
- Estrogen is the principal cause of the events of puberty in females (maturation of ova, enlargement of the uterus and fallopian tubes, deposition of fat in the breasts and hips, and characteristic hair growth).
- Puberty changes for the male (onset of spermatogenesis; enlargement of the penis, scrotum, and testes; voice changes; and characteristic hair growth) occur as a result of increased testosterone production by the testes.
- The female reproductive system consists of the ovaries, where female germ cells and female sex hormones are formed; the fallopian tubes, which capture the ovum and allow transport to the uterus; the uterus, which is the implantation site for the fertilized ovum (blastocyst); the cervix, which is a protective portal for the body of the uterus and the connection between the vagina and the uterus; and the vagina, which is the passageway from the external genitals to the uterus and provides for discharge of menstrual products to the outside of the body.
- The female reproductive cycle may be described in terms of the ovarian cycle, during which ovulation occurs, and the menstrual cycle, during which menstruation occurs. These two cycles take place simultaneously and are under neurohormonal control.
- The ovarian cycle has two phases: the follicular phase and the luteal phase. During the follicular phase, the primordial follicle matures under the influence of FSH and LH until ovulation occurs. The luteal phase begins when the ovum leaves the follicle and the corpus luteum develops under the influence of LH. The corpus luteum produces high levels of progesterone and low levels of estrogen.
- The menstrual cycle has four phases: menstrual, proliferative, secretory, and ischemic. Menstruation is the actual shedding of the endometrial lining, when estrogen levels are low. The proliferative phase begins when the endometrial glands begin to enlarge under the influence of estrogen and cervical mucosal changes occur; the changes peak at ovulation. The secretory phase follows ovulation, and, influenced primarily by progesterone, the uterus increases its vascularity to make ready for possible implantation. The ischemic phase is characterized by degeneration of the corpus luteum, decreases in both estrogen and progesterone levels, constriction of the spiral arteries, and escape of blood into the stromal cells of the endometrium.
- The male reproductive system consists of the testes, where male germ cells and male sex hormones are formed; a series of continuous ducts through which spermatozoa are transported outside the body; accessory glands that produce secretions important to sperm nutrition, survival, and transport; and the penis, which serves as the reproductive organ of intercourse.

CRITICAL THINKING IN ACTION

You are working in the OB/GYN clinic when Sally Smith, a 17-year-old teenager, comes in complaining of irregular menses. She believes her periods are really "messed up" and interfering with her active schedule. She wants them to be more regular and asks you for birth control. She tells you that she is a member of the swimming team and is a senior in high school. She says she is planning to start community college next year to obtain an associate degree in computer technology. You assess Sally's history as follows: menarche began at age 12; periods occur every 28 to 32 days. She usually experiences cramping in the first 2 days and the flow lasts 4 to 5 days. She uses an average of 4 to 5 tampons a day during her period. She has never been hospitalized, has no prior medical problems, and is up-to-date on her immunizations except for meningitis.

1. Based on your knowledge of menstruation, how would you describe Sally's menstrual cycle?
2. What is your primary goal in discussing Sally's menstrual cycle with her?
3. What information would you give Sally relating to her menstrual cycle?
4. What important request does Sally have?
5. Sally expresses problems dealing with the cramping she experiences with the first 2 days of her menses. What would you suggest to Sally to cope with the discomfort?

CHAPTER 11

Conception and Fetal Development

My friends tease me when I say this, but I know the moment my daughter was conceived. My husband and I had both been so busy at work, but we finally went away for a long weekend together. It was wonderful—we got back some of the magic as we took long walks and talked and talked. Until that weekend, whenever we discussed having children it was always "maybe someday." On the second night we decided to skip the birth control for the first time ever. Our lovemaking seemed so special that evening, a true reflection of the emotional closeness we had recaptured. I never went back to using birth control after that weekend, but I am convinced that Jennifer is the result of that night together!

LEARNING OUTCOMES

1. Differentiate between mitotic cellular division and meiotic cellular division.
2. Compare the processes by which ova and sperm are produced.
3. Analyze the components of the process of fertilization as to how each may impact fertilization.
4. Analyze the processes that occur during the cellular multiplication and differentiation stages of intrauterine development and their effects on the structures that form.
5. Compare the factors and processes by which fraternal (dizygotic) and identical (monozygotic) twins are formed.
6. Describe the development, structure, and functions of the placenta and umbilical cord during intrauterine life (embryonic and fetal development).
7. Summarize the significant changes in growth and development of the fetus at 4, 6, 12, 16, 20, 24, 28, 32, 36, and 40 weeks' gestation.
8. Identify the factors that influence congenital malformations of the organ systems and the resulting congenital malformations.

The human genome contains *genes*, which are units of genetic information. Genes are encoded in the deoxyribonucleic acid (DNA) that makes up the chromosomes in the nucleus of each cell. These chromosomes, which determine the structure and function of organ systems and traits, are of the same biochemical substances. How then does each person become unique? The answer lies in the physiologic mechanisms of heredity, the processes of cellular division, and the environmental factors that influence our development from the moment we are conceived. This chapter explores the processes involved in conception and fetal development—the basis of human uniqueness.

Chromosomes

Human (body) cells contain within their nuclei threadlike bodies known as **chromosomes**, which are composed of strands of deoxyribonucleic acid (DNA) and protein. Each chromosome contains two longitudinal halves called *chromatids,* which are joined together at a point called the *centromere* (Figure 11-1A ■). Chromosomes are classified according to their length and to the position of their centromere. When the centromere is centrally located, the longitudinal halves are divided into one short arm region and one long arm region, and the chromosome resembles an X. This is the shape of most human chromosomes.

Every body (somatic) cell in the human body contains 46 chromosomes, referred to as the **diploid number of chromosomes**. These are divided into 23 pairs. There are 22 pairs of similar cells in both males and females, called *autosomes,* and one pair of sex chromosomes (XX in females, XY in males). One chromosome of each pair is contributed by the individual's mother, and the other is contributed by the father. The two chromosomes carrying matching genetic information that make up each pair are called *homologous chromosomes* or *homologs.*

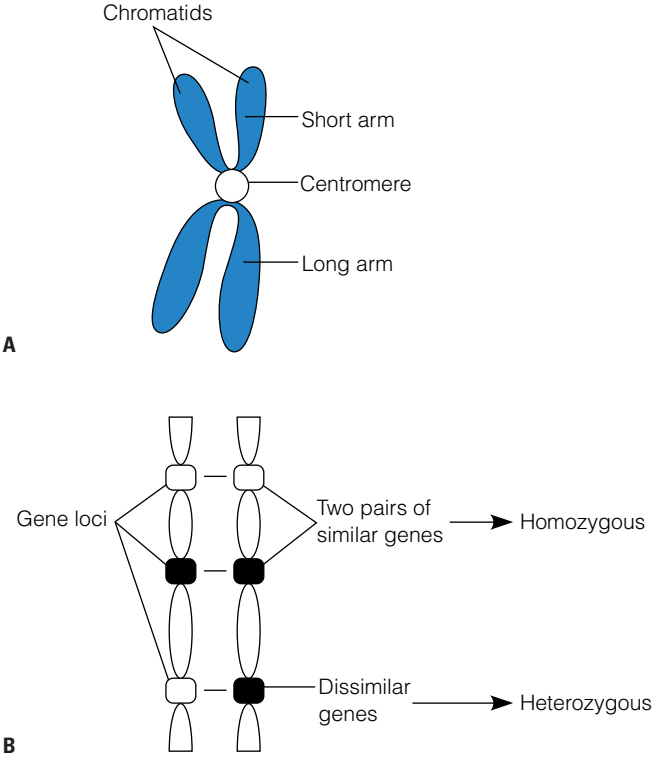

Figure 11-1 ■ A. Chromosomes contain two longitudinal halves called *chromatids,* which are joined together at a point called the *centromere.* B. One pair of homologous chromosomes with similar (homozygous) genes and dissimilar (heterozygous) genes.

Genes are regions in the DNA strands that contain coded information used to determine the unique characteristics—or *traits*—of an individual. Genes in the autosomes determine such traits as hair color or blood type, whereas genes in the sex chromosomes determine the individual's gender. Genes are arranged in linear order on the chromosomes and can be numbered and studied accordingly.

Each homologous chromosome pair carries genes coding for similar traits in identical locations on the chromosomes. Genes that are similar are called *homozygous* genes, whereas dissimilar genes are referred to as *heterozygous* genes (Figure 11-1B ■). When an individual is homozygous for a particular trait, he or she has inherited similar genes for that trait from each parent. Genetics is discussed in greater detail in chapter 12 ∞.

Cellular Division

Each human begins life as a single cell called a fertilized ovum or zygote. This single cell reproduces itself, and in turn each new cell also reproduces itself in a continuing process. The new cells are similar to the cells from which they came. Cells are reproduced either by mitosis or meiosis, two different but related processes.

Mitosis

Mitosis is a process of cell division that results in daughter cells that are exact copies of the original cell. During mitosis, the cell undergoes several changes, ending in cell division. As the last phase of cell division nears completion, a furrow develops in the cell cytoplasm, which divides it into two daughter cells, each with its own nucleus. They are identical to the parent cell and to each other. These cells contain a full set of chromosomes or genetic material and are called diploid because of this. Mitosis makes growth and development possible, and in mature individuals it is the process by which the (somatic) body cells continue to divide and replace themselves.

Although mitosis is a continuous process, it is generally divided into five stages: interphase, prophase, metaphase, anaphase, and telophase (Figure 11-2A ■).

Interphase: Before cell division takes place during interphase, the deoxyribonucleic acid (DNA) within the chromosomes replicates so that the genes will be doubled. Mitosis begins when the cell enters prophase.

Prophase: During prophase, the chromosomes condense and form the shape we usually recognize as a chromosome. Next comes the appearance of a mitotic apparatus known as a spindle, in which fine threads extend from the top and bottom poles of the nucleus. At each pole of the spindle, a body known as the *centrosome* is formed, so the threads of the spindle extend from one centrosome to the other. Next the nuclear membrane, which separates the nucleus from the cytoplasm,

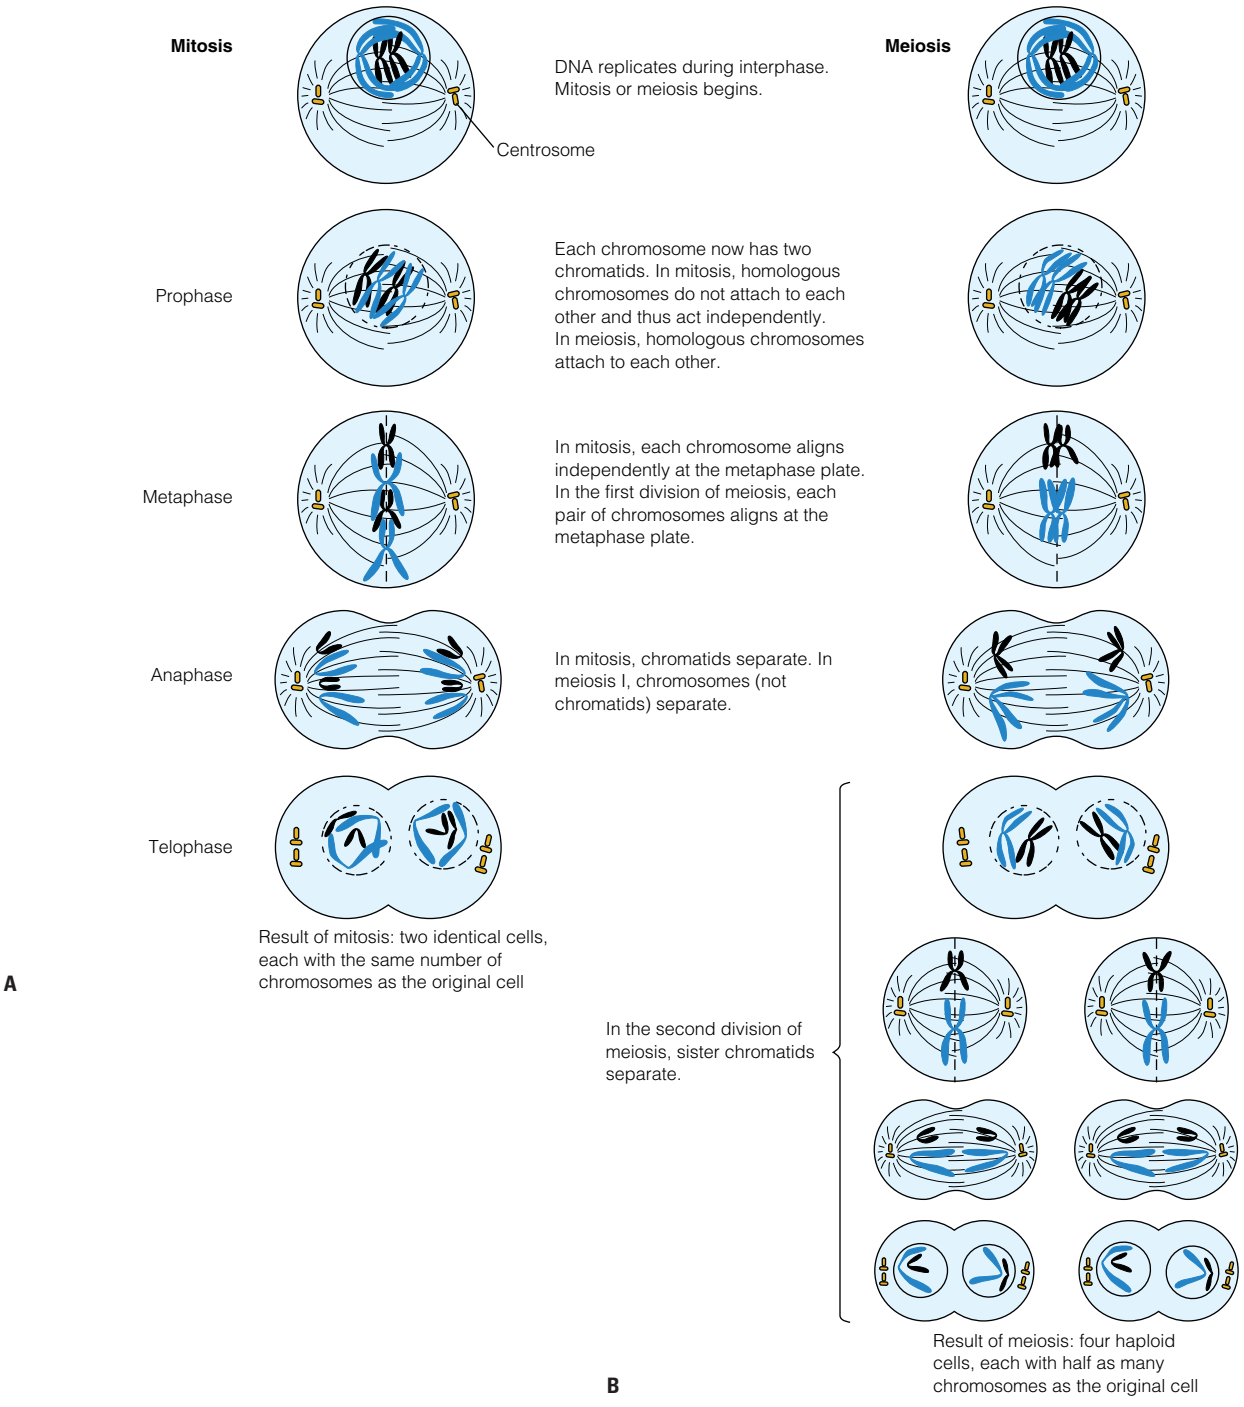

Figure 11-2 ■ Comparison of: A. Mitosis. B. Meiosis.

disappears, the nucleus as a separate entity disappears, and the cell enters metaphase.

Metaphase: During metaphase, the chromosomes line up at the equator (midway between the poles) of the spindle. Metaphase is followed by anaphase.

Anaphase: During anaphase the two chromatids of each chromosome separate and move to opposite ends of the spindle, where they cluster in masses near the two poles of the cell.

Telophase: Essentially the opposite of prophase, during telophase a new nuclear membrane forms, separating each newly formed nucleus from the cytoplasm. The spindle disappears, and the centrioles relocate outside of each new nucleus. Within the nucleus the chromosomes lengthen and become threadlike. As telophase nears completion, a furrow develops in the cell cytoplasm and divides it into two daughter cells, each with its own nucleus. Daughter cells have the same diploid number of chromosomes (46) and the same genetic makeup as the cell from which they came. At the end of mitosis, a cell with 46 chromosomes results in two identical cells, each with 46 chromosomes.

Meiosis

Meiosis is a special type of cell division by which diploid cells give rise to **gametes** (sperm and ova). These cells are different from other somatic (body) cells because they contain half the genetic material of the parent cell—only 23 chromosomes—the **haploid number of chromosomes**.

Meiosis consists of two successive cell divisions (see Figure 11-2B ■). In the first division, the chromosomes replicate. Next a pairing takes place between homologous chromosomes (Sadler, 2010). Instead of separating immediately, as in mitosis, the similar chromosomes become closely intertwined. At each point of contact, there is a physical exchange of genetic material between the chromatids (arms of the chromosomes). New combinations are provided by the newly formed chromosomes; these combinations account for the wide variation of traits, such as hair or eye color. The chromosome pairs then separate, each member of a pair moving to opposite sides of the cell. (In contrast, during mitosis the chromatids of each chromosome separate and move to opposite poles.) The cell divides, forming two daughter cells, each with 23 double-structured chromosomes—the same amount of DNA as a normal somatic cell. In the second division, the chromatids of each chromosome separate and move to opposite poles of each of the daughter cells. Cell division occurs, resulting in the formation of four cells, each containing 23 single chromosomes, the haploid number of chromosomes. These daughter cells contain only half the DNA of a normal somatic cell (Sadler, 2010).

The process of meiosis is important for the following reasons:

- It maintains the *constancy of the chromosome number* from one generation to the next by reducing the chromosome number from diploid to haploid, thereby producing haploid gametes.
- It allows random assortment of *maternal and paternal chromosomes* between the gametes.
- It relocates segments of maternal and paternal chromosomes by *crossing over of chromosome segments,* which "shuffles" the genes and produces a recombination of genetic material.

Mutations may occur during the second meiotic division if two of the chromatids do not move apart rapidly enough when the cell divides. The still-paired chromatids are carried into one of the daughter cells and eventually form an extra chromosome. This condition is referred to as an *autosomal nondisjunction* (chromosomal mutation) and is harmful to the offspring that may result should fertilization occur. Another type of chromosomal mutation can occur if chromosomes break during meiosis. If the broken segment is lost, the result is a shorter chromosome; this is known as a *deletion.* If the broken segment becomes attached to another chromosome, a harmful mutation called a *translocation* is the result. The effects of nondisjunction and translocation are described in chapter 12 ∞. See Table 11-1 for a comparison of meiosis and mitosis.

TABLE 11-1 Comparison of Meiosis and Mitosis

	Meiosis	Mitosis
Purpose	Produce reproductive cells (gametes). Reduction of chromosome number by half (from diploid [46] to haploid [23]), so that when fertilization occurs the normal diploid number is restored. Introduces genetic variability.	Produce cells for growth and tissue repair. Cell division characteristic of all somatic cells.
Cell Division	Two-stage reduction.	One-stage cell division.
Number of Daughter Cells	Four daughter cells, each containing one half the number of chromosomes as the mother cell, or 23 chromosomes. Nonidentical to original cell.	Two daughter cells identical to the mother cell, each with the diploid number (46 chromosomes).

Oogenesis | Spermatogenesis | Oogenesis and Spermatogenesis Compared

Gametogenesis

Meiosis occurs during **gametogenesis**, the process by which germ cells, or gametes (ovum and sperm), are produced. These cells contain only half the genetic material of a typical body cell. The gametes must have a haploid number (23) of chromosomes so that when the female gamete (egg or ovum) and the male gamete (sperm or spermatozoon) unite to form the **zygote** (fertilized ovum), the normal human diploid of chromosomes (46 chromosomes)—half of it from the mother and half from the father, is reestablished.

Oogenesis

Oogenesis is the process that produces the female gamete, called an ovum (egg). As discussed in chapter 10 ∞, the ovaries begin to develop early in the fetal life of the female. All the ova that the female will produce in her lifetime are present at birth. The ovary gives rise to oogonial cells, which develop into oocytes. Meiosis (cell replication by division) begins in all oocytes before the female infant is born but stops before the first division is complete and remains in this arrested phase until puberty. During puberty the mature primary oocyte continues through the first meiotic division in the graafian follicle of the ovary.

The first meiotic division produces two cells of unequal size with different amounts of cytoplasm but with the same number of chromosomes. One of these cells is the *secondary oocyte* and the other is a minute *polar body.* Both the secondary oocyte and the first polar body contain 22 double-structured autosomal chromosomes and one double-structured sex chromosome (X).

At the time of ovulation, the second meiotic division begins immediately and proceeds as the oocyte moves down the fallopian tube. Division is again not equal, and the secondary oocyte moves into the metaphase stage of cell division, where its meiotic division is arrested until and unless the oocyte is fertilized.

When the secondary oocyte completes the second meiotic division after fertilization, the result is a mature ovum with

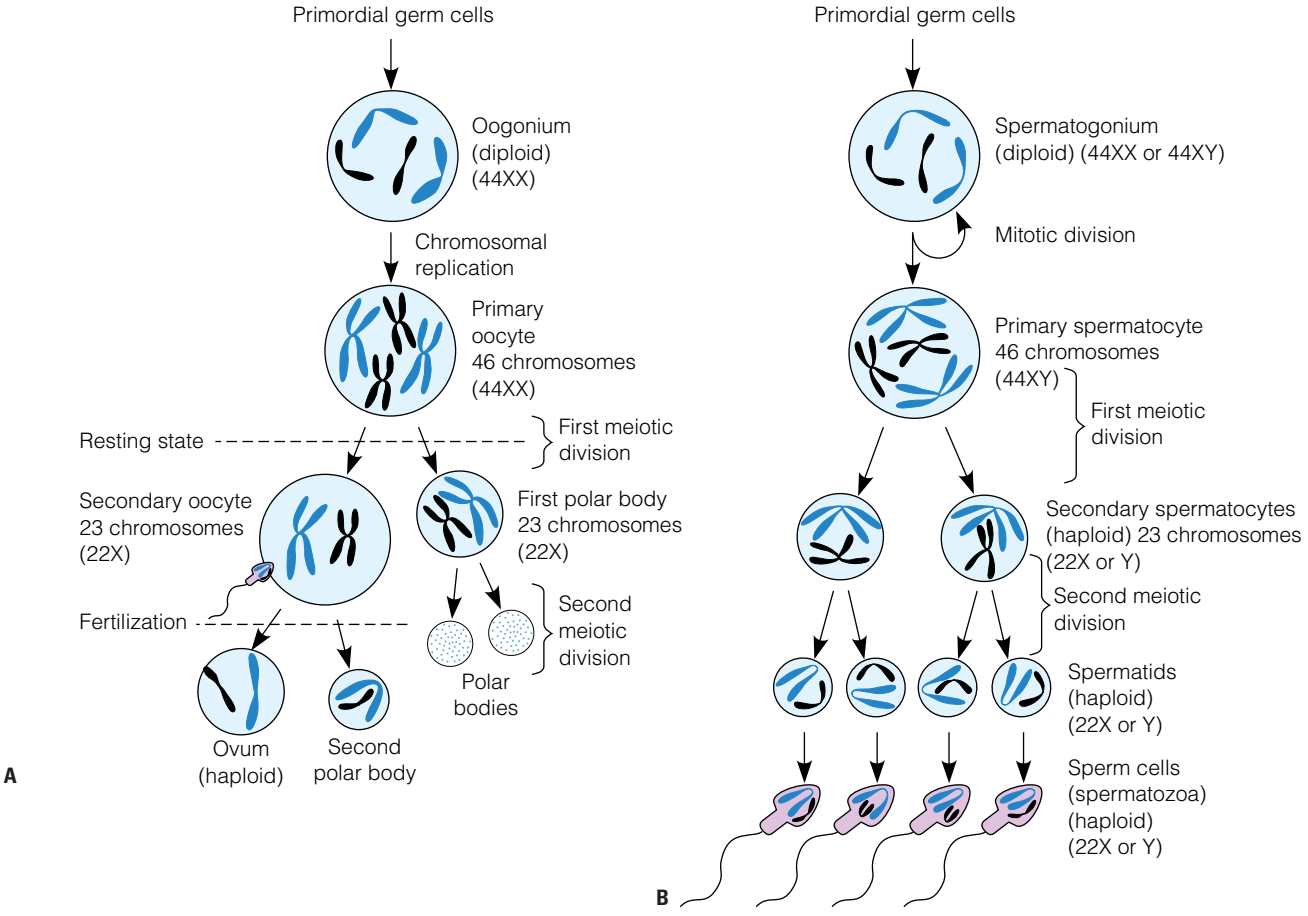

Figure 11-3 ■ Gametogenesis involves meiosis within the ovary and testis. A. During meiosis, each oogonium produces a single haploid ovum once some cytoplasm moves into the polar bodies. B. Each spermatogonium, in contrast, produces four haploid spermatozoa.

Activity: Matching Oogenesis and Spermatogenesis

the haploid number of chromosomes and virtually all the cytoplasm. In addition, the second polar body (also haploid) forms at this time (Figure 11-3A ■). The first polar body has now also divided, producing two additional polar bodies. Thus when meiosis is completed, four haploid cells have been produced: three small polar bodies, which eventually disintegrate, and one ovum (Sadler, 2010).

Spermatogenesis

During puberty, the germinal epithelium in the seminiferous tubules of the testes begins the process of spermatogenesis, which produces the male gametes (sperm). The diploid spermatogonium replicates before it enters the first meiotic division, during which it is called the *primary spermatocyte.* During this first meiotic division, the spermatogonium replicates and forms two haploid cells termed *secondary spermatocytes,* each of which contains 22 double-structured autosomal chromosomes and either a double-structured X sex chromosome or a double-structured Y sex chromosome. During the second meiotic division, they divide to form four spermatids, each with the haploid number of chromosomes (see Figure 11-3B ■). The spermatids undergo a series of changes during which they lose most of their cytoplasm and become sperm (spermatozoa). The nucleus becomes compacted into the head of the sperm, which is covered by a cap called an acrosome that is, in turn, covered by a plasma membrane. A long tail is produced from one of the centrioles.

The Process of Fertilization

Fertilization is the process by which a sperm fuses with an ovum to form a new diploid cell, or zygote. The zygote begins life as a single cell with a complete set of genetic material, 23 chromosomes from the mother's ovum and 23 chromosomes from the father's sperm for a total of 46 chromosomes. The following events lead to fertilization.

Preparation for Fertilization

The mature ovum and spermatozoa have only a brief time to unite. Ova are considered fertile for about 12 to 24 hours after ovulation. Sperm can survive in the female reproductive tract for 48 to 72 hours but are believed to be healthy and highly fertile for only about the first 24 hours.

The ovum's cell membrane is surrounded by two layers of tissue. The layer closest to the cell membrane is called the *zona pellucida.* It is a clear, noncellular layer whose thickness influences the fertilization rate. Surrounding the zona pellucida is a ring of elongated cells, called the *corona radiata,* because they radiate from the ovum like the gaseous corona around the sun. These cells are held together by hyaluronic acid. The ovum has no power of

movement of its own. During ovulation, high estrogen levels increase peristalsis within the fallopian tubes, which helps move the ovum through the tube toward the uterus. The high estrogen levels also cause a thinning of the cervical mucus, easing passage of the sperm through the cervix, into the uterus, and up the fallopian tube.

The process of fertilization usually takes place in the ampulla (outer third) of the fallopian tube. In a single ejaculation, the male deposits approximately 200 to 500 million spermatozoa in the vagina, of which only hundreds of sperm actually reach the ampulla (Sadler, 2010). Fructose in the semen, secreted by the seminal vesicles, is the energy source for the sperm. The spermatozoa propel themselves up the female tract by the flagellar movement of their tails. Transit time from the cervix into the fallopian tube can be as short as 5 minutes but usually takes an average of 2 to 7 hours after ejaculation (Sadler, 2010). Prostaglandins in the semen may increase uterine smooth muscle contractions, which help transport the sperm. The fallopian tubes have a dual ciliary action that facilitates movement of the ovum toward the uterus and movement of the sperm from the uterus toward the ovary.

The sperm must undergo two processes before fertilization can occur: capacitation and the acrosomal reaction. **Capacitation** is the removal of the plasma membrane and glycoprotein coat overlying the spermatozoa's acrosomal area and the loss of seminal plasma proteins. If the glycoprotein coat is not removed, the sperm will not be able to fertilize the ovum (Sadler, 2010). Capacitation occurs in the female reproductive tract (aided by uterine enzymes) and is thought to take about 7 hours. Sperm that undergo capacitation take on three characteristics: (1) the ability to undergo the acrosomal reaction, (2) the ability to bind to the zona pellucida, and (3) the acquisition of hypermotility.

The **acrosomal reaction** follows capacitation. The acrosome caps of the sperm surrounding the ovum release their enzymes (hyaluronidase, a protease called acrosin, and trypsin-like substances). These enzymes break down the hyaluronic acid that holds the elongated cells of corona radiata, the outer layer of the ovum, together (Sadler, 2010). Hundreds of acrosomes must rupture to clear enough hyaluronic acid for even a single sperm to penetrate the ovum successfully.

At the moment of penetration by a fertilizing sperm, the zona pellucida undergoes a reaction that prevents additional sperm from entering a single ovum. This is known as the *block to polyspermy.* This cellular change is mediated by release of materials from the cortical granules, organelles found just below the ovum's surface, and is called the *cortical reaction* (Figure 11-4 ■).

The Moment of Fertilization

After the sperm enters the ovum, a chemical signal prompts the secondary oocyte to complete the second meiotic division, forming the nucleus of the ovum and ejecting the second polar body. Then the nuclei of the ovum and sperm swell and approach each other. The true moment of fertilization occurs as the nuclei unite. Their individual nuclear membranes disappear, and their chromosomes pair up to produce the diploid zygote. Because each nucleus contains a haploid number of chromosomes (23), this union restores the diploid number (46). The zygote contains a new combination of genetic material that results in an individual different from either parent and from anyone else.

It is also at the moment of fertilization that the sex of the zygote is determined. The two chromosomes (the sex chromosomes) of the 23rd pair—either XX or XY—determine the sex of an individual. X chromosomes are larger and bear more genes than Y chromosomes. Females have two X chromosomes, and males have an X and a Y chromosome. The mature ovum produced by oogenesis can have only one type of sex chromosome—an X—while spermatogenesis produces two sperm with an X chromosome and two sperm with a Y chromosome. When each gamete contributes an X chromosome, the resulting zygote is female. When the ovum contributes an X chromosome and the sperm contributes a Y, the resulting zygote is male. As discussed in chapter 12 ∞, certain traits are termed *sex-linked* because they are controlled by the genes on the X sex chromosome. Two examples of sex-linked traits are color blindness and hemophilia.

DEVELOPING CULTURAL COMPETENCE

Iraqi Childbirth Customs

"My sister, she did not have baby for very, very long time, you see. This is very sad where I am from [Iraq]. Her husband's family wanted him to leave her and we so feared he would. Then my sister became pregnant and it was very nice, we all so happy you see. Then I learned my sister birthed a baby girl and I cried and cried for a week. My mother cried too, so sad all this time no baby come and then finally to have a girl. I still feel sad for her."

Source: Excerpt from author's interview with an Iraqi woman on childbirth customs in Iraq.

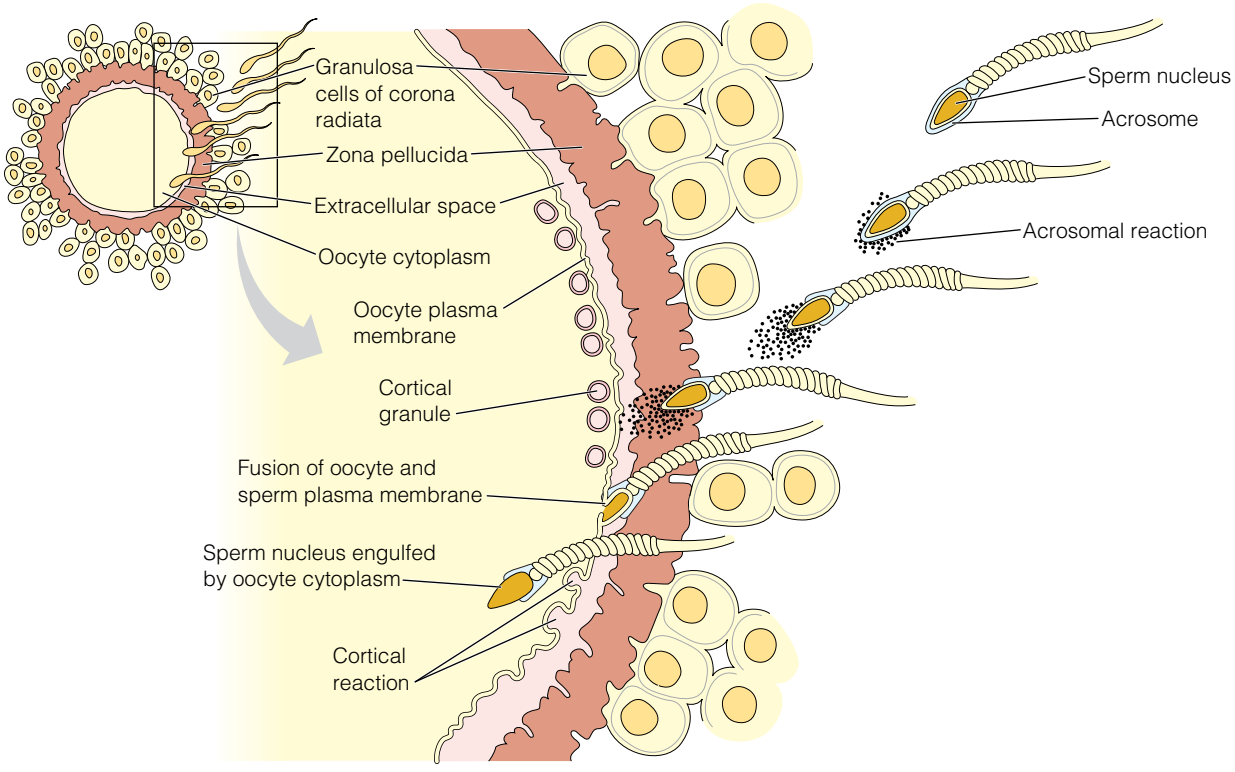
Preembryonic Stage

The first 14 days of human development, starting on the day the ovum is fertilized (conception), are referred to as *the preembryonic stage,* or *the stage of the ovum.* Development after fertilization can be divided into two phases: cellular multiplication and cellular differentiation. These phases are characterized by rapid cellular multiplication and differentiation and the establishment of the primary germ layers and embryonic membranes. Synchronized development of both the endometrium and embryo is a prerequisite for implantation to succeed (Moore & Persaud, 2008). These phases and the process of implantation (nidation), which occurs between them, are discussed next.

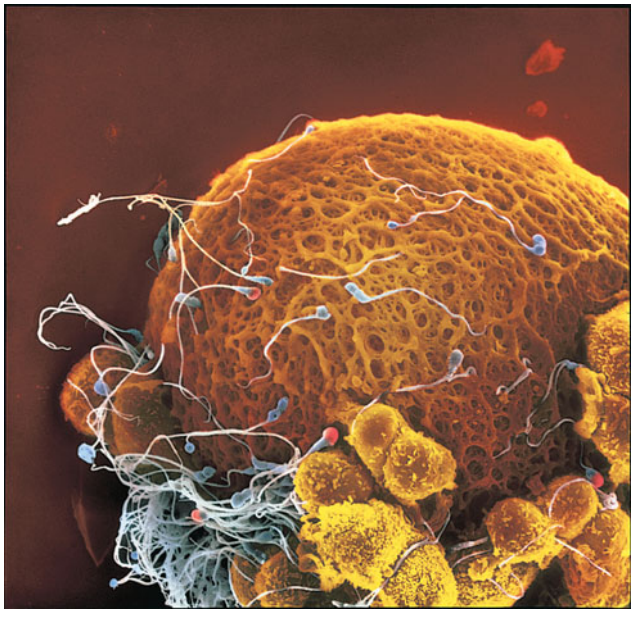
Cellular Multiplication

Cellular multiplication begins as the zygote moves through the fallopian tube toward the cavity of the uterus. This transportation takes 3 days or more and is accomplished mainly by a very weak fluid current in the fallopian tube resulting from the beating action of the ciliated epithelium that lines the tube.

The zygote now enters a period of rapid mitotic divisions called **cleavage**, during which it divides into two cells, four cells, eight cells, and so on. These cells, called *blastomeres,* are so small that the developing cell mass is only slightly larger than the original zygote. The blastomeres are held together by the zona pellucida, which is under the corona radiata. The blastomeres will eventually form a solid ball of 12 to 16 cells called the **morula**.



A



B

Figure 11-4 ■ Sperm penetration of an ovum. A. The sequential steps of oocyte penetration by a sperm are depicted moving from top to bottom. B. Scanning electron micrograph of human sperm surrounding a human oocyte (750×). The smaller spherical cells are granulosa cells of the corona radiata.

Source: B. Used with permission from Nilsson, L. (1990). A child is born. *New York, NY: Dell Publishing.*

As the morula enters the uterus, two things happen: the intracellular fluid in the morula increases, and a central cavity forms within the cell mass. Inside this cavity is an inner solid mass of cells called the **blastocyst**. The outer layer of cells that surround the cavity and have replaced the zona pellucida is the **trophoblast**. Eventually, the trophoblast develops into one of the embryonic membranes, called the chorion. The blastocyst develops into a double layer of cells called the *embryonic disc*, from which the embryo and the amnion (embryonic membrane) will develop. The journey of the fertilized ovum to its destination in the uterus is illustrated in Figure 11-5 ■.

Early pregnancy factor (EPF), an immunosuppressant, is secreted by the trophoblastic cells. EPF appears in the maternal serum within 24 to 48 hours after fertilization and forms the basis of a pregnancy test during the first 10 days of development (Moore & Persaud, 2008).

Implantation (Nidation)

While floating in the uterine cavity, the blastocyst is nourished by the uterine glands, which secrete a mixture of lipids, mucopolysaccharides, and glycogen. The trophoblast attaches itself to the surface of the endometrium for further nourishment. The most frequent site of attachment is the upper part of the posterior uterine wall (Figure 11-5). Between days 7 and 10 after fertilization, the zona pellucida disappears, and the blastocyst implants itself by burrowing into the uterine lining and penetrating down toward the maternal capillaries until it is completely covered (Moore & Persaud, 2008). The lining of the uterus thickens below the implanted blastocyst, and the cells of the trophoblast grow down into the thickened lining, forming processes called chorionic villi.

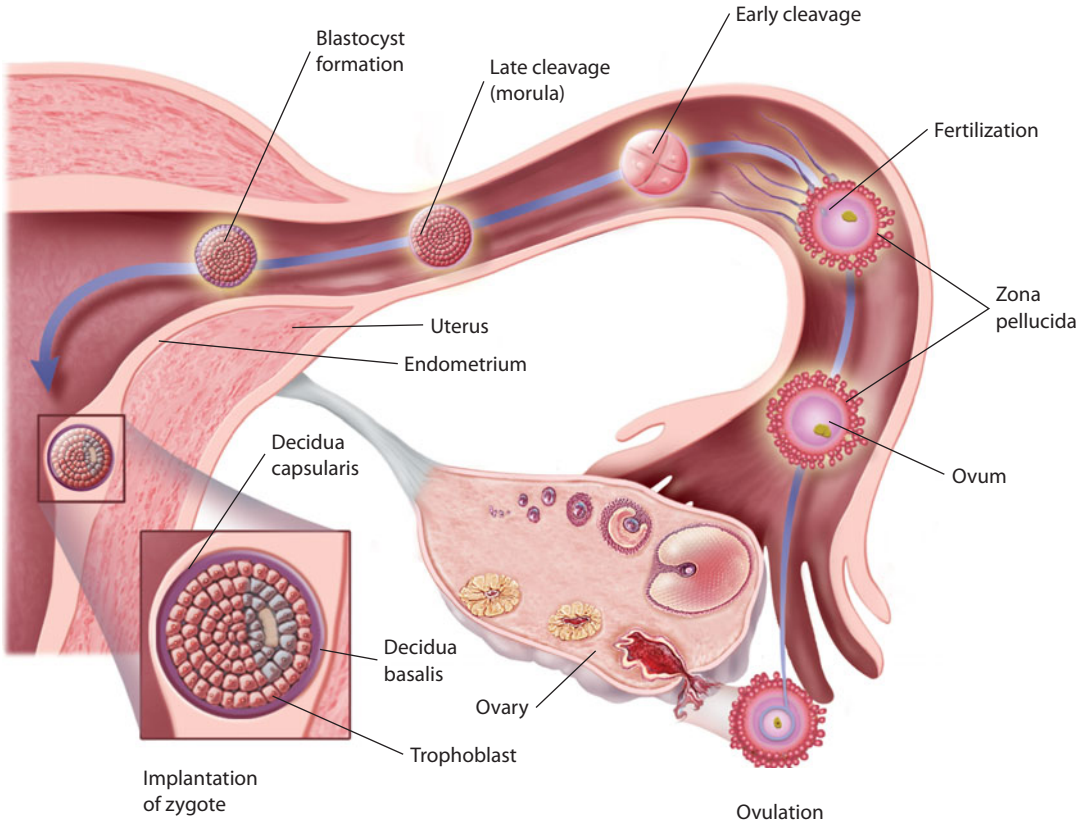


Figure 11-5 ■ During ovulation, the ovum leaves the ovary and enters the fallopian tube. Fertilization generally occurs in the outer third of the fallopian tube. Subsequent changes in the fertilized ovum from conception to implantation are depicted.

Under the influence of progesterone, the endometrium increases in thickness and vascularity in preparation for implantation and nourishment of the ovum. After implantation, the endometrium is called the decidua. The portion of the decidua that covers the blastocyst is called the **decidua capsularis**; the portion directly under the implanted blastocyst is the **decidua basalis**; and the portion that lines the rest of the uterine cavity is the **decidua vera (parietalis)** (see Figure 11-5, inset) (Benirschke, 2009a). The maternal part of the placenta develops from the decidua basalis, which contains large numbers of blood vessels. The chorionic villi (discussed shortly) in contact with the decidua basalis will form the fetal portion of the placenta.

Cellular Differentiation

Primary Germ Layers

About 10 to 14 days after conception, the homogenous mass of blastocyst cells differentiates into the primary germ layers. These layers—the **ectoderm**, **mesoderm**, and **endoderm** (see Figure 11-6 ■)—are formed at the same time as the embryonic membranes. All tissues, organs, and organ systems will develop from these primary germ cell layers (Table 11-2). For example, differentiation of the endoderm results in the formation of the epithelium lining the respiratory and digestive tracts (Figure 11-7 ■).

Embryonic Membranes

The **embryonic membranes** begin to form at the time of implantation (Figure 11-8 ■). These membranes protect and support the embryo as it grows and develops inside the uterus. The first and outermost membrane to form is the **chorion**. This thick membrane develops from the trophoblast and has many fingerlike projections, called *chorionic villi,* on its surface. These chorionic villi can be used for early genetic testing of the embryo at 8 to 11 weeks' gestation by chorionic villi sampling (see chapter 21 ∞). As the pregnancy progresses, the villi begin to degenerate, except for those just under the embryo, which grow and branch into depressions in the uterine wall, forming the fetal portion of the placenta. By the fourth month of pregnancy, the surface of the chorion is smooth except at the place of attachment to the uterine wall.

The second membrane, the amnion, originates from the ectoderm, a primary germ layer, during the early stages of embryonic development. The **amnion** is a thin protective membrane that contains amniotic fluid. The space between the amniotic membrane and the embryo is the *amniotic cavity.* This cavity surrounds the embryo and yolk sac, except where the developing embryo (germ layer disc) attaches to the trophoblast via the umbilical cord. As the embryo grows, the amnion expands until it comes in contact with the chorion. These two slightly adherent membranes form the fluid-filled amniotic sac, also called **bag of waters (BOW)**, which protects the floating embryo.

Amniotic Fluid

The primary functions of **amniotic fluid** are to:

- Act as a cushion to protect the embryo against mechanical injury.

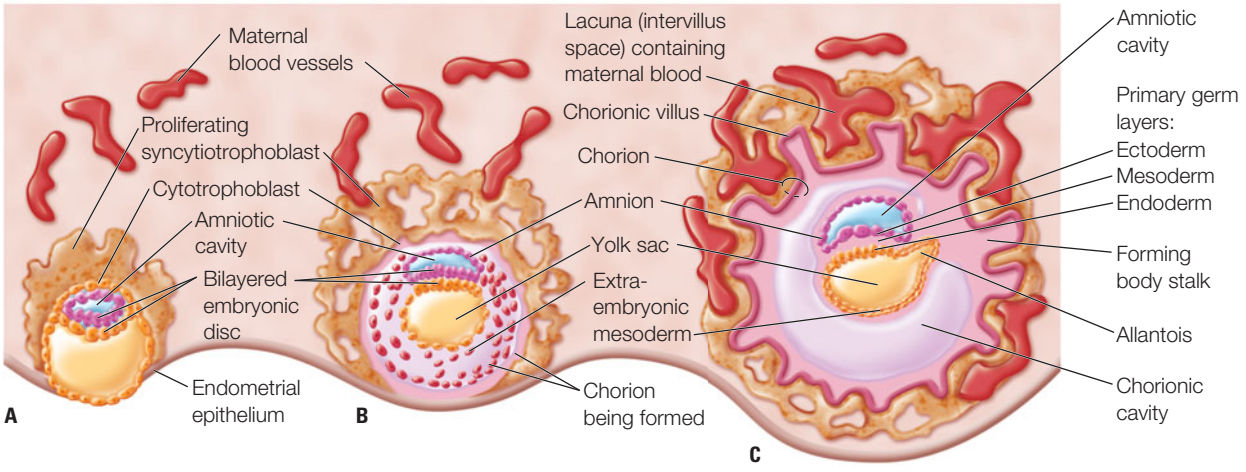

Figure 11-6 ■ Formation of primary germ layers. A. Implantation of a 7 1/2-day blastocyst in which the cells of the embryonic disc are separated from the amnion by a fluid-filled space. The erosion of the endometrium by the syncytiotrophoblast is ongoing. B. Implantation is completed by day 9, and extraembryonic mesoderm is beginning to form a discrete layer beneath the cytotrophoblast. C. By day 16, the embryo shows all three germ layers, a yolk sac, and an allantois (an outpouching of the yolk sac that forms the structural basis of the body stalk, or umbilical cord). The cytotrophoblast and associated mesoderm has become the chorion, and chorionic villi are developing.

- Help control the embryo's temperature (relies on the mother to release heat).
- Permit symmetric external growth and development of the embryo.
- Act as an extension of fetal extracellular space (hydropic infants have increased amniotic fluid).
- Prevent adherence of the embryo-fetus to the amnion (decreases chance of amniotic band syndrome) to allow freedom of movement so that the embryo-fetus can change position (flexion and extension), thus aiding in musculoskeletal development.
- Allow the umbilical cord to be relatively free of compression.
- Act as a wedge during labor.
- Provide fluid for analysis to determine fetal health and maturity.

Amniotic fluid is slightly alkaline and contains albumin, urea, uric acid, creatinine, lecithin, sphingomyelin, bilirubin, fat, fructose, leukocytes, proteins, epithelial cells, enzymes, and fine hair called **lanugo**. The amount of amniotic fluid at 10 weeks is about 30 ml and increases to 350 ml at 20 weeks. After 20 weeks the volume ranges from 700 to 1000 ml. The amniotic fluid volume is constantly changing as the fluid moves back and forth across the placental membrane. Water and solutes must pass between the amniotic fluid and fetus. As the pregnancy continues, the fetus contributes to the volume of amniotic fluid by excreting urine. The fetus also swallows up to 262 ml/kg/day. Approximately 400 ml of amniotic fluid flows out of the fetal lungs each day (Gilbert, 2007). Abnormal variations in amniotic fluid volume are *oligohydramnios* (less than 400 ml of amniotic fluid) and *hydramnios* (more than 2000 ml or amniotic fluid index greater

TABLE 11-2 Derivation of Body Structures from Primary Cell Layers

ECTODERM	MESODERM	ENDODERM
Epidermis	Dermis	Respiratory tract epithelium
Sweat glands	Wall of digestive tract	Epithelium (except nasal), including pharynx, tongue, tonsils, thyroid, parathyroid, thymus tympanic cavity
Sebaceous glands	Kidneys and ureter (suprarenal cortex)	Lining of digestive tract
Nails	Reproductive organs (gonads, genital ducts)	Primary tissue of liver and pancreas
Hair follicles	Connective tissue (cartilage, bone, joint cavities)	Urethra and associated glands
Lens of eye	Skeleton	Urinary bladder (except trigone)
Sensory epithelium of internal and external ear, nasal cavity, sinuses, mouth, anal canal	Muscles (all types)	Vagina (parts)
Central and peripheral nervous systems	Cardiovascular system (heart, arteries, veins, blood, bone marrow)	
Nasal cavity	Pleura	
Oral glands and tooth enamel	Lymphatic tissue and cells	
Pituitary gland	Spleen	
Mammary glands		

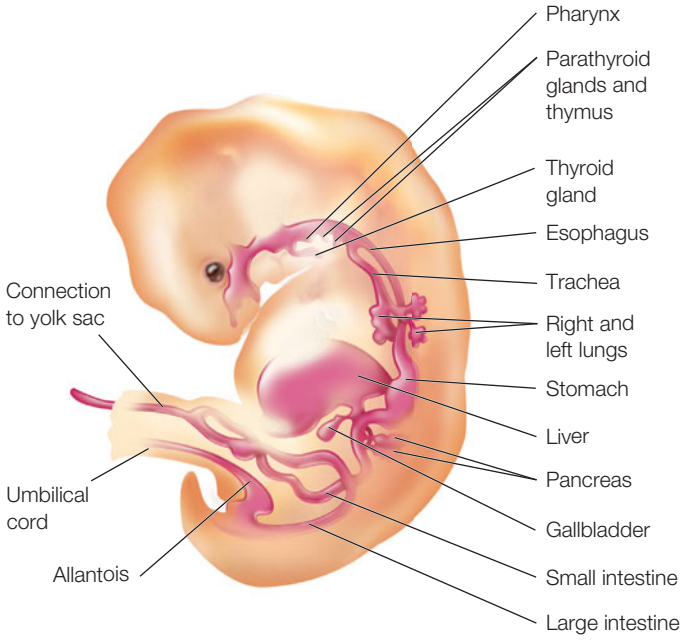

Figure 11-7 ■ Endoderm differentiates to form the epithelial lining of the digestive and respiratory tracts and associated glands.

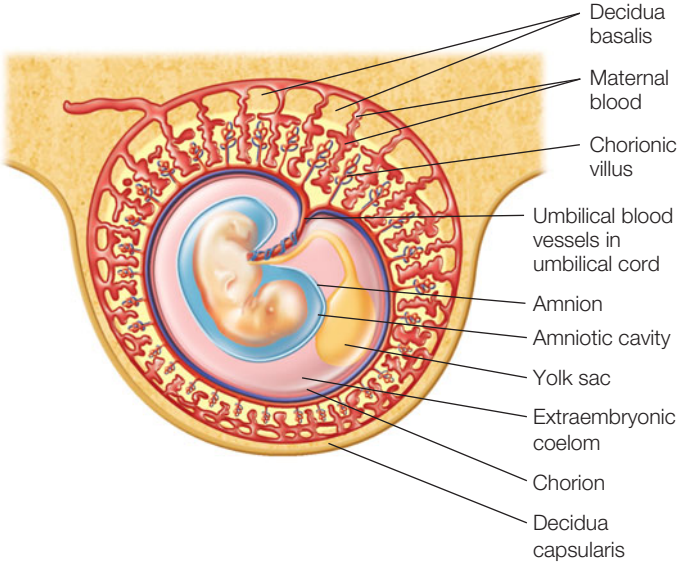

Figure 11-8 ■ Early development of primary embryonic membranes. At 4 1/2 weeks, the decidua capsularis (placental portion enclosing the embryo on the uterine surface) and decidua basalis (placental portion encompassing the elaborate chorionic villi and maternal endometrium) are well formed. The chorionic villi lie in blood-filled intervillous spaces within the endometrium. The amnion and yolk sac are well developed.

than 97.5 percentile for the corresponding gestational age). Hydramnios is also called *polyhydramnios.* Chapter 27 ∞ discusses alterations in amniotic fluid volume. Figure 11-9 ■ summarizes the major pathways of exchange.

Early in the first trimester of pregnancy, amniotic fluid is isoosmolar with fetal and maternal plasma and is secreted from the developing trophoblast or embryo. Water and solutes move freely across the fetal skin before the time of skin keratinization. After 23 to 25 weeks, thickening of the fetal skin inhibits this diffusion. During the rest of the pregnancy, the fetal kidneys are the major source of fluid that enters the amniotic sac. Abnormalities of fetal urine production can result in changes in amniotic fluid volume. For example, with obstruction of urine outflow, as in Potter's syndrome, oligohydramnios develops. Conversely, Bartter's syndrome results in a fetal diuresis and hydramnios. The fetal lungs are also significant contributors to amniotic fluid. Fetal breathing movements are associated with the bidirectional flow of fluid through the trachea. Net outflow from the fetal lungs averages 4.3 ml/kg/hr or 10% of body weight per day. This outflow of lung and tracheal fluid is used as the basis for amniotic fluid tests of fetal lung maturity.

The major mechanism by which amniotic fluid is removed in the last half of the pregnancy is fetal swallowing, which occurs mostly during periods of fetal breathing movements. In pregnancy, when the fetus does not swallow normal amounts of amniotic fluid (as in esophageal atresia and anencephalus), hydramnios will result. A potential route of amniotic fluid removal is by the transmembranous pathway; that is, the movement of fluid across the amniochorion and into the maternal circulation within the uterine wall. Another major regulator of amniotic fluid volume and composition is the intramembranous pathway. This pathway causes amniotic water and/or solutes to be absorbed by the fetal blood that perfuses the fetal surface of the placenta.

Yolk Sac

In humans the yolk sac is small and functions only in early embryonic life. It develops as a second cavity in the blastocyst, about day 8 or 9 after conception, and forms primitive red blood cells during the first 6 weeks of development until the embryo's liver takes over the process. As the embryo develops, the yolk sac is incorporated in the umbilical cord, where it can be identified as a degenerate structure after birth.

Umbilical Cord

As the placenta is developing, the **umbilical cord** is also being formed from the amnion. The *body stalk,* which attaches the embryo to the yolk sac, contains blood vessels that extend into the chorionic villi. The body stalk fuses with the embryonic portion of the placenta to provide a circulatory pathway from the chorionic villi to the embryo (see Figure 11-9). As the body stalk elongates to become the umbilical cord, the vessels in the cord decrease to one large vein and two smaller arteries. About 1% of umbilical cords have only two vessels, an artery and a vein; this condition may be associated with congenital malformations, primarily of the renal, cardiovascular, and gastrointestinal systems. A specialized connective tissue known as **Wharton's jelly** surrounds the blood vessels in the umbilical cord. This tissue, plus the high blood volume pulsating through the vessels, prevents compression of the umbilical cord in utero. The umbilical cord has no sensory or motor innervation, so cutting the cord after birth is not painful. At term (38 to 42 weeks' gestation), the average cord is 2 cm (0.8 in.) across and about 55 cm (22 in.) long. The cord can attach

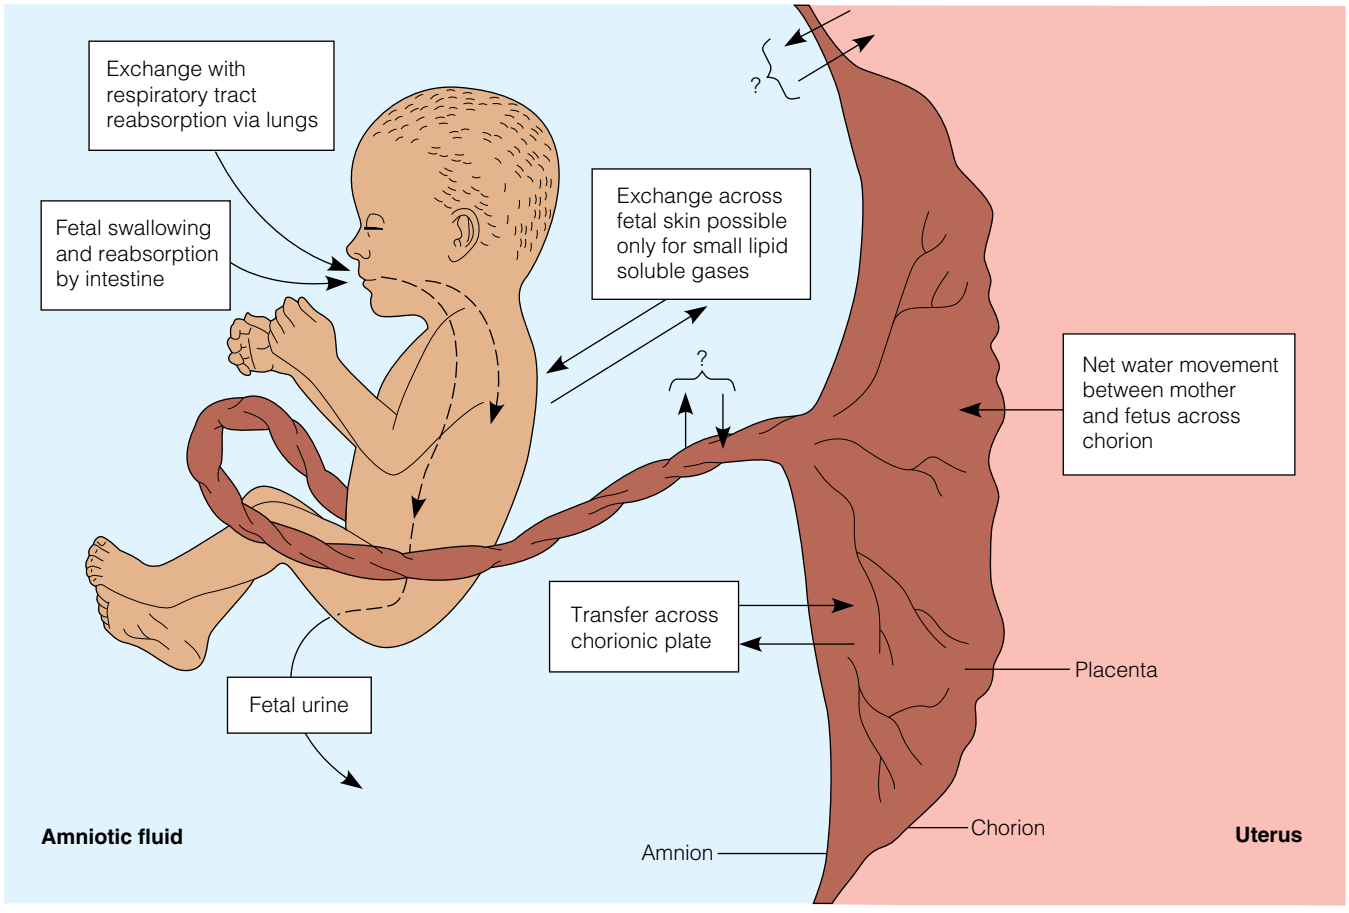

Figure 11-9 ■ Summary of the significant pathways of water and solute exchange between the amniotic fluid and fetus.

itself to the placenta at various sites. Central insertion into the placenta is considered normal. (Chapter 26 ∞ discusses the various attachment sites.)

Umbilical cords appear twisted or spiraled. This is most likely caused by fetal movement. A true knot in the umbilical cord rarely occurs; if it does, the cord is usually long. More common are so-called false knots caused by the folding of cord vessels. A nuchal cord exists when the umbilical cord encircles the fetal neck.

Twins

Twinning occurs in approximately 1 in 43 pregnancies, and triplets in 1 in 1341 pregnancies (Benirschke, 2009b). Among all groups, as parity (having given birth to a viable infant) increases, so does the chance for multiple births.

Twins may be either fraternal or identical (Figure 11-10 ■). If they are fraternal, they are dizygotic, which means they arise from two separate ova fertilized by two separate spermatozoa. There are two placentas, two chorions, and two amnions; however, the placentas sometimes fuse and look as if they are one. Despite their birth relationship, fraternal twins are no more similar to each other than they would be to siblings born singly. They may be the same or different sex.

Dizygotic twinning increases with maternal age up to about 35 years and then decreases abruptly. The chance of dizygotic twins increases with parity, in conceptions that occur in the first 3 months of a relationship, and with increased coital frequency. The chance of dizygotic twinning decreases during periods of malnutrition and during winter and spring for women living in the Northern hemisphere. Studies indicate that dizygotic twins tend to occur in certain families, perhaps because of genetic factors that result in elevated serum gonadotropin levels leading to double ovulation (Moore & Persaud, 2008). Fraternal (dizygotic) twins have been reported to occur more often among black than among white women and more often among white individuals than among women of Asian origin (Moore & Persaud, 2008).

Identical, or monozygotic, twins develop from a single fertilized ovum. They are of the same sex and have the same phenotype (appearance). Identical twins usually have a common placenta (see Figure 11-10). Monozygosity is not affected by environment, race, physical characteristics, or fertility.

Monozygotic twins originate from division of the fertilized ovum at different stages of early development, after the zygote consists of thousands of cells. Complete separation of the cellular mass into two parts is necessary for twin formation. The number of amnions and chorions present depends on the timing of the division.

- If division occurs within 3 days of fertilization (before the inner cell mass and chorion are formed), two embryos, two amnions,

Care Plan Activity: Client Fearful of Multiple Gestations

Application: Fraternal or Identical Twins

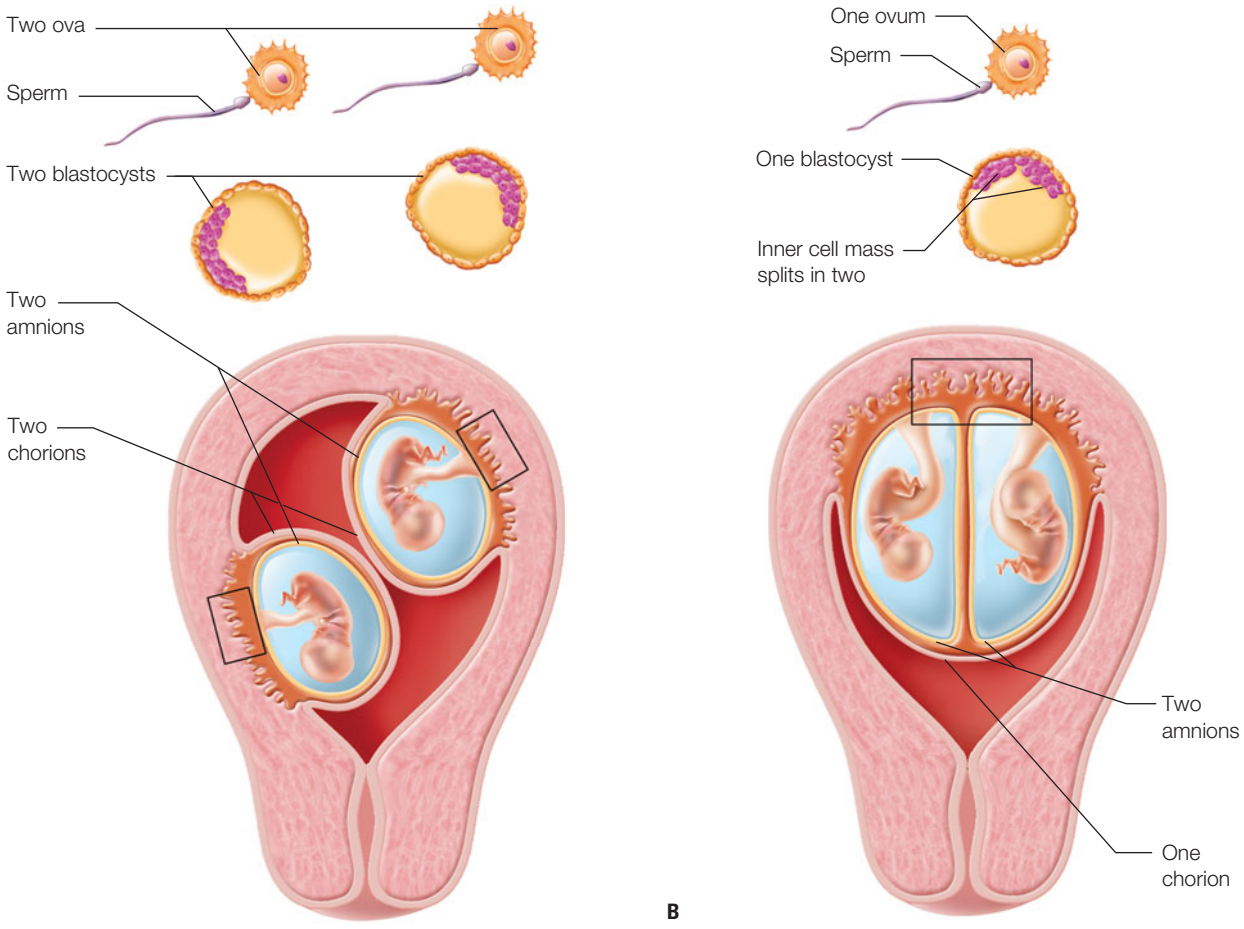

Figure 11-10 ■ A. Formation of fraternal twins. (Note separate placentas.) B. Formation of identical twins.

and two chorions will develop. This dichorionic-diamniotic situation occurs about 20% to 30% of the time, and there may be two distinct placentas or a single fused placenta.

- If division occurs about 5 days after fertilization (when the inner cell mass is formed and the chorion cells have differentiated but those of the amnion have not), two embryos develop with separate amnion sacs. These sacs will eventually be covered by a common chorion; thus there will be a monochorionic-diamniotic placenta.
- If the amnion has already developed approximately 7 to 13 days after fertilization, division results in two embryos with a common amnion sac and a common chorion. This type occurs rarely.

Monozygotic twinning is considered a random event and occurs in approximately 3.5 per 1000 live births (Benirschke, 2009b). The survival rate of monozygotic twins as a group is 10% lower than that of dizygotic twins, and congenital anomalies are more prevalent. Both twins may have the same malformation.

Development and Functions of the Placenta

The **placenta** is the means of metabolic and nutrient exchange between the embryonic and maternal circulations. Placental development and circulation does not begin until the third week of embryonic development. The placenta develops at the site where the developing embryo attaches to the uterine wall. Expansion of the placenta continues until about 20 weeks, when it covers about half the inside of the uterus. After 20 weeks' gestation, the placenta becomes thicker but not wider. At 40 weeks' gestation, the placenta is about 15 to 20 cm (5.9 to 7.9 in.) in diameter and 2.5 to 3 cm (1 to 1.2 in.) in thickness. It weighs approximately 400 to 600 g (14 to 21 oz).

The placenta has two parts: the maternal portion and the fetal portion. The maternal portion consists of the decidua basalis and its circulation. Its surface is red and fleshlike (often called *Dirty Duncan*). The fetal portion consists of the chorionic villi and their circulation. The fetal surface of the placenta is covered by the amnion, which gives it a shiny, gray appearance (often called *Shiny Schultz*) (Figures 11-11 ■ and 11-12 ■).

The placenta begins to form at implantation when the trophoblastic cells of the chorionic villi form spaces in the tissue of the decidua basalis. These spaces fill with maternal blood, and the chorionic villi grow into these spaces. As the chorionic villi differentiate, two trophoblastic layers appear: an outer layer called the *syncytium* (consisting of syncytiotrophoblasts), and an inner layer known as the *cytotrophoblast* (Figure 11-13 ■). The cytotrophoblast thins out and disappears about the fifth month, leaving only a single layer of syncytium covering the chorionic villi. The syncytium is in direct contact with the maternal blood

in the intervillous spaces. It is the functional layer of the placenta and secretes the placental hormones of pregnancy.

A third, inner layer of connective mesoderm develops in the chorionic villi, forming *anchoring villi.* These anchoring villi eventually form the *septa* (partitions) of the placenta. These septa divide the mature placenta into 15 to 20 segments called **cotyledons** (subdivisions of the placenta made up of anchoring villi and decidual tissue). In each cotyledon, the *branching villi* form a highly complex vascular system that allows compartmentalization of the uteroplacental circulation. The exchange of gases and nutrients takes place across these vascular systems.

Exchange of substances across the placenta is minimal during the first 3 to 5 months of development because the villous membrane is initially too thick, which limits its permeability. As the villous membrane thins, the placental permeability increases until about the last month of pregnancy, when permeability begins to decrease as the placenta ages. In the fully developed placenta, fetal blood in the villi and maternal blood in the intervillous spaces are separated by three to four thin layers of tissue.

Placental Circulation

After implantation of the blastocyst, the cells differentiate into fetal cells and trophoblastic cells. The proliferating trophoblast successfully invades the decidua basalis of the endometrium, first opening the uterine capillaries and later opening the larger uterine vessels. The chorionic villi are an outgrowth of the blastocystic tissue. As these villi continue to grow and divide, the fetal vessels begin to form. The intervillous spaces in the decidua basalis develop as the endometrial spiral arteries are opened.

The completion of the maternal-placental-fetal circulation occurs about 17 days after conception, when the embryonic heart begins functioning (Moore & Persaud, 2008). By the end of the fourth week, embryonic blood is circulating between the embryo and the chorionic villi. In the intervillous spaces, maternal blood supplies oxygen and nutrients to the embryonic capillaries in the villi. The placenta has begun to function as a means of metabolic exchange between embryo and mother. Waste products and carbonic dioxide diffuse into the maternal blood. By 14 weeks the placenta is a discrete organ. It has grown in thickness as a result of growth in the length and size of the chorionic villi and accompanying expansion of the intervillous space.

The *cotyledons* of the maternal surface contain branches of a single placental mainstream villus, allowing for some compartmentalization of the uteroplacental circulation. Each cotyledon is a vascular unit containing branching vessels that are distributed throughout a particular lobule and partially separated from other lobules by the cotyledon's thin septal partitions.

Figure 11-13 ■ Longitudinal section of placental villus. Spaces formed in the maternal decidua are filled with maternal blood; chorionic villi proliferate into these maternal blood-filled spaces and differentiate into a syncytium layer and a cytotrophoblast layer.

The capillaries of the villi are lined with an extremely thin endothelium and are surrounded by a layer of mesenchymal (connective) tissue. This connective tissue is covered by chorionic epithelium consisting of cytotrophoblast and syncytiotrophoblast (see Figure 11-13). As previously discussed, the cytotrophoblast thins out and disappears after the fifth month.

In the fully developed placenta's umbilical cord, fetal blood flows through the two umbilical arteries to the capillaries of the villi, and oxygen-enriched blood flows back through the umbilical vein to the fetus (Figure 11-14 ■). Late in pregnancy, a soft blowing sound (*funic souffle*) can be heard over the area of the umbilical cord of the fetus. The sound is synchronous with the fetal heartbeat and the flow of fetal blood through the umbilical arteries.

Maternal blood, rich in oxygen and nutrients, moves from the arcuate artery to the radial artery to the uterine spiral arteries and then spurts into the intervillous spaces. These spurts are produced by the maternal blood pressure. The spurt of blood is directed toward the chorionic plate, and as the blood flow loses pressure, it becomes lateral (spreads out). Fresh blood continually enters and exerts pressure on the contents of the intervillous spaces, pushing blood toward the exits in the basal plate. Blood is then drained through the uterine and other pelvic veins. A *uterine souffle* is also heard in the latter months of pregnancy. This uterine souffle, which is timed precisely with the mother's pulse and heard just above the mother's symphysis pubis, is caused by the augmented blood flow entering the dilated uterine arteries.

Circulation within the intervillous spaces depends on maternal blood pressure producing a gradient between arterial and venous channels. The lumen of the spiral uterine artery is narrow when it pierces the chorionic plate and enters the intervillous space, resulting in an increased blood pressure. The pressure in the arteries forces the blood into the intervillous spaces and bathes the numerous small villi in oxygenated blood. As the pressure decreases, the blood flows back from the chorionic plate toward the decidua, where it enters the endometrial veins.

Braxton Hicks contractions (see chapter 14 ∞) are believed to facilitate placental circulation by enhancing the movement of blood from the center of the cotyledon through the intervillous space. Placental blood flow is thought to be enhanced when the woman is lying on her left side, because the venous return from the lower extremities is not compromised (Blackburn, 2007).

Placental Functions

Placental exchange functions occur only in those fetal vessels that are in intimate contact with the covering syncytial membrane. The syncytium villi have brush borders containing many microvilli, which greatly increase the exchange rate between maternal and fetal circulation (Sadler, 2010).

The placental functions, many of which begin soon after implantation, include fetal respiration, nutrition, and excretion. To carry out these functions, the placenta is involved in metabolic and transfer activities. In addition, it has endocrine functions and special immunologic properties (see discussion later in this section).

Metabolic Activities

The placenta produces glycogen, cholesterol, and fatty acids continuously for fetal use and hormone production. The placenta also produces numerous enzymes required for fetoplacental transfer

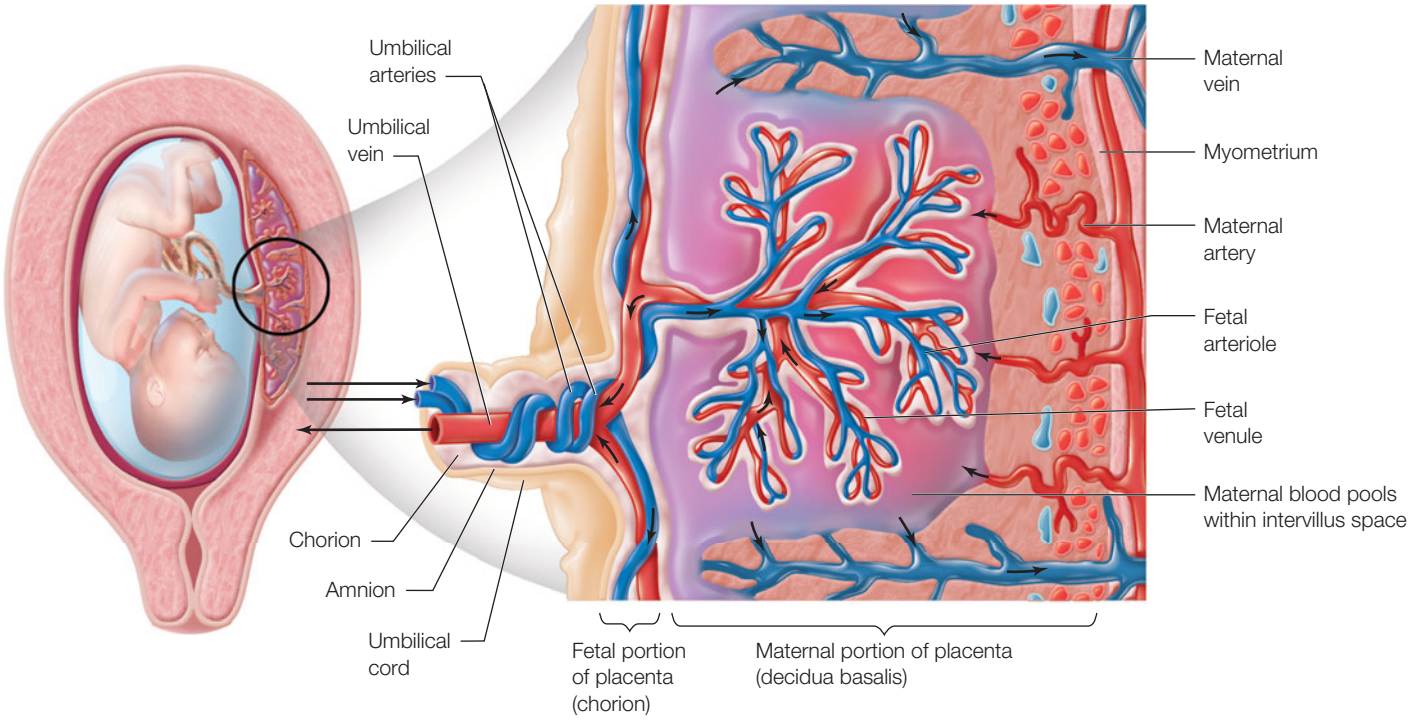

Figure 11-14 ■ Vascular arrangement of the placenta. Arrows indicate the direction of blood flow. Maternal blood flows through the uterine arteries to the intervillous spaces of the placenta and returns through the uterine veins to maternal circulation. Fetal blood flows through the umbilical arteries into the villous capillaries of the placenta and returns through the umbilical vein to the fetal circulation.

such as sulfatase, which enhances excretion of fetal estrogen precursors, and insulinase, which increases the barrier to insulin. It breaks down certain substances, such as epinephrine and histamine (Blackburn, 2007). In addition it stores glycogen and iron.

Transport Functions

The placental membranes actively control the transfer of a wide range of substances by a variety of transport mechanisms.

1. *Simple diffusion* moves substances from an area of higher concentration to an area of lower concentration. Substances that move across the placenta by simple diffusion include water, oxygen, carbon dioxide, electrolytes (sodium and chloride), anesthetic gases, and drugs. Insulin and steroid hormones originating from the adrenal glands and thyroid hormones also cross the placenta but at a very slow rate. The rate of oxygen transfer across the placental membrane is greater than that allowed by simple diffusion, indicating that oxygen is also transferred by some type of facilitated diffusion. Unfortunately many substances of abuse, such as cocaine and heroin, cross the placenta via simple diffusion.
2. *Facilitated transport* involves a carrier system to move molecules from an area of greater concentration to an area of lower concentration. Molecules such as glucose, galactose, and some oxygen are transported by this method. The glucose level in the fetal blood is ordinarily 20% to 30% lower than the glucose level in the maternal blood, because glucose is being metabolized rapidly. This in turn causes rapid transport of additional glucose from the maternal blood into the fetal blood.
3. *Active transport* can work against a concentration gradient, allowing molecules to move from areas of lower concentration to areas of higher concentration. Amino acids, calcium, iron, iodine, water-soluble vitamins, and glucose are transferred across the placenta this way. The measured amino acid content of fetal blood is greater than that of maternal blood, and calcium and inorganic phosphate occur in greater concentration in fetal blood than in maternal blood (Blackburn, 2007).

Other modes of transport also exist. *Pinocytosis* is important for transferring large molecules, such as albumin and gamma globulin. Materials are engulfed by amoeba-like cells forming plasma droplets. *Hydrostatic and osmotic pressures* allow the bulk flow of water and some solutes. Fetal red blood cells pass into the maternal circulation through breaks in the placental membrane, particularly during labor and birth. Certain cells, such as maternal leukocytes, and microorganisms, such as viruses (e.g., HIV, which causes AIDS) and the bacterium *Treponema pallidum,* which causes syphilis, can also cross the placental membrane under their own power (Moore & Persaud, 2008). Some bacteria and protozoa infect the placenta by causing lesions and then entering the fetal blood system.

Several factors, including the following, affect transfer rate:

- Molecular size
- Electrical charge
- Lipid solubility
- Placental surface area
- Diffusion distance
- Maternal-placental-fetal blood flow
- Blood saturation with gases and nutrients
- pK_a of the substance
- Maternal-placental-fetal metabolism of the substance

Substances that have a molecular weight of 1000 daltons or more have difficulty crossing the placenta by simple diffusion. Therefore, heparin, with a molecular weight above 6000, does not cross the placenta, but warfarin sodium (Coumadin), which has a molecular weight in the 300 to 400 range, crosses easily. Electrically charged molecules cross the placenta more slowly. An example is the muscle relaxant succinylcholine. A lipid-soluble substance moves quickly across the placenta into the fetal circulation.

Reduction of the placental surface area, as with abruptio placentae (partial or complete premature separation of a normally implanted placenta), will lessen the area that is functional for exchange. Placental diffusion distance also affects exchange. In conditions such as diabetes and placental infection, edema of the villi increases the diffusion distance, thus increasing the distance the substance has to be transferred.

Blood flow alteration changes the transfer rate of substances, the ratio of blood on each side of the placenta, and the binding and dissociation abilities of carrier molecules in the blood. Decreased intervillous space blood flow is seen during labor and with certain maternal disease conditions such as hypertension. Mild fetal hypoxia increases the umbilical blood flow, but severe hypoxia results in decreased blood flow.

As the maternal blood picks up fetal waste products and carbon dioxide, it drains back into the maternal circulation through the veins in the basal plate. Fetal blood is hypoxic by comparison; it, therefore, attracts oxygen from the mother's blood. Affinity for oxygen also increases as the fetal blood gives up its carbon dioxide, which decreases its acidity.

Endocrine Functions

The placenta produces hormones that are vital to survival of the fetus. These include human chorionic gonadotropin (hCG); human placental lactogen (hPL); and two steroid hormones, estrogen and progesterone.

The hormone hCG is similar to luteinizing hormone (LH) and prevents the normal involution of the corpus luteum at the end of the menstrual cycle (see chapter 10 ∞). If the corpus luteum stops functioning before the 11th week of pregnancy, spontaneous abortion occurs. The hCG also causes the corpus luteum to secrete increased amounts of estrogen and progesterone.

After the 11th week, the placenta produces enough progesterone and estrogen to maintain pregnancy. In the male fetus, hCG also exerts an interstitial cell–stimulating effect on the testes, resulting in the production of testosterone. This small secretion of testosterone during embryonic development causes male sex organs to grow. The hormone hCG may play a role in the trophoblast's immunologic capabilities (ability to exempt the placenta and embryo from rejection by the mother's system). This hormone is used as a basis for pregnancy tests (for discussion of pregnancy tests, see chapter 14 ∞).

The hormone hCG is present in maternal blood serum 8 to 10 days after fertilization, just as soon as implantation has occurred, and is detectable in maternal urine at the time of the missed menses. Chorionic gonadotropin reaches its maximum level at 50 to 70 days' gestation and then begins to decrease as placental hormone production increases.

Progesterone is a hormone essential for pregnancy. It increases the secretions of the fallopian tubes and uterus to provide appropriate nutritive matter for the developing morula and blastocyst. It also appears to aid in ovum transport through the fallopian tube. Progesterone causes decidual cells to develop in the uterine endometrium, and it must be present in high levels for implantation to occur. Progesterone also decreases the contractility of the uterus, thus preventing uterine contractions from causing spontaneous abortion.

Before hCG stimulation, the production of progesterone by the corpus luteum reaches a peak about 7 to 10 days after ovulation. Implantation occurs at about the same time as this peak. At 16 days after ovulation, the production of progesterone reaches a level between 25 and 50 mg per day and continues to rise slowly in subsequent weeks. After 11 weeks, the placenta (specifically, the syncytiotrophoblast) takes over the production of progesterone and secretes it in tremendous quantities, reaching levels of more than 250 mg per day late in pregnancy.

By 7 weeks, the placenta produces more than 50% of the estrogens in the maternal circulation. *Estrogens* serve mainly a proliferative function, causing enlargement of the uterus, breasts, and breast glandular tissue. Estrogens also have a significant role in increasing vascularity and vasodilation, particularly in the villous capillaries, near the end of pregnancy. Placental estrogens increase markedly toward the end of pregnancy to as much as 30 times the daily production in the middle of a normal monthly menstrual cycle. The primary estrogen secreted by the placenta is different from that secreted by the ovaries. The placenta secretes mainly *estriol,* whereas the ovaries secrete primarily estradiol. The placenta cannot synthesize estriol by itself. Essential precursors such as dehydroepiandrosterone sulfate (DHEA-S) is provided by the fetal adrenal glands, processed by the fetal liver, and transported to the placenta for the final conversion to estrone, estradiol, and estriol (Blackburn, 2007).

The hormone hPL (human placental lactogen; sometimes referred to as human chorionic somatomammotropin, or hCS) is similar to human pituitary growth hormone; hPL stimulates certain changes in the mother's metabolic processes. These changes ensure that more protein, glucose, and minerals are available for the fetus. Secretion of hPL can be detected by about 4 weeks.

Immunologic Properties

The placenta and embryo are transplants of living tissue within the same species and are, therefore, considered *homografts.* Unlike other homografts, the placenta and embryo appear exempt from immunologic reaction by the host. Most recent data suggest that the placental hormones (progesterone and hCG) suppress cellular immunity during pregnancy. One theory posits that chorionic villi syncytiotrophoblastic tissue is immunologically inert. The chorionic villi may lack major histocompatibility (HC) antigens and thus do not evoke rejection responses. It does, however, protect against antibody formation. Extravillous trophoblast (EVT) cells, which invade the uterine decidas, have human leukocyte antigen G (HLA-G), which is not readily recognized by sensitized T lymphocytes and natural killer cells (Cunningham et al., 2010).

Development of the Fetal Circulatory System

The circulatory system of the fetus has several unique features that, by maintaining the blood flow to the placenta, provide the fetus with oxygen and nutrients while removing carbon dioxide and other waste products.

Most of the blood supply bypasses the fetal lungs because they do not carry out respiratory gas exchange. The placenta assumes the function of the fetal lungs by supplying oxygen and allowing the fetus to excrete carbon dioxide into the maternal bloodstream. Figure 11-15 ■ shows the fetal circulatory system. The blood from the placenta flows through the umbilical vein, which enters the abdominal wall of the fetus at the site that, after birth, is the umbilicus (belly button). As umbilical venous blood approaches the liver, a small portion of the blood enters the liver sinusoids, mixes with blood from the portal circulation, and then enters the inferior vena cava via hepatic veins. Most of the umbilical vein's blood flows through the **ductus venosus** directly into the inferior vena cava, bypassing the liver. This blood then enters the right atrium, passes through the **foramen ovale** into the left atrium, and pours into the left ventricle, which pumps it into the aorta. Some blood returning from the head and upper extremities by way of the superior vena cava is emptied into the right atrium and passes through the tricuspid valve into the right ventricle. This blood is pumped into the pulmonary artery, and a small amount passes to the lungs and provides nourishment only. The larger portion of blood passes from the pulmonary artery through the **ductus arteriosus** into the descending aorta, bypassing the lungs. Finally, blood returns to the placenta through the two umbilical arteries, and the process is repeated.

Fetal Circulation

The fetus receives oxygen via diffusion from the maternal circulation because of the gradient difference of P_{O_2} of 50 mmHg in maternal blood in the placenta to a 30 mmHg P_{O_2} in the fetus. At term the fetus receives oxygen from the mother's circulation at a rate of 20 to 30 ml/min (Sadler, 2010). Fetal hemoglobin facilitates obtaining oxygen from the maternal circulation because it carries as much as 20% to 30% more oxygen than adult hemoglobin. For further discussion, see chapter 29 ∞.

Embryonic Heart Formation and Circulation

Fetal circulation delivers the highest available oxygen concentration to the head, neck, brain, and heart (coronary circulation) and a lesser amount of oxygenated blood to the abdominal organs and the lower body. This circulatory pattern leads to cephalocaudal (head-to-tail) development in the fetus.

Fetal Heart

The heart of the fetus, as in the adult, is under the control of its own pacemaker. The sinoatrial (SA) node sets the rate and is supplied by the vagus nerve. Bridging the atrium and the ventricle is

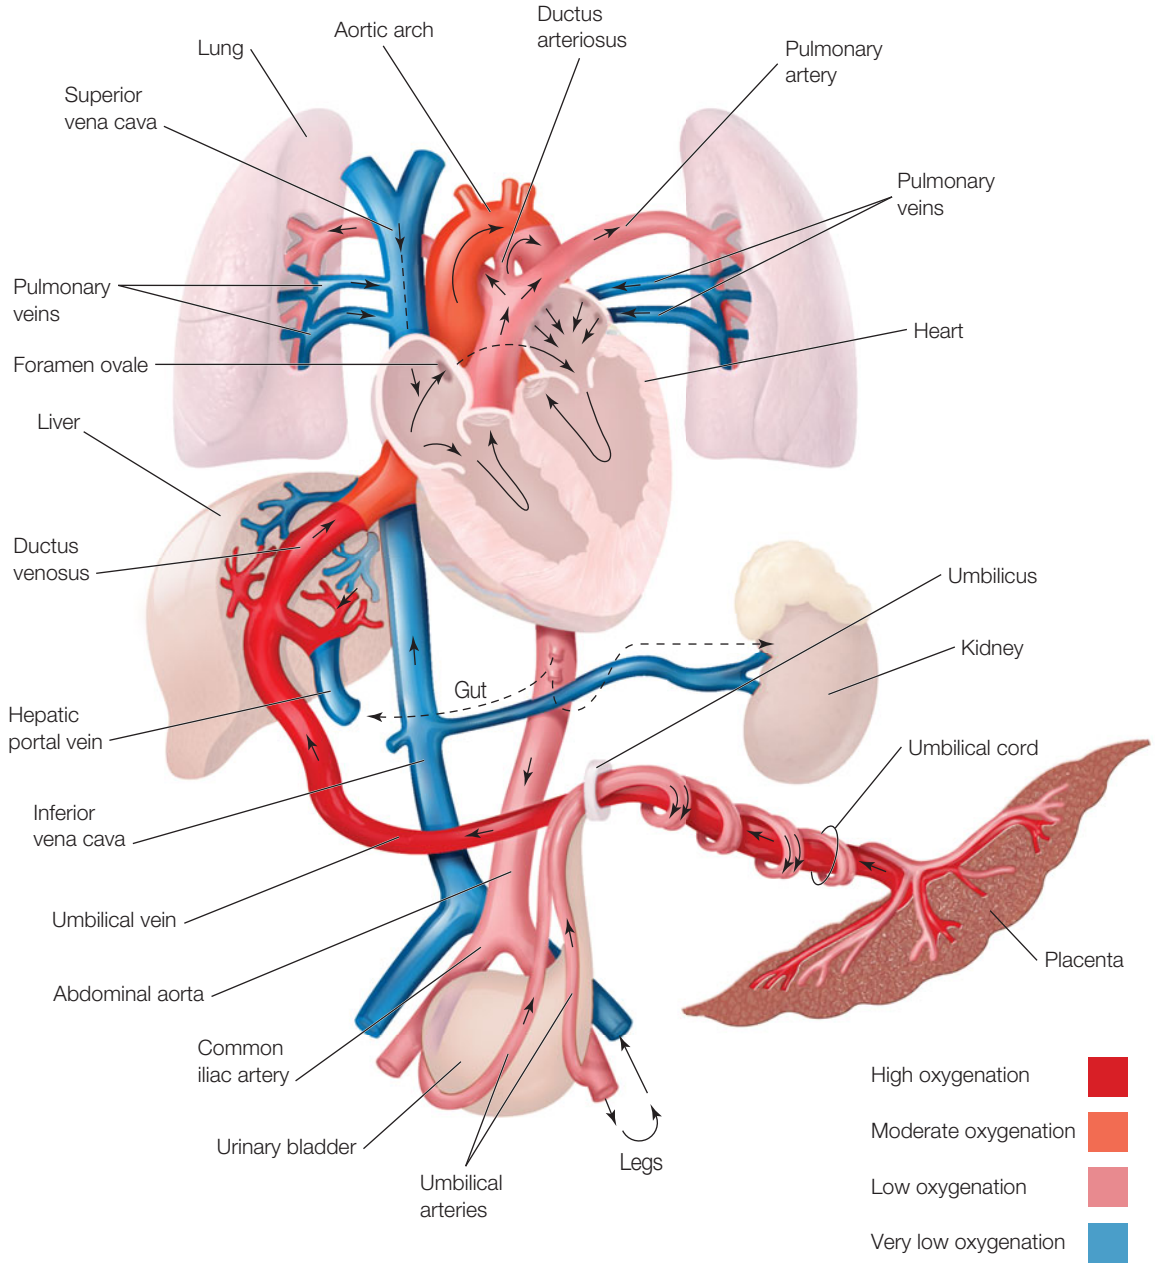

Figure 11-15 ■ Fetal circulation. Blood leaves the placenta and enters the fetus through the umbilical vein. After circulating through the fetus, the blood returns to the placenta through the umbilical arteries. The ductus venosus, the foramen ovale, and the ductus arteriosus allow the blood to bypass the fetal liver and lungs.

the atrioventricular (AV) node, also supplied by the vagus nerve. Baseline changes in the fetal heartbeat have been shown to be under the influence of this nerve. Atropine will block this effect.

When the fetus is stressed, the sympathetic nervous system causes the release of norepinephrine, which increases the fetal heart rate. To counteract the increase in blood pressure, baroreceptors, which respond to the increase pressure, are present in the vessel walls at the junction of the internal and external carotid arteries. When stimulated, these receptors, under the influence of the vagus and glossopharyngeal nerves, cause the heart rate to slow.

Chemoreceptors in the fetal peripheral and central nervous systems respond to decreased oxygen tensions and to increased carbon dioxide tensions, leading to fetal tachycardia and an increase in blood pressure. The central nervous system (CNS) also has control over heart rate. Increased activity of the fetus in a wakeful period is exhibited in an *increase in the beat-to-beat variability* of the fetal heart baseline. Sleep patterns demonstrate a *decrease in the beat-to-beat baseline variability.* In cases of severe hypoxia, increased levels of epinephrine and norepinephrine act on the fetal heart to produce a faster and stronger rate.

Embryonic and Fetal Development

Pregnancy is calculated to last an *average* of 10 lunar months: 40 weeks, or 280 days. This period of 280 days is calculated from the beginning of the last normal menstrual period to the

time of birth. Estimated date of birth (EDB), sometimes referred to as the *estimated date of delivery (EDD),* is usually calculated by this method. Most fetuses are born within 10 to 14 days of the calculated date of birth. The fertilization age (or postconception age) of the fetus is calculated to be *about* 2 weeks less, 266 days (38 weeks) or 9 1/2 calendar months. The latter measurement is more accurate because it measures time from the fertilization of the ovum, or conception.

The basic events of organ development in the embryo and fetus are outlined in Table 11-3. The time periods used in Table 11-3 are **postconception age periods**. During the period from fertilization to the end of the embryonic period (8 weeks), age is often expressed in days but can be given in weeks. During the fetal period (9th week until birth), age is given in weeks (Moore & Persaud, 2008). For a detailed discussion of each body system's development, see chapter 28 ∞; the foldout poster in the middle of the book summarizes fetal development.

In review, human development follows three stages. The preembryonic stage just discussed consists of the first 14 days

TABLE 11-3 Summary of Organ System Development

Age: 2–3 Weeks

Length: 2 mm C–R (Crown to rump).
Nervous system: Groove forms along middle back as cells thicken; neural tube forms from closure of neural groove.
Cardiovascular system: Beginning of blood circulation; tubular heart begins to form during third week.
Gastrointestinal system: Liver begins to function.
Genitourinary system: Formation of kidneys beginning.
Respiratory system: Nasal pits forming.
Endocrine system: Thyroid tissue appears.
Eyes: Optic cup and lens pit have formed; pigment in eyes.
Ears: Auditory pit is now enclosed structure.

Age: 4 Weeks

Length: 4–6 mm C–R.
Weight: 0.4 g.
Nervous system: Anterior portion of neural tube closes to form brain; closure of posterior end forms spinal cord.
Musculoskeletal system: Noticeable limb buds.
Cardiovascular system: Tubular heart beats at 28 days, and primitive red blood cells circulate through fetus and chorionic villi.
Gastrointestinal system: Mouth: formation of oral cavity; primitive jaws present; esophagotracheal septum begins division of esophagus and trachea. Digestive tract: stomach forms; esophagus and intestine become tubular; ducts of pancreas and liver forming.

Age: 5 Weeks

Length: 8 mm C–R.
Weight: Only 0.5% of total body weight is fat (to 20 weeks).
Nervous system: Brain has differentiated and cranial nerves are present.
Musculoskeletal system: Developing muscles have innervation.
Cardiovascular system: Atrial division has occurred.

Age: 6 Weeks

Length: 12 mm C–R.
Musculoskeletal system: Bone rudiments present; primitive skeletal shape forming; muscle mass begins to develop; ossification of skull and jaws begins.
Cardiovascular system: Chambers present in heart; groups of blood cells can be identified.
Gastrointestinal system: Oral and nasal cavities and upper lip formed; liver begins to form red blood cells.
Respiratory system: Trachea, bronchi, and lung buds present.
Ears: Formation of external, middle, and inner ear continues.
Sexual development: Embryonic sex glands appear.

Age: 7 Weeks

Length: 18 mm C–R.
Cardiovascular system: Fetal heartbeats can be detected.
Gastrointestinal system: Mouth: tongue separates; palate folds. Digestive tract: stomach attains final form.
Genitourinary system: Separation of bladder and urethra from rectum.
Respiratory system: Diaphragm separates abdominal and thoracic cavities.
Eyes: Optic nerve formed; eyelids appear, thickening of lens.
Sexual development: Differentiation of sex glands into ovaries and testes begins.

Age: 8 Weeks

Length: 2.5–3 cm C–R.
Weight: 2 g.
Musculoskeletal system: Digits formed; further differentiation of cells in primitive skeleton; cartilaginous bones show first signs of ossification; development of muscles in trunk, limbs, and head; some movement of fetus now possible.
Cardiovascular system: Development of heart essentially complete; fetal circulation follows two circuits—four extraembryonic and two intraembryonic. Heartbeat can be heard with Doppler at 8–12 weeks.
Gastrointestinal system: Mouth: completion of lip fusion. Digestive tract: rotation in midgut; anal membrane has perforated.
Ears: External, middle, and inner ear assuming final forms.
Sexual development: Male and female external genitals appear similar until end of ninth week.

Age: 10 Weeks

Length: 5–6 cm C–R.
Weight: 14 g.
Nervous system: Neurons appear at caudal end of spinal cord; basic divisions of brain present.
Musculoskeletal system: Fingers and toes begin nail growth.
Gastrointestinal system: Mouth: separation of lips from jaw; fusion of palate folds. Digestive tract: developing intestines enclosed in abdomen.
Genitourinary system: Bladder sac formed.
Endocrine system: Islets of Langerhans differentiated.
Eyes: Eyelids fused closed; development of lacrimal duct.
Sexual development: Males: production of testosterone and physical characteristics between 8 and 12 weeks.

Age: 12 Weeks

Length: 8 cm C–R; 11.5 cm C–H (crown to heel).
Weight: 45 g.
Musculoskeletal system: Clear outlining of miniature bones (12–20 weeks); process of ossification is established throughout fetal body; appearance of involuntary muscles in viscera.
Gastrointestinal system: Mouth: completion of palate. Digestive tract: appearance of muscles in gut; bile secretion begins; liver is major producer of red blood cells.
Respiratory system: Lungs acquire definitive shape.
Skin: Pink and delicate.
Endocrine system: Hormonal secretion from thyroid; insulin present in pancreas.
Immunologic system: Appearance of lymphoid tissue in fetal thymus gland.

Age: 16 Weeks

Length: 13.5 cm C–R; 15 cm C–H.
Weight: 200 g.
Musculoskeletal system: Teeth beginning to form hard tissue that will become central incisors.
Gastrointestinal system: Mouth: differentiation of hard and soft palate. Digestive tract: development of gastric and intestinal glands; intestines begin to collect meconium.
Genitourinary system: Kidneys assume typical shape and organization.
Skin: Appearance of scalp hair; lanugo present on body; transparent skin with visible blood vessels; sweat glands developing.
Eyes, ears, and nose: Formed.
Sexual development: Sex determination possible.

(continued)

TABLE 11-3 Summary of Organ System Development continued

Age: 18 Weeks

Musculoskeletal system: Teeth beginning to form hard tissue (enamel and dentine) that will become lateral incisors.
Cardiovascular system: Fetal heart tones audible with fetoscope at 16–20 weeks.

Age: 20 Weeks

Length: 19 cm C–R; 25 cm C–H.
Weight: 435 g (6% of total body weight is fat).
Nervous system: Myelination of spinal cord begins.
Musculoskeletal system: Teeth beginning to form hard tissue that will become canine and first molar. Lower limbs are of final relative proportions.
Gastrointestinal system: Fetus actively sucks and swallows amniotic fluid; peristaltic movements begin.
Skin: Lanugo covers entire body; brown fat begins to form; vernix caseosa begins to form.
Immunologic system: Detectable levels of fetal antibodies (immunoglobin G [IgG] type).
Blood formation: Iron is stored and bone marrow is increasingly important.

Age: 24 Weeks

Length: 23 cm C–R; 28 cm C–H.
Weight: 780 g.
Nervous system: Brain looks like mature brain.
Musculoskeletal system: Teeth are beginning to form hard tissue that will become the second molars.
Respiratory system: Respiratory movements may occur (24–40 weeks). Nostrils reopen. Alveoli appear in lungs and begin production of surfactant; gas exchange possible.
Skin: Reddish and wrinkled, vernix caseosa present.
Immunologic system: IgG levels reach maternal levels.

Age: 28 Weeks

Length: 27 cm C–R; 35 C–H.
Weight: 1200–1250 g.
Nervous system: Begins regulation of some body functions.
Skin: Adipose tissue accumulates rapidly; nails appear; eyebrows and eyelashes present.
Eyes: Eyelids open (26–29 weeks).
Sexual development: Males: testes descend into inguinal canal and upper scrotum.

Age: 32 Weeks

Length: 31 cm C–R; 38–43 cm C–H.
Weight: 2000 g.
Nervous system: More reflexes present.

Age: 36 Weeks

Length: 35 cm C–R; 42–48 cm C–H.
Weight: 2500–2750 g.
Musculoskeletal system: Distal femoral ossification centers present.
Skin: Pale; body rounded, lanugo disappearing, hair fuzzy or woolly; few sole creases; sebaceous glands active and helping to produce vernix caseosa (36–40 weeks).
Ears: Earlobes soft with little cartilage.
Sexual development: Males: scrotum small and few rugae present; descent of testes into upper scrotum to stay (36–40 weeks). Females: labia majora and minora equally prominent.

Age: 38–40 Weeks

Length: 40 cm C–R; 48–52 C–H.
Weight: 3200+ g (16% of total body weight is fat).
Respiratory system: At 38 weeks, lecithin-sphingomyelin (L/S) ratio approaches 2:1 (indicates decreased risk of respiratory distress from inadequate surfactant production if born now).
Skin: Smooth and pink; vernix present in skin folds; moderate to profuse silky hair; lanugo on shoulders and upper back; nails extend over tips or digits; creases cover sole.
Ears: Earlobes firmer due to increased cartilage.
Sexual development: Males: rugous scrotum. Females: labia majora well developed and minora small or completely covered.

Note: Age refers to postfertilization or postconception age.
Source: Data from Sadler, T. W. (2010). Langman's medical embryology *(11th ed). Philadelphia, PA: Lippincott, Williams & Wilkins.*

of development after the ovum is fertilized; the embryonic stage covers the period from day 15 until approximately the end of the eighth week postconception; and the fetal stage extends from the end of the eighth week until birth. (See the detailed discussion of the embryonic and fetal stages next.)

Embryonic Stage

The stage of the **embryo** starts on day 15 (beginning of the third week after conception) and continues until approximately 8 weeks or until the embryo reaches a crown-to-rump (C–R) length of 3 cm (1.2 in.). This length is usually reached about 56 days after fertilization (the end of the eighth gestational week). During the embryonic stage, tissue differentiates into essential organs, and the main external features develop (Figure 11-16 ■). The embryo is most vulnerable to teratogens during this period. These are discussed in more depth later in the chapter.

Three Weeks

In the third week, the embryonic disc becomes elongated and pear-shaped, with a broad cephalic end and a narrow caudal end. The ectoderm has formed a long cylindrical tube called the notochord for brain and spinal cord development. The gastrointestinal tract, created from the endoderm, appears as another tubelike structure communicating with the yolk sac. The most advanced organ is the heart. At 3 weeks, a single tubular heart forms just outside the body cavity of the embryo.

Four to Five Weeks

During days 21 to 32, *somites,* a series of mesodermal blocks, form on either side of the embryo's midline. The vertebrae that form the spinal column will develop from these somites. Before 28 days, arm and leg buds are not visible, but the tail bud is present. The pharyngeal arches—which will form the lower jaw (mandibular arch), hyoid bone, and cartilage of the larynx—develop at this time. The pharyngeal pouches appear now; these pouches will form the eustachian tube and cavity of the middle ear, the tonsils, and the parathyroid and thymus glands. The primordia of the ear and eye are also present (Figure 11-17 ■). By the end of 28 days, the tubular heart is beating at a regular rhythm and pushing its own primitive blood cells through the main blood vessels.

During the fifth week, the optic cups and lens vesicles of the eye form and the nasal pits develop. Partitioning in the heart occurs with the dividing of the atrium. The embryo has a marked C-shaped body, accentuated by the rudimentary tail and the large head folded over a protuberant trunk (Figure 11-18 ■). By

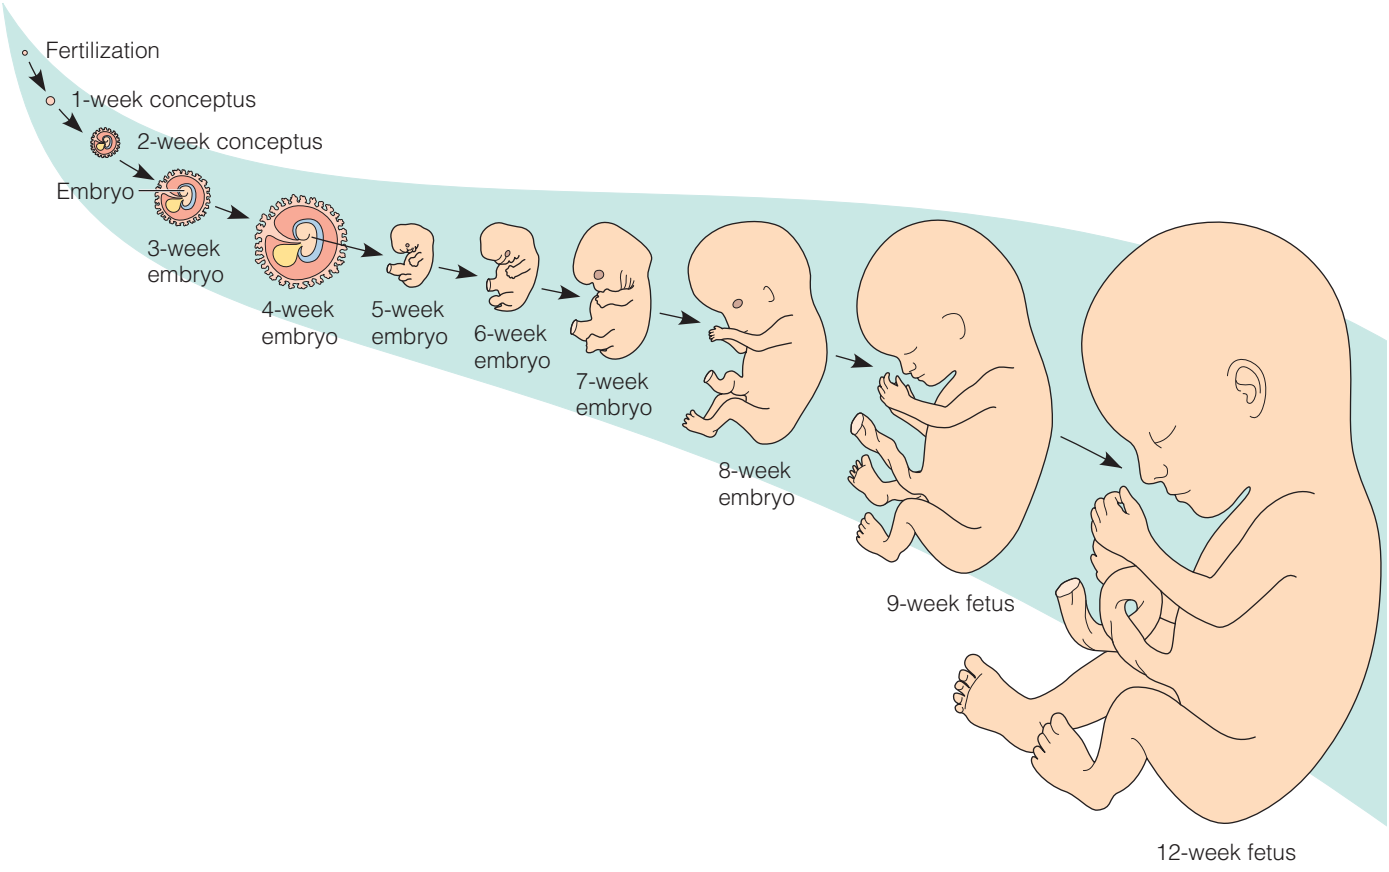

Figure 11-16 ■ The human conceptus from fertilization to the early fetal stage. The embryonic stage begins in the third week after fertilization; the fetal stage begins in the ninth week.

day 35, the arm and leg buds are well developed with paddle-shaped hand and foot plates. The heart, circulatory system, and brain show the most advanced development. The brain has differentiated into five areas, and 10 pairs of cranial nerves are recognizable.

Six Weeks

At 6 weeks, the head structures are more highly developed, and the trunk is straighter than in earlier stages. The upper and lower jaws are recognizable, and the external nares are well formed. The trachea has developed, and its caudal end is bifurcated for beginning lung formation. The upper lip has formed, and the palate is developing. The ears are developing rapidly. The arms have begun to extend ventrally across the chest, and both arms and legs have digits, although they may still be webbed. There is a slight elbow bend in the arm, which is more advanced in development than the leg. Beginning at this stage the prominent tail will recede. The heart now has most of its definitive characteristics, and fetal circulation begins to be established. The liver begins to produce blood cells.

Seven Weeks

At 7 weeks, the head of the embryo is rounded and nearly erect (Figure 11-19 ■). The eyes have shifted from their original lateral position to a forward location, where they are closer together, and the eyelids are beginning to form. The palate is nearing completion, and the tongue is developing in the formed mouth. The gastrointestinal and genitourinary tracts undergo significant changes during the seventh week. Before this time the rectal and urogenital passages formed one tube that ended in a blind pouch; they now separate into two tubular structures. The intestines enter the extraembryonic coelom in the area of the umbilical cord (called umbilical herniation) (Moore & Persaud, 2008). The beginnings of all essential external and internal structures are present.

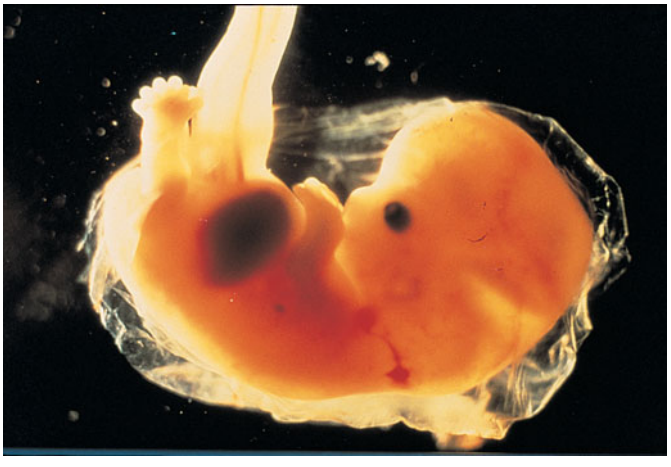

Figure 11-19 ■ The embryo at 7 weeks. The head is rounded and nearly erect. The eyes have shifted forward and are closer together, and the eyelids begin to form.

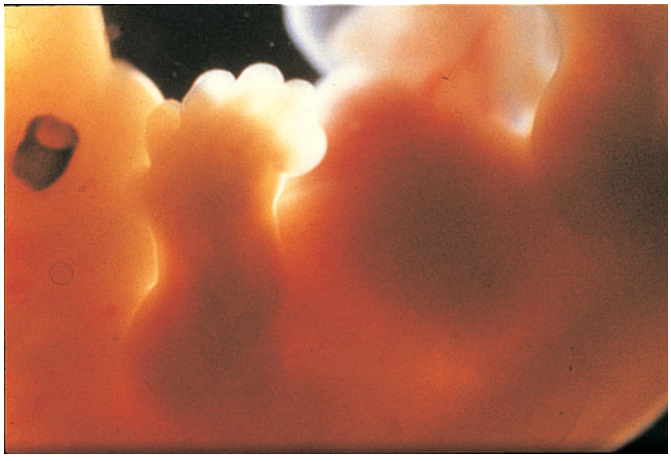

Figure 11-20 ■ The embryo at 8 weeks. Although only 3 cm in C–R length, the embryo clearly resembles a human being. Facial features continue to develop.

Source: Petit Format/Nestle/Science Source/Photo Researchers, Inc., 60 East 56th Street, New York, NY 10022, www.photoresearchers.com, info@photoresearchers.com

Eight Weeks

At 8 weeks, the embryo is approximately 3 cm (1.2 in.) C–R and clearly resembles a human being (Figure 11-20 ■). Facial features continue to develop. The eyelids begin to fuse. Auricles of the external ears begin to assume their final shape, but they are still set low (Moore & Persaud, 2008). External genitals appear, but the embryo's sex is not clearly identifiable. The rectal passage opens with the perforation of the anal membrane. The circulatory system through the umbilical cord is well established. Long bones are beginning to form, and the large muscles are now capable of contracting.

Fetal Stage

By the end of the eighth week, the embryo is sufficiently developed to be called a **fetus**. Every organ system and external structure that will be found in the full-term newborn is present. The remainder of gestation is devoted to refining structures and perfecting function.

Nine to Twelve Weeks

By the end of the ninth week, the fetus reaches a C–R length of 5 cm (2 in.) and weighs about 14 g (0.5 oz). The head is large and comprises almost half of the fetus's entire size (Figure 11-21 ■).

At 12 weeks, the fetus reaches an 8 cm (3.2 in.) C–R length and weighs about 45 g (1.6 oz). The face is well formed, with the nose protruding, the chin small and receding, and the ears acquiring a more adult shape. The eyelids close at about the 10th week and will not begin to reopen until about the 26th to 29th week. Some movements of the lips suggestive of the sucking reflex have been observed at 3 months. Tooth buds now appear for all 20 of the child's first teeth (baby teeth). The limbs are long and slender with well-formed digits. The fetus can curl the fingers toward the palm and make a tiny fist. The legs are still shorter and less developed than the arms. The urogenital tract completes its development, well-differentiated genitals appear, and the kidneys begin to produce urine. Red blood cells are produced primarily by the liver. Spontaneous movements of

Figure 11-21 ■ The fetus at 9 weeks. Every organ system and external structure is present.

Source: Used with permission from Nilsson, L. (1990). A child is born. *New York, NY: Dell Publishing.*

the fetus occur. Fetal heart tones (the sound of the heartbeat) can be ascertained by electronic devices between 8 and 12 weeks. The heart rate is 120 to 160 beats per minute.

Thirteen to Sixteen Weeks

This is a period of rapid growth. At 13 weeks, the fetus weighs 55 to 60 g (1.9 to 2.1 oz) and is about 9 cm (3.6 in.) in C–R length. Lanugo, or fine hair, begins to develop, especially on the head. Blood vessels are clearly visible beneath transparent skin. More muscle tissue and body skeleton have developed, which holds the fetus more erect (Figure 11-22 ■). Active movements are present—the fetus stretches and exercises its arms and legs. It makes sucking motions, swallows amniotic fluid, and produces meconium in the intestinal tract. Bronchial tubes are branching out in the primitive lungs, and sweat glands are developing. The liver and pancreas now begin production of their appropriate secretions. By the beginning of week 16, skeletal ossification is clearly identifiable.

Twenty Weeks

The fetus doubles its C–R length and now measures about 19 cm (8 in.). Fetal weight is between 435 and 465 g (15.2 and 16.3 oz). Lanugo covers the entire body and is especially prominent on the shoulders. Subcutaneous deposits of brown fat, which has a rich

Figure 11-22 ■ The fetus at 14 weeks. During this period of rapid growth, the skin is so transparent that blood vessels are visible beneath it. More muscle tissue and body skeleton have developed, which holds the fetus more erect.

blood supply, make the skin a little less transparent. Nipples now appear over the mammary glands. The head is covered with fine, "woolly" hair, and the eyebrows and eyelashes are beginning to form (Figure 11-23 ■). Nails are present on both fingers and toes. Muscles are well developed, and the fetus is active. Fetal movement, known as quickening, is felt by the mother. The fetal

Figure 11-23 ■ The fetus at 20 weeks. The fetus weighs approximately 435 to 465 g and measures about 19 cm. Subcutaneous deposits of brown fat make the skin less transparent. "Woolly" hair covers the head, and nails have developed on the fingers and toes.

heartbeat is audible through the fetoscope. Quickening and fetal heartbeat can help in validating the EDB.

Twenty-Four Weeks

The fetus at 24 weeks reaches a crown-to-heel (C–H) length of 28 cm (11.2 in.). It weighs about 780 g (1 lb 10 oz). The hair on the head is growing long, and eyebrows and eyelashes have formed. The eyes are structurally complete and will soon open. The fetus has a reflex hand grip (grasp reflex) and, by the end of 6 months, a startle reflex. Skin covering the body is reddish and wrinkled, with little subcutaneous fat. Skin on the hands and feet has thickened, with skin ridges on palms and soles forming distinct footprints and fingerprints. The skin over the entire body is covered with a protective cheeselike fatty substance, called **vernix caseosa**, secreted by the sebaceous glands. The alveoli in the lungs are just beginning to form.

Twenty-Five to Twenty-Eight Weeks

At about 25 weeks, the fetal skin is still red, wrinkled, and covered with vernix caseosa. The brain is developing rapidly, and the nervous system is complete enough to provide some degree of regulation of body functions. The eyelids open and close under neural control. The fetus has nails on both fingers and toes. If the fetus is a male, the testes begin to descend into the scrotal sac. Even though the lungs are still physiologically immature, they are sufficiently developed to provide gas exchange. A fetus born at this time will require immediate and prolonged intensive care to survive and then to decrease the risk of major handicap. The fetus at 28 weeks is about 27 cm (10.8 in.) C–R or 35 to 38 cm (14 to 15 in.) long C–H and weighs 1200 to 1250 g (2 lb 10.5 oz to 2 lb 12 oz).

Twenty-Nine to Thirty-Two Weeks

At 30 weeks, the pupillary light reflex is present (Moore & Persaud, 2008). The fetus is gaining weight from an increase in body muscle and fat and weighs about 2000 g (4 lb 6.5 oz) with a C–R of 31 cm (12.4 in.) or C–H length of about 38 to 43 cm (15 to 17 in.) by 32 weeks of age. The central nervous system (CNS) has matured enough to direct rhythmic breathing movements and partially control body temperature. However, the lungs are not yet fully mature. Bones are now fully developed but are soft and flexible. The fetus begins storing iron, calcium, and phosphorus. In males, the testicles may be located in the scrotal sac but are often still high in the inguinal canals.

Application: Fetal Development

Thirty-Five to Thirty-Six Weeks

The fetus is beginning to get plump with less-wrinkled skin covering the deposits of subcutaneous fat. Lanugo hair is beginning to disappear, and the nails reach the edge of the fingertips. By 35 weeks, the fetus has a firm grasp and exhibits spontaneous orientation to light. By 36 weeks of age, the weight is usually 2500 to 2750 g (5 lb 12 oz to 6 lb 11.5 oz), and the C–H length of the fetus is about 42 to 48 cm (17 to 19 in.) or C–R 35 cm (14 in.). An infant born at this time has a good chance of surviving but may require some special care, especially if there is intrauterine growth restriction.

Fetal Development Overview

Thirty-Eight to Forty Weeks

The fetus is considered full term at 38 weeks and up to 40 weeks after conception. The C–H length varies from 48 to 52 cm (19 to 21 in.) or C–R of 40 cm (16 in.), with males usually longer than females. Males also usually weigh more than females. The weight at term is about 3000 to 3600 g (6 lb 10 oz to 7 lb 15 oz) and varies in different ethnic groups. The skin has a smooth, polished look. The only lanugo left is on the upper arms and shoulders. The hair on the head is no longer woolly but coarse and about an inch long. Vernix caseosa is present, with heavier deposits remaining in creases and folds of the skin. The body and extremities are plump, with good skin turgor, and the fingernails extend beyond the fingertips. The chest is prominent but still a little smaller than the head, and mammary glands protrude in both sexes. The testes are in the scrotum or are palpable in the inguinal canals.

As the fetus enlarges, amniotic fluid diminishes to about an average of 500 ml, and the fetal body mass fills the uterine cavity (Beall & Ross, 2009). The fetus assumes what is called its *position of comfort,* or lie. The head is generally pointed downward, following the shape of the uterus (and also possibly because the head is heavier than the feet). The extremities and often the head are well flexed. After 5 months, feeding patterns, sleeping patterns, as well as activity patterns become established, so the fetus at term has its own body rhythms and individual style of response. See Table 11-4 for important developmental milestones. For a detailed discussion of each body system's transition to and their functioning in the newborn see chapter 29 ∞.

TABLE 11-4 Embryonic and Fetal Development: What Parents Want to Know

4 weeks	The fetal heart begins to beat.
8 weeks	All body organs are formed.
8–12 weeks	Fetal heart tones can be heard by Doppler device.
16 weeks	Baby's sex can be seen. Although thin, the fetus looks like a baby.
20 weeks	Heartbeat can be heard with fetoscope. Mother feels movement (quickening). Baby develops a regular schedule of sleeping, sucking, and kicking. Hands can grasp. Baby assumes a favorite position in utero. Vernix (lanolin-like covering) protects the body, and lanugo (fine hair) keeps oil on skin. Head hair, eyebrows, and eyelashes present.
24 weeks	Weighs 780 g (1 lb 10 oz). Activity is increasing. Fetal respiratory movements begin.
28 weeks	Eyes begin to open and close. Baby can breathe at this time. Surfactant needed for breathing at birth is formed. Baby is two thirds its final size.
32 weeks	Baby has fingernails and toenails. Subcutaneous fat is being laid down. Baby appears less red and wrinkled.
38+ weeks	Baby fills total uterus. Baby gets antibodies from mother.

Factors Influencing Embryonic and Fetal Development

Factors that may affect embryonic development include the quality of the sperm or ovum from which the zygote was formed, the genetic code established at fertilization, and the adequacy of the intrauterine environment. If the environment is unsuitable before cellular differentiation occurs, all the cells of the zygote are affected. The cells may die, which causes spontaneous abortion, or growth may be slowed, depending on the severity of the situation. When differentiation is complete and the fetal membranes have formed, an injurious agent has the greatest effect on those cells undergoing the most rapid growth. Thus the time of injury is critical in the development of anomalies.

Because organs are formed primarily during embryonic development, the growing organism is considered most vulnerable to hazardous agents during the first months of pregnancy. Table 11-5 lists potential malformations related to the time of insult. Any agent (e.g., drug, virus, or radiation) that can cause development of abnormal structures in an embryo is referred to as a **teratogen**. It is important to remember that the effects of teratogens depend on the (1) maternal and fetal genotype, (2) stage of development when exposure occurs, and (3) dose and duration of exposure of the agent (Chambers & Weiner, 2009). Chapter 14 ∞ discusses the effects of specific teratogenic agents on the developing fetus.

Adequacy of the maternal environment is also important during the periods of rapid embryonic and fetal development. Maternal nutrition can affect brain and neural tube development. The period of maximum brain growth and myelination begins with the fifth lunar month before birth and continues during the first 6 months after birth, when there is a twofold increase in myelination (Volpe, 2008). Amino acids, glucose, and fatty acids are considered to be the primary dietary factors in brain growth. A subtle type of damage that affects the associative capacity of the brain, possibly leading to learning disabilities, may be caused by nutritional deficiency at this stage. Vitamins and folic acid supplements taken before conception can reduce the incidence of neural tube defects (Volpe, 2008). Maternal nutrition may also predispose to the development of adult coronary heart disease, hypertension, and diabetes in babies who were small or disproportionate at birth. Maternal nutrition is discussed in depth in chapter 18 ∞. Cigarette smoking during pregnancy negatively impacts neurodevelopment of the fetus (Shea & Steiner, 2008).

TABLE 11-5 Developmental Vulnerability Timetable

WEEKS SINCE CONCEPTION	POTENTIAL TERATOGEN-INDUCED MALFORMATION
3	Ectromelia (congenital absence of one or more limbs)
	Ectopia cordis (heart lies outside thoracic cavity)
4	Omphalocele (herniation of abdominal viscera into the umbilical cord)
	Tracheoesophageal fistula (abnormal connection between trachea and esophagus) (4–5 weeks)
	Hemivertebra (4–5* weeks)
5	Nuclear cataract
	Microphthalmia (abnormally small eyeballs) (5–6* weeks)
	Facial clefts
	Carpal or pedal ablation (5–6* weeks)
6	Gross septal or aortic abnormalities
	Cleft lip, agnathia (absence of the lower jaw)
7	Interventricular septal defects
	Pulmonary stenosis
	Cleft palate, micrognathia (smallness of the jaw)
	Epicanthus
	Brachycephalism (shortness of the head) (7–8* weeks)
	Mixed sexual characteristics
8	Persistent ostium primum (persistent opening in atrial septum)
	Digital stunting (shortening of fingers and toes)

*May occur in several periods after conception.

Case Study: Teaching About Pregnancy

CLINICAL JUDGMENT

Case Study: Melodie Chong

Melodie Chong, in her third week of pregnancy, develops a fever of 104°F (40°C) and flulike symptoms but refuses to take any medication because she is afraid that drugs will harm her baby. Many factors—maternal, fetal, and environmental—may affect prenatal growth.

Critical Thinking

What would you advise Melodie about use of medication in this situation and to do during her pregnancy to decrease her chances of problems?

Melodie asks when her baby is most vulnerable for abnormal growth or structure. How would you answer?

See www.nursing.pearsonhighered.com for possible responses.

Another prenatal influence on the intrauterine environment is maternal hyperthermia associated with sauna baths or hot tub use. Studies of the effects of maternal hyperthermia during the first trimester have raised concern about possible spontaneous abortion, central nervous system (CNS) defects, and failure of neural tube closure (see Table 11-5). Maternal substance abuse also affects the intrauterine environment and is discussed in chapter 19 ∞ and chapter 32 ∞.

FOCUS YOUR STUDY

- Humans have 46 chromosomes, which are divided into 23 pairs—22 pairs of autosomes and 1 pair of sex chromosomes.
- Mitosis is the process by which additional somatic (body) cells are formed. It provides growth and development of the organs and replacement of body cells.
- Meiosis produces cells called gametes (ova and sperm) that are necessary for reproduction of the species. It occurs during gametogenesis (oogenesis and spermatogenesis) and consists of two successive cell divisions (reduction division), which produce a gamete with 23 chromosomes (22 chromosomes and 1 sex chromosome)—the haploid number of chromosomes.
- Gametes must have a haploid number (23) of chromosomes so that when the female gamete (ovum) and the male gamete (spermatozoon) unite to form the zygote, the normal human diploid number of chromosomes (46) is reestablished.
- An ovum is considered fertile for about 12 to 24 hours after ovulation, and the sperm is believed to be capable of fertilizing the ovum for about 24 hours after it is deposited in the female reproductive tract.
- Fertilization usually takes place in the ampulla (outer third) of the fallopian tube. Both capacitation and the acrosomal reaction must occur for the sperm to fertilize the ovum. Capacitation is the removal of the plasma membrane, which exposes the acrosomal covering of the sperm head. The acrosomal reaction is the deposit of hyaluronidase in the corona radiata, which allows the sperm head to penetrate the ovum.
- Sex chromosomes are referred to as X and Y. Females have two X chromosomes, and males have an X and a Y chromosome. Y chromosomes are carried only by the sperm. To produce a female child, both the mother and the father contribute an X chromosome. To produce a male child, the mother contributes an X chromosome and the father contributes a Y chromosome.
- Intrauterine development first proceeds via cellular multiplication in which the zygote undergoes rapid mitotic division called cleavage. As a result of cleavage, the zygote divides and multiplies into cell groupings called blastomeres, which are held together by the zona pellucida. The blastomeres will eventually become a solid ball of cells called the morula. When a cavity forms in the morula cell mass, the inner solid cell mass is called the blastocyst.
- Implantation usually occurs in the upper part of the posterior uterine wall when the blastocyst burrows into the uterine lining.
- After implantation, the endometrium is called the decidua. Decidua capsularis is the portion that covers the blastocyst. Decidua basalis is the portion that is directly under the blastocyst. Decidua vera is the portion that lines the rest of the uterine cavity.
- Embryonic membranes are called the amnion and the chorion. The amnion is formed from the ectoderm and is a thin protective membrane that contains the amniotic fluid and the embryo. The chorion is a thick membrane that develops from the trophoblast and encloses the amnion, embryo, and yolk sac.
- Amniotic fluid cushions the fetus against mechanical injury, controls the embryo's temperature, allows symmetric external growth, prevents adherence to the amnion, and permits freedom of movement.
- Primary germ layers will give rise to all tissues, organs, and organ systems. The three primary germ cell layers are the ectoderm, endoderm, and mesoderm.
- The umbilical cord contains two umbilical arteries, which carry deoxygenated blood from the fetus to the placenta, and one umbilical vein, which carries oxygenated blood from the placenta to the fetus. The umbilical cord has a central insertion into the placenta. Wharton's jelly, a specialized connective tissue, prevents compression of the umbilical cord in utero.
- Twins are either dizygotic (fraternal) or monozygotic (identical). Dizygotic twins arise from two separate ova fertilized by two separate spermatozoa. Monozygotic twins develop from a single ovum fertilized by a single spermatozoon.
- The placenta, which develops from the chorionic villi and the decidua basalis, has two parts. The maternal portion, consisting of the decidua basalis, is red and flesh-looking; the fetal portion, consisting of chorionic villi, is covered by the amnion and appears shiny and gray. The placenta is made up of 15 to 20 segments called cotyledons.
- The placenta serves metabolic functions, endocrine functions (production of human placental lactogen (hPL), human chorionic gonadotropin (hCG), estrogen, and progesterone), and immunologic functions. It acts as the fetus's respiratory organ, is an organ of excretion, and aids in the exchange of nutrients.
- Fetal circulation is a specially designed circulatory system that provides for oxygenation of the fetus while bypassing the fetal lungs.
- Stages of fetal development include the preembryonic stage (the first 14 days of human development starting at

fertilization), the embryonic stage (from day 15 after fertilization, or the beginning of the third week, until approximately 8 weeks after conception), and the fetal stage (from 8 weeks until birth at approximately 38 weeks postconception).

- Significant events that occur during the embryonic stage are that at 4 weeks the fetal heart begins to beat and at 6 weeks fetal circulation is established.
- The fetal stage is devoted to refining structures and perfecting function. The following are some significant developments during the fetal stage:

  At 8 to 12 weeks, all organ systems are formed and now require maturation.

  At 16 weeks, the sex of the fetus can be determined visually.

  At 20 weeks, fetal heartbeat can be auscultated by a fetoscope, and the mother can feel movement (quickening).

  At 24 weeks, vernix caseosa covers the entire body.

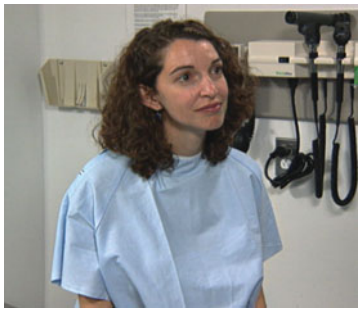
  At 26 to 28 weeks, the eyes reopen.

  At 32 weeks, skin appears less wrinkled and red because subcutaneous fat has been laid down.

  At 35 weeks, fingernails reach the ends of fingers.

  At 38 weeks, vernix caseosa is apparent only in creases and folds of skin, and lanugo remains on upper arms and shoulders only.
- The embryo is particularly vulnerable to teratogenesis during the first 8 weeks of cell differentiation and organ system development.

CRITICAL THINKING IN ACTION



You are working at the local clinic when Frances, a 28-year-old G2 P1001 at 11 weeks' gestation, comes into the office. Frances tells you that early in the first trimester, her husband experienced a flulike syndrome and that he was later diagnosed with cytomegalovirus (CMV) pneumonia. She tells you that his physician found an enlarged supraclavicular lymph node and an ulcer on one tonsil. Laboratory testing revealed elevated liver enzymes. Further testing led to the discovery of positive cytomegalovirus (CMV) lgM levels. She has come today with symptoms including night sweats, persistent sore throat, joint pain, headache, vomiting, and fatigue. You obtain vital signs of temperature 90°F, pulse 90, respirations 14, BP 110/70. Her physical exam is normal; no lymphadenopathy are present. Her weight gain is 2 lb even with nausea and some vomiting. She is worried that her husband's illness could be related to her current symptoms.

1. How would you respond to Frances's concern?
2. Frances asks you if her baby is formed. How would you discuss the three stages of development?
3. Frances asks when her baby is most vulnerable for abnormal growth or structure. How would you answer?
4. Frances asks what stage her baby is in. What would you tell her?

CHAPTER 12

Special Reproductive Concerns: Infertility and Genetics

As we sat in the waiting room at the in vitro clinic, I felt great apprehension. For 4 years we had been unable to conceive. I'd been through two surgeries, dozens of blood tests, and hormone drugs that made me irrational and emotional. It was difficult at times—I blamed myself, felt out of control, and had surprisingly painful reactions to seeing mothers with babies. After many long talks we decided that if in vitro didn't work for us, we would adopt. Still, we felt that we wanted to experience childbirth together.

LEARNING OUTCOMES

1. Identify the components of fertility.
2. Describe the elements of the preliminary investigation of infertility and the nurse's role in supporting/teaching patients during this phase.
3. Summarize the indications for the tests and associated treatments, including assisted reproductive technologies, that are done in an infertility workup.
4. Relate the physiologic and psychologic effects of infertility on a couple to the nursing care management of the couple.
5. Describe the nurse's roles as counselor, educator, and advocate during infertility evaluation and treatment.
6. Identify couples who may benefit from preconceptual chromosomal analysis and prenatal testing.
7. Identify the characteristics of autosomal dominant, autosomal recessive, and X-linked (sex-linked) recessive disorders.
8. Compare prenatal and postnatal diagnostic procedures used to determine the presence of genetic disorders.
9. Explain the nurse's role in supporting the family undergoing genetic counseling.
10. Discuss the emotional impact on a couple coping with the birth of a baby with a genetic disorder and the nurse's role in supporting the family.

Zygote intrafallopian transfer (ZIFT) *259*

Most couples who want children conceive with little difficulty. Pregnancy and childbirth usually take their normal course, and a healthy baby is born. But some less fortunate couples are unable to fulfill their dream of having a healthy baby because of infertility or genetic problems.

This chapter explores two particularly troubling reproductive problems facing some couples: the inability to conceive and the risk of bearing babies with genetic problems.

Infertility

Infertility is defined by the failure to achieve a successful pregnancy after 12 months or more of regular unprotected intercourse (American Society for Reproductive Medicine [ASRM], 2008b). It has a profound emotional, psychologic, and economic impact on both the affected couple and society. *Sterility* is a term applied when there is an absolute factor preventing reproduction. **Subfertility** is used to describe a couple having difficulty conceiving because both partners have reduced fertility. The term **secondary infertility** is applied to couples who have been unable to conceive after one or more successful pregnancies. The medical causes are similar to those of infertility in general.

Approximately 10% to 15% of couples in their reproductive years are infertile in the United States (Wright & Johnson, 2008). Public perception is that the incidence of infertility is increasing, but in fact there has been no significant change in the proportion of infertile couples in the United States. What has changed is the composition of the infertile population; the infertility diagnosis has increased in the age group 25 to 44 years because of delayed childbearing and the entry of the baby-boom cohort into this age range in Western society. The mean age for a first birth is now 4.5 years older than that of women 2 decades ago (Balen & Rutherford, 2007).

Many factors affect male and female fertility, including environmental factors such as weight, sexually transmitted infections, stress, and smoking. Cigarette smoking in females can delay time to conception and increase the risk for spontaneous abortion, preterm labor, and low birth weight. The quantity and quality of male sperm is also affected by cigarette smoking (ASRM, 2008k). The ASRM promotes maintenance of a healthy weight and body mass index (BMI) to protect fertility in women. Women weighing >120% or <95% of their predicted ideal body weight can alter the production and storage of sex steroid hormones, which in turn affect a woman's reproductive cycle. It is estimated that 12% or more of infertile couples have an abnormal body weight as the cause of their infertility and 70% of women will conceive spontaneously if their weight disorder is corrected (ASRM, 2008f). Male obesity is associated with increased incidence of low sperm concentration and poor sperm motility (ASRM, 2008e). Sexually transmitted infections, such as *Chlamydia trachomatis*, can cause salpingitis and subsequent tubal obstruction, leading to infertility or ectopic pregnancy (ASRM, 2008h).

Endocrine disrupting chemicals (EDC) are common environmental pollutants and exposures to natural and synthetic chemicals that can affect reproductive health. Some of the common EDCs include bisphenol A (BPA), phthalates, and certain pesticides. Maternal and paternal exposure to these compounds can affect fertility and the ability to reproduce. Heavy metals, such as lead, are known to cause decreased fertility and increased pregnancy loss. Preconceptual exposure to pesticides in agricultural and horticultural settings has also been associated with infertility (Woodruff, Carlson, Schwartz et al., 2008).

The perception that infertility is on the rise may be related to the following factors:

- The deferring of marriage and then the desire to have a family shortly after marriage
- The increase in assisted reproduction techniques
- The increase in availability and use of infertility services
- The increase in insurance coverage of some socioeconomic groups for diagnosis of and treatment for infertility
- The increased number of childless women over 35 seeking medical attention for infertility

Essential Components of Fertility

Understanding the elements essential for normal fertility can help the nurse identify the many factors that may cause infertility. The components necessary for normal fertility are correlated with possible causes of deviation in Table 12-1. In addition, adequate reproductive hormones must be present.

With the intricacies of timing and environment playing such a crucial role, it is an impressive natural phenomenon that the majority of couples in the United States are able to conceive. The remaining couples experience infertility due to a male factor (20%), a female factor (40%), or either an unknown cause (unexplained infertility) or a problem with both partners (30% to 40%) (ASRM, 2008g). Professional intervention can help approximately 65% of infertile couples achieve pregnancy.

Young couples with no history that is suggestive of reproductive disorders should be referred for infertility evaluation if they have been unable to conceive after at least 1 year of attempting to achieve pregnancy. An earlier workup is indicated in couples with positive history for fertility-lowering disease or advancing maternal age (Wright & Johnson, 2008). In women over 35 years of age, it is appropriate to refer the couple after only 6 months of unprotected intercourse without conception or earlier if clinically indicated (ASRM, 2008b). The most important determinant of a couple's fertility is the age of the woman. The cumulative conception rate for women up to age 25 is 60% at 6 months and 85% at 1 year (Balen & Rutherford, 2007).

Initial Investigation: Physical and Psychosocial Issues

The easiest and least intrusive infertility testing approach is used first. Extensive testing is avoided until data confirm that the timing of intercourse and the length of coital exposure have been adequate. The nurse informs the couple of the most fertile times to have intercourse during the menstrual cycle. Teaching the couple factors that influence fertility, the signs and timing of ovulation, and the most effective timing

TABLE 12-1 Possible Causes of Infertility

NECESSARY NORMS	DEVIATIONS FROM NORMAL
Female	
Favorable cervical mucus	Cervicitis, cervical stenosis, use of coital lubricants, antisperm antibodies (immunologic response)
Clear passage between cervix and tubes	Myomata, adhesions, adenomyosis, polyps, endometritis, cervical stenosis, endometriosis, congenital anomalies (e.g., septate uterus, diethylstilbestrol [DES] exposure)
Patent tubes with normal motility	Pelvic inflammatory disease, peritubal adhesions, endometriosis, intrauterine device [IUD], salpingitis (e.g., chlamydia, recurrent sexually transmitted infections [STIs]), neoplasm, ectopic pregnancy, tubal ligation
Ovulation and release of ova	Primary ovarian failure, polycystic ovarian disease, hypothyroidism, pituitary tumor, lactation, periovarian adhesions, endometriosis, premature ovarian failure, hyperprolactinemia, Turner syndrome
No obstruction between ovary and tubes	Adhesions, endometriosis, pelvic inflammatory disease
Endometrial preparation	Anovulation, luteal phase defect, malformation, uterine infection, Asherman syndrome
Male	
Normal semen analysis	Abnormalities of sperm or semen, polyspermia, congenital defect in testicular development, mumps after adolescence, cryptorchidism, infections, gonadal exposure to x-rays, chemotherapy, smoking, alcohol abuse, malnutrition, chronic or acute metabolic disease, medications (e.g., morphine, aspirin [ASA], ibuprofen), cocaine use, marijuana use, constrictive underclothing, heat
Unobstructed genital tract	Infections, tumors, congenital anomalies, vasectomy, strictures, trauma, varicocele
Normal genital tract secretions	Infections, autoimmunity to semen, tumors
Ejaculate deposited at the cervix	Premature ejaculation, impotence, hypospadias, retrograde ejaculation (e.g., diabetic), neurologic cord lesions, obesity (inhibiting adequate penetration)

TABLE 12-2 Suggestions for Improving Fertility

- Avoid douching and artificial lubricants (gels, oils, saliva) that can alter sperm mobility. Prevent alteration of pH of vagina and introduction of spermicidal agents.
- Promote retention of sperm. The male superior position with the female remaining recumbent for at least 20–30 minutes after intercourse maximizes the number of sperm reaching the cervix.
- Avoid leakage of sperm. Elevate the woman's hips with a pillow after intercourse for 20–30 minutes to allow liquefaction of seminal fluid and motility of the sperm toward the egg. Avoid getting up to urinate, shower, or douche for 1 hour after intercourse.
- Maximize the potential for fertilization. Instruct the couple that it is optimal if sexual intercourse occurs every other day during the fertile period. Because each woman's menstrual cycle varies in length, the fertile period can extend from cycle day (CD) 7 through CD 17. Note: CD 1 is considered the first day of actual menstrual flow.
- Avoid emphasizing conception during sexual encounters to decrease anxiety and potential sexual dysfunction.
- Maintain adequate nutrition and reduce stress. Stress reduction techniques and good nutritional habits increase sperm production.
- Explore other methods to increase fertility awareness, such as home assessment of cervical mucus and basal body temperature (BBT) recordings.
- Seek counsel and advice from a valued friend or family member.
- Consider incorporating culturally appropriate methods to enhance fertility.

for intercourse within the cycle may solve the problem (Table 12-2). Primary assessment, including a comprehensive history (with a discussion of genetic conditions) and physical examination for any obvious causes of infertility, is done before a costly, time-consuming, and emotionally trying investigation is initiated.

The initial infertility evaluation offers nurses a unique opportunity to initiate preconception counseling, thereby helping infertile couples maximize their chances of delivering a healthy baby. Prenatal vitamins are often one of the earliest recommendations for women planning to conceive. Studies show that folic acid supplementation of at least 400 micrograms (0.4 mg/day) taken 1 to 3 months preconceptually and continued through the first trimester greatly reduces the incidence of neural tube defects such as anencephaly and spina bifida. Preconception is the optimal time to review the importance of rubella and varicella immunity and the risk of congenital anomalies associated with exposure. It also provides the opportunity to address risks associated with alcohol, tobacco, and medications. Women may warrant a change in medications or stricter management of chronic illnesses.

The mutual desire to have children is a cornerstone of many marriages. A fertility problem is a deeply personal, emotion-laden area in a couple's life. The self-esteem of one or both partners may be threatened if the inability to conceive is seen as a lack of virility or femininity (Paterno, 2008). It is never easy to discuss one's sexual activity, especially when potentially irreversible problems with fertility may exist. The nurse can provide comfort to couples by offering a sympathetic ear, a nonjudgmental approach, and appropriate information and instructions throughout the diagnostic and therapeutic process (McGrath, Samra, Zukowsky, et al., 2010). Because counseling includes discussion of very personal matters, nurses who are comfortable with their own sexuality are more capable of establishing rapport and eliciting relevant information from couples with fertility problems.

The first interview should involve both partners and include a comprehensive history and a physical examination. Table 12-3 lists the items in a complete infertility physical workup and laboratory evaluation for both partners. Because

TABLE 12-3 Initial Infertility Physical Workup and Laboratory Evaluations

FEMALE

Physical Examination

Assessment of height, weight, blood pressure, temperature, and general health status
Endocrine evalution of thyroid for exophthalmos, lid lag, tremor, or palpable gland
Optic fundi evaluation for presence of increased intracranial pressure, especially in oligomenorrheal or amenorrheal women (possible pituitary tumor)
Reproductive features (including breast and external genital area)
Physical ability to tolerate pregnancy

Pelvic Examination

Papanicolaou (PAP) smear
Culture for gonorrhea if indicated and possibly chlamydia or mycoplasma culture (opinions vary)
Signs of vaginal infections (see chapter 6 ∞)
Shape of escutcheon (e.g., does pubic hair distribution resemble that of a male's?)
Size of clitoris (enlargement caused by endocrine disorders)
Evaluation of cervix: old lacerations, tears, erosion, polyps, condition and shape of os, signs of infections, cervical mucus (evaluate for estrogen effect of spinnbarkheit and cervical ferning)

Bimanual Examination

Size, shape, position, and motility of uterus
Presence of congenital anomalies
Presence of endometriosis
Evaluation of adnexa: ovarian size, cysts, fixations, or tumors

Rectovaginal Examination

Presence of retroflexed or retroverted uterus
Presence of rectouterine pouch masses
Presence of possible endometriosis

Laboratory Examination

Complete blood count
Sedimentation rate if indicated
Serology
Urinalysis
Rh factor and blood grouping
Rubella immunoglobulin (IgG)
Follicle-stimulating hormone (FSH) level regardless of age and regularity of menstrual cycles

If indicated depending on age and regularity of menstrual cycles: thyroid-stimulating hormone (TSH), prolactin levels (PRL), glucose tolerance test, hormonal assays including estradiol (E_2), luteinizing hormone (LH), midluteal progesterone (MLP), dehydroepiandrosterone sulfate (DHEAS), androstenedione, testosterone, 17 α-hydroxyprogesterone (17-OHP).

MALE

Physical Examination

General health (assessment of height, weight, blood pressure)
Endocrine evaluation (e.g., presence of gynecomastia)
Visual fields evaluation for bitemporal hemianopia (blindness in one-half of the visual field)
Abnormal hair patterns

Urologic Examination

Presence or absence of phimosis
Location of urethral meatus
Size and consistency of each testis, vas deferens, and epididymis
Presence of varicocele

Rectal Examination

Size and consistency of the prostate with microscopic evaluation of prostate fluid for signs of infection
Size and consistency of seminal vesicles

Laboratory Examination

Complete blood count
Sedimentation rate if indicated
Serology
Urinalysis
Rh factor and blood grouping
Semen analysis
If indicated, testicular biopsy, buccal smear
Hormonal assays, FSH, LH, prolactin

at least 20% of infertility is due to a male factor, a semen analysis should be one of the first diagnostic tests performed before moving on to the more invasive diagnostic procedures involving the woman. Figure 12-1 ■ outlines the historic database, diagnostic tests usually performed, and healthcare interventions in cases of infertility.

Assessment of the Woman's Fertility

After a thorough history and physical examination, both partners may undergo tests to identify causes of infertility. A thorough evaluation of the woman's fertility includes assessment of the hypothalamic-pituitary axis in terms of ovulatory function as well as structure and function of the cervix, uterus, fallopian tubes, and ovaries.

Evaluation of Ovulatory Factors

Ovulation problems account for approximately 25% of couples' infertility. For review of the characteristics of the female reproductive cycle, see Table 12-4 and Figure 12-2 ■. For an in-depth discussion on female reproductive cycle characteristics, see chapter 10 ∞.

BASAL BODY TEMPERATURE RECORDING One basic test of ovulatory function is the **basal body temperature (BBT)** recording, which aids in identifying follicular and luteal phase abnormalities. At the initial visit, the nurse instructs the woman in the technique of recording BBT on a special form. The woman is instructed to begin a new chart on the first day of every monthly cycle. The temperature can be taken with a standard oral or rectal thermometer calibrated by tenths of a degree, making slight temperature changes readily apparent. A special kind of thermometer (BBT) may be used to measure temperature only between 35°C and 37.8°C (96°F and 100°F). In addition to traditional or digital thermometers, tympanic thermometry, which provides a reading in only a few seconds, may also be a valid method.

The woman records daily variations on a temperature graph. The temperature graph typically shows a biphasic pattern

Activity: Ovulation

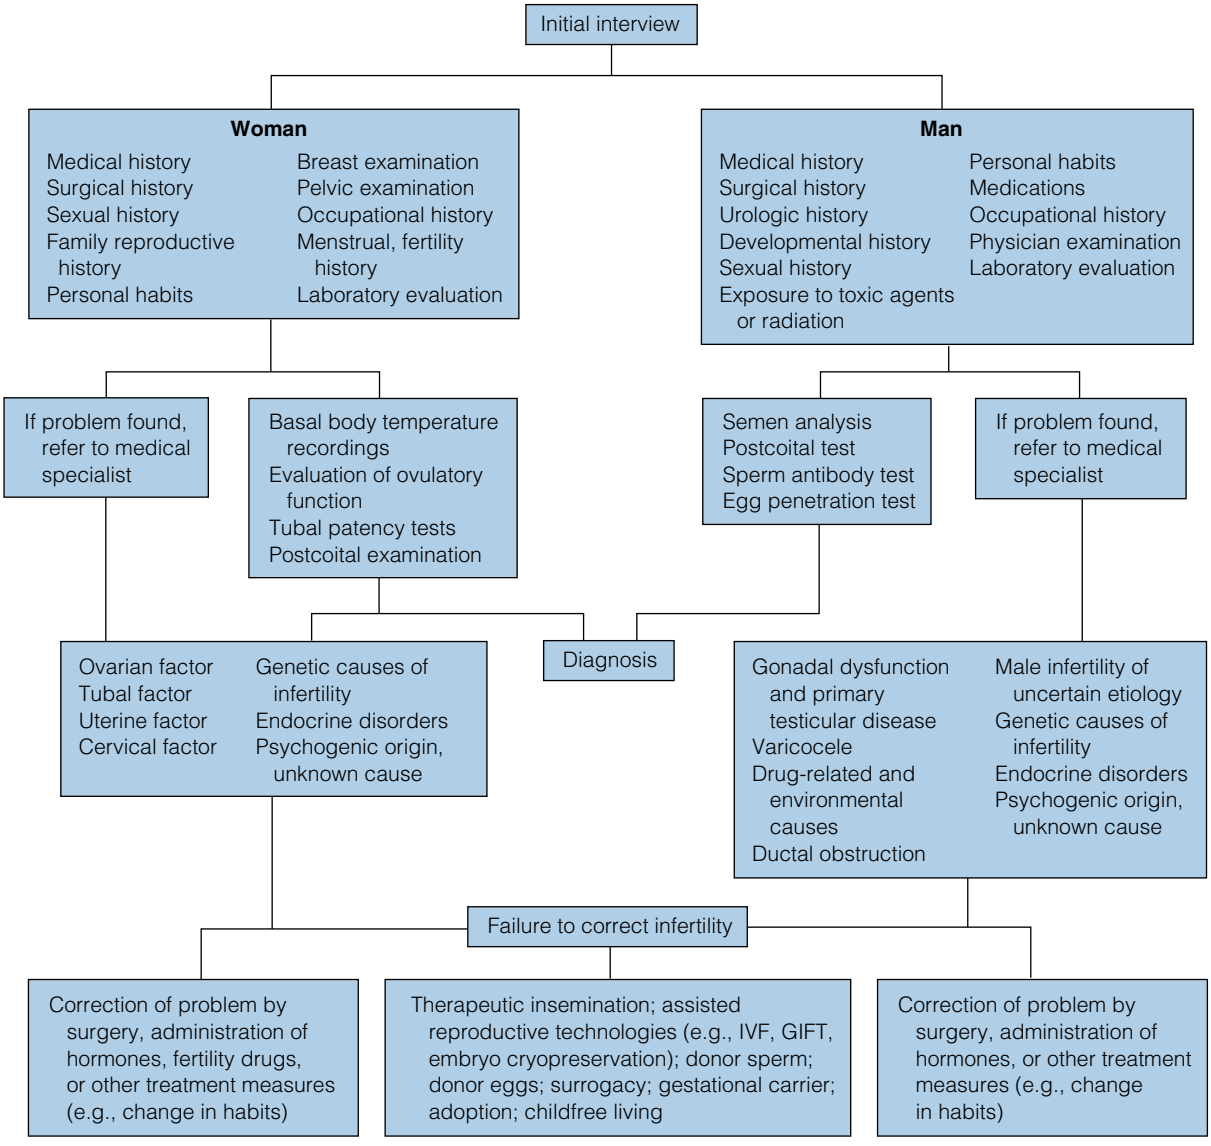

Figure 12-1 ■ Flow chart for management of the infertile couple.

TABLE 12-4 Female Reproductive Cycle

OVARIAN CYCLE	MENSTRUAL CYCLE
Follicular phase (days 1–14): Primordial follicle matures under influence of FSH and LH up to the time of ovulation.	*Menstrual phase* (days 1–6): Estrogen levels are low; cervical mucus is scant, viscous, and opaque.
Luteal phase (days 15–28): Ovum leaves follicle, corpus luteum develops under LH influence and produces high levels of progesterone and low levels of estrogen.	*Proliferative phase* (days 7–14): Estrogen peaks just before ovulation. Cervical mucus at ovulation is clear, thin, watery, alkaline, and more favorable to sperm; shows ferning pattern; and has spinnbarkheit greater than 8 cm. At ovulation body temperature drops then rises sharply and remains elevated under influence of progesterone.
	Secretory phase (days 15–26): Estrogen drops sharply and progesterone dominates.
	Ischemic phase (days 27–28): Both estrogen and progesterone levels drop.

during ovulatory cycles, whereas in anovulatory cycles it remains monophasic. The woman uses the readings on the temperature graph to detect ovulation and direct the timing of intercourse (Figure 12-3A ■).

Basal temperature for females in the preovulatory (follicular) phase is usually below 36.7°C (98°F). As ovulation approaches, production of estrogen increases and at its peak may cause a slight drop, then rise, in the basal temperature. The slight drop in temperature before ovulation is often difficult to capture on the BBT chart. After ovulation there is a surge of luteinizing hormone (LH), which stimulates production of progesterone. Because progesterone is thermogenic (produces heat), it causes a 0.3°C to 0.6°C (0.5°F to 1°F) sustained rise in basal temperature during the second half of the menstrual cycle (luteal phase). Immediately before or coincident with the onset of menses, the temperature falls below 36.7°C (98°F). These changes in the basal temperature create the typical biphasic pattern. Figure 12-3B ■ shows a biphasic ovulatory BBT chart. Temperature elevation does not predict the day of

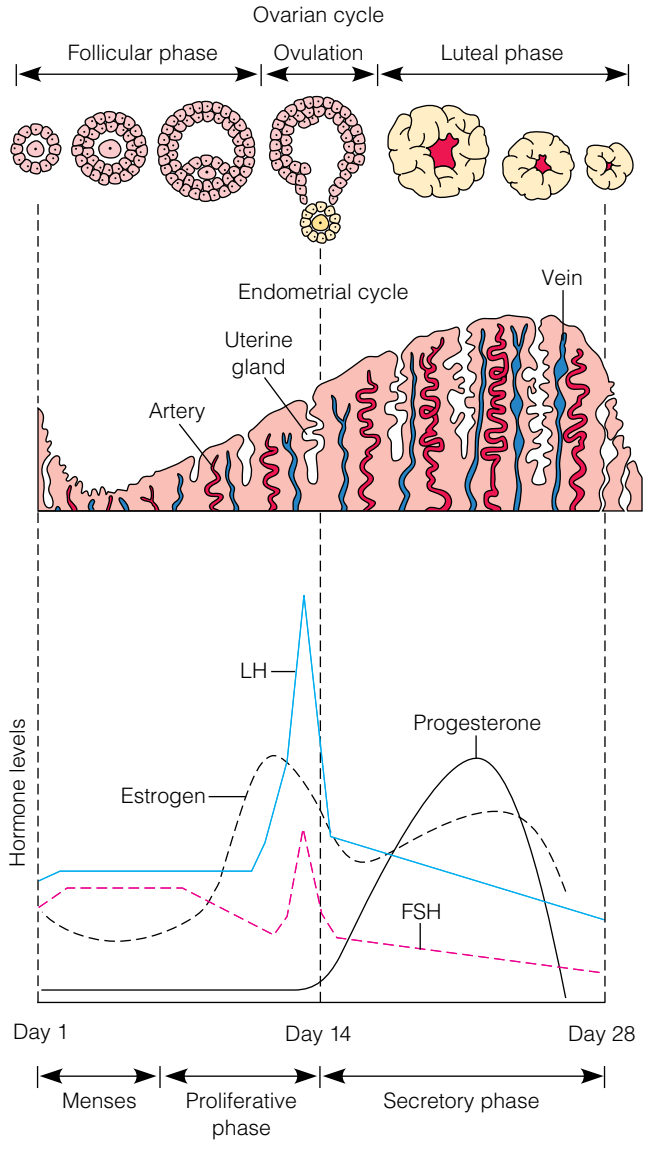

Figure 12-2 ■ Sequence of events in a normal reproductive cycle showing the relationship of hormone levels to events in the ovarian and endometrial cycles.

ovulation but provides supportive evidence of ovulation about a day after it has occurred.

Although there are other, more reliable methods to detect ovulatory function, BBT offers couples a low-tech, noninvasive, and inexpensive option. Based on serial BBT charts, the clinician might recommend sexual intercourse *every other day* beginning 3 to 4 days before and continuing for 2 to 3 days after the expected time of ovulation. See Patient Teaching: Methods of Determining Ovulation on pages 250–251.

HORMONAL ASSESSMENTS OF OVULATORY FUNCTION

Hormonal assessments of ovulatory function fall into the following categories:

1. ***Gonadotropin levels (FSH, LH):*** Baseline hormonal assessment of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) provides valuable information about normal ovulatory function. Measured on cycle day (CD) 3, FSH is the single most valuable test in assessing ovarian reserve (number of remaining oocytes or follicles in the ovary) and function. FSH should always be measured, particularly in women over 30, to predict the potential for successful treatment with ovulation induction treatment cycles (Wright & Johnson, 2008). LH levels may be measured early in the cycle to rule out disorders associated with androgen excess, causing a disruption in normal follicular development and oocyte maturation. Daily sampling of serum LH at midcycle can detect the LH surge. The day of the LH surge is believed to be the time of maximum fertility. Ovulation occurs 24 to 26 hours after the onset of the LH surge and 10 to 12 hours after the peak of the LH surge. Urine LH ovulation prediction and serum LH assay (predictor) kits (such as First Response Ovulation Test ©) are available for home use to better time postcoital testing, insemination, and intercourse (Kumar, Ghadir, Eskandari et al., 2007).
2. ***Progesterone assays:*** Progesterone levels furnish the best evidence of ovulation and corpus luteum function. Serum levels begin to rise with the LH surge and peak about 8 days later. A level of 3 ng/ml 3 days after the LH surge generally confirms ovulation (Wright & Johnson, 2008). On day 21 (7 days postovulation) a level of 10 ng/ml or higher generally indicates an adequate luteal phase.
3. ***Prolactin:*** Elevated levels of the anterior pituitary hormone prolactin are a frequent cause of ovulatory dysfunction, which may range from a luteal phase defect to anovulation to amenorrhea.
4. ***Thyroid-stimulating hormone (TSH):*** Thyroid hormone is necessary for most body functions, not only metabolism but also specific tissue activities. TSH stimulates prolactin secretion by the pituitary gland. Hypothyroidism may have a dramatic effect on ovulatory function and cause menstrual irregularities and bleeding irregularities.
5. ***Androgen levels (testosterone, DHEAS, androstenedione):*** Androgen excess can originate from the adrenal glands, ovaries, or peripheral tissue. Despite the origin, it usually results in specific clinical symptoms such as acne, hirsutism, virilization, and ovulatory dysfunction—which can range from oligomenorrhea to anovulation to amenorrhea.

ENDOMETRIAL BIOPSY **Endometrial biopsy (EMB)** provides information about the effects of progesterone produced by the corpus luteum after ovulation and endometrial receptivity. EMB is reliable for determining the presence of ovulation. Histologic evidence of a secretory endometrium detected by endometrial biopsy shows ovulation and corpus luteum formation. However, it is not effective for diagnosing luteal phase deficiency (Wright & Johnson, 2008).

TRANSVAGINAL ULTRASOUND **Transvaginal ultrasound** is the method of choice for follicular monitoring of women undergoing ovulation induction cycles, for timing ovulation for insemination and intercourse, for retrieving oocytes for in vitro fertilization (IVF), and for monitoring early pregnancy. The use of transvaginal color flow Doppler to investigate uterine

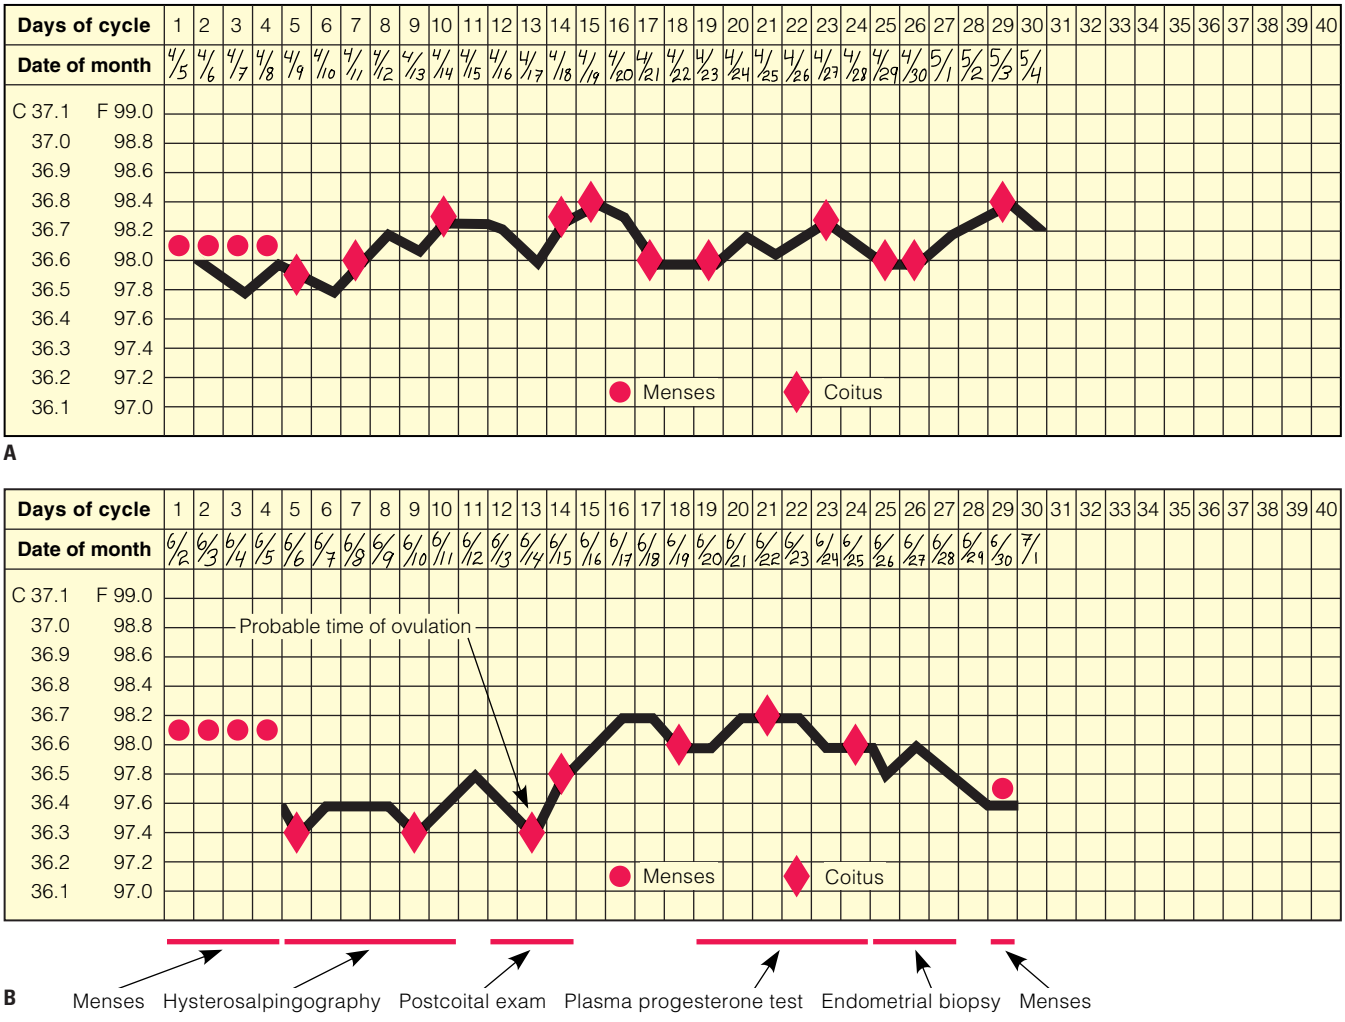

Figure 12-3 ■ A. A monophasic, anovulatory basal body temperature (BBT) chart. B. A biphasic BBT chart illustrating probable time of ovulation, the different types of testing, and the time in the cycle that each would be performed.

blood flow may in the future help the endocrinologist evaluate the adequacy of the developing follicle, further assessing oocyte maturity and endometrial development and patterns, and improve the diagnosis of luteal phase defects. For the procedure, the woman does not need to have a full bladder. In addition, if the woman finds it more comfortable to do so, she can insert the lubricated transvaginal probe herself (Thomas & Van Voorhis, 2008).

Evaluation of Cervical Factors

The mucus cells of the endocervix consist predominantly of water. As ovulation approaches, the ovary increases its secretion of estrogen and produces changes in the cervical mucus. The amount of mucus increases 10-fold, and the water content rises significantly. At ovulation, mucus elasticity, called **spinnbarkheit**, increases to at least 5 cm in length and the viscosity decreases. Excellent spinnbarkheit exists when the mucus can be stretched 8 to 10 cm or longer. Mucus elasticity is determined by using two glass slides (Figure 12-4A ■) or by grasping some mucus at the external os. (See Patient Teaching: Methods of Determining Ovulation.)

The **ferning capacity** (crystallization) (Figure 12-4B ■ and C ■) of the cervical mucus also increases as ovulation approaches. Ferning is caused by decreased levels of salt and water interacting with the glycoproteins in the mucus during the ovulatory period and is thus an indirect indication of estrogen production. To test for ferning, mucus from the cervical os is spread on a glass slide, allowed to air dry, and then examined under the microscope. Within 24 to 48 hours postovulation, rising levels of progesterone cause a marked decrease in the quantity of cervical mucus and an increase in viscosity and cellularity. The resulting absence of spinnbarkheit and ferning capacity decreases sperm survival.

To be receptive to sperm, cervical mucus must be thin, clear, watery, profuse, alkaline, and acellular. As shown in Figure 12-5 ■, the mazelike microscopic mucoid strands align in a parallel manner to allow for easy sperm passage. The mucus is termed *inhospitable* if these changes do not occur.

Cervical mucus inhospitable to sperm survival can have several causes, some of which are treatable. For example, estrogen secretion may be inadequate for the development of receptive mucus. Cone biopsy, electrocautery, or cryosurgery of the cervix may remove large numbers of mucus-producing glands, creating

a "dry cervix" that decreases sperm survival. Treatment with clomiphene citrate may have deleterious effects on cervical mucus because of its antiestrogenic properties. Therapy with supplemental estrogen for approximately 6 days before expected ovulation is sometimes employed to encourage formation of suitable spinnbarkheit. However, intrauterine insemination (IUI) is more often the most appropriate therapy to overcome these obstacles. When mucosal hostility to sperm is due to cervical infection, antimicrobial therapy may be effective.

The cervix can also be the site of secretory immunologic reactions in which antisperm antibodies are produced, causing agglutination or immobilization of sperm. The most widely used serum sperm bioassay to detect specific classes of antibodies in serum and seminal fluid is direct immunobead binding testing (IBT) (Lu, Huang, & Lu, 2008). The IBT is considered clinically significant when 50% of the sperm are coated with immunobeads. The treatment for antisperm antibodies may include IUI of the male's washed sperm to bypass the cervical factor.

The *postcoital test (PCT),* also called the Huhner test, is performed 1 or 2 days before the expected date of ovulation as determined by previous BBT charts, the length of prior cycles, or urinary LH kit. This examination evaluates the cervical mucus, the number of active sperm in the cervical mucus, and the length of sperm survival (in hours) after intercourse. Its use is controversial and has limited use in infertility workups because its value in assessing cervical hostility to sperm has never been proven (Wright & Johnson, 2008). Tests that can potentially predict the fertilizing ability of sperm include the zona-free hamster egg penetration assay and the hemizona test.

Evaluation of Uterine Structures and Tubal Patency

Uterine abnormalities are a relatively uncommon cause of infertility but should always be considered. A few tests offer the ability to evaluate the uterine cavity and tubal patency simultaneously. These tests are usually done after BBT evaluation, semen analysis, and the other less invasive tests. Tubal patency and uterine assessment are usually evaluated by hysterosalpingography or laparoscopy. Other invasive tests used to evaluate only the uterine cavity are hysteroscopy and sonohysterography.

PATIENT TEACHING Methods of Determining Ovulation

PATIENT GOALS At the completion of the teaching the woman will be able to:

1. Accurately identify cervical mucus changes.
2. Accurately take and record BBT.
3. Discuss the changes in BBT and cervical mucus that indicate ovulation.
4. Discuss alternative methods of ovulation detection.
5. Summarize physical symptoms that may indicate ovulation has occurred.

TEACHING PLAN

Content	Teaching Method
Basal Body Temperature (BBT) Method	
The basal body temperature (BBT) method relies on assessing the woman's temperature pattern.	Choose a private location, free of distractions for the discussion.
Describe the expected findings with an ovulatory (biphasic) cycle and stress the need to monitor BBT for 3 to 4 months to establish a pattern. BBT can be used to time intercourse if pregnancy is desired or as a method of natural family planning. Describe the timing of intercourse to achieve or avoid pregnancy.	Create a supportive, comfortable atmosphere by attitude and communication style. *Briefly* explain how BBT can indicate ovulation. Use pictures or graphs to demonstrate the BBT changes that indicate ovulatory and ovulatory cycles.
Procedure for Measuring BBT: ■ Using a BBT thermometer, the woman chooses one site (oral, vaginal, or rectal), which she uses consistently. ■ The woman takes her temperature every day before arising and before starting any activity, including smoking. Any activity can produce an increase in body temperature.	Break content down into smaller steps to facilitate learning. Show the woman the BBT thermometer and demonstrate its use. *Note:* A tympanic (ear) electric thermometer may also be used. Remind the woman to use the same type of thermometer throughout the menstrual cycle.
Note: Read and follow manufacturers' instructions for each type of BBT thermometer in regard to amount of time needed for accurate reading. ■ The result is then recorded immediately on a special BBT chart, and the temperature dots for each day are connected to form a graph. ■ The woman then shakes the thermometer down in preparation for use the next day.	Provide a blank chart. Ask the woman to chart 3 days' findings using temperature results you identify. Remind the woman that BBT charts are not a prediction of ovulation and that the temperature rise is a response to ovulation that has already occurred. Provide the woman with an example of LH testing results for comparison. Provide a handout summarizing the procedure. Provide frequent opportunities for questions and discussion.
Explain that certain situations can disturb body temperature such as large alcohol intake, sleeplessness, fever, warm climate, jet lag, shift work, the use of an electric blanket, or use of a heated waterbed.	
Cervical Mucus Method	
Explain that cervical mucus characteristics change throughout a woman's menstrual cycle, and that the quality of the mucus can be used to predict ovulation.	Discuss the various characteristics of the mucus throughout the menstrual cycle and the rationale for the changes. Explore the woman's feelings about using the procedure.
Procedure for Assessing Cervical Mucus Changes: ■ Every day when she uses the bathroom the woman checks her vagina, either by dabbing the vaginal opening with toilet paper or by putting a finger in the opening. ■ She notes the wetness (presence of mucus), collects some mucus, determines its color and consistency, and records her findings on a chart. For discussion of mucus characteristics, see page 248. ■ She washes her hands before and after the procedure.	Show pictures of the mucus changes, including spinnbarkheit of different degrees of elasticity. Encourage the woman to ask questions. Stress that it may take several cycles for the woman to become familiar with the pattern. Explain that the presence and consistency of the mucus are altered by vaginal infection, vaginal medications, spermicides, lubricants, douching, sexual arousal and semen.
LH Predictor Kit Method	
Explain that LH kits are a good predictor of ovulation for a woman with a history of regular menstrual cycles. Describe the procedures for using an LH predictor kit: ■ Determine the length of the woman's menstrual cycle. Use a calendar to determine the cycle day the woman will initiate testing. ■ The testing must occur the same time daily. The morning is recommended, because the LH concentration is highest upon wakening. ■ Begin testing with the first morning urine void and examine the test strips for color changes that indicate if ovulation has occurred or is close to occurring.	

PATIENT TEACHING Methods of Determining Ovulation continued

TEACHING PLAN

Content	Teaching Method
Mittelschmerz	
Explain that mittelschmerz (midcycle pain) located in the lower pelvis is a common symptom of ovulation.	
Encourage the woman to document this occurrence (or absence) on her BBT chart.	

Evaluation	Documentation
Evaluate the learning by providing time for discussion, questions, and practice using the charts and thermometer. Ask the woman to describe the selected procedure in her own words. Provide a written handout describing the process and findings so that the woman has information readily available. Review at a follow-up visit the BBT and cervical mucus assessment from the previous cycle(s).	The nurse should document the information that was given, the type of teaching method used, indicate if the patient performed BBT thermometer assessment, if it was demonstrated, or if verbal or written directions were given. Verbalization of understanding and clarification of any information should be documented. Safety issues and instruction were reviewed.

Hysteroscopy may be performed earlier in the evaluation if the woman's history suggests the potential for adhesive disease or uterine abnormalities.

HYSTEROSALPINGOGRAPHY **Hysterosalpingography (HSG)**, or hysterogram, involves an instillation of a radiopaque substance into the uterine cavity. In addition, the oil-based dye and injection pressure used in HSG may have a therapeutic effect. This effect may be caused by the flushing of debris, breaking of adhesions, or induction of peristalsis produced by the instillation.

The HSG should be performed in the follicular phase of the cycle to avoid interrupting an early pregnancy. This timing also avoids the lush secretory changes in the endometrium that occur after ovulation, which may prevent the passage of the dye through the tubes and present a false picture of obstruction of the entry point of the fallopian tube into the uterus. HSG causes moderate discomfort. The pain is referred from the peritoneum (which is irritated by the subdiaphragmatic collection of gas) to the shoulder. The cramping may be decreased if the radiopaque dye is warmed to body temperature before instillation. Women can take an over-the-counter (OTC) prostaglandin synthesis inhibitor (such as ibuprofen) 30 minutes before the procedure to decrease the pain, cramping, and discomfort. HSG can also cause serious recurrence of pelvic inflammatory disease, so prophylactic antibiotics are recommended to prevent infection that could be triggered by the procedure (Wright & Johnson, 2008).

HYSTEROSCOPY *Hysteroscopy* is the definitive method for both diagnosis and treatment of intrauterine pathology (Speroff & Fritz, 2005). Hysteroscopy allows the physician to further evaluate any areas of suspicion within the uterine cavity revealed by HSG. It can be done in conjunction with a laparoscopy or independently in the office and does not require general anesthesia. A fiberoptic instrument called a hysteroscope is placed into the uterus and allows direct visualization of the size; shape; and location of any intrauterine pathology, such as polyps, myomata (fibroids), or structural variations (Goldstein, 2008). The newest generation hysteroscope allows for minor operative procedures to be performed in the office setting.

LAPAROSCOPY **Laparoscopy** enables direct visualization of the pelvic organs; it is not routinely advised after a normal HSG unless symptoms suggest the need for earlier evaluation (Wright & Johnson, 2008). Diagnostic laparoscopy is an outpatient procedure requiring the use of general anesthesia. Generally a three-puncture approach is used; entry is made through the umbilical area, and supporting instruments are inserted in two suprapubic incisions. The peritoneal cavity is distended with carbon dioxide gas, and the pelvic organs can be directly visualized with a fiberoptic instrument. Tube patency can be assessed by instilling dye into the uterine cavity through the cervix. The pelvis is evaluated for endometriosis, adhesions, organ fixations, pelvic inflammatory disease, tumors, and cysts. The intraperitoneal gas is usually manually expressed at the end of the procedure. In routine preanesthesia instructions, the woman is told that she may have some discomfort from organ displacement and shoulder to chest pain caused by gas in the abdomen. She should be informed that she can resume normal activities as tolerated after 24 hours. Using postoperative pain medication and assuming a supine position may help relieve residual shoulder and chest discomfort caused by any remaining gas.

Activity: Infertility Testing

Assessment of the Man's Fertility

Male infertility can be caused by numerous factors, some of which can be identified and are reversible, such as ductal obstruction and varicocele. Varicocele, which is an abnormal dilation of scrotal veins, is present in 15% of the normal population and accounts for approximately 40% of male infertility (ASRM, 2008j). Other identifiable conditions are not reversible, such as bilateral testicular atrophy secondary to viral orchitis and congenital bilateral absence of the *vas deferens* (CBAVD). Idiopathic male factor infertility occurs when the etiology of an abnormal semen analysis is not identifiable.

If a male infertility factor is present, it is usually defined by the findings of an abnormal semen analysis (ASRM, 2008c). A semen analysis of sperm quality, quantity, and motility is the single most important diagnostic study of the man. It should be done early in the couple's evaluation, before invasive testing of the woman.

To obtain accurate results, the specimen is collected after 2 to 3 days of abstinence and usually by masturbation to avoid contamination or loss of any ejaculate. If the man has difficulty producing sperm by masturbation, special medical grade condoms are available to collect the sperm during intercourse. Regular latex and nonlatex condoms should not be used because they contain agents that impair the mobility of sperm and because sperm can be lost in the condom. Most lubricants also are spermicidal and should not be used unless approved by the andrology laboratory. If the specimen is obtained at home, it needs to be brought to the laboratory within 1 hour and kept at body temperature so as not to impair motility.

Both seasonal and incidental variability may be seen in count and motility in successive semen samples from the same person. Thus a repeat semen analysis may be required to assess the man's fertility potential adequately; a minimum of two separate analyses is recommended for confirmation. In a case in which a known testicular insult has occurred, such as infection, high fevers, or surgery, a repeat analysis may not be done for at least 2.5 months to allow for new sperm maturation.

Semen analysis provides information about sperm motility and morphology as well as a determination of the absolute number of spermatozoa present (Table 12-5). Although it is known that low numbers and motility may indicate compromised fertility, other parameters such as morphology, volume, motion patterns, viscosity, pH, and progression are important prognostic indicators. Values previously thought to indicate subfertility may in fact be compatible with normal fertility when these factors are considered. The quality of sperm decreases with increasing paternal age and may result in chromosomal damage. For example, fathers older than 40 years may be at an increased risk for offspring with chromosome abnormalities or new gene mutations (Toriello & Meck, 2008).

TABLE 12-5 Normal Semen Analysis

FACTOR	VALUE
Volume	Greater than 2 ml
pH	7 to 8
Total sperm count	Greater than 20 million/ml
Liquefaction	Complete in 1 hour
Motility	50% or greater forward progression
Normal forms	30% or greater
Round cells	Less than 5 million/ml
White cells	Less than 1 million/ml

Source: Courtesy of the World Health Organization. (1999). WHO Laboratory Manual for the Examination of Human Semen and Sperm-Cervical Mucus Interaction *(4th ed., pp. 9–106). Cambridge, UK: Cambridge University Press.*

Genetic factors may affect male fertility. Men with oligospermia (semen with a low concentration of sperm) and nonobstructive azoospermia (impaired or nonexistent sperm production) have an increased risk for chromosome abnormalities and Y chromosome deletions. The chance of detecting one of these abnormalities is approximately 10% in oligospermic men and 30% in azoospermic men (ASRM, 2008c). Men with obstructive azoospermia, such as congenital bilateral absence of the vas deferens (CBAVD) have an up to 80% risk for cystic fibrosis genetic mutations (ASRM, 2008c).

Spermatozoa have been shown to possess intrinsic antigens that can provoke male immunologic infertility. Any disruption in the blood-testes barrier, such as vasectomy reversals, or genital trauma, such as testicular torsion, can lead to the production of antisperm antibodies (ASA) (Lee et al., 2009). Treatment for antisperm antibodies is directed toward preventing the formation of antibodies or arresting the underlying mechanism that compromises sperm function. Therapies such as immunosuppression with corticosteroids and IUI have not proved effective. The treatment of choice for clinically significant antisperm antibodies is intracytoplasmic sperm injection (ICSI) in conjunction with IVF.

Tests such as the hamster sperm penetration assay (SPA), hemizona (HZA), acrosome reaction assay, and sperm density evaluation may be performed, but their usefulness is controversial. If the man's history indicates, he may be referred to a urologist for further testing.

Methods of Managing Infertility

Methods of managing infertility include pharmacologic agents, therapeutic insemination, IVF, and other assisted reproductive techniques. In addition, many couples choose adoption as their preferred response to infertility.

Pharmacologic Agents

This section provides a brief overview of the drugs commonly used for ovarian stimulation in the follicular phase, control of midcycle release, and luteal phase support. The pharmacologic treatment chosen depends on the specific cause of the infertility. Table 12-6 lists some of the drugs commonly used and indications for use.

CLOMIPHENE CITRATE If a woman has normal ovaries, a normal prolactin level, and an intact pituitary gland, *clomiphene citrate* (Clomid, Serophene) is often used as first-line therapy to induce ovulation. See Drug Guide: Clomiphene Citrate. This medication induces ovulation in 70% of women by action at both the hypothalamic and ovarian levels; 30% to 40% of these women will become pregnant. Approximately 10% of women develop multiple gestation pregnancies, almost exclusively twins (Storment, 2006). Clomiphene citrate works by stimulating the hypothalamus to secrete more gonadotropin-releasing hormone (GnRH), which increases the secretion of FSH and LH. These stimulate follicular growth and facilitate the release of ova (Speroff & Fritz, 2005).

For the first course the woman usually takes 50 mg/day orally for 5 days from cycle day (CD) 3 to day 7 or CD 5 to day 9. In nonresponders, the dose may be increased to 100 mg/day

TABLE 12-6 Drugs Commonly Used to Treat Infertility

	INDICATIONS	
DRUGS	**WOMEN**	**MEN**
Clomiphene citrate (Clomid, Serophene)	• Polycystic ovarian syndrome (PCOS) • Hyperandrogenemia • Premature follicle rupture	• Low levels of gonadotropins • Hypothalamic hypogonadism
Human menopausal gonadotropin (hMG) (Repronex, Bravelle)	• Hypothalamic ovulatory dysfunction (after failure of clomiphene) • Hypopituitarism • PCOS (rarely) • Luteinized unruptured follicle syndrome (after failure of hCG alone) • Inadequate cervical mucus • In vitro fertilization, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT) • Controlled superovulation	• Hypothalamic pituitary failure due to Kallmann syndrome or delayed puberty • Hypogonadotrophic hypogonadism (deficiency of FSH and LH)
Recombinant follicle-stimulating hormone (rFSH) (Follistim, Gonal-F)	• PCOS • Too long cycles • In vitro fertilization, GIFT, ZIFT	
Human chorionic gonadotropin (hCG) (Pregnyl, Novarel, A.P.L.)	• Induces dominant follicle to release egg • Luteinized unruptured follicle syndrome	
Bromocriptine (Parlodel) Cabergoline (Dostinex)	• Pituitary adenoma • Hyperpituitarism	• Hyperprolactinemia (functional or pituitary adenoma)
Gonadotropin releasing hormone (GnRh) (Factrel, Lutre-pulse)	• Hypothalamic ovulatory dysfunction—to ensure a pulsatile release of GnRH by a small pump	• Hypothalamic pituitary failure due to Kallmann syndrome or delayed puberty (pulsed infusion)
GnRh Analogs • Leuprolide acetate (Lupron) • Nafarelin acetate (Synarel) • Goserelin acetate (Zoladex)	• Premature follicular rupture • In vitro fertilization, GIFT, ZIFT • Endometriosis	• Hypogonadotrophic hypogonadism
GnRH Antagonists • Ganirelix acetate (Antagon)	• Same as GnRH analogs	
Progesterone (Crinone, Prometrium, progesterone in oil)	• Luteal phase dysfunction • Luteal phase support	

Source: Adapted from American Society for Reproductive Medicine Booklet. (2006). Medications for inducing ovulation—A guide for patients. *Retrieved from http://www.asrm.org/Patientbooklets/ovulation_drugs.pdf; Shane, J. (1993). Evaluation and treatment of infertility.* Clinical Symposia, 45, 2; *Wilson, B. A., Shannon, M. T., & Shields, K. M. (2010).* Prentice Hall nurse's drug guide 2010. *Upper Saddle River, NJ: Pearson Education.*

to a maximum of 250 mg/day, although doses in excess of 100 mg/day are not approved by the Food and Drug Administration (FDA) (Wilson, Shannon, & Shields, 2010). The woman may need to take estrogen simultaneously if a decrease in cervical mucus occurs.

The woman is informed that if ovulation occurs, it is expected to occur 5 to 9 days after the last dose. The nurse determines if the couple has been advised to have sexual intercourse every other day for 1 week, beginning 5 days after the last day of medications. Upon a negative pregnancy test, another trial of clomiphene can be initiated. After the first treatment cycle, a pelvic ultrasound should be done to rule out ovarian enlargement, ovarian cysts, or hyperstimulation. Ovarian enlargement and abdominal discomfort (bloating) may result from follicular growth and the formation of multiple corpus lutea. Persistence of ovarian cysts is a contraindication for subsequent treatment cycles. Other side effects include hot flashes, abdominal distention, bloating, breast discomfort, nausea and vomiting, vision problems (such as visual spots), headache, and dryness or loss of hair (Wright & Johnson, 2008). Supplemental low-dose estrogen may be given to ensure appropriate quality and quantity of cervical mucus, or IUI may be employed to overcome this obstacle. Women can assess the presence of ovulation and possible response to clomiphene therapy by doing BBT and urinary LH tests. The woman should be knowledgeable about side effects and call her healthcare provider if they occur. When visual disturbances (flashes, blurring, spots) occur, the woman should avoid bright lighting. This side effect disappears within a few days or weeks after discontinuation of therapy. Hot flashes may be due to the antiestrogenic properties of clomiphene citrate. The woman can obtain some relief through increasing intake of fluids and using fans. Fecundability (the ability to become pregnant) declines with advancing age as described earlier; therefore, prolonged treatment with clomiphene is unjustified in women in their later reproductive years. Clomiphene treatment should generally be limited to the minimum effective dose and to no more than six ovulatory cycles. Failure to conceive after clomiphene induction is an indication to expand the diagnostic evaluation or to change the overall treatment plan if evaluation is complete.

DRUG GUIDE Clomiphene Citrate (Clomid, Milophene, Serophene)
Pregnancy Category: X

OVERVIEW OF ACTION

Clomiphene citrate stimulates follicular growth by stimulating the release of FSH and LH. Ovulation is expected to occur 5 to 9 days after the last dose. Used when anovulation is caused by hypothalamic dysfunction, luteal phase dysfunction, or oligo-ovulation, as seen in polycystic ovary syndrome (PCOS).

ROUTE, DOSAGE, FREQUENCY

Administered orally. Treatment should begin with a low dose, 50 mg/day (one tablet) for 5 days from cycle day 3 to day 7 or cycle day 5 to day 9. In nonresponders, the dose may be increased to 100 mg/day to a maximum of 250 mg/day, although doses in excess of 100 mg/day are not approved by the FDA (Wilson et al., 2010). May need to give estrogen simultaneously if decrease in cervical mucus occurs.

CONTRAINDICATIONS

Presence of ovarian enlargement, ovarian cysts, hyperstimulation syndrome, liver disease, visual problems, pregnancy. *Interaction:* Herbal: Black cohosh may antagonize infertility treatments (Wilson et al., 2010).

SIDE EFFECTS

Antiestrogenic effects may cause decrease in cervical mucus production and endometrial lining development. Other side effects include vasomotor flushes; abdominal distention and ovarian enlargement secondary to follicular growth (bloating) and multiple corpus luteum formation; pain, soreness, breast discomfort; nausea and vomiting; visual symptoms (spots, flashes); headaches, dryness or loss of hair; multiple pregnancies.

NURSING CONSIDERATIONS

- Determine if the couple has been advised to have sexual intercourse every other day for 1 week, beginning 5 days after the last day of medications. If insemination is the preferred treatment strategy ascertain that this is appropriately timed within the ovulatory window (24 to 36 hours of an LH surge).
- Instruct the couple on use of the BBT chart to assess whether ovulation has occurred, or instruct on the use of urinary LH kits to predict the onset of LH surge. Also inform the couple that plasma progesterone, cervical mucus, and postcoital tests may be done. Remind couples of the need to confirm the outcome with a pregnancy test with either a home pregnancy test or a serum blood test. Clomiphene cycle may be cancelled for ovarian hyperstimulation and subsequent risk of a high-order multiple pregnancy.

INSULIN SENSITIZING AGENTS Insulin resistance and hyperinsulinemia are now recognized as a common feature of polycystic ovary syndrome (PCOS) and a contributing cause of chronic anovulation. Anovulatory women with PCOS are hyperinsulinemic and subsequently are more resistant to clomiphene treatment. Recently, studies have shown that oral hypoglycemia agents (e.g., metformin and rosiglitazone) can induce ovulation in women with PCOS. Clinical trials are under way to determine the appropriateness of oral hypoglycemic agents with and without clomiphene in the infertility setting.

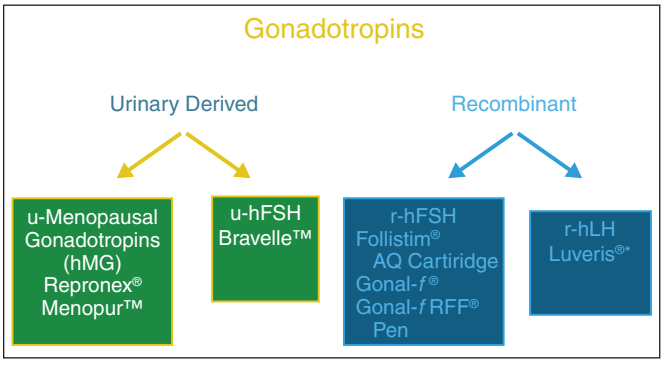
GONADOTROPINS Therapy using *human menopausal gonadotropins (hMG)*, which include menotropins (Repronex and Menopur) and urofollitropin (Bravelle), is indicated as a first line of therapy for the anovulatory infertile woman with low to normal levels of gonadotropins (FSH and LH) and as a second line of therapy in women who fail to ovulate or conceive with clomiphene citrate therapy and in women undergoing controlled ovarian stimulation with assisted reproduction. Menotropin is a mixture of FSH and LH, and urofollitropin is a further purified form and contains mainly FSH with trace amounts of LH. Immediately before injection, the powder is reconstituted with a diluent and injected subcutaneously.

More recently, however, recombinant gonadotropins (rFSH and rLH) have been produced through genetic engineering, giving rise to more consistent preparations. Recombinant FSH is homogenous and free of contaminants by proteins. It is marketed under the names Gonal-F (follitropin alpha) and Follistim (follitropin beta). Luveris, a recombinant form of LH, is used concomitantly with recombinant FSH in women with profound LH deficiency such as hypogonadotropic hypogonadism. It is thought that the use of recombinant gonadotropins will eventually become the preferred preparation and that the use of urinary preparations will be phased out (Figure 12-6 ■).

Gonadotropin therapy requires close observation with serum estradiol levels and ultrasound. Follicle development must be monitored to minimize the risk of multiple pregnancy and to avoid ovarian hyperstimulation syndrome. The daily dose of medication given is titrated based on serum estradiol and ultrasound findings. Then once optimal follicle growth has occurred, human chorionic gonadotropin (hCG) may be administered by either intramuscular or subcutaneous injection to induce final follicular maturation and stimulate ovulation. The couple is advised to have intercourse 24 to 36 hours after hCG administration and for the next 2 days. Women who elect to undergo ovarian stimulation with gonadotropins have usually passed through all other forms of management without conceiving. Strong emotional support and thorough education are needed because of the numerous office visits and injections. Often the partner is instructed, with return demonstration, to administer the daily injections.

BROMOCRIPTINE High prolactin levels may impair production of FSH and LH or block their action on the ovaries. When hyperprolactinemia accompanies anovulation, the infertility may be treated with bromocriptine (Parlodel). This medication acts directly on the prolactin-secreting cells in the anterior pituitary. It inhibits the pituitary's secretion of prolactin—thus

A



B

Figure 12-6 ■ A. A selection of commonly prescribed medications for ovulation induction. B. Derivation of gonadotropin medications.

Source: A. Courtesy of PENN Fertility Care, Philadelphia, PA. B. Courtesy of Serono, Inc., Rockland, MA.

preventing suppression of the pulsatile secretion of FSH and LH. This restores normal menstrual cycles and induces ovulation by allowing FSH and LH production. If treatment is successful, the tests of ovulatory function will indicate that ovulation is occurring with a normal luteal phase. Bromocriptine should be discontinued if pregnancy is suspected or at the anticipated time of ovulation because of its possible teratogenic effects. Other side effects, which include nausea, diarrhea, dizziness, headache, and fatigue, can be attributed to the dopaminergic action of bromocriptine. To mimimize side effects for women who are extremely sensitive, treatment may be initiated with a dose of 1.25 mg, slowly building tolerance toward the usual dose of 2.5 mg bid. Intravaginal administration also has been shown to decrease the occurrence of side effects (Wright & Johnson, 2008).

DANAZOL When endometriosis is determined to be the cause of the infertility, *danazol* (Danocrine) may be given to suppress ovulation and menstruation and to affect atrophy of the ectopic endometrial tissue. Temporary suppression has been shown to result in healing of the endometriosis. The treatment regimen may last for 6 to 12 months or longer, depending on the severity of the disease. Other pharmacologic treatments involve use of the oral contraceptives or oral medroxyprogesterone acetate, and GnRH agonists. For in-depth discussion of the management and care needed for endometriosis, see chapter 7 ∞.

GONADOTROPIN-RELEASING HORMONE (GNRH) *GnRH* is a therapeutic tool for inducing ovulation, but its use is limited to women who have insufficient endogenous release of GnRH. Administration is usually by continuous intravenous infusion accomplished by a portable infusion pump with a pulsatile mechanism worn on a belt around the waist. The length of treatment varies from 2 to 4 weeks, and hCG is also given to stimulate ovulation. The risk of multiple gestation and hyperstimulation of the ovaries is less than with gonadotropin therapy, and the treatment is also less expensive. Significant patient education and support are necessary for effective use of the pump. Some women find the pump cumbersome.

GnRH agonists (Lupron) and antagonists (Cetrotide and Ganirelix) are often used adjunctively with gonadotropin therapy to suppress the pituitary secretion of endogenous LH and FSH. This is often referred to as down-regulation.

PROGESTERONE Treatment of luteal phase defects may include the use of progesterone to augment luteal phase progesterone levels or the use of ovulation induction agents, such as clomiphene citrate or gonadotropins (discussed previously), which will augment proliferative phase FSH production of the developing follicle. Women with luteal phase defects have been found to have decreased FSH production in the proliferative phase. This is associated with a decline in luteal phase progesterone and estrogen production and is manifested by an out-of-phase endometrial biopsy. It is also common to use progesterone supplementation in conjunction with these ovulation induction agents for luteal phase support, thereby increasing endometrial receptivity for embryonic implantation. The initiation of progesterone (vaginal or rectal suppositories, intramuscular injections, or orally) occurs after the hCG injection in ovulation induction cycles or IVF cycles with gonadotropins; the treatment continues until pregnancy testing and may continue further if pregnancy testing is positive. Occasionally, hCG therapy may be used in the luteal phase to stimulate corpus luteum production of progesterone.

COMPLEMENTARY AND ALTERNATIVE THERAPIES FOR INFERTILITY Couples experiencing infertility may seek out alternative treatments. Some common treatments include acupuncture and herbs.

Acupuncture: Acupuncture is a therapy used in traditional Chinese medicine (TCM), and has become a popular complementary treatment. Acupuncture involves inserting sterile needles into specific points on the body to control the flow of chi, or life energy. Acupuncture treatment would focus on balancing the flow of chi in the kidneys and adrenal glands. Several clinical studies have shown acupuncture to be effective in treating infertility in both men and women (Cheong, Hung Yu Ng, & Ledger, 2008).

Herbal treatments: Herbs frequently recommended to treat infertility include ginseng and astragalus. Herbalists cite the healing and hormone-balancing effects of these herbs.

Ginseng has historically been used in TCM to enhance male virility and fertility. Several studies also cite ginseng, as well as astragalus, in enhancing in vitro sperm motility (Skidmore-Roth, 2010).

The nurse should be alert for signs that the couple is pursuing complementary therapies out of desperation. A sensitive, nonjudgmental approach will go a long way toward comforting a couple and assuring them that many complementary therapies used are helpful and not harmful.

Therapeutic Insemination

Therapeutic insemination has replaced the previously used term *artificial insemination* and involves depositing sperm at the cervical os or in the uterus by mechanical means. *Therapeutic donor insemination* (*TDI*) is the current term for use of donor semen, and *therapeutic husband insemination* (*THI*) is the current term for use of the husband's semen.

THI is generally indicated for such seminal deficiencies as oligospermia (low sperm count), asthenospermia (decreased motility), and teratospermia (low percentage, abnormal morphology); for anatomic defects that are accompanied by inadequate deposition of sperm, such as hypospadias (a congenital abnormal male urethral opening on the underside of the penis); and for ejaculatory dysfunction, such as retrograde ejaculation. THI is also indicated in unexplained infertility and some cases of female factor infertility, specifically infertility due to cervical factors, such as scant or inhospitable mucus, persistent cervicitis, or cervical stenosis. In such cases, IUI would be indicated to bypass the cervical factor. Because the seminal fluid contains high levels of prostaglandins, IUI prevents the violent reaction of nausea, severe cramps, abdominal pain, and diarrhea that can result from the absorption of prostaglandins by the uterine lining. Sperm preparation for IUI involves washing sperm from the seminal plasma. IUI, with or without ovulation induction therapy, is an option for many couples before more aggressive treatments such as IVF are employed.

TDI is considered in cases of azoospermia (absence of sperm), severe oligospermia or asthenospermia, inherited male sex-linked disorders, and autosomal dominant disorders. In the past several years, indications for donor insemination have expanded to include single women or lesbians desirous of pregnancy. Some states have specified the parental rights of the single woman and the donor, but most are silent on this issue.

TDI has become more complicated and expensive in the last decade because of the need for strict screening and processing procedures to prevent transmission of a genetic defect or sexually transmitted infection to the offspring or recipient. Guidelines were established and updated by the American Society for Reproductive Medicine (2008d) that include mandatory medical and infectious disease screening of both donor and recipient, the need for informed consent from all parties, the need to limit the number of pregnancies per donor, and the need to establish an accurate means of record keeping. Finally, because of the risk of transmitting infectious disease, donated sperm must be frozen and quarantined for 6 months from the time of acquisition and the donor must be retested before sperm can be released for use.

RESEARCH EVIDENCE IN PRACTICE

Cervical Insemination Versus Intrauterine Insemination of Donor Sperm

CLINICAL QUESTION

Which method of insemination of sperm results in the best pregnancy rate with the lowest costs and risks?

RESEARCH EVIDENCE

One out of ten couples is considered subfertile, in that they cannot conceive spontaneously within a year. Subfertility may be due to severe male factor infertility, and for these couples, insemination with donor sperm is a viable option. Insemination may be the only option for single women or same-sex female couples. There are two techniques for insemination—cervical and intrauterine. In cervical insemination, sperm is deposited near the cervix. In intrauterine insemination, the sperm is deposited in the uterine cavity. It has been assumed that intrauterine insemination is superior because the sperm is deposited more closely to the fallopian tubes and, therefore, has a better chance of fertilizing the ovum, resulting in a successful pregnancy. However, intrauterine insemination requires an invasive procedure of dilating the cervix and inserting instrumentation into the uterus. This procedure is more costly than cervical insemination, can be painful, and carries the risk of uterine perforation and infection.

In a systematic review published in the Cochrane Collaborative (a strong source of high-quality research evidence) and a meta-analysis of studies, intrauterine insemination was found to be superior to cervical insemination in terms of achievement of pregnancy. There were no differences in the two approaches in adverse outcomes or complications.

WHAT QUESTIONS REMAIN UNANSWERED?

Intrauterine insemination requires laboratory preparation of cryosperm and administration of follicle-stimulating drugs in the mother. Cervical insemination often uses live sperm with no stimulating drugs. Would the less invasive method be as effective if follicle-stimulating drugs were administered?

WHAT IS BEST PRACTICE?

Intrauterine insemination with cryopreserved sperm, preceded by follicle-stimulating drugs for the mother, has the most successful pregnancy rate without increased adverse complications.

CRITICAL THINKING

Are there couples for whom the less invasive cervical procedure may be as effective? How can the woman be counseled about the risks and benefits of each procedure?

Numerous factors must be evaluated before TDI is performed. Has every possible effort been made to diagnose and treat the cause of the male infertility? Do tests indicate normal ovulation and sperm/ovum transport in the woman? Has the couple had an opportunity to discuss this option with an infertility counselor to explore the issues of secrecy, disclosure, and potential feelings of loss that the couple (particularly the male partner) may feel because of their inability to have a genetic child? After making the decision, the couple should allow themselves time to assess their concerns further and explore their feelings individually and together to ensure that this option is acceptable to both.

In Vitro Fertilization

In vitro fertilization (IVF) is selectively used in cases in which infertility has resulted from tubal factors, mucus abnormalities, male infertility, unexplained infertility, male and female immunologic infertility, and cervical factors. In IVF, a woman's eggs are collected from her ovaries, fertilized in the laboratory, and placed into her uterus after normal embryo development has begun. If the procedure is successful, the embryo continues to develop in the uterus, and pregnancy proceeds naturally.

DEVELOPING CULTURAL COMPETENCE

Infertility Treatments

The acceptance of infertility treatments varies widely around the world. Some belief systems do not allow various treatments, because using a treatment is considered interfering with God's design or because the treatment itself is seen as tainted or sinful. For example, fertility practices in Arab cultures are influenced by traditional Arab Bedouin values that support tribal dominance and beliefs that "God decides family sizes." In Arab cultures, procreation is the purpose of marriage.

If a couple is infertile, the approved methods for treating infertility are limited to use of therapeutic insemination using the husband's sperm and IVF involving the fertilization of the wife's ovum by the husband's sperm because of lineage concerns (Purnell & Paulanka, 2008).

Sterility in a woman can lead to rejection and divorce. Also with the advent of ICSI (intracytoplasmic sperm injection), male-initiated divorce is becoming more common for aging wives of infertile husbands (Inhorn, 2006). Contemporary Islamic religious opinion forbids any kind of egg, embryo, or semen donation, as well as surrogacy (Inhorn, 2006).

In Jewish cultures, infertile couples are to try all possible means to have children, including egg and sperm donation. However, Orthodox Jewish opinion is virtually unanimous in prohibiting artificial insemination when the semen donor is a Jewish man other than the woman's husband, because it may constitute adultery (Purnell & Paulanka, 2008). If the infertility is because of a male factor, artificial insemination with sperm from a non-Jewish sperm donor is acceptable because "Jewishness" is conferred through the matriline. IVF and embryo transfer (ET) are also acceptable artificial insemination methods because they do not involve putting sperm into another's wife (Schenker, 2010).

The potential for a successful pregnancy with IVF is maximized by replacing three to four embryos (rather than one). For this reason, fertility drugs are used to induce ovulation before the process. Follicular growth is monitored frequently with ultrasound and hormonal assays. Monitoring usually begins around cycle day 5, and medications are titrated according to individual response. When the follicles have grown to an appropriate size, hCG is given to induce final egg maturation and control the induction of ovulation. Egg retrieval is performed approximately 35 hours later, before ovulation occurs.

In the majority of cases, egg retrieval is performed by a transvaginal approach under ultrasound guidance (Figure 12-7A ■). It is an outpatient procedure performed with intravenous sedation and a cervical block for anesthesia. A needle guide that helps direct the aspirating needle through the posterior vaginal wall into the follicle is attached to the vaginal ultrasound probe (Figure 12-7B ■). Many follicles can be aspirated with only one puncture, and the procedure generally lasts no more than 30 minutes. Once the eggs are fertilized and progress to the embryo stage, the

embryos are placed in the uterus. This occurs 1 to 2 days after conception. After the procedure, the woman is advised to engage in only minimal activity for 12 to 24 hours. Progesterone supplementation is prescribed to promote implantation and support the early pregnancy; therefore, the woman will not have a period even if she is not pregnant (the pregnancy is usually determined by transvaginal ultrasound).

Sperm used to fertilize the eggs in vitro can be obtained naturally or surgically via microsurgical epididymal sperm aspiration (MESA) and testicular sperm aspiration (TESA). These are procedures that address severe male factor infertility. MESA and TESA involve the retrieval of sperm from the gonadal tissue of men who have azoospermia or an ejaculatory disorder. Percutaneous epididymal sperm aspiration (PESA) and TESA are replacing MESA as the preferred techniques for retrieval of sperm because they are not surgical procedures. ICSI is a microscopic procedure to inject a single sperm into the outer layer of an ovum so that fertilization will occur (Devine, 2008).

Success with IVF depends on many factors, the two most important of which are the woman's age and the indication. Women with an average of three cycles of IVF have a good chance of achieving pregnancy. Many couples find the emotional, physical, and financial costs of going beyond three cycles too great. Costs vary by treatment and by region of the country (ASRM, 2010). Clinical birth rates in the United States reported by the Society of Assisted Technology (SART) were 50% per egg donation for women regardless of age or indication (ASRM, 2008d). The increase in maternal and neonatal morbidity associated with IVF because of the multiple gestation rates remains an issue.

Other Assisted Reproductive Techniques

Other assisted reproductive techniques include procedures for transferring gametes, zygotes, or embryos; cryopreservation of embryos; IVF using donor oocytes; micromanipulation techniques; and use of a gestational carrier (Figure 12-8 ■).

GAMETE INTRAFALLOPIAN TRANSFER **Gamete intrafallopian transfer (GIFT)** involves the retrieval of oocytes by laparoscopy; immediate placement of the oocytes in a catheter with washed, motile sperm; and placement of the gametes into the fimbriated end of the fallopian tube. Fertilization occurs in the fallopian tube as with normal conception (in vivo), rather than in the laboratory (in vitro). The fertilized egg then travels through the fallopian tube to the uterus for implantation as in normal reproduction. GIFT may be more acceptable than other procedures such as ZIFT to adherents of some religions (Roman Catholic), because fertilization does not occur outside the woman's body.

GIFT has proven to be a very effective therapy for couples whose infertility results from various seminal deficiencies, unexplained factors, cervical factors, immunologic factors, and endometriosis when less aggressive means of therapy have failed. In cases of male factor infertility, GIFT offers an opportunity for

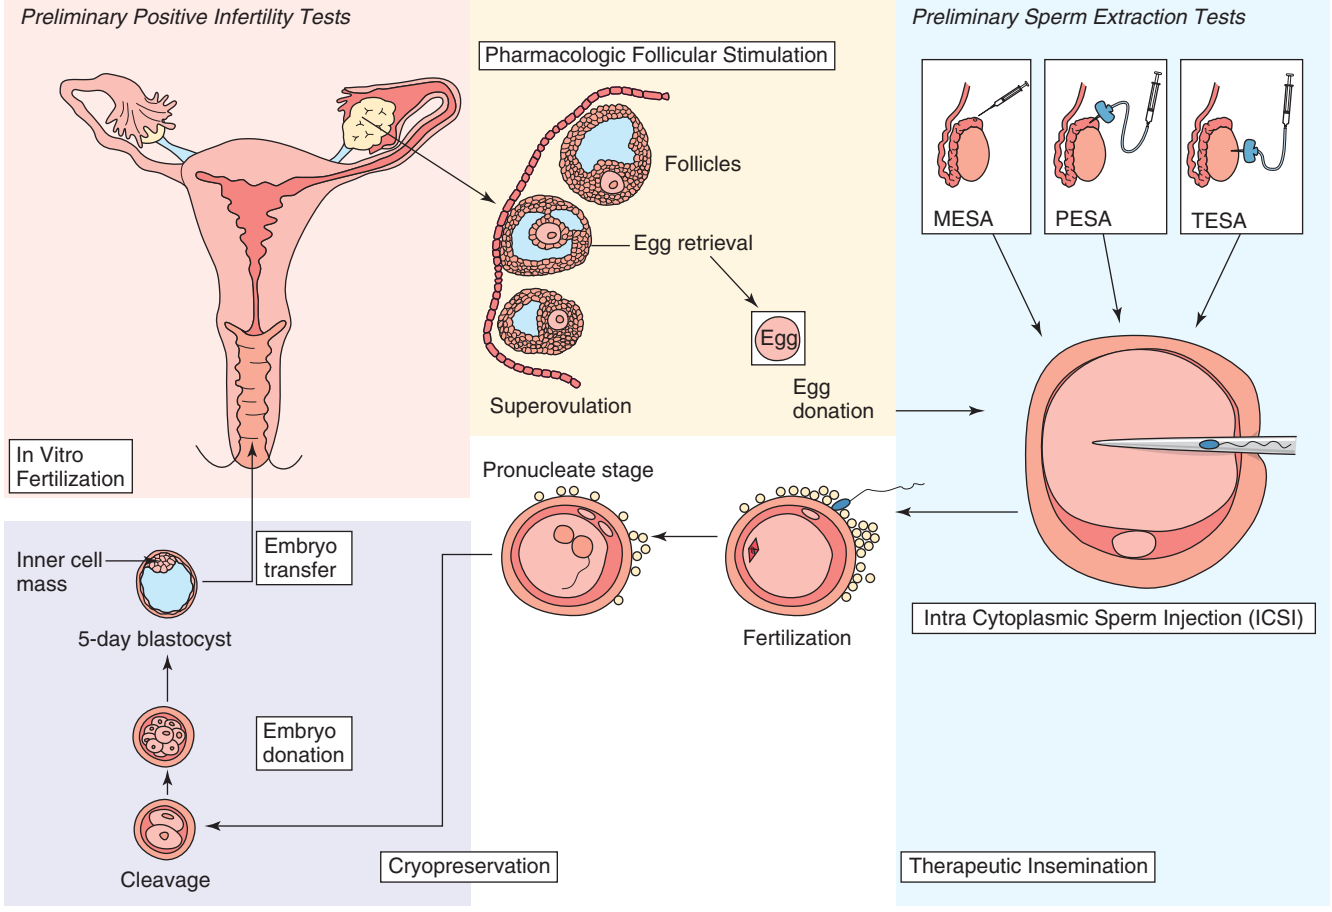

Figure 12-8 ■ Assisted reproductive techniques.

the egg and an adequate concentration of sperm to meet in the fallopian tube; with coitus, in contrast, sperm with low count or motility may never reach the tube. The major prerequisite for GIFT is the presence of at least one normal fallopian tube. It is not an appropriate therapy for any woman with a history of pelvic inflammatory disease, tubal disease, or ectopic gestation because the passage of the fertilized ova to the uterus is slowed, thereby increasing the chance of sustaining an ectopic tubal pregnancy.

From the GIFT technology evolved several other transfer procedures such as **zygote intrafallopian transfer (ZIFT)** and **tubal embryo transfer (TET)**. In these procedures eggs are retrieved and incubated with the man's sperm. However, the eggs are transferred back to the woman's body at a much earlier stage of cell division than in IVF and, as in GIFT, are placed in the fallopian tube or tubes and not in the uterus. In TET, the placement is done at the embryo stage. These procedures allow fertilization to be documented, which is not possible with GIFT, and the pregnancy rate is theoretically increased when the fertilized ovum is placed in the fallopian tube.

When considering IVF and the transfer procedures, several factors must be weighed. IVF success rates approximate those that have been achieved with the transfer procedures, and IVF is a much less invasive and costly procedure. For these reasons, the transfer procedures have lost some acceptance and IVF techniques are more often used.

EMBRYO CRYOPRESERVATION Research has shown that replacing three to four embryos in a treatment cycle offers the best chances for pregnancy. Replacing more than four only increases the chance for a multiple pregnancy. To minimize this risk, excess embryos may be stored using freezing, or cryopreservation. Should a pregnancy not ensue, frozen embryos can be thawed. After they are maintained in culture for a short time to confirm resumption of growth, they are replaced in the woman's uterus at the appropriate time in her menstrual cycle. Thus freezing affords the couple another attempt at pregnancy without having to undergo stimulation and egg retrieval again.

Ethical issues to consider in this situation include the following: Who has legal custody of the embryos? How long can they be frozen? What options does the couple have in the event of divorce, if one or both partners die, or if they do not wish to use the embryos at a later date? These issues must be addressed with all couples so that they can make informed decisions when executing their consent forms and legal statements. Reproductive endocrine nurses need to be involved in establishing standards and guidelines for assisted reproduction technologies. Clinically, the reproductive endocrine nurse is instrumental in providing support, education, and counseling to couples considering assisted reproductive methods. The nurse assesses the couple for personal, marital, and parenting difficulties and initiates interventions that help establish family roles and bonds. Follow-up care mechanisms can be set, thereby aiding in individual growth, marital stability, and family development.

IN VITRO FERTILIZATION USING DONOR OOCYTES The use of donor eggs, a natural extension of IVF, is reserved for women who do not produce viable eggs because of premature ovarian failure, surgical removal of the ovaries, advanced maternal age, chemotherapy or radiation exposure, or inherent oocyte defects but who do have a functional uterus. Women with normal ovarian function may also benefit from egg donation if they have an autosomal dominant or sex-linked genetic disorder such as hemophilia or Duchenne muscular dystrophy.

Oocyte donors may be either known or anonymous. In either case, both donors and recipients undergo psychologic evaluation and counseling to ensure that all parties have explored and discussed potential issues and are comfortable with the process. The donors are subject to extensive medical and genetic testing. The FDA has instituted screening and testing requirements for all tissue donors, which includes donors of oocytes, sperm, and embryos (ASRM, 2008d). The nurse functions as a case manager by coordinating the many tests, procedures, and educational and counseling sessions that are involved for the donor and recipient couple.

Once donor eggs are available, they are inseminated with the sperm of the recipient's partner. After fertilization has occurred and embryo development has begun, the embryos are placed in the recipient's uterus. Pregnancies can be achieved and maintained in these women with an estrogen/progesterone replacement protocol. When pregnancy occurs, hormonal support is continued until the placenta is capable of supporting the pregnancy, usually at 10 to 12 weeks.

EMBRYO DONATION Much like egg donation, embryo donation offers couples another option in creating a family. Couples who have gone through assisted reproductive technology (ART) and have completed their family may choose to donate their cryopreserved embryos to another couple. There are two types of donation, known or directed donation and anonymous donation. Couples interested in being the recipients of these donations include those with severe or untreatable male and female factor infertility, those who have experienced repeated treatment failures or multiple pregnancy losses not due to implantation problems, and those at risk for transmitting genetic diseases to their offspring. Screening and assessment guidelines have been established by the American Society of Reproductive Medicine (2008d).

MICROMANIPULATION AND BLASTOMERE ANALYSIS Micromanipulation allows individual eggs and sperm to be handled through the use of very fine, specialized instruments. Using the micromanipulators allows the clinician to handle cells under the microscope with magnification of 200 to 400 times and to inject a sperm cell directly into an egg. This procedure, known as *ICSI,* has revolutionized the treatment of severe male factor infertility. The procedure has achieved fertilization in cases of extremely low sperm concentrations, in cases of absence of motility, and in cases where previous IVF therapy failed.

Assisted embryo hatching is another micromanipulation procedure that has proved to be an effective adjunct therapy in IVF. It is indicated for women in whom the normal "hatching" process may be impeded because of a hardening or thickening of the zona pellucida, most commonly seen in women of advanced maternal age. Assisted hatching involves creating a small opening in the zona pellucida of the embryo using micromanipulators (Figure 12-9 ■).

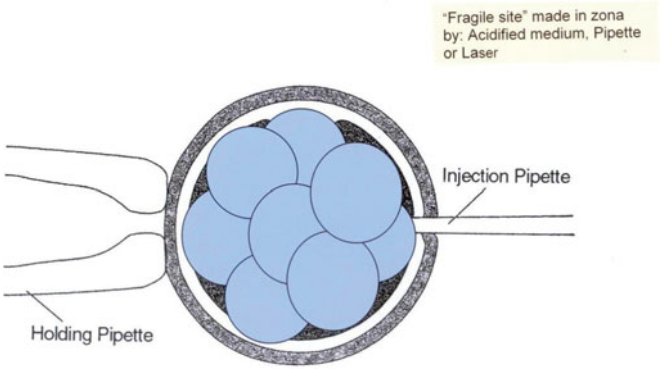

Figure 12-9 ■ Assisted hatching of embryo.
Source: Courtesy of Serono, Inc., Rockland, MA.

The small opening may facilitate the natural hatching process, allowing the embryo to escape from the zona pellucida and interact with the endometrium for implantation.

PREIMPLANTATION GENETIC DIAGNOSIS (PGD) Other recent advances in micromanipulation allow a single cell to be removed from the oocyte (polar body) or embryo (blastomere or trophoectoderm cells) for genetic study. Couples at risk for having a detectable single gene or chromosomal anomaly may wish to undergo such preimplantation genetic testing. *Preimplantation genetic diagnosis* (PGD) is a term used when one or both genetic parents carry a gene mutation or balanced chromosome rearrangement and testing is performed to determine whether that mutation or unbalanced chromosomal compliment has been passed to the oocyte or embryo (ASRM, 2008i). Preimplantation genetic screening (PGS) is a term used when the genetic parents are known or presumed to have normal chromosomes, and their embryos are screened for aneuploidy with the purpose of increasing the likelihood of a viable pregnancy with normal chromosomes (ASRM, 2008i). Specific genetic disorders or chromosome abnormalities can be tested for using the polymerase chain reaction (PCR) technique or fluorescence in situ hybridization (FISH). The cell's deoxyribonucleic acid (DNA) is amplified 1,000,000 times and examined so that embryos affected with a particular genetic disease or chromosome abnormality are not placed in the mother. Results of genetic testing on the preimplantation embryos are available in 4 to 24 hours, so unaffected embryos may still be transferred during the required biologic window of time without the need for cryopreservation. Both PGD and PGS can produce false positive and false negative results. Prenatal diagnostic testing to confirm the results is strongly encouraged (ASRM, 2008i).

The diagnosis of genetic disorders before implantation provides couples with the option of forgoing the attempt to establish a pregnancy and thereby avoiding a difficult decision about terminating an affected pregnancy (Kuliev & Verlinsky, 2010). This technology also raises several ethical issues, including the following:

- Identification of couples at risk. There is a need for criteria that identify couples at risk for diseases that constitute significant hardship and suffering so that "wrongful birth" cases can be avoided.
- Availability of and access to centers providing PGD. Should society provide access for those at risk for genetic transfer of disease but without the financial resources to pay for the services?
- Analysis of blastomeres for sex chromosome testing when a genetic disorder carried on the sex chromosomes is suspected. In X-linked diseases, this may mean selecting against the blastomere with the Y chromosome.
- Identification of late-onset diseases. The Human Genome Project has aided in the identification of genetic markers for late-onset disease. Couples may wish to choose to implant blastomeres that do not carry these markers.
- Effect on the offspring as a result of removing cells from the embryo.
- Selection for nonmedical reasons and potential concern of eugenics "designer babies."

SPERM SORTING Sperm sorting is a technology designed to separate sperm that primarily produce females or those that primarily produce males. Sorted sperm enriched with male- or female-producing sperm is then used for IUI or IVF. The accuracy depends on the laboratory that performs the sorting and the technology it uses. Study data indicate that 9 out of 10 patients sorting for a girl will conceive a female. Approximately 3 out of 4 patients that sort for a boy will conceive a male. This technology is used to increase the likelihood of having a child of a particular gender in couples at risk for an X-linked genetic disorder or for couples interested in family balancing (gender selection when a couple has two or more children of the same gender) (Gleicher & Nakajima, 2009).

IN VITRO FERTILIZATION USING A GESTATIONAL CARRIER A *gestational carrier* is a woman who has contracted with the infertile woman or couple to carry an embryo/fetus that is not genetically her own offspring. This must be distinguished from surrogate motherhood, wherein the surrogate is both gestational carrier and gamete donor. IVF using a gestational carrier is appropriate for the infertile woman who is able to produce her own eggs but unable to carry a pregnancy because of (1) congenital absence or surgical removal of her uterus; (2) a reproductively impaired uterus, myomas, uterine synechiae (adhesion of uterus), or any other congenital abnormalities; or (3) a medical condition that might be life threatening during pregnancy such as diabetes; immunologic problems; or a severe heart, kidney, or liver disease. Use of a gestational carrier allows a couple with any of these conditions to have a child who is a genetic relation (American College of Obstetricians and Gynecologists [ACOG], 2008). All participants are required to have medical and psychologic screening as well as legal counsel before acceptance into the program.

Adoption

Infertile couples consider various alternatives for resolving their infertility; adoption is one option that will be considered at several points during the treatment process. As couples begin to consider adoption, an important aspect of this exploration is the reading of books, magazines, and informational Web sites such as the National Adoption Information Clearinghouse; attending

adoption support groups and conferences; and meeting with adoptive parents to discuss their experiences with adoption.

The adoption of an infant in the United States can be difficult and frustrating, often involving long waiting periods, continual setbacks, and high costs. Thus many couples seek international adoptions or consider adopting older children, children with disabilities, or children of mixed racial parentage, because the adoption process in such cases is quicker and more children are available. Nurses in the community can assist couples considering adoption by providing information on community resources for adoption as well as by providing support throughout the adoption process. Informational books, Web sites, and support groups such as San Francisco RESOLVE's "Living Without Children" are available for couples who remain childless by choice or circumstances.

Pregnancy After Infertility

The feeling of being infertile does not necessarily disappear with pregnancy. Although there may be initial ecstasy, the couple may also face a whole new arena of fear and anxieties, and the parents-to-be often do not know where they "fit in." They may feel a great sense of loss and isolation because those who have had no trouble conceiving cannot relate to the physical and emotional pain they endured to achieve the pregnancy. Contact with their past "infertile" support system may vanish when peers learn that the couple has resolved their infertility. Although the desperation to become pregnant may have superseded the couple's ability to acknowledge their concerns about undergoing various treatments or procedures, questions about the repeated cycle of fertility drugs or the achievement of pregnancy through IVF technology or cryopreservation may now arise. The expectant couple may be very concerned about the potential of these treatments for adverse effects on the fetus (McGrath et al., 2010; Wright & Johnson, 2008). Couples may need much reassurance throughout the pregnancy to allay these anxieties. The nurse can assist couples who conceive after infertility by acknowledging their past experience of infertility treatment; validating their fears and anxieties as they face childbirth classes, birth, and parenting issues; and providing education and support regarding what to anticipate physically and emotionally throughout the pregnancy. The nurse can also counsel couples that infertility due to nonstructural causes may correct itself following a successful pregnancy and delivery; therefore, postdelivery contraception counseling may be warranted. These interventions will go a long way toward normalizing the experience for the couple.

Recurrent Pregnancy Loss

Recurrent pregnancy loss (RPL) is a disease distinct from infertility, defined by two or more failed pregnancies (ASRM, 2008b). Estimates suggest that RPL occurs in 0.5% to 1% of fertile couples attempting pregnancy (Warren & Silver, 2008). There are several etiologies, including maternal medical complications, chromosome abnormalities and other genetic conditions, autoimmune disorders, and thrombotic causes. However, in up to 50% of couples with RPL, an etiology will not be identified.

Maternal medical complications associated with RPL include luteal phase defects or progesterone deficiency and congenital uterine abnormalities. Autoimmune disorders such as antiphospholipid antibody syndrome, alloimmune factors, and blood group isoimmunization have been associated with RPL. Chromosome abnormalities such as recurrent aneuploidy and parental chromosome abnormalities are associated with RPL. One partner will have a balanced chromosome rearrangement in 3% to 5% of couples with RPL (Warren & Silver, 2008). Single gene disorders such as alpha-thalassemia major, some metabolic diseases, and some X-linked dominant disorders that are lethal *in utero* in males can account for RPL. Hereditary thrombophilias, such as factor V Leiden, prothrombin gene, protein C or S deficiency, and antithrombin III deficiency are known to predispose individuals to pregnancy complications including RPL.

NURSING CARE MANAGEMENT

Care Plan Activity: Infertile Couple

Infertility therapy taxes a couple's financial, physical, and emotional resources. Treatment can be costly, and often insurance coverage is limited. Years of effort and numerous evaluations and examinations may take place before a conception occurs, if one occurs at all. In a society that values children and considers them to be the natural result of marriage, infertile couples may face a myriad of tensions and discrimination.

The clinic nurse needs to be constantly aware of the emotional needs of the couple confronting infertility evaluation and treatment. Often an intact marriage will become stressed with the intrusive but necessary infertility procedures and treatments. Constant attention to temperature charts and instructions about their sex life from a person outside the relationship naturally affect the spontaneity of a couple's interactions.

Tests and treatments may heighten feelings of frustration or anger between partners. The need to share this intimate area of a relationship, especially when one or the other is identified as "the cause" of infertility, may precipitate feelings of guilt or shame. Infertility often becomes a central focus for role identity, especially for women (Devine, 2008).

The couple may experience feelings of loss of control, feelings of reduced competency and defectiveness, loss of status and ambiguity as a couple, a sense of social stigma, stress on the marital and sexual relationship, and a strained relationship with healthcare providers. The nurse's roles can be summarized as those of counselor, educator, and advocate.

Tasks of the infertile couple and appropriate nursing interventions are summarized in Table 12-7. Throughout the evaluation process, nurses can play a key role in lessening the stress these couples must endure by providing them with appropriate resources and accurate information about what treatment entails and what physical, emotional, and financial demands they can anticipate throughout the process (Paterno, 2008).

The nurse's ability to assess and respond to emotional and educational needs is essential to give infertile couples control and help them negotiate the treatment process. An assessment tool such as an infertility questionnaire (Table 12-8) can be helpful. Extensive and repeated explanations and written instruction may be necessary because the couple's anxiety often overwhelms

TABLE 12-7 Tasks of the Infertile Couple

(This item omitted from WebBook edition)

TABLE 12-8 Infertility Questionnaire

(This item omitted from WebBook edition)

Case Study: Infertility

their ability to retain all the information given. It is important to use a nursing framework that recognizes the multidimensional needs of the infertile individual or couple within physical, social, psychologic, spiritual, and environmental contexts.

Infertility may be perceived as a loss by one or both partners. Affected individuals have described this as loss of their relationship with spouse, family, or friends; their health; their status or prestige; their self-esteem and self-confidence; their security; and the potential child. Any one of these types of losses may lead to depression and, in many cases, the crisis of infertility evokes feelings similar to ones associated with all these losses (Paterno, 2008). Each couple passes through several stages, not unlike those identified by Kübler-Ross: surprise, denial, anger, isolation, guilt, grief, and resolution. The impact of these feelings on the couple and how fast they move into resolution, if ever, may depend on the cause and duration of treatment. Each partner may progress through the stages at different rates (McGrath et al., 2010). Nonjudgmental acceptance and a professional, caring attitude on the nurse's part can go far to dissipate the negative emotions the couple may experience while going through these stages.

This is also a time when the nurse may assess the quality of the couple's relationship: Are they able and willing to communicate verbally and share feelings? Are they mutually supportive? The answers to these questions may help the nurse identify areas of strength and weakness and construct an appropriate plan of care.

Referral to mental health professionals is helpful when the emotional issues become too disruptive in the couple's relationship or life. Couples should be made aware of infertility support and education organizations such as RESOLVE (National Infertility Association), which may help meet some of these needs and validate their feelings. Finally, individual or group counseling with other infertile couples may help the couple resolve feelings brought about by their own difficult situation.

Genetics

Genetic Disorders

Even when conception has been achieved, families can have special reproductive concerns. The desired and expected outcome of any pregnancy is the birth of a healthy, "perfect" baby. Parents experience grief, fear, and anger when they discover that their baby has been born with a defect or a genetic disease. Such an abnormality may be evident at birth or may not appear for some time. The baby may have inherited a disorder from one parent or both, creating guilt and strife within the family.

Regardless of the type or scope of the problem, parents will have many questions: "What did I do?" "What caused it?" "How do I cope with it?" "Will it happen again?" The nurse must anticipate the parents' questions and concerns, direct the family to the appropriate resources, and support the family. To do so, the nurse must have a basic knowledge of genetics and genetic counseling. Professional nurses can help expedite this questioning process if they understand the principles involved and can direct the family to the appropriate resources.

Chromosomes and Chromosomal Analysis

All hereditary material is carried on tightly coiled strands of deoxyribonucleic acid (DNA) known as **chromosomes**. The

Figure 12-10 ■ Normal female karyotype.

Source: Courtesy of Susan Olson, PhD., The Oregon Health & Science University Cytogenics Laboratory.

chromosomes carry the *genes,* the smallest unit of inheritance, as discussed in greater detail in chapter 11 ∞. The Human Genome Project has made remarkable advances toward determining the exact DNA sequence of human genes and the precise genes that are associated with certain abnormalities, such as fragile X syndrome and cystic fibrosis, as discussed later in this chapter (Ward, 2008).

All *somatic* (*body*) *cells* contain 46 chromosomes, which is the *diploid* number; the sperm and egg contain half as many (23) chromosomes, or the *haploid* number (see chapter 11 ∞). There are 23 pairs of homologous chromosomes (a matched pair of chromosomes, one inherited from each parent). Twenty-two of the pairs are known as **autosomes** (nonsex chromosomes), and one pair is the sex chromosome, X and Y. A normal female has a 46, XX chromosome constitution, the normal male, 46, XY (Figures 12-10 ■ and 12-11 ■).

The **karyotype**, or pictorial analysis of an individual's chromosomes, is usually obtained from specially treated and stained peripheral blood lymphocytes. Placental tissue or amniotic fluid can be obtained prenatally and sent for karyotyping of the fetus.

Chromosome abnormalities can occur in either the autosomes or the sex chromosomes and can be divided into two categories: abnormalities of number and abnormalities of structure. Even small alterations in chromosomes can cause problems, especially those associated with delayed growth and

Figure 12-11 ■ Normal male karyotype.

development. Some of these abnormalities can also be passed on to other offspring. Thus, in some cases, chromosomal analysis is appropriate even if clinical manifestations are mild.

Abnormalities of Chromosome Number

Abnormalities of chromosome number are most commonly seen as trisomies, monosomies, and as mosaicism. In all three cases, the abnormality is most often caused by nondisjunction, a failure of paired chromosomes to separate during cell division. If nondisjunction occurs in either the sperm or the egg before fertilization, the resulting zygote (fertilized egg) will have an abnormal chromosome makeup in all of the cells (trisomy or monosomy). If nondisjunction occurs after fertilization, the developing zygote will have cells with two or more different chromosome makeups, evolving into two or more different cell lines (mosaicism).

Trisomies are the product of the union of a normal gamete (egg or sperm) with a gamete that contains an extra chromosome. The individual will have 47 chromosomes and be trisomic (have three copies of the same chromosome) for whichever chromosome is extra (Table 12-9). Down syndrome is the most common trisomy abnormality seen in children (Figure 12-12 ■). The presence of the extra chromosome 21 produces distinctive clinical features (Figure 12-13 ■). Although children born with Down syndrome can have a variety of physical ailments, advances in medical science and early intervention services have improved their quality of life and extended their life expectancy.

TABLE 12-9 Chromosomal Syndromes

Altered Chromosome: 21	Characteristics
Genetic defect: trisomy 21 (Down syndrome) (secondary nondisjunction or unbalanced translocation involving chromosome 21) (see Figures 12-12 and 12-13) Incidence: average 1 in 700 live births, incidence variable with age of woman	Central nervous system (CNS): mild to moderate intellectual disability (mental retardation); hypotonia at birth Head: flattened occiput; depressed nasal bridge; mongoloid slant of eyes; epicanthal folds; white specking of the iris (Brushfield spots); protrusion of the tongue; high, arched palate; low-set ears Hands: broad, short fingers; abnormalities of finger and foot; dermal ridge patterns (dermatoglyphics); transverse palmar crease (simian line) Other: congenital heart disease in 30% to 60%, usually correctible by surgery.
Altered Chromosome: 18	**Characteristics**
Genetic defect: trisomy 18 Incidence: 1 in 3000 live births	CNS: intellectual disability; severe hypotonia Head: prominent occiput; low-set ears; corneal opacities; ptosis (drooping of eyelids) Hands: third and fourth fingers overlapped by second and fifth fingers; abnormal dermatoglyphics; syndactyly (webbing of fingers) Other: congenital heart defects (>90%); renal abnormalities; single umbilical artery; gastrointestinal tract abnormalities; rocker-bottom feet; cryptorchidism; various malformations of other organs
Altered Chromosome: 13	**Characteristics**
Genetic defect: trisomy 13 Incidence: 1 in 5000 live births	CNS: intellectual disability; severe hypotonia; seizures; anatomic defects of the brain (holoprosencephaly) in 60% Head: microcephaly; microphthalmia and/or coloboma (keyhole-shaped pupil); malformed ears; aplasia of external auditory canal; micrognathia (abnormally small lower jaw); cleft lip and palate Hands: polydactyly (extra digits); abnormal posturing of fingers; abnormal dermatoglyphics Other: omphalocele; congenital heart defects; hemangiomas; gastrointestinal tract defects; kidney defects; various malformations of other organs
Altered Chromosome: 5p	**Characteristics**
Genetic defect: deletion of short arm of chromosome 5 (cri du chat, or cat cry, syndrome) (see Figure 12-17) Incidence: 1 in 20,000 live births	CNS: severe intellectual disability; a catlike cry in infancy Head: microcephaly; hypertelorism (widely spaced eyes); epicanthal folds; low-set ears Other: failure to thrive; various organ malformations
Altered Chromosome: X (sex chromosome)	**Characteristics**
Genetic defect: only one X chromosome in female (Turner syndrome) Incidence: 1 in 5000 live female births (see Figure 12-18)	CNS: no intellectual impairment; some perceptual difficulties Head: low hairline; webbed neck Increased risk for intrauterine fetal death (IUFD) (>95% of all conceptions) Trunk: short stature; cubitus valgus (increased carrying angle of arm); excessive nevi (congenital discoloration of skin due to pigmentation); broad shieldlike chest with widely spaced nipples; puffy feet; no toenails Other: fibrous streaks in ovaries; underdeveloped secondary sex characteristics; primary amenorrhea; usually infertile; renal anomalies; coarctation of the aorta
Altered Chromosome: XXY (sex chromosome)	**Characteristics**
Genetic defect extra X chromosome in male (Klinefelter syndrome) Incidence: 1 in 1000 live male births	CNS: mild intellectual disability Trunk: occasional gynecomastia (abnormally large male breasts); abnormal body proportions (long legs, short trunk, shoulder equal to hip size) Other: small firm testes; underdeveloped secondary sex characteristics; reduced fertility

The other two common trisomies are trisomy 18 and trisomy 13 (see Table 12-9 and Figures 12-14 ■ and 12-15 ■). The prognosis for both trisomy 18 or 13 is extremely poor. Most children (70%) die within the first 3 months of life as a result of complications related to respiratory and cardiac abnormalities. However, 10% survive the first year of life; therefore, the family needs to plan for the possibility of long-term care of a severely affected infant and for family support.

Monosomies, occur when a normal gamete unites with a gamete that is missing a chromosome. In this case, the individual will have only 45 chromosomes and is said to be *monosomic*. Monosomy of an entire autosomal chromosome is incompatible with life. The only monosomy of an entire chromosome that is compatible with life is 45, X (Turner syndrome).

Mosaicism occurs after fertilization and results in an individual with two different cell lines, each having a different

chromosomal number. Mosaicism tends to be more common in the sex chromosomes; when it does occur in the autosomes, it is most common in Down syndrome.

Abnormalities of Chromosome Structure

Abnormalities of chromosome structure involve only parts of the chromosome and generally occur in the form of translocation, deletions, or duplications. Most (>95%) children born with Down syndrome have trisomy 21, whereas some (<5%) have an abnormal rearrangement of chromosomal material known as *translocation.* Clinically, the two types of Down syndrome are indistinguishable; the only way to distinguish them is to do a chromosome analysis.

A translocation is the transfer of a segment of one chromosome to another chromosome. If the two chromosomes are nonhomologous the translocation is *reciprocal*. Reciprocal translocations are relatively common and are found in 1 in 600 newborns. If there is no deletion or duplication of chromosome material, the translocation is considered to be *balanced*. Individuals with a balanced translocation generally do not have any health concerns related to the rearrangement. However, they can have offspring with an *unbalanced* translocation. If there is chromosome material deleted or duplicated, the translocation is considered *unbalanced* and can lead to pregnancy loss, congenital anomalies, intellectual disability (mental retardation)/developmental disabilities, or other health concerns. Translocations that involve two acrocentric chromosomes (chromosomes 13, 14, 15, 21, and 22) that fuse near the centromere regions with loss of the short (p) arms are called *Robertsonian translocations*. An individual with a balanced Robertsonian translocation will have 45 chromosomes, including the translocation chromosome, which is made up of the long arms of two chromosomes (Figure 12-16 ■). For example, the two most common Robertsonian translocations are 13q14q (the long arm of one chromosome 13 is fused to the long arm of one chromosome 14) and 14q21q. The translocation involving 13q and 14q is found in about 1 person out of 1300 and is the most common chromosome rearrangement in humans. Individuals with Robertsonian translocations are at risk to have offspring with unbalanced translocations. This may lead to pregnancy loss or offspring with trisomy 13 or trisomy 21.

Structural abnormality is also caused by *duplications* or *deletions* of chromosomal material. Any portion of a chromosome may be lost or added, generally leading to some adverse effect. Depending on how much chromosomal material is involved, the clinical effects may be mild or severe. Many types of duplications and deletions have been described, such as a deletion of the short arm of chromosome 5 (cri du chat, or cat cry, syndrome [Figure 12-17 ■]). Table 12-9 lists other chromosomal syndromes.

Abnormalities of the Sex Chromosome

To better understand abnormalities of the sex chromosomes, the nurse should know that in females, at an early embryonic stage, one of the two normal X chromosomes becomes inactive. This phenomenon is called *X-inactivation* or *Lyonization*. The inactive X chromosome forms a dark-staining area known as the *Barr body,* or sex chromatin body. The typical female has one Barr body because one of her two X chromosomes has been inactivated. The typical male has no Barr bodies because he has only one X chromosome.

The most common sex chromosome abnormalities are Turner syndrome in females (45, X with no Barr bodies present) and Klinefelter syndrome in males (47, XXY with one Barr body present). See Figure 12-18 ■ and Table 12-9 for clinical descriptions of these abnormalities.

There is a concern that children born as a result of intracytoplasmic sperm injection (ICSI) might be at increased risk for chromosomal and other major congenital anomalies, cancer, or infertility, because ICSI may override natural safeguards that serve to prevent fertilization. Therefore it is strongly recommended that karyotyping and Y chromosome deletion analysis be offered to all men with severe male factor infertility who are candidates for in vitro fertilization (IVF) with ICSI (ASRM, 2008a).

Modes of Inheritance

Many inherited diseases are produced by an abnormality in a single gene or pair of genes. In such instances the chromosomes are grossly normal. The defect is at the gene level. Some of these gene defects can be detected by technologies including DNA sequencing and other biochemical assays.

There are two major categories of inheritance: **mendelian (single-gene) inheritance** and **nonmendelian (multifactorial) inheritance**. Each single-gene trait is determined by a pair of genes working together. These genes are responsible for the observable expression of the traits (e.g., brown eyes, dark skin), referred to as the **phenotype**. The total genetic makeup of an individual is referred to as the **genotype** (pattern of the genes on the chromosomes).

One of the genes for a trait is inherited from the mother; the other, from the father. Individuals who have two identical genes at a given locus are considered to be *homozygous* for that trait. Individuals are considered to be *heterozygous* for a particular trait when they have two different alleles (alternate forms of the same gene) at a given locus on a pair of homologous chromosomes.

The best known modes of single-gene inheritance are autosomal dominant, autosomal recessive, and X-linked (sex-linked).

Autosomal Dominant Inheritance

A person is said to have an autosomal dominantly inherited disorder if the disease trait is heterozygous; that is, the abnormal

gene overshadows the normal gene of the pair to produce the trait. The genetic condition may be familial, meaning it was passed to an individual from one of his or her parents; or it may be the result of a *de novo* (new) mutation that occurred during meiosis of the egg or sperm that created the individual, and he or she is the first and only affected person in the family. In autosomal dominant inheritance, the following occurs:

- An affected individual may have an affected parent. The family **pedigree** (graphic representation of a family tree) usually shows multiple generations having the disorder.
- Affected individuals have a 50% chance of passing on the abnormal gene to each of their children (Figure 12-19 ■).
- Males and females are equally affected, and a father can pass the abnormal gene on to his son. This is an important principle when distinguishing autosomal dominant disorders from X-linked disorders.
- Autosomal dominant inherited disorders have varying degrees of presentation. This is an important factor when counseling families concerning autosomal dominant disorders. Although a parent may have a mild form of the disease, the child may have a more severe form.

Some autosomal dominant conditions have differences in their expression and can lead to difficulties in diagnosis. These differences in expression are known as reduced penetrance, variable expressivity, and pleiotropy. *Penetrance* is the possibility

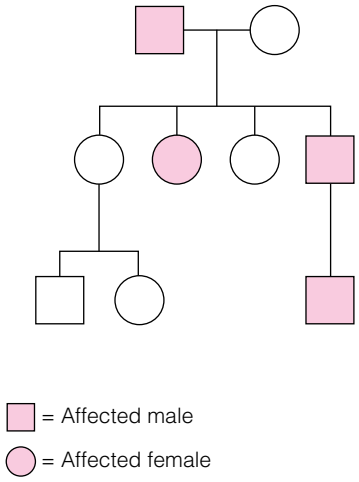

Figure 12-19 ■ Autosomal dominant pedigree. One parent is affected. Statistically, 50% of offspring will be affected, regardless of sex.

that a gene will have any phenotypic expression at all. When an individual with the genetic trait for a condition fails to express features of the disorder, the gene is said to show reduced penetrance. *Expressivity* is the severity of expression of the phenotype. When the severity of the condition differs in people who have the same genotype, the phenotype is said to have variable expressivity. When a single abnormal gene produces diverse phenotypic effects, such as which organ systems are affected and which symptoms occur, the expression is said to be *pleiotropic*.

Some autosomal dominant disorders are caused by a phenomenon known as *anticipation*. Anticipation occurs when a trinucleotide repeat expands during meiosis, resulting in a gene passed from generation to generation with a larger and larger number of triplet repeats. A larger number of repeats is associated with phenotypic expression of the condition and, typically, the larger the number of repeats the more severe the condition. More than a dozen diseases are known to result from triplet repeat expansion, including autosomal dominant disorders such as Huntington disease and myotonic dystrophy, fragile X syndrome (an X-linked disorder), and Friedreich ataxia (an autosomal recessive disorder).

Autosomal Recessive Inheritance

In an autosomal recessively inherited disorder, the individual must have two abnormal genes to be affected. A *carrier* is an individual who is heterozygous for the abnormal gene and clinically normal. It is not until two carriers mate and pass on the same abnormal gene that affected children may appear. In autosomal recessive inheritance, the following occurs:

- An affected individual can have clinically normal parents, but both parents are generally carriers of the abnormal gene (Figure 12-20 ■).
- In the case where both parents are carriers, there is a 25% chance that the abnormal gene will be passed on to any of their offspring. Each pregnancy has a 25% chance of resulting in an affected child.
- If the child of two carrier parents is clinically normal, there is a two-thirds chance that the child is a carrier of the gene.

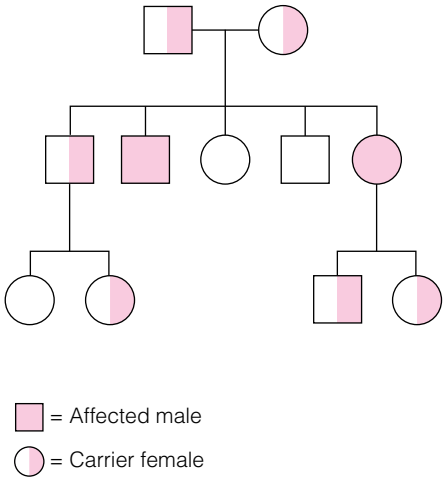

Figure 12-20 ■ Autosomal recessive pedigree. Both parents are carriers. Statistically, 25% of offspring will be affected, regardless of sex.

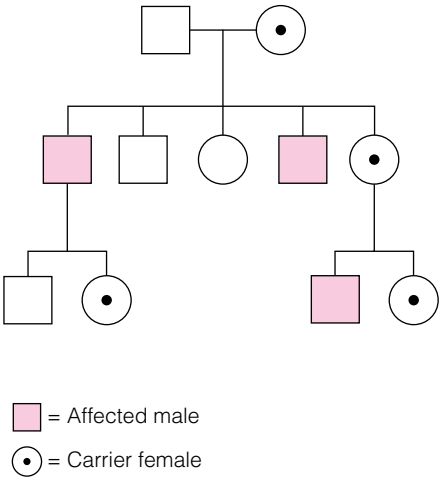

Figure 12-21 ■ X-linked recessive pedigree. The mother is the carrier. Statistically, 50% of male offspring will be affected, and 50% of female offspring will be carriers.

- Both males and females are equally affected.
- There is an increased history of consanguineous matings (mating of blood relatives).

Some common autosomal recessive inherited disorders are cystic fibrosis, phenylketonuria (PKU), galactosemia, sickle cell anemia, Tay-Sachs disease, and many metabolic disorders.

X-Linked Recessive Inheritance

X-linked, or sex-linked, disorders are those for which the abnormal gene is carried on the X chromosome. Thus an X-linked disorder is manifested in a male who carries the abnormal gene on his only X chromosome and is considered *hemizygous* for the condition. Approximately two thirds of the time, the mother of a male with an X-linked disorder will be a carrier. Most carrier females (known as *heterozygous females*) do not have symptoms of the condition. However, in some X-linked conditions heterozygous females can manifest symptoms of the disorder due to skewed Lyonization, but the symptoms tend to be milder and have later onset. In X-linked recessive inheritance, the following occurs:

- There is no male-to-male transmission. Affected males are related through the female line (Figure 12-21 ■).
- There is a 50% chance that a carrier mother will pass the abnormal gene to each of her sons, who will thus be affected.
- There is a 50% chance that a carrier mother will pass the normal gene to each of her sons, who will thus be unaffected.
- There is a 50% chance that a carrier mother will pass the abnormal gene to each of her daughters, who become carriers.
- Fathers affected with an X-linked disorder cannot pass the disorder to their sons, but all their daughters become carriers of the disorder.

Common X-linked recessive disorders are hemophilia, Duchenne muscular dystrophy, and some forms of color blindness. Fragile X syndrome is an X-linked recessive disorder that exhibits anticipation. This condition is the most common form of inherited intellectual disability (mental retardation) second only to Down syndrome. It is caused by an increased number of CGG trinucleotide repeats in the *FMR1* gene, located at a "fragile site" on the long arm of the X chromosome. The normal number of CGG repeats is up to 60. Individuals with a repeat number ranging between 60 and 200 have a *premutation* allele, meaning the copy number can increase during maternal (but not paternal) meiosis. If the CGG repeat number increases over 200, the individual (particularly hemizygous males) can have fragile X syndrome. Approximately one third of females with over 200 CGG repeats will be affected with fragile X syndrome, one third will have mild developmental or learning disabilities, and one third will have no symptoms at all.

X-Linked Dominant Inheritance

X-linked dominant disorders are rare, the most common being vitamin D–resistant rickets. When X-linked dominance does occur, the pattern is similar to X-linked recessive inheritance except that heterozygous females can also be affected. In X-linked dominant inheritance, there is no male-to-male transmission. Affected fathers will have affected daughters but no affected sons. Some types of X-linked dominant disorders are so severe that they can be lethal in utero or in the newborn period in hemizygous males (e.g., Rett syndrome or severe forms of otopalataldigital [OPD] syndrome).

Multifactorial Inheritance

Many common congenital malformations, such as cleft palate, heart defect, spina bifida, dislocated hips, clubfoot, and pyloric stenosis do not follow a clear pattern of mendelian inheritance. They are generally caused by an interaction of many genes and environmental factors and are considered to have "multifactorial" inheritance. In multifactorial inheritance, the following occurs:

- The malformations may vary from mild to severe. For example, spina bifida may range in severity from mild, as spina bifida occulta, to more severe, as a myelomeningocele. The risk may be greater when the disorder is severe.
- There is often a sex bias, and the risk is higher for relatives of a patient of the sex in which the condition is less common. Pyloric stenosis is more common in males, whereas cleft palate is more common among females. When a member of the less

commonly affected sex shows the condition, a greater number of genes must usually be present to cause the defect.
- Not only is increased risk greatest among closest relatives and decreases with distance of relationship, but the risk is increased when multiple family members are affected.

Although most congenital malformations are multifactorial, a careful family history should always be taken because, occasionally, cleft lip and palate, certain congenital heart defects, and other malformations can also be inherited as autosomal dominant or recessive traits. Other disorders thought to be within the multifactorial inheritance group are diabetes, hypertension, some heart diseases, and mental illness.

Prenatal Diagnostic Tests

Parent-child and family-planning counseling have become a major responsibility of professional nurses. To be effective counselors, nurses need to have the most current knowledge available concerning prenatal testing options. Appropriate counseling should occur before prenatal screening or diagnostic testing is done. It is essential that the couple be completely informed as to the known and potential risks of each of the genetic diagnostic procedures. The prescreening counseling should include the conditions detectable by the screen, diagnostic test available if the screen is positive, risk to mother and pregnancy if the test is performed, accuracy of the test, and limitations of the test (Lashley, 2007). The nurse needs to recognize the emotional impact on the family of a decision to undergo or not to undergo a genetic diagnostic procedure. The ability to diagnose certain genetic diseases by various diagnostic tools has enormous implications for the practice of preventive health care. Several methods are available for prenatal diagnosis, although some are still experimental.

Genetic Ultrasound

Ultrasound may be used to assess the fetus for genetic or congenital problems. With ultrasound, one can visualize the fetal head for abnormalities in size, shape, and structure. (For a detailed discussion of ultrasound technology, see chapter 21 ∞.) Craniospinal defects (anencephaly, microcephaly, hydrocephalus), gastrointestinal malformations (omphalocele, gastroschisis), renal malformations (dysplasia or obstruction), and skeletal malformations (caudal regression, conjoined twins) are only some of the disorders that can be diagnosed in utero by ultrasound. Screening by ultrasound for congenital anomalies is best done at 18 to 20 weeks, when fetal structures have completed development. With the addition of fetal nuchal translucency measurement at 10 to 13 weeks, there is high correlation with fetal chromosome abnormalities (ACOG, 2007). The nuchal translucency is a fluid-filled space at the back of the fetal neck. An increased amount of fluid is associated with an increased risk for chromosome abnormalities, birth defects, genetic syndromes, and poor pregnancy outcome—the larger the nuchal translucency, the higher the risk for abnormalities. The nuchal translucency should only be measured by a specifically trained sonographer or physician. There is no information documenting harm to the fetus or long-term effects with exposure to ultrasound. However, there is no guarantee of complete safety; therefore, the practitioner and the parents must evaluate the risks against the benefits on an individual basis.

Screening and invasive diagnostic testing for chromosome abnormalities should be available to all women who present for prenatal care before 20 weeks of pregnancy regardless of maternal age (ACOG, 2007). Women should be counseled regarding the differences between screening and invasive diagnostic testing. Screening tests, such as the nuchal translucency ultrasound and maternal serum screening, are designed to gather information about the risk that the pregnancy could have chromosome abnormalities or open spina bifida. If the risk is increased above a specific cutoff, the woman is offered invasive prenatal diagnosis. Prenatal diagnostic techniques, such as amniocentesis and chorionic villus sampling (CVS), obtain cells from the pregnancy to rule out or diagnose a chromosome abnormality or certain genetic disorders. They are associated with a small risk of pregnancy complications, including miscarriage.

Maternal Serum Screening

Measuring specific hormones and proteins in the maternal serum during the first and/or second trimester can determine the risk for Down syndrome, trisomy 18, or open spina bifida. In the first trimester, the nuchal translucency measurement is often added to improve the detection rate for Down syndrome and trisomy 18. Detection and false-positive rates differ depending on the type of screening test that is performed and may also differ depending on the laboratory that performs the screening.

Genetic Amniocentesis

A major method of prenatal diagnosis is genetic amniocentesis (Figure 12-22 ■). The procedure is described in chapter 21 ∞. The risk for pregnancy complications, including infection and miscarriage, are thought to be less than 0.5%.The indications for genetic amniocentesis include the following:

- ***Maternal age 35 or older:*** Women 35 or older are at greater risk for having children with chromosome abnormalities. Chromosomal abnormalities due to maternal age are trisomy 21, 13, 18, XXX, or XXY. The risk of having a live-born infant with a chromosome problem is 1 in 200 for a 35-year-old woman; the risk for trisomy 21 is 1 in 365. At age 45 the risks are 1 in 20 and 1 in 40, respectively (Ward, 2008).
- ***Previous child born with a chromosomal abnormality:*** Couples who have had a child with trisomy 21, 18, or 13 have approximately a 1% risk or their age-related risk, whichever is higher, of a future child having a chromosome abnormality.
- ***Parent carrying a chromosomal abnormality (balanced translocation):*** These couples are at an increased risk to have conceptions with an unbalanced translocation. Depending on the chromosomes involved in the translocation, there may be an increased risk for pregnancy loss or a viable offspring with congenital anomalies and/or intellectual disability. For example, a woman who carries a balanced 14/21 translocation has a risk of approximately 10% to 15% that her children will be affected with the unbalanced translocation of Down syndrome; if the father is a carrier, there is a 2% to 5% risk.
- ***Mother carrying an X-linked disease:*** Prenatal diagnosis may be available for families in which the woman is a known

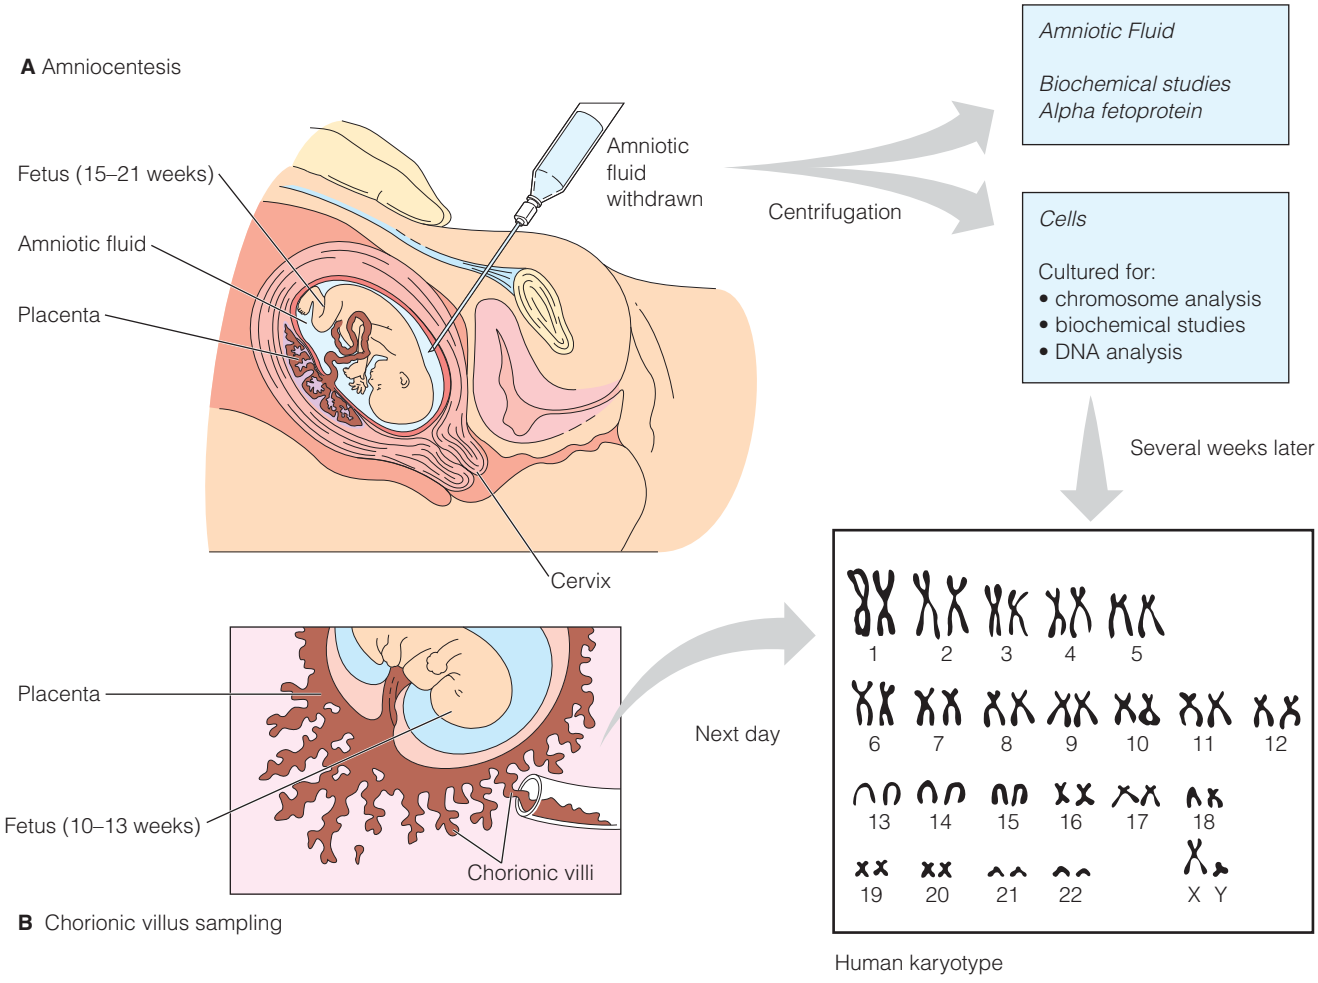

Figure 12-22 ■ A. Genetic amniocentesis for prenatal diagnosis is done at 15–21 weeks' gestation. B. Chorionic villus sampling is done at 10–13 weeks, and the cells are cultured and karyotyped. Results generally take 7–14 days.

or possible carrier of an X-linked disorder, such as Duchenne muscular dystrophy or hemophilia A or B. For a known female carrier, the risk of having an affected male fetus is 25%. DNA testing may make it possible to distinguish affected males from nonaffected males in some disorders.

- ***Parents carrying an inborn error of metabolism that can be diagnosed in utero:*** Many metabolic disorders are detectable *in utero* by DNA analysis or biochemical testing. Examples include argininosuccinicaciduria, cystinosis, Fabry disease, galactosemia, Gaucher disease, homocystinuria, Hunter syndrome, Hurler disease, Krabbe disease, Lesch-Nyhan syndrome, maple syrup urine disease, Niemann-Pick disease, Pompe disease, Sanfilippo syndrome, and Tay-Sachs disease.
- ***Both parents carrying an autosomal recessive disease:*** When both parents are carriers of an autosomal recessive disease, there is a 25% risk for *each pregnancy* that the fetus will be affected. Autosomal recessive diseases identified by amniocentesis include hemoglobinopathies such as sickle cell anemia or thalassemia and cystic fibrosis.
- ***Family history of neural tube defects:*** Genetic amniocentesis is available to those couples who have had a child with neural tube defects or who have a family history of these conditions, which include anencephaly, spina bifida, and myelomeningocele. The diagnosis is made by measuring amniotic fluid alpha-feto protein (AFP) and a neurotransmitter called acetylcholinesterase. Neural tube defects are usually multifactorial traits.

Chorionic Villus Sampling

Chorionic villus sampling (CVS) is a technique that obtains chorionic villi tissue from the placenta either transabdominally or transcervially. Its diagnostic capability is similar to that of amniocentesis. Its advantages are that diagnostic information is available at 10 to 13 weeks' gestation. The risk for pregnancy complications, including infection and pregnancy loss, is estimated to be around 1%. (For further discussion, see chapter 21 ∞.)

Percutaneous Umbilical Blood Sampling

Percutaneous umbilical blood sampling (PUBS) is a technique that obtains blood from the umbilical cord during pregnancy. Obtaining fetal blood cells allows for more rapid chromosome diagnosis, or for transfusion for Rh isoimmunization or hydrops fetalis. (For more in-depth discussion, see chapter 21 ∞.)

Noninvasive Prenatal Diagnosis (NIPD)

In the near future, noninvasive methods of prenatal diagnosis for chromosome abnormalities or genetic disorders will be

available by obtaining maternal blood as early as 8 weeks of pregnancy. Fetal ribonucleic acid (RNA) and/or DNA can be isolated in the maternal serum to test for specific disorders. This technology is currently used for fetal Rh determination in women who are Rh negative. Commercial biotechnology companies plan to introduce this testing, particularly for the diagnosis of chromosomal trisomies such as Down syndrome. Preliminary data estimate that the accuracy of the test is >99%.

Implications of Prenatal Diagnostic Testing

It is imperative that counseling precede any procedure for prenatal diagnosis. Many questions and points must be considered if the family is to reach a satisfactory decision.

With the advent of diagnostic techniques such as amniocentesis and CVS, at-risk couples who would not otherwise have a first child or additional children can decide to conceive. Following prenatal diagnosis a couple can decide not to have a child with a genetic disease. For many couples, prenatal diagnosis is not selected because abortion is not an option for them. The decision whether to use prenatal diagnosis can be made only by the family. Even when termination is not an option, prenatal diagnosis can give parents an opportunity to prepare for the birth of a child with special needs, to contact other families with children with similar problems, or to contact support services before the birth.

It is important to remember that prenatal screening and diagnosis are optional and not required as part of routine prenatal care. Nurses should present these options to patients using a nondirective manner. *Nondirective counseling* is a technique designed to allow patients or clients to talk about their problems or emotional difficulties and reach a decision best for themselves or their families with a minimum of direction from the person serving as their counselor. While it is imperative that nurses give their patients accurate, up-to-date information about the various prenatal screening and diagnostic testing options, they must remain impartial and not recommend any specific course of action. It is also important for nurses to remember that the language they use when discussing these options with patients matters (see Table 12-10 Health Promotion Education: Couples Who May Benefit From Prenatal Diagnosis). For example, when discussing prenatal screening for Down syndrome, terms such as *handicapped* or *retarded* should be replaced with *disabled* and/or *developmentally/cognitively/intellectually disabled*. Instead of using the word *risk*, consider using the terms *chance* or *possibility*.

Every pregnancy has a 3% to 5% risk of resulting in an infant with a birth defect, chromosome abnormality, genetic disease, or developmental disability. When an abnormality is detected or suspected, an attempt is made to determine the diagnosis by assessing the family health history (via the pedigree) and the pregnancy history and by evaluating the fetal anomaly or anomalies via ultrasound. Experts on a specific disorder are consulted, and healthcare professionals can then present the parents with information and options. Treatment of prenatally diagnosed disorders may begin during the pregnancy, thus possibly preventing irreversible damage. In light of the philosophy of preventive health care, information on what data can be obtained prenatally should be made available to all couples who are expecting a baby or who are contemplating pregnancy.

TABLE 12-10 Health Promotion Education: Couples Who May Benefit from Prenatal Diagnosis

- Women age 35 or over at time of birth
- Couples with a balanced translocation (chromosomal abnormality)
- Family history of known or suspected mendelian genetic disorder (e.g., cystic fibrosis, hemophilia A & B; Duchenne muscular dystrophy)
- Couples with a previous child with chromosomal abnormality
- Couples in which either partner or a previous child is affected with, or in which both partners are carriers for, a diagnosable metabolic disorder
- Family history of birth defects and/or intellectual disability (mental retardation) (e.g., neural tube defects, congenital heart disease, cleft lip and/or palate).
- Ethnic groups at increased risk for specific disorders (see Developing Cultural Competence: Genetic Screening Recommendations for Various Ethnic and Age Groups)
- Couples with a history of two or more first trimester spontaneous abortions
- Women with an abnormal maternal serum screening test
- Women with a teratogenic risk secondary to an exposure or maternal health condition (e.g., diabetes)

Postnatal Diagnosis

Human Genome Project

Questions concerning genetic disorders (cause, treatment, and prognosis) are most often first discussed in the newborn nursery or during the infant's first few months of life. When a child is born with anomalies, has a stormy neonatal period, or does not progress as expected, a genetic evaluation may well be warranted. Accurate diagnosis and an optimal treatment plan incorporate the following:

- Complete and detailed histories to determine whether the problem is prenatal (congenital), postnatal, or familial in origin.
- Thorough physical and dysmorphology examination by a trained clinical geneticist.
- Laboratory analysis, which includes chromosome analysis; enzyme assay for inborn errors of metabolism (see chapter 33 ∞ for further discussion on these specific tests); DNA studies (both direct and by linkage); and antibody titers for infectious teratogens, such as toxoplasmosis, rubella, cytomegalovirus, and herpes virus (TORCH syndrome) (see chapter 19 ∞).

To make an accurate diagnosis, the geneticist consults with other specialists and reviews the current literature. This lets the geneticist evaluate all the available information before arriving at a diagnosis and plan of action.

PROFESSIONALISM IN PRACTICE

2008 Prenatally and Postnatally Diagnosed Conditions Act

The Prenatally and Postnatally Diagnosed Conditions Act was signed into law in 2008. This law requires that medical providers give parents accurate, updated, and scientific information regarding their child's diagnosis, prognosis, treatment, and life expectancy. Nurses are often an important source of information and support when a prenatal or postnatal diagnosis of a genetic condition or birth defect is made.

The Human Genome Project will have significant implications for the identification and management of inherited disorders. Once genes have been identified, it will be possible to detect their presence in carriers and lead to better genetic counseling. However, concerns have been voiced about ethical considerations with genetic research. What guidelines are needed to protect children and families so that genetic testing does not lead to discrimination in future employment or health insurance? Who should be tested for genetic diseases, and who should have access to the results? Because children cannot yet give informed consent for genetic testing (see chapter 1 ∞ for discussion of informed consent), it is recommended that children and adolescents should have genetic testing *only* when medical treatment could help if the disease is identified, or when another family member might benefit from the knowledge for his or her own health and the child will not be harmed by the testing (American Academy of Pediatrics, Committee on Genetics, 2000, reaffirmed 2009). Whenever genetic testing is performed, counseling about the results must be available.

Genetic Counseling

Genetic counseling is a communication process in which the genetic counselor, physician, or specially trained and certified nurse helps a family or individuals understand and adapt to the medical, psychologic, and familial implications of genetic contributions to disease (National Society of Genetic Counselors [NSGC], 2005).

Referral

Genetic counseling referral is advised for any of the following categories:

- ***Congenital abnormalities, including intellectual disability:*** Any couple who has a child or a relative with a congenital malformation may be at an increased risk and should be so informed. If intellectual disability of unidentified cause has occurred in a family, there may be an increased risk of recurrence. In some cases, the genetic counselor will identify the cause of a malformation as a teratogen (see chapter 16 ∞). The family should be aware of teratogenic substances so they can avoid exposure during any subsequent pregnancy.
- ***Familial disorders:*** Families should be told that certain diseases may have a genetic component and that the risk of their occurrence in a particular family may be higher than that for the general population. Such disorders as diabetes, heart disease, cancer, and mental illness fall into this category.
- ***Known inherited diseases:*** Families may know that diseases are inherited but not know the mechanism or the specific risk for them. An important point to remember is that family members who are not at risk for passing on a disorder should be as well informed as family members who are at risk.
- ***Metabolic disorders:*** Any families at risk for having a child with a metabolic disorder or biochemical defect should be referred for genetic counseling. Because most inborn errors of metabolism are autosomal recessively inherited ones, a family may not be identified as at risk until the birth of an affected child. Carriers of the sickle cell trait can be identified before pregnancy is begun, and the risk of having an affected child can be determined.
- ***Chromosomal abnormalities:*** As discussed previously, any couple who has had a child with a chromosomal abnormality may be at an increased risk of having another child similarly affected. This group includes families in which there is concern for a possible translocation.

After the couple has been referred to the genetic clinic, they are sent a form requesting information on the health status of various family members. This information assists the genetic counselor in creating the family's pedigree. The pedigree and health history facilitate identification of other family members who might also be at risk for the same disorder (Figure 12-23 ■). The couple being counseled may wish to notify those relatives at risk so that they, too, can be given genetic counseling. When done correctly, the family history and pedigree are two of the most powerful and useful tools for determining a family risk.

Initial Session

During the initial session, the counselor gathers additional information about the pregnancy, the affected child's growth and development, and the family's understanding of the problem. The counselor also elicits information concerning ethnic background and family origin. Many genetic disorders are more common among certain ethnic groups or in particular geographic areas.

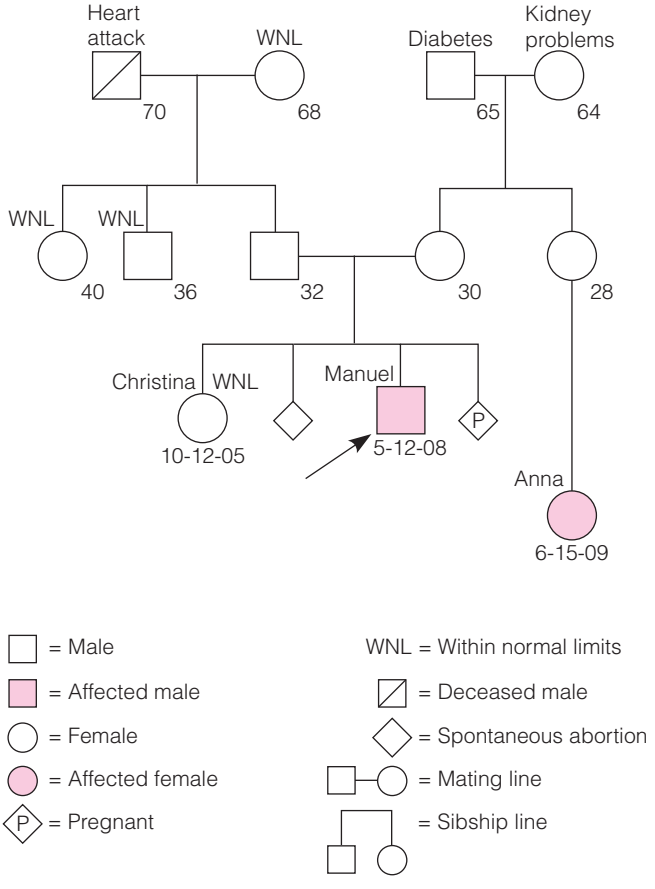

Figure 12-23 ■ Screening pedigree. Arrow indicates the nearest family member affected with the disorder being investigated. Numbers refer to the ages or birth dates of family members.

DEVELOPING CULTURAL COMPETENCE

Consanguineous Marriages

In the United States, marriage between related individuals is generally taboo. In Western medicine, there is a concern that a child conceived by people who are related by blood may have an increased risk for birth defects. This has not, however, been supported by recent research unless the relationship is closer than first cousins. In many other cultures, marriage of first cousins and others who are related by blood is acceptable and even common. Egypt has a high rate of consanguineous (blood relationship) marriages. Reasons for consanguineous marriage include: "increase family links," "they knew each other and everything would be clear before marriage," "customs and traditions," and "less cost." The most common type of consanguineous marriage in Egypt is between first cousins.

For example, families from the British Isles are at higher risk of having children with neural tube defects; Ashkenazi Jews (from eastern Europe) and French Canadians are at higher risk for Tay-Sachs disease; people of African descent for sickle cell anemia; Mennonites for maple syrup urine disease; and people of Mediterranean heritage for thalassemias. (See Developing Cultural Competence: Genetic Screening Recommendations for Various Ethnic and Age Groups.)

Generally the child is given a physical examination. Other family members may also be examined. If any laboratory tests, such as chromosomal analysis, genetic testing, metabolic studies, or viral titers, are indicated, they are performed at this time. The genetic counselor may then give the family some preliminary information based on the data at hand.

Follow-Up Counseling

When all the data have been carefully examined and analyzed the family returns for a follow-up visit. At this time the parents are given all the information available, including the medical facts, diagnosis, probable course of the disorder, and any available management; the inheritance pattern for this particular family and their risk of recurrence; and the options or alternatives for dealing with the risk of recurrence. The remainder of the counseling session is spent discussing the course of action that seems appropriate to the family in view of their risk and family goals. For couples who desire to become parents or who want a subsequent child, options include prenatal diagnosis; early detection and treatment; and, in some cases, adoption, preimplantation genetic diagnosis or other assisted reproduction techniques, or delayed childbearing.

The couple may consider assisted reproduction techniques, such as therapeutic donor insemination (TDI), discussed earlier in this chapter. This alternative is appropriate in several instances; for example, if the man has an autosomal dominant disease, TDI would decrease to zero the risk of having an affected child (if the sperm donor is not at risk) because the child would not inherit any genes from the affected parent. If the man is affected with an X-linked disorder and does not wish to continue the gene in the family (all his daughters will be carriers), TDI would be an alternative to terminating all pregnancies with a female fetus. If the man is a carrier for a balanced translocation and if termination of pregnancy is against family ethics, TDI is an appropriate alternative. If both parents are carriers of an autosomal recessive disorder, TDI lowers the risk to a very low level or to zero if a carrier test is available. Finally, TDI may be appropriate if the family is at high risk for a multifactorial disorder.

DEVELOPING CULTURAL COMPETENCE

Genetic Screening Recommendations for Various Ethnic and Age Groups

Background of Population at Risk	Disorder	Screening Test	Definitive Test
Ashkenazi Jewish, French-Canadian, Cajun	Tay-Sachs disease	Decreased serum hexosaminidase-A or DNA mutation analysis	CVS* or amniocentesis for hexosaminidase-A assay or DNA mutation analysis
Ashkenazi Jewish	Cystic fibrosis, Canavan disease, familial dysautonomia, several other disorders	DNA mutation analysis	CVS or amniocentesis for DNA mutation analysis
African; Hispanic from Caribbean, Central America, or South America; Arab, Egyptian; Asian Indian	Sickle cell anemia	Presence of sickle cell hemoglobin; confirmatory hemoglobin electrophoresis	CVS or amniocentesis for DNA mutation analysis
Greek, Italian	Beta-thalassemia	Mean corpuscular volume less than 80% confirmatory hemoglobin electrophoresis	CVS or amniocentesis for DNA mutation analysis
Southeast Asian (Vietnamese, Laotian, Cambodian), Filipino	Alpha-thalassemia	Mean corpuscular volume less than 80%; confirmatory hemoglobin electrophoresis	CVS or amniocentesis for DNA mutation analysis or gene deletion studies
Women over age 35 (all ethnic groups)	Chromosomal trisomies	Prenatal serum and/or ultrasound screening	CVS or amniocentesis for cytogenetic analysis
Women of any age (all ethnic groups; particularly suggested for women from British Isles, Ireland)	Neural tube defects and selected other anomalies	Maternal serum alpha-fetoprotein (MSAFP)	Amniocentesis for amniotic fluid alpha-fetoprotein (AFP) and acetylcholinesterase assays
Caucasian (northern European, Celtic population), Ashkenazi Jewish	Cystic fibrosis	DNA mutation analysis of the cystic fibrosis transmembrane regulation (CFTR) gene	CVS or amniocentesis for DNA mutation analysis

*Chorionic villus sampling.

TABLE 12-11 Nursing Responsibilities in Genetic Counseling

- Identify families at risk for genetic problems.
- Determine how the genetic problem is perceived and what information is desired before proceeding.
- Assist families in acquiring accurate information about the specific problem.
- Act as liaison between family and genetic counselor.
- Assist the family in understanding and dealing with information received.
- Provide information on support groups.
- Aid families in coping with this crisis.
- Provide information about known genetic factors.
- Ensure continuity of nursing care to the family.

Couples who are young and at risk may decide to delay childbearing for a few years. These couples may find in a few years that prenatal diagnosis will be available or that a disease can be detected and treated early to prevent irreversible damage.

When the parents have completed the counseling sessions, the counselor sends them and their physician a letter, detailing the contents of the sessions. The family keeps this document for reference. See Table 12-11 for a list of nursing responsibilities in genetic counseling.

NURSING CARE MANAGEMENT

In both prospective and retrospective genetic counseling, timely nursing intervention is a crucial factor. During annual examinations and other clinical appointments, the nurse should interview all women of childbearing age to determine any family history or other risk factors for genetic disorders. If the woman is planning to conceive, genetic counseling should be encouraged before discontinuation of contraception.

The nurse has a key role in preventing recurrence. One cannot expect a couple who has just learned that their child has a birth defect or Down syndrome to take in any information concerning future risks. However, the couple should never be "put off" from genetic counseling for so long that they conceive another affected child because of lack of information. The perinatal nursing team frequently has the first contact with the family who has a newborn with a congenital abnormality. At the birth of an affected child, the nurse can inform the parents that before they attempt having another child, genetic counseling is available. After genetic counseling, the nurse with the appropriate knowledge of genetics is in an ideal position to help families review what has been discussed during the sessions and to answer any additional questions they might have. As the family returns to the daily aspects of living, the nurse can provide helpful information on the day-to-day aspects of caring for the child, answer questions as they arise, support parents in their decisions, and refer the family to other health and community agencies.

The family may return to the genetic counselor a number of times to air their questions and concerns, especially if the couple is considering having more children, or if siblings want information about their affected brother or sister. It is most desirable for the nurse working with the family to attend many or all of these counseling sessions. Because the nurse has already established a rapport with the couple, the nurse can act as a liaison between the family and the genetic counselor. Hearing directly what the genetic counselor says helps the nurse clarify issues for the family, which in turn helps them formulate questions. Many genetic centers have found the public health nurse to be the ideal health professional to provide such follow-up care.

Nurses must be careful not to assume a diagnosis, determine carrier status or recurrence risks, or provide genetic counseling without adequate information and training. Inadequate, inappropriate, or inaccurate information may be misleading or harmful. Healthcare professionals need to learn the appropriate referral systems and options for care in their region.

FOCUS YOUR STUDY

- A couple is considered infertile when they do not conceive after 1 year of unprotected coitus.
- At least 8% of couples in the United States are infertile.
- A thorough history and physical of both partners is essential as a basis for infertility investigation.
- General fertility investigations include evaluation of ovarian function, cervical mucus adequacy and receptivity to sperm, sperm number and function, tubal patency, general condition of the pelvic organs, and certain laboratory tests.

- Among cases of infertility, 20% involve male factors, 40% involve female factors, and 30% to 40% involve either an unknown cause (unexplained infertility) or a problem with both partners.
- Medications may be prescribed to induce ovulation, facilitate cervical mucus formation, reduce antibody concentration, increase sperm count and motility, and suppress endometriosis.
- The emotional aspect of infertility may be more difficult for the couple than the testing and therapy.
- The nurse needs to be prepared to provide accurate information about infertility and dispel myths.
- The nurse assesses coping responses and initiates counseling referrals as indicated.
- In autosomal dominant disorders, an affected parent has a 50% chance of having an affected child. Such disorders equally affect both males and females. The characteristic presentation will vary in each individual with the gene. Some of the common autosomal dominant inherited disorders are Huntington disease, polycystic kidney disease, and neurofibromatosis (von Recklinghausen disease).
- Autosomal recessive disorders are characterized by both parents being carriers; each offspring has a 25% chance of having the disease, a 25% chance of not being affected, and a 50% chance of being a carrier. Males and females are equally affected. Some common autosomal recessive inheritance disorders are cystic fibrosis, phenylketonuria (PKU), galactosemia, sickle cell anemia, Tay-Sachs disease, and most metabolic disorders.
- X-linked recessive disorders are characterized by no male-to-male transmission; effects limited to males; a 50% chance that a carrier mother will pass the abnormal gene to her sons; a 50% chance that her daughters will be carriers; and a 100% chance that daughters of affected fathers will be carriers. Common X-linked recessive disorders are hemophilia, some forms of color blindness, and Duchenne muscular dystrophy.
- Multifactorial inheritance disorders include cleft lip and palate, spina bifida, dislocated hips, clubfoot, and pyloric stenosis.
- Some genetic conditions that can currently be diagnosed prenatally are neural tube and cranial defects, renal malformations, hemophilia, fragile X syndrome, thalassemia, cystic fibrosis, and many inborn errors of metabolism such as Tay-Sachs disease. This list expands daily as new technology allows more conditions to be detected.
- The chief tools of prenatal diagnosis are ultrasound, maternal serum alpha-fetoprotein testing, amniocentesis, chorionic villus sampling, and percutaneous umbilical blood sampling.
- Based on sound knowledge about common genetic problems, the nurse should prepare the family for counseling and act as a resource person during and after the counseling sessions. Many nurses with advanced training are entering the field of genetic counseling.

CRITICAL THINKING IN ACTION

Source: George Dodson/Pearson Education.

Marie Neives, age 19, presents while you are working at a Planned Parenthood Clinic. She is there for a GYN exam and tells you that she is sexually active with her boyfriend but doesn't want to become pregnant. Since she lives at home with her parents, she does not want to use "the pill" because her mother might find out. Marie tells you she has a family history of cystic fibrosis and is concerned that she will pass the disease on. Marie asks you for information concerning fertility awareness. You obtain a menstrual history as follows: menarche age 12, cycle every 28 days for 5 days, dysmenorrhea the first 2 days with moderate flow. She has had one sexual partner. She states her boyfriend doesn't like to use condoms and that she has been lucky so far in not getting pregnant. You assist the nurse practitioner with a physical and pelvic exam. The results show that Marie is essentially healthy. The nurse practitioner asks you to review with Marie the basal body temperature (BBT) method of fertility awareness.

1. Explore with Marie "natural family planning." How would you explain this to her?
2. Briefly explain why the basal body temperature (BBT) method can predict ovulation.
3. How would you describe to Marie the procedure for obtaining BBT?
4. After figuring out her menstruation cycle, to avoid conception when would you tell Marie to abstain from unprotected intercourse?

See www.nursing.pearsonhighered.com for possible responses.

Preparation for Parenthood

I couldn't wait to begin our childbirth classes. Attending the classes with the other expectant parents made the pregnancy and upcoming labor seem so much more real. Our childbirth educator helped ease our anxiety and gave us guidance on how to make the most of the birth. I still keep in contact with a few of my classmates and send an annual holiday greeting card with my son's photograph to our instructor.

LEARNING OUTCOMES

1. Apply the nursing process to help couples prepare for childbirth.
2. Identify the various issues related to preconception counseling, pregnancy, labor, and birth that require decision making by parents.
3. Discuss the basic goals of childbirth education.
4. Summarize the role of the doula/labor companion during labor and birth.
5. Describe the types of prenatal education programs available to expectant couples and their families.
6. Delineate the childbirth educator's role in promoting relaxation for pregnant women.
7. Compare methods of childbirth preparation.

Prenatal education *284*
Progressive relaxation *290*
Touch relaxation *291*

Preparation for parenthood begins with one's own birth into a family. Attitudes, feelings, and fears about pregnancy, birth, and parenthood are molded by numerous factors, including relationships within and outside one's own family, cultural conditioning, personal history, and discussions with healthcare providers, friends, and other women.

A person's experiences with parenting or children may have been pleasant or uncomfortable. A person's information about parenthood and related areas may or may not be accurate. Because people bring their beliefs and fears with them to the childbearing period, the nurse can do much to correct misconceptions and calm fears about pregnancy, childbirth, and early parenting. Although some women may approach labor and birth with great excitement and anticipation, others may view it as a fearful, unpleasant experience. One way that people can cope with feelings about impending parenthood is to assume an active, participatory role during the preconception, prenatal, intrapartum, and postpartum periods. This involvement offers them a degree of control over what could otherwise be an overwhelming experience.

Some of the decisions that the childbearing family must consider are presented in this chapter. These include the decision to have a baby; choice of care provider; type of childbirth preparation; type of prenatal care including group or individual care, place of birth, activities during the birth, method of infant feeding, and choices surrounding the care of the newborn. The chapter also considers the role of the nurse, who provides information that enables the family to make informed decisions.

Throughout this chapter the term "childbearing family" is used to include all family types. In today's society, the childbearing family may be composed of a man and a woman joined by marriage or simply by mutual personal commitment, a single woman living alone or with a friend or family member, or a lesbian couple. No matter what the family structure and configuration, the expectant woman and her support person have similar concerns and educational needs during this time.

Today's professional nurse has many opportunities to help the childbearing family make the decisions that are part of pregnancy and birth. The nurse can help families seek preconceptual counseling, select a healthcare provider, find prenatal classes that meet their needs, and make informed choices. Even more important, as the family members work through these decisions, the nurse is able to affirm their decision-making abilities and their ability to take on parenting roles. For first-time parents in particular, the decisions may seem numerous, complicated, and sometimes overwhelming. The nurse has a unique opportunity to help these families establish a pattern of decision making that will serve them well in their years as parents (Figure 13-1 ■).

Preconception Counseling

One of the first questions a couple should ask before conception is whether they wish to have children. This involves consideration of each person's goals, expectations of their relationship, and desire to be a parent. At times one individual wishes to have a child, whereas the other does not. In such situations, an open discussion is essential to reach a mutually acceptable decision. In some cases, professional counseling for the couple may be necessary.

Couples who wish to have children face a decision about the timing of pregnancy. At what point in their lives do they believe it would be best to become parents? Pregnancy comes as a surprise even when the decision about timing is made, but at least the couple has some control over it.

For couples who have religious beliefs that do not support contraception or who feel that family planning is unnatural and wrong, planning the timing of pregnancy is unacceptable and

Care Plan Activity: Preconception Counseling

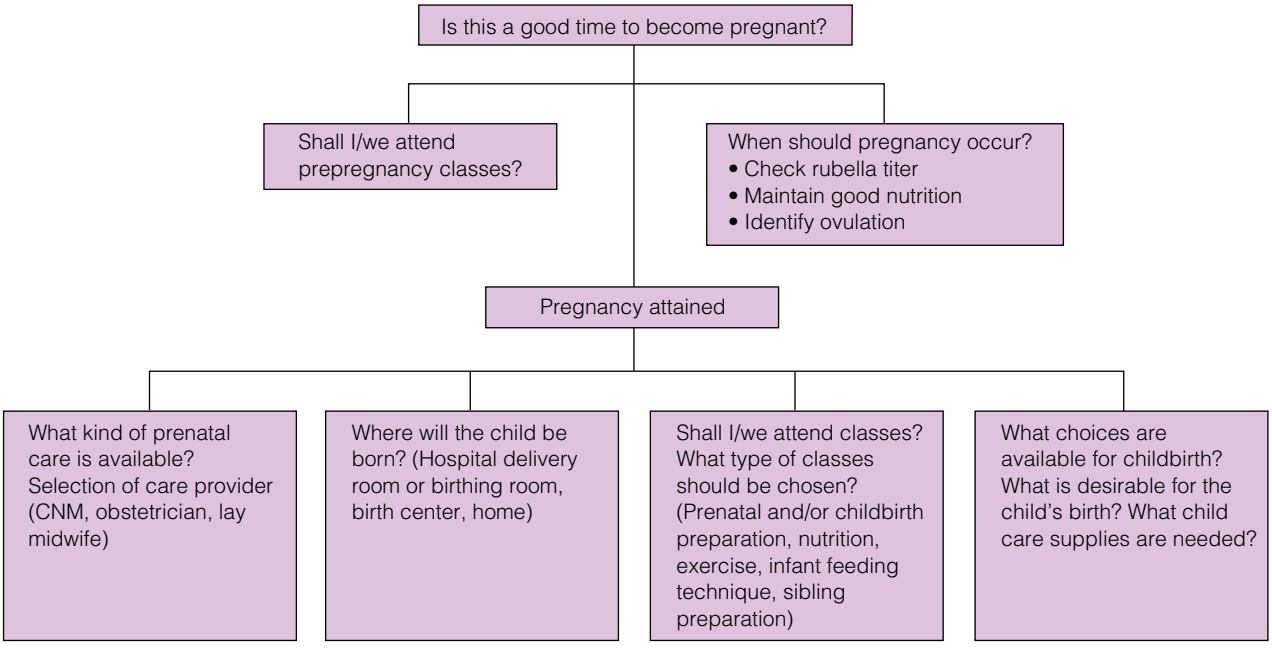

Figure 13-1 ■ Pregnancy decision tree.

irrelevant. These couples can still take steps to ensure that they are in the best possible physical and mental health when pregnancy occurs.

Ideally, the decision to become pregnant and have a child should be a conscious one; however, this is not always the case. Nearly half of the pregnancies in the United States are unintended or unplanned (Jones, Zolna, Henshaw, et al., 2008). Couples with unplanned pregnancies may need additional support from the nurse, such as information about community resources available for the couple and their infant. Encouragement and reassurance are especially needed for these families.

Preconception Health Measures

Case Study: Preparing for Pregnancy

The professional role of the nurse working with women or couples during the preconception period includes conveying information about known or suspected health risks. After a thorough assessment, the nurse advises the woman to cease smoking if possible, or to at least limit her cigarette intake. Placenta previa, abruptio placentae, preterm rupture of membranes, and pregnancy loss are risk factors that are increased in mothers who smoke. According to the Centers for Disease Control and Prevention (CDC), 13% of women reported smoking during the last 3 months of pregnancy. Furthermore, pregnant women exposed to secondhand smoke have 20% higher odds of giving birth to a low-birth-weight baby (CDC, 2009). Secondhand smoke has been found to increase the risk of small-for-gestational-age infants; therefore, partners of pregnant women should refrain from smoking in the woman's presence. Research has found that smoking during pregnancy is a significant risk factor in the incidence of sudden infant death syndrome (SIDS) (Einarson & Riordan, 2009). (See chapter 37 ∞ for a detailed discussion on SIDS prevention.)

The effects of caffeine are less clearly understood; however, as a precaution the woman is advised to avoid caffeine or limit her intake. Research shows that high doses of caffeine ingested during pregnancy increases the risk of miscarriage (Weng, Odouli, & Li, 2008). Alcohol, social drugs, and street drugs pose a real threat to the fetus. Alcohol consumed during pregnancy can result in fetal alcohol syndrome, birth defects, and low birth weight (Bailey & Sokol, 2008). A woman who uses any prescription or over-the-counter medications needs to discuss the implications of their use with her healthcare provider. It is best to avoid using any medication if possible. Because of the possible teratogenic effects of environmental hazards in the workplace, the nurse urges the couple contemplating pregnancy to determine whether they are exposed to any environmental hazards at work or in their community.

Physical Examination

It is advisable for both partners to have a physical examination to identify any health problems that might affect pregnancy so that they can be corrected if possible. These might include medical conditions, such as high blood pressure or obesity; problems that pose a threat to fertility, such as certain sexually transmitted infections; or conditions that keep the individual from achieving optimal health, such as anemia or colitis. If the family history indicates previous genetic disorders, or if the couple is planning pregnancy when the woman is over age 35, the healthcare provider may suggest that the couple consider genetic counseling.

In addition to the history and physical exam, the woman may have the following laboratory tests: urinalysis, complete blood count, blood type and Rh factor, venereal disease research laboratory (VDRL) test, Pap smear, gonorrhea culture, chlamydia screen, and rubella and hepatitis screens. Women who are nonimmune to rubella should be counseled about the possible effects on the fetus should infection occur during the first trimester of pregnancy. If a woman decides to receive the rubella vaccine, the nurse must inform her to wait 3 months before conceiving to eliminate the risk of prenatal infection. These women should be counseled to use contraception during the 3-month period to prevent pregnancy. Before conception, the woman is also advised to have a dental examination and any necessary dental work completed to avoid exposure to x-rays and the risk of infection.

Women should also be asked questions regarding their psychologic history and assessed for mental illness. Certain classes of medications may be contraindicated during pregnancy and drug changes may be needed prior to conception to prevent adverse maternal or fetal effects.

Nutrition

Before conception, it is advisable for the woman to be at an average weight for her body build and height. The nurse can discuss nutrition and recommend that the woman follow a nutritious diet that contains ample quantities of all the essential nutrients. Some nutritionists advocate emphasizing the following nutrients: calcium, protein, iron, B complex vitamins, vitamin C, magnesium, and folic acid. Folic acid supplementation should be initiated before conception because it decreases the incidence of neural tube defects in infants. (See the discussion in chapter 18 ∞.) The Institute of Medicine recommends that women of childbearing age consume 4 milligrams of folic acid per day before conception, and women who are pregnant should consume 6 milligrams (March of Dimes, 2009). Consumption of a balanced diet with the appropriate distribution of the basic food pyramid groups is especially important during pregnancy (American College of Obstetricians and Gynecologists [ACOG], 2008). Diet can be affected by food preferences, cultural beliefs, and eating patterns. Excessive intake of certain vitamins can cause severe fetal problems and should be avoided.

Exercise

A woman is advised to establish a regular exercise plan beginning at least 3 months before she plans to attempt to become pregnant. The exercise should be one she enjoys and will continue. It needs to provide some aerobic conditioning and some general toning. Exercise improves the woman's circulation and general health and tones her muscles. Once an exercise program is well established, the woman is generally encouraged to continue it during pregnancy. Prepregnancy obesity, defined as a body mass index of 30 or above, has been associated with severe pregnancy and delivery complications (Jain, Denk, Kruse, et al., 2007); therefore, advocating weight reduction for obese women who want to become pregnant is advisable.

Contraception

A woman who takes birth control pills is advised to stop the pill and have two or three normal menses before attempting to conceive. This allows the natural hormonal cycle to return and facilitates dating the subsequent pregnancy. A woman using an intrauterine device is advised to have it removed and wait 1 month before attempting to conceive. This allows the endometrium to be resterilized. Other methods of contraception that women can use during the waiting period include a variety of barrier methods of contraception (condoms, diaphragm, or cervical cap with a spermicide).

Conception

Most preconception recommendations focus on helping the couple attain their best possible health state so that they do not enter pregnancy with unnecessary risks. Conception is a personal and emotional experience and, even if a couple is prepared, the individuals may feel some ambivalence. This is a normal response, but they may require reassurance that the ambivalence will pass. The prospective parents may get so caught up in preparation and in their efforts to "do things right" that they lose sight of the pleasure they derive from each other and their lives together and cease to value the joy of spontaneity in their relationship. It is often helpful for the healthcare provider to remind an overly zealous couple that moderation is always appropriate and that there is value in "taking time to smell the roses."

Childbearing Decisions

Childbearing decisions are decisions parents face about their childbirth preferences and experiences. A method that has assisted many couples in making these choices is called a birth plan. In the **birth plan**, prospective parents identify aspects of the childbearing experience that are most important to them. (A sample birth plan is presented in Figure 13-2 ■.) The birth plan helps identify available options and becomes a tool for communication among the expectant parents, the healthcare providers, and the healthcare professionals at the birth setting.

The birth plan also helps pregnant women and couples set priorities. Using the plan, they identify areas that they want to incorporate in their own birth experience. Then they can take the birth plan to a visit with their certified nurse-midwife (CNM) or other care provider and use it in discussing and comparing their wishes with the philosophy and beliefs of the provider. It is imperative that the couple discuss their preferences at a prenatal visit before labor. Sometimes couples may include requests that need clarification. For example, if the couple states they do not want any external monitoring, the provider needs to explain that intermittent monitoring could be provided but that eliminating all monitoring during labor could jeopardize both the mother and the fetus. Possible obstetric interventions that may be needed should also be part of the birth plan. They can also take the birth plan to the birth setting and use it as a basis for communicating their wishes during the childbirth experience.

Today, there are many more choices that pregnant women and couples make. Some of these are explored in Table 13-1. Although most birth experiences are close to the desired experience, at times expectations cannot be met. This may be because of the unavailability of some choices in the community or unexpected problems during pregnancy or birth. It is important for nurses to help expectant parents keep sight of what is realistic for their situation. Maternal satisfaction is obviously important when outcomes of childbirth are considered. However, it must not be seen as separate from, or a greater priority than, the physical safety of both mother and child (Bailey, Crane, & Nugent, 2008).

Sample Birth Plan

Choice	*Choice*
Care provider:	Position during birth:
Certified nurse-midwife	On side
Obstetrician	Hands and knees
Family physician	Kneeling
Lay midwife	Squatting
Birth setting:	Birthing chair
Hospital:	Birthing bed
Birthing room	Other:
Delivery room	Family present (sibs)
Birth center	Filming of birth (videotaping)
Home	Photography of birth
Support during labor and birth:	Leboyer
Partner present	Episiotomy
Doula present	No sterile drapes
During labor:	Partner to cut umbilical cord
Ambulate as desired	Hold baby immediately after birth
Shower if desired	Breastfeed immediately after birth
Wear own clothes	No separation after birth
Use hot tub	Save the placenta
Use own rocking chair	Collect cord blood for banking
Have perineal prep	Newborn care:
Have enema	Eye treatment for the baby
Water birth	Vitamin K injection
Electronic fetal monitor	Heptovac injection
Membranes:	Breastfeeding
Rupture naturally	Formula feeding
Amniotomy if needed	Pacifier use
Labor stimulation if needed	Glucose water
Medication:	Circumcision
Identify type desired	Postpartum care:
Fluids or ice as desired	Short stay
Music during labor and birth	48-hour stay after vaginal birth
Massage	Home visits after discharge
Therapeutic touch	Home doula
Healing touch	Other:

Figure 13-2 ■ Birth plan for childbirth choices. The columns list various choices that the couple may consider during their childbirth experience. Once the couple has considered each of the choices, they may circle the items they desire.

Healthcare Provider

One of the first decisions facing expectant parents is the selection of a healthcare provider. The nurse assists them by explaining the various options and outlining what can be expected from each. A thorough understanding of the differences of educational preparation, skill level, practice style, and general philosophy and characteristics of practice of certified nurse-midwives, obstetricians, family practice physicians, and lay midwives is essential. The nurse can encourage expectant parents to investigate the care provider's credentials, basic and special education and training, fee schedule, and availability to new patients; this is often accomplished by telephoning the provider's office.

TABLE 13-1 Benefits and Risks of Some Consumer and Medical Decisions During Pregnancy, Labor, and Birth

ISSUE	BENEFITS	RISKS
Breastfeeding	• No additional expense • Contains maternal antibodies • Decreases incidence of infant otitis media, vomiting, and diarrhea, hospitalizations during the first year of life, and allergies • Easier to digest than formula • Immediately after birth, promotes uterine contractions and decreases incidence of postpartum hemorrhage • Promotes maternal-infant bonding	• Transmission of maternal infections to newborn, such as HIV • Irregular ovulation and menses can cause false sense of security and nonuse of hormonal contraceptives • Increased nutritional requirement in mother

Ambulation during labor	• Comfort for laboring woman
	• May assist in labor progression by
	  • Stimulating contractions
	  • Allowing gravity to help descent of fetus
	  • Giving sense of independence and control
		• Cord prolapse with rupture of membranes unless engagement has occurred
		• Birth of infant in undesirable locations (hallways, outdoors, waiting area)
		• Inability to monitor fetal heart rate (FHR) unless telemetry unit available

Electronic fetal monitoring	• Helps evaluate fetal well-being • Helps identify fetal stress • Useful in diagnostic testing • Helps evaluate labor progress	• Supine postural hypotension • Intrauterine perforation (with internal uterine pressure device) • Infection (with internal monitoring) • Decreases personal interaction with mother because of attention paid to the machine • Mother is unable to ambulate or change her position freely
Whirlpool (jet hydrotherapy)	• Increased relaxation • Decreased anxiety • Stimulation of labor • Provides pain relief • Slight decrease in blood pressure (BP) • Increased diuresis • Decreased incidence of vacuum and forceps deliveries • Increased pain threshold • Higher satisfaction with birth • Decreased use of pain medication (Stark, Rudell, & Haus, 2008)	• May slow contractions if used before active labor is established • Possible risk of infection if membranes are ruptured • Slight increase in maternal temperature and pulse in tub • Hypothermia • Increases fetal heart rate (FHR) by 10–20 beats/min
Analgesia	• Maternal relaxation facilitates labor	• All drugs reach the fetus in varying degrees and with varying effects
Episiotomy	• Decreases irregular tearing of perineum • Easier to repair for practitioner	• Increased pain after birth and for 1–3 months following birth • Dyspareunia • Infection • Increased frequency of third- and fourth-degree lacerations (Frankman, Wang, Bunker, et al., 2009)

The nurse can also help the woman/couple develop a list of interview questions for their first visit to a care provider. These could include the following:

- Who is in practice with you, or who covers for you when you are unavailable?
- At what point after admission do you come to the hospital or birth setting to provide support?
- How do your partners' philosophies compare to yours?
- How do you feel about my partner, other support person, or other children coming to the prenatal visits?
- Do you offer centering (group care) or individual prenatal care visits?
- What weight gain do you recommend and why?
- What are your feelings about (fill in special desires for the birth event, such as different positions assumed during labor, avoidance of an episiotomy, induction of labor, other people present during the birth, pain control measures, breastfeeding immediately after the birth, no separation of infant and parents following birth, and so on)?
- If a cesarean is necessary, can my partner be present?
- What are your feelings regarding complementary treatments during labor (herbs to augment labor, use of acupressure/massage/hypnosis, use of oils for perineal massage, and so on)?

Expectant parents also need to discuss the qualities they want in a care provider for the newborn. They may want to visit several pediatric healthcare providers before the birth to select someone who will meet their needs and those of their child.

PROFESSIONALISM IN PRACTICE

Referrals

The nurse provides referrals to appropriate providers, hospitals, and clinics as needed to ensure that the woman receives competent, professional medical care.

Prenatal Care Services

The nurse can assist expectant parents in obtaining the type of prenatal care services that are most appropriate for their personal needs. Most practitioners offer individual prenatal care services in which the woman or the woman and her family at-

tend a clinic or office visit on a regular basis depending on her stage of pregnancy. Recently, the concept of **centering**, or group prenatal care, has begun to evolve.

In the centering model, expectant women and their families or support persons attend a group session with other women in the same stage of pregnancy. During each session, women voice their questions and gather support from their pregnant peers. The practitioner meets with each woman individually before the group to perform basic assessments and examinations as appropriate; however, women benefit greatly from the group support and learning that occurs in the centering groups. Women who opt for the centering model of prenatal care typically experience more satisfaction with their prenatal care experience (Robertson, Aycock, & Darnell, 2009). Women express a sense of empowerment and benefit from the group interaction. In addition, centering has shown to be an effective model for both adolescents and immigrant women (Robertson et al., 2009). Outcomes are the same as traditional prenatal care, making it both cost effective and safe for participants.

Birth Setting

The nurse can help expectant parents choose a birth setting by suggesting they tour facilities and talk with nurses there as well as talk with friends or acquaintances who are recent parents. Questions that may be asked of new parents include the following:

- What kind of support did you receive during labor? Was it what you wanted?
- If the setting has both labor and delivery rooms and birthing rooms, was a birthing room available when you wanted it?
- Were you encouraged to be mobile during labor or to do what you wanted to do (walking, sitting in a rocking chair, remaining in bed, sitting in a hot tub, standing in a shower, and so on)?
- How was your labor partner or coach treated?
- Were you allowed to take an active role in decision making throughout the birth process?
- If you had a doula, was her role respected? Was she welcome in the birth setting?
- Was your birth plan respected? Did you share it with the facility before the birth? If something did not work, why do you think there were problems?
- Did the nurse offer suggestions regarding comfort measures?
- Did the healthcare team provide emotional support?
- How were medications handled during labor? Were you comfortable with this?
- Were siblings welcomed in the birth setting? At the birth? After the birth?
- Did you feel you were given ample time to spend with your baby immediately after childbirth?
- Was the nursing staff helpful after the baby was born? Did you receive self-care and infant care information? Was it in a usable form? Did you have a choice about what information you got? Did they let you decide what information you needed?
- Did you feel your choice of feeding method was supported?

The nurse helps expectant parents understand the array of choices available to them. The nurse can encourage them to consider options early in the pregnancy to allow time for talking with other parents and touring facilities.

> **"What I've seen time and again is that the technology of the hospital overwhelms patients' natural instincts; they are intimidated, afraid of appearing stupid or clumsy or sentimental in a surrounding that seems too efficient and immaculate and intelligent."**
>
> — *A Midwife's Story*

Nurses involved in childbirth education need to include the concept of individuality when providing information to expectant parents about the process of childbirth and their own pattern of coping. The wave of the future in childbirth education is to encourage women to incorporate their natural responses into coping with the pain of labor and birth. Alternative self-care activities should be explored with the expectant couple to identify preferences.

Nurses should encourage expectant women and couples to personalize the birth setting. The woman might plan, for example, to bring items from home to enhance relaxation and comfort, such as warm socks, slippers, bath powder, lotion, or a favorite blanket. She may wish to bring photographs of children, parents, or friends who cannot be there to share the birth experience. Many expectant parents enjoy listening to tapes of favorite music or watching home videotapes or favorite films. Such personalization of the birth setting may give expectant parents feelings of increased serenity and empowerment.

CLINICAL TIP

Call the birthing facilities in your community and inquire about what choices are available in each facility so that you can answer expectant parents' questions.

Labor Support Person

Some of the first formal childbirth preparation classes were patterned after a book entitled *Husband Coached Childbirth* by Dr. Robert Bradley, published in 1965. Since that time, husbands and other partners of expectant women have been very involved in acting as "coaches" or support persons during childbirth classes, labor, and birth. Although some men or support persons welcome the role and look forward to providing emotional and physical support, others do not. Some men may become anxious and fearful. These feelings can be related to past experiences and/or cultural factors. In these situations, the nurse provides encouragement and support to both the woman and her support person. Women who had continuous intrapartum support were less likely to have intrapartum analgesia, operative birth, or to report dissatisfaction with their childbirth experiences (Hodnett, Gates, Hofmeyr, et al., 2007). A woman's satisfaction with childbirth is directly affected by the relationship with the caregiver, the support she received from caregivers, personal expectations, and her involvement with decision making. Clearly, the role of the nurse cannot be overestimated.

Doulas of North America

Application: Benefits of Having a Doula

For centuries, women have been serving and assisting other women in childbirth. Out of this need for companionship and special support in the birthing journey, the role of the **doula** has evolved. *Doula* is a Greek word that means "woman's servant." In the birthing environment, a doula is a companion who provides support but does not perform any clinical tasks. The doula provides **labor support**, which includes emotional, physical, and informational support and acts as an advocate for the woman and her family by verbalizing their wishes to the nurses and physicians or certified nurse-midwives. Continuous labor support facilitates birth; enhances the mother's memory of the experience; strengthens mother-infant bonding; increases breastfeeding success; and significantly reduces many forms of medical intervention, including cesarean delivery and the use of analgesia, anesthesia, vacuum extraction, and forceps (McGrath & Kennell, 2008). A doula may also be trained to provide support and care during the postpartum period. Later postpartum benefits include increased bonding/interaction with the infant and decreased symptoms of depression. The doula may accompany the childbearing couple on a volunteer basis or may be paid a fee by the family. Another support person who has been involved in labor and birthing is a monitrice. *Monitrice* is a French word that refers to a specially trained nurse who provides assessment, nursing care, and support. The role of monitrice is not common in the United States.

Siblings at Birth

Some couples decide to have their other children present at the birth. Children who will attend a birth can be prepared through books, audiovisual materials, models, discussion, and sibling classes. Nurses can assist parents with sibling preparation by helping them understand the stresses a child may experience. For example, the child may feel left out when there is a new child to love or disappointed if a brother is born when a sister is expected.

It is imperative that the child has his or her own support person or coach whose sole responsibility is tending to the needs of that child during the labor and birth experience. The support person should be familiar to the child, warm, sensitive, flexible, knowledgeable about the birth process, and comfortable with sexuality and birth. This person must be prepared to interpret to the child what is happening and to intervene when necessary. The support person should not be one who would hesitate to leave the birthing room (such as a maternal grandmother) but should be amenable to the child's desire to leave. The support person for the child should assume responsibility for providing distractions when needed. Trips to the cafeteria, visits to the nursery window, outdoor walks, and other age-appropriate activities should be available for the child.

Children should be given the option of relating to the birth in whatever manner they choose as long as it is not disruptive. Children should understand that it is their own choice to be there and that they may stay or leave the room as they choose. To help children recognize their needs and desires, the nurse may wish to elicit exactly what they expect from the experience. Children need to feel free to ask questions and express feelings.

In general, the presence of siblings at birth engenders feelings of interest (Kuramoto, 2008) and the desire to nurture "our" baby, as opposed to jealousy and rivalry directed at "Mom's" baby. The mother does not disappear mysteriously into the hospital and return with a demanding outsider. Instead, the family attending the birth together finds a new opportunity for closeness and growth by sharing in the birth of a new member.

DEVELOPING CULTURAL COMPETENCE

Female Relatives as Caregivers

In most Middle Eastern countries, childbirth is exclusively attended to by women. A woman in labor is most commonly surrounded by female relatives and friends. It is customary for the husband to be excluded from the delivery room. In Iran, full segregation is mandated by law. Women can only be cared for by female healthcare providers.

Classes for Family Members During Pregnancy

Childbirth classes are routinely taught by certified childbirth educators (CBEs or CCEs). These are individuals who have received specific educational preparation related to pregnancy, labor, birth, and postpartum/newborn care and issues. Many CBEs are also registered nurses; however, nursing training is not required. The majority of the certification programs do, however, require witnessing a minimum number of births.

The CBE should consider elements developed by authoritative organizations such as the Coalition for Improving Maternity Services (CIMS) when developing their own Philosophy of Childbirth for their classes. The "Mother-Friendly Childbirth Initiative" was created in 1996 by the CIMS, a national alliance of more than 50 childbirth organizations and many prominent individuals. The coalition's mission is to promote a wellness model of maternity care that will improve birth outcomes and substantially reduce costs. The philosophic cornerstones of mother-friendly care are: (1) normalcy of the birthing process, (2) empowerment, (3) autonomy, (4) do no harm, and (5) responsibility (Coalition for Improving Maternity Services [CIMS], 2009).

Prenatal education programs provide important opportunities to share information about pregnancy, childbirth, coping mechanisms, and choices available for the woman and her support person. Studies have shown that prepared childbirth education programs can have a beneficial effect on performance in labor and delivery. The prenatal period should be used to expose the prospective parents to information about labor and delivery, pain relief, obstetric complications and procedures, breastfeeding, normal newborn care, and postpartum adjustment. Along with this information, women need up-to-date, evidence-based information to help them make decisions regarding their choices during pregnancy and childbirth (Lothian, 2008). The content of each class is generally directed by the overall goals of the program. For example, in classes that aim to provide preconception information, preparations for becoming pregnant would be the major topics. Other classes may be directed toward childbirth choices available today, preparation of the mother for pregnancy and birth, preparation for cesarean birth, preparation for vaginal birth after cesarean, preparation for couples who desire an unmedicated birth, and

preparation of specific people such as grandparents or siblings for the birth. The nurse who knows the types of prenatal programs available in the community can direct expectant parents to programs that meet their special needs and learning goals. Childbirth preparation classes usually contain information about changes in the woman and the developing baby (Table 13-2).

From the expectant parents' point of view, class content is best presented in chronology with the pregnancy (Figure 13-3 ■). It is important that the classes begin by identifying the parents' needs, goals, and learning styles. Although both parents expect to learn breathing and relaxation techniques and infant care, fathers usually expect facts and mothers expect coping strategies. Women's goals commonly include gaining information, reducing anxiety/increasing confidence, having their partner present and involved, and having a positive emotional experience in childbirth. Classes that provide an environment supportive of practicing newly learned techniques and the freedom to ask questions and receive explanations are beneficial in helping class participants obtain these goals. By the end of the class, parents should feel that they will be able to make appropriate and informed decisions by participating in a class where information is given in a nonjudgmental, nonthreatening environment. Classes may be divided into early and late classes so specific needs can be addressed.

Figure 13-3 ■ In a group setting with a nurse-instructor, expectant parents share information about pregnancy and childbirth.

TABLE 13-2 Possible Content of Classes for Childbirth Preparation

Early Classes (First Trimester)

Early gestational changes
Self-care during pregnancy including diet and exercise
Fetal development, environmental dangers for the fetus
Sexuality in pregnancy
Birth settings and types of care providers
Nutrition, rest, and exercise suggestions
Relief measures for common discomforts of pregnancy
Psychologic changes in pregnancy
Information for getting pregnancy off to a good start
Danger signs that warrant immediate medical attention
Choosing a pediatrician
Feeding choices/benefits of breastfeeding
Depression and other psychologic disorders that can occur with pregnancy

Later Classes (Second and Third Trimesters)

Preparation for birth process
Postpartum self-care
Common birthing procedures (episiotomy, medications, fetal monitoring, perineal prep, enema, etc.)
Relaxation techniques
Breathing techniques
Alternative therapies in pregnancy and labor
Newborn care (feeding, bathing, dressing)
How to recognize when the baby is ill
Infant stimulation
Newborn safety issues, such as car seats and sleeping positions

Adolescent Preparation Classes

Stresses specific to adolescents
Newborn care
Health dangers for the baby
Weight gain issues and nutrition
How to recognize when the baby is ill
Baby care: physical and emotional
Sexuality
Peer relationships

Breastfeeding Programs

Advantages and disadvantages
Medical benefits of breastfeeding
Maternal nutrition
Techniques of breastfeeding (positions, latching on, engorgement, etc.)
Involvement of fathers in the feeding process
Cultural considerations

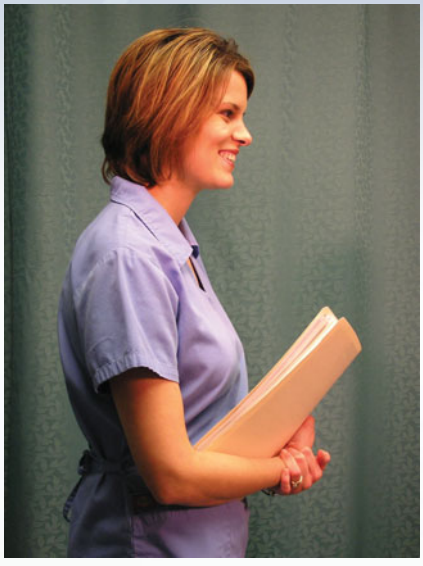
Early Classes: First Trimester

Early prenatal classes may include prepregnant women and couples as well as those in early pregnancy. As shown in Table 13-2, the classes cover early gestational changes; self-care during pregnancy; fetal development and environmental dangers for the fetus; sexuality in pregnancy; birth settings and types of care providers; nutrition, rest, and exercise suggestions; common discomforts of pregnancy and relief measures; psychologic changes in pregnancy for the woman and man; and getting the pregnancy off to a good start by following a healthful lifestyle, learning methods of coping with stress, and avoiding alcohol and smoking. Early classes should provide information about factors that place the woman at risk for preterm labor and about how to recognize symptoms of preterm labor. Early classes should also present the advantages and disadvantages of formula feeding or breastfeeding. The majority of women (50% to 80%) have made their infant feeding decision before the sixth month of pregnancy.

Later Classes: Second and Third Trimesters

The later classes focus on preparation for the birth, infant care and feeding, postpartum self-care, common birthing procedures (episiotomy, medications, fetal monitoring, perineal prep, enema, and so forth), and newborn safety issues. Many childbirth education programs now provide labor preparation classes that focus on preparation for the birth, birth options, and postpartum self-care with expectant parents attending separate classes that focus singly on breastfeeding or newborn care. Subjects such as emergency situations or labor and birth complications should be reviewed during the class. This includes information regarding assisting with an unattended birth when the couple fails to reach the hospital in a timely manner.

Through the Eyes of a Nurse
Childbirth Education



Family Experience

"I can't help but be nervous about labor and the pain I will feel. All my friends are asking me what childbirth preparation method I am going to use. I did some research on the Internet; there are a ton of different opinions. It is almost overwhelming!"

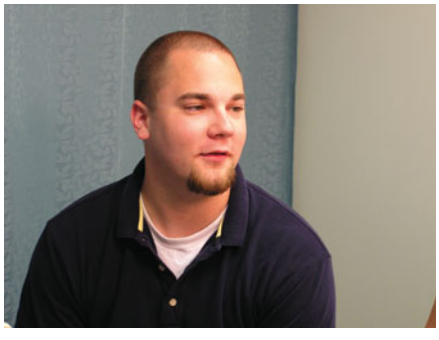
Nurse's Response

"Many women are anxious about the labor and birth process. These are normal feelings and your concerns are very common. It is helpful to use a method of childbirth preparation because it will give you some sense of control.

"Many couples, especially first-time parents, enroll in childbirth education courses. I can give you information about the classes offered at the birthing center, the hospital, and the community center. These classes tell you about pregnancy and teach relaxation and breathing techniques that can help you in labor. If you take classes, I encourage you to practice these techniques at home. Some families choose to gain information from instructional videos, books, or the Internet. There are even Web-based specialty programs that address specific needs, such as vaginal birth after cesarean (VBAC), or breastfeeding interventions for women who are having problems with nursing."

Nurse's Actions and Rationale

The nurse provides information about educational opportunities such as classes, videos, books, and the Internet. Some couples may not be able to attend classes due to financial restraints, child care issues, or work conflicts. Providing alternatives to traditional classroom instruction enables the family to pursue other educational sources. Recent studies have examined alternative resources like Web-based childbirth classes and found that they are effective in teaching couples childbirth education information and relaxation practice techniques (Wang, Chung, Sung, et al., 2006). The nurse bases advice to the family on evidence-based practice and current research.



> "As a childbirth educator, I find one of the least favorite topics to discuss in class is unexpected outcomes, a topic that introduces the topic of grief that may be related to various situations. This can apply to patients who feel that they did not experience their envisioned perfect birth, or on a much more serious note, those who have a baby who is ill, has a disability, or those who have experienced a fetal loss. I have found it helpful to share a short story written by Emily Pearl Kingsley, a mother who explains her journey raising a child with special needs. She says it is rather like leaving on a trip to Italy that you have planned in detail for a long time, but instead of landing in Italy, you find yourself in Holland. . . . It is not bad, it is just different. She explains that if you spend the rest of your life mourning the fact you didn't get to Italy, you may never be free to enjoy the very special, the very lovely things about Holland."
>
> — (Amis & Green, 2002)

Infant stimulation concepts can easily be incorporated into infant care class content. This will aid in the development of parenting skills and enhance prenatal and neonatal bonding. Stimulation methods that can be used include tactile, vestibular, auditory, and visual stimulation. Parents who use these methods may have better parenting skills and higher self-esteem. Infant massage classes are becoming very popular as an instructional series that parents attend after pregnancy with their infants to learn and practice different massage strokes to use on their infant as she or he grows. Vimala McClure, the founder of the International Association of Infant Massage, states that infant massage has physiologic and psychologic benefits for babies and their caregivers, providing colic relief, parent-infant bonding, as well as other benefits. Numerous studies support its use in infants. Infants who receive infant massage have exhibited decreased stress levels, increased weight gain, and improved motor function when compared with nonmassaged controls (Gonzalez et al., 2009).

Tactile stimulation can be discussed when maternal physiology is being presented. As the uterine wall thins during the pregnancy, the mother and father are better able to feel the baby, and the fetus can sense the parents' stroking and patting through the abdominal wall. *Effleurage* (a light, stroking movement made with the fingertips) can also be used over the abdominal wall to provide tactile stimulation to the fetus. Vestibular stimulation through movement of the fetus is provided while the expectant woman does the pelvic-tilt exercise. Rocking in a rocking chair is also a comfortable way to provide relaxation for the expectant woman and vestibular stimulation for the fetus. Auditory stimulation can be provided by playing music. Classical music (such as Vivaldi, Mozart, Beethoven, and Bach) is found to be pleasing to the fetus. In the prenatal period, actual visual stimulation for the fetus is not possible.

Adolescent Parenting Classes

Adolescents have special learning needs during pregnancy. Adolescents often need more support and more extensive teaching during pregnancy (Devito, 2007). Pregnant teens face a myriad of both psychologic and physical risks throughout pregnancy. Prenatal education and mentoring are essential. The childbirth educator should consider the teenager's need for privacy, acceptance, and respect. For this reason, classes designed specifically for the teenage population are highly desirable because many teenagers may feel that they may not receive this in a standard adult-centered childbirth class. Often teenage mothers face pregnancy and childbirth without adequate support from a partner or parents. Prenatal education classes specifically designed for teens can provide a forum for verbalization of fears and concerns. The nurse can also identify community resources for young mothers and their infants.

Breastfeeding Programs

Programs offering information on breastfeeding are increasing. For decades, a primary source of information has been La Leche League. Information can also be obtained from lactation consultants, peer counselors, labor and postpartum nurses, birthing centers, hospitals, and health clinics. Rates of breastfeeding in the United States are well below the *Healthy People 2010* objective of 75% (Cramton, Zain-Ul-Abideen, & Whalen, 2009). Breastfeeding education and support is positively correlated to successful breastfeeding. A goal of the surgeon general's national breastfeeding conference is to have 25% of women breastfeeding their infants a minimum of 1 full year by 2010 compared with the current data showing most mothers wean before the recommended 6 months (Forste & Hoffmann, 2008). Dennis's (2002) data stated that this was because of perceived difficulties with breastfeeding rather than because of maternal choice. Lack of education and knowledge, both on the part of caregivers and mothers, is the biggest barrier to breastfeeding; therefore, outpatient pediatric healthcare providers can be instrumental in preventing early weaning (Geraghty, Riddle, & Shaikh, 2008).

The father's support and encouragement of the mother is vital, so it is important to include him in the educational program and involve him in the decision making. Some fathers may feel negative and resentful about breastfeeding and need opportunities in the prenatal period for discussion and sharing of information. The decision to breastfeed is strongly related to the father's feeding preference.

Sibling Preparation: Adjustment to a Newborn

The birth of a new sibling is a significant event in a child's life. Positive adjustment can be enhanced by attendance at formal sibling preparation classes (Figure 13-4 ■). Typically, the classes are attended by children ages 3 to 12 years. Children younger than 3 tend to have shorter attention spans and may have difficulty participating in the class; however, many facilities will allow younger children to attend, especially if an older sibling is enrolled in the class. These classes can assist with decreasing sibling rivalry and reducing children's anxiety. They help children

Figure 13-4 ■ It is especially important that siblings be well prepared when they are going to be present at the birth. However, even siblings who will not be present at the birth can benefit from information about birth and the new baby ahead of time.

feel that they are part of the birthing process. The classes also enable parents to identify children's concerns related to the new baby. They provide a means to facilitate communication and explore children's feelings. They also provide basic information about pregnancy, childbirth, and the characteristics and behavior of newborns.

Typically, parents and their children attend the class together. Many activities are devised to help each child feel special. Time is usually allotted at the end of the class for talking with parents about coping skills and providing hints about dealing with sibling jealousy. Class content typically includes care and behavior of new babies, a practice session holding anatomically correct dolls, changing diapers, and a tour of the "bedroom" and the nursery where Mom and baby will stay. Many times, a newborn is held up at the nursery window so the children can see a "real baby." Some facilities give the children a special gift for attendance or a trip to the cafeteria for a special treat.

Sibling preparation can be addressed through a formal class like the one just described, or in a less formal way by preparing a booklet for parents that addresses issues affecting both parents and children. Also, several excellent books and videos are available to help children prepare for a new sibling.

Classes for Grandparents

Grandparents are an important source of support and information for prospective and new parents. They are now being included in the birthing process more frequently. Prenatal programs for grandparents can address current roles, transitioning to a new role, beliefs regarding childbirth, and ways to support the new family unit. Grandparents can also benefit from educational information, such as the benefits of breastfeeding, and updates on infant care, such as proper infant sleep positions and when to introduce foods. If they plan to be integral members of the labor and birth team, they will need information about being coaches.

Education of the Family Having Cesarean Birth

Cesarean birth is an alternative method of birth via an abdominal and uterine incision.

Preparation for Cesarean Birth

Because one out of every three or four births is a cesarean, preparation for this possibility should be an integral part of every childbirth education curriculum. The national cesarean rate has rebounded to 31.1% (Lothian, 2008). The instructor should treat cesarean birth as a normal event and present factual information that allows expectant parents to make choices and be full participants in their birth experience. The instructor can emphasize the similarities between cesarean and vaginal births to minimize undertones of "normal" versus "abnormal" birth. This helps diminish the feelings of anger, loss, and grief that often accompany cesarean births.

Cesarean birth classes should cover what the parents can expect to happen during a cesarean birth, what they will feel, and what they can do. All pregnant women and couples should be encouraged to discuss with their certified nurse-midwife or physician what the approach would be in the event of a cesarean. They can also discuss their needs and preferences regarding the following:

- Participating in the choice of anesthetic.
- Father (or significant other) being present during the birth.
- Planning initial contact with their newborn.

> "As a nurse midwife, I felt extremely disappointed when I learned I would have to have a cesarean birth with my second child. I had great expectations about how much easier my second birth would be, and how I would 'do everything different this time.' I was amazed at how satisfied and happy I was immediately after the cesarean birth. During the birth, I asked the physician if the baby was almost out and how things were progressing. In the end, I had a beautiful, healthy baby and it turned out to be even a better experience than my first birth. I always try to comfort women who have medically indicated cesarean births by telling them it is still an amazing experience and a wonderful birthday!"

Preparation for Repeat Cesarean Birth

When expectant parents are anticipating a repeat cesarean birth, they have time to plan and prepare. Many hospitals or local groups (such as C-Sec, Inc.) provide preparation classes for cesarean birth. Parents who have had previous negative experiences need an opportunity to describe what contributed to their feelings. They should be encouraged to identify what they would like to change and to list interventions that would make the experience more positive. Those who have had positive experiences need reassurance that their needs and desires will be met in the same manner. In addition, all parents are encouraged to air any fears or anxieties.

A specific concern of the woman facing a repeat cesarean is anticipation of pain. She needs reassurance that subsequent cesareans are often less painful than the first. If her first cesarean was preceded by a long or strenuous labor, she will not experience the same fatigue. Giving this information will help her cope more effectively with all stressful stimuli, including pain. The nurse can remind the woman that she has already had experience with how to prevent, cope with, and alleviate painful stimuli.

Preparation for Parents Desiring Vaginal Birth After Cesarean Birth

Parents who are anticipating a vaginal birth after cesarean birth (VBAC) have unique needs. Because they may have unresolved questions and concerns about the last birth, it is helpful to begin the series of classes with an informational session. During this session, they can ask questions, share experiences, and begin to form bonds with one another. The nurse can supply information regarding the criteria necessary to attempt a trial of labor and identify decisions regarding the birth experience. Concerns regarding the complications associated with VBAC can also be discussed. Some women may wish to undergo a repeat cesarean birth to avoid the risk of uterine rupture associated with a trial of labor. Some certified childbirth educators (CBEs) find it helpful to have the parents prepare two birth plans: one for vaginal birth and one for cesarean birth. The preparation of the two plans seems to help parents take more control of the birth experience and tends to increase the positive aspects of the experience.

After an informational session, the classes may be divided according to the needs of the expectant parents. Those with recent coached childbirth experiences may need only refresher classes, whereas others may need complete training. Some parents may choose to attend regular classes after participating in the informational session.

Methods of Childbirth Preparation

Various methods of childbirth preparation are taught in North America. The most common methods of this type are Lamaze (psychoprophylactic), Kitzinger (sensory memory), Bradley (partner-coached childbirth), and HypnoBirthing. Many hospital-based classes use a combination of these methods and are education focused. See Table 13-3 for differentiating characteristics of each method.

TABLE 13-3 Summary of Selected Childbirth Preparation Methods

METHOD	PURPOSE OR PHILOSOPHY	GOALS	TECHNIQUES	CLASS CONTENT
Bradley	To have the best, safest, and most rewarding birth experience possible.	• Natural childbirth. • Active participation of the husband as coach. • Excellent nutrition. • Breastfeeding, beginning at birth.	• Working in harmony with your body using controlled breathing and deep abdominopelvic breathing (Bradley, 1974) • Promoting general body relaxation (Bradley, 1974)	• Nutrition • Coach's role • Introduction to stages of labor • Birth planning • Variations and complications of labor • Postpartum preparation • Advanced first- and second-stage techniques • Preparation for your new family
Lamaze	Childbirth education empowers women to make informed choices in health care, to assume responsibility for their health, and to trust their inner wisdom.	• Birth is normal, natural, and healthy. • The experience of birth profoundly affects women and their families. • Women's inner wisdom guides them through birth. • Women have the right to give birth free from routine medical interventions.	• Disassociation relaxation • Controlled muscular relaxation • Breathing patterns	• Nutrition • Gestational changes • Labor and birth techniques for easing pain • Breathing techniques • Positioning during labor
Kitzinger	Sheila Kitzinger campaigns for women to have the information they need to make choices about childbirth. She is a strong believer in the benefits of home birth for women who are not high risk.	• Uses sensory memory to help the woman understand and work with her body in preparation for birth.	• Uses chest breathing in conjunction with abdominal relaxation • Incorporates elements of the Stanislavesky method of acting in a way to teach relaxation	• Antenatal care • Birth plans • Therapeutic touch during labor • Post-traumatic stress following childbirth • Breastfeeding
HypnoBirthing	HypnoBirthing is about eliminating fear and experiencing birth in a stress-free, calm, and gentle environment that most resembles nature's own design.	• With both mind and body relaxed, the muscles of the uterus work in complete neuromuscular harmony. • When in a relaxed state, the body releases endorphins, the body's natural anesthesia.	• Relaxation techniques • Deep breathing • Slow breathing • Breathing your baby down • Maintaining comfort and eliminating pain	• HynoBirthing philosophy • Rapid, progressive relaxation/deepening techniques for transition • Visualizations for labor • Composing a birth plan • Early signs of labor • Birthing companion's integral role in labor • Pushing techniques • Postnatal bonding of parents with baby

The programs in prepared childbirth share some similarities. All have an educational component to help eliminate fear and teach coping mechanisms. The classes vary in coverage of subjects related to the maternity cycle, but all teach relaxation techniques and all prepare the participants for what to expect during labor and birth. Most methods also feature exercises to condition muscles and use breathing patterns needed in labor. The greatest differences among the methods lie in the theories of why they work and in the relaxation techniques and breathing patterns they teach.

There are several advantages to these methods of childbirth preparation. The most important is that the baby may be healthier because of the reduced need for analgesics and anesthetics. Another is the satisfaction of the parents for whom childbirth becomes a shared and profound emotional experience over which they feel a sense of control. In addition, each method has been shown to shorten labor. All nurses must know how these methods differ, so that they can support each birth experience effectively.

The International Childbirth Education Association (ICEA) is a well-known organization that provides antepartum education. Although this is not a method of preparation, it offers education and resources to the certified childbirth educator (CBE) with a philosophy grounded in providing support to the individual couple's choices and decisions. Many couples find ICEA classes appealing because they discuss all alternatives and choices that are available. Many hospital-based childbirth education programs now use this approach.

Body-Conditioning Exercises

Some body-conditioning exercises, such as the pelvic tilt, pelvic rock, and Kegel exercises, are taught in childbirth preparation classes. Other exercises strengthen the abdominal muscles for the expulsive phase of labor. (See chapter 16 ∞ for a description of recommended exercises.)

Relaxation Exercises

Relaxation during labor allows the woman to conserve energy and allows the uterine muscles to work more efficiently. Without practice it is very difficult to relax the whole body in the midst of intense uterine contractions. However, many people can quickly master one or more of the following exercises.

Progressive Relaxation

In **progressive relaxation** exercises, the woman learns how to tense and then relax one muscle group at a time. An example follows:

- Lie down on your back or side. (The left side position is best for pregnant women.)

TABLE 13-4 Touch Relaxation

Practice is vital to the following exercises, which require that the pregnant woman and her partner work very closely together. Tell the woman, "With practice you will train yourself to release not only in response to your partner's touch, but also to the touch of doctors or nurses as they examine you. This technique will also help you to be more comfortable with your own body."

Goals

(For her) To recognize and release tension in response to partner's touch; to be able to do this automatically and spontaneously.

(For partner) To recognize her tension in its very early stages; to learn how to touch in a firm yet sensitive way; to concentrate on her problem areas.

Tools

(For her) Conscious relaxation, comfortable positioning, and trust.

(For partner) Sensitivity, patience, and warm hands!

Procedure

She tenses.

Partner touches.

She immediately releases toward touch.

Partner strokes "drawing" tension from her.

She releases all residual tension.

Sequence

- Contract muscles of the scalp and raise eyebrows. Partner cups hands on either side of the scalp. Immediately release tension in response to the pressure of your partner's touch. Then release any residual tension as your partner strokes your head.
- Frown, wrinkle nose, and squeeze eyes shut. Partner rests hands on brow and then strokes down over temples. Release.
- Grit teeth and clench jaw. Partner rests hands on either side of jaw. Release.
- Press shoulder blades back. Partner rests hands on front of shoulders. Release.
- Pull abdominal wall toward spine. Partner rests hands on sides of abdomen and then strokes down over her hips. Partner might also stroke the lower curve of abdomen across pubic symphysis. Release.
- Press thighs together. Partner touches outside of each leg. Relax and let legs move apart. Partner strokes firmly down outside of leg with light strokes up on inner thigh.
- Press legs outward, still flexed but forcing thighs apart. Partner rests hands with fingers pointing downward, on inner thighs. Firmly strokes down to knees, then lightly strokes upward on outside of leg. Release.
- Tense arm muscles. Partner places hands on the upper arm and shoulder area, one on the inside and one on the outside of the arm. Strokes down to the elbow and then down forearm to wrist, and over fingertips. Release. Repeat with other arm.
- Tighten leg muscles, being careful not to cramp them. Partner touches foot around the instep, firmly without tickling. Release whole leg. Partner moves hands up, placing one on either side of the thigh, stroking down to the knee then down the calf to the foot and over the toes. Release. Repeat with other leg.
- Change to the Sims, lateral, or side-lying position. Raise chin, contracting the muscles at the back of the neck. Partner rests hand on nape of neck and massages. Release.
- Curl into fetal position, drawing shoulders forward. Partner applies pressure to back of shoulders. Strokes upper back. Release.
- Hollow the small of back by arching back. Partner rests hands against either side of spine and follows with stroking down over buttocks. Release.
- Press buttocks together. Partner rests one hand on each buttock. After initial release, strokes down toward thighs.

Source: O'Halloran, S. (1984). Pregnant and prepared: A guide to preparing for childbirth *(p. 45). Wayne, NJ: Avery Publishing Group.*

- Tighten your muscles in both feet. Hold the tightness for a few seconds, and then relax the muscles completely, letting all the tension drain out.
- Tighten your lower legs, hold for a few seconds, and then relax the muscles, letting all the tension drain out.
- Continue tensing and relaxing parts of your body, moving up the body as you do so.

Touch Relaxation

Another type of relaxation exercise, called **touch relaxation**, requires cooperation between the woman and her coach. It is particularly useful in working together during labor. An example is provided in Table 13-4.

Disassociation Relaxation

An additional exercise, **disassociation relaxation**, is used in both Lamaze and Bradley methods. The woman is taught to become familiar with the sensation of contracting and relaxing the voluntary muscle groups throughout her body. She then learns to contract a specific muscle group and relax the rest of her body. This process of isolating the action of one group of voluntary muscles from the rest of the body is called *neuromuscular disassociation.* The exercise conditions the woman to relax uninvolved muscles while the uterus contracts, creating an active relaxation pattern (Table 13-5).

Although it is not possible to simulate the pain of uterine contractions, the coach may use one of two methods to induce some discomfort so the woman can practice the relaxation exercises:

1. The coach places both hands in a grasping position firmly on the upper arm and turns them in opposite directions to create a burning sensation. This is begun slowly and gently and increased at the direction of the woman as she continues to practice relaxation breathing techniques (Figure 13-5 ■).
2. The coach places a hand on the woman's inner thigh just above the knee and pinches the area.

While practicing, the coach checks the woman's neck, shoulders, arms, and legs for relaxation. As tense areas are found, the coach encourages the woman to relax those particular body parts. The woman learns to respond to her own perceptions of tense muscles and also to the suggestion from others.

Figure 13-5 ■ To help the woman practice relaxing in the presence of discomfort, the coach can induce discomfort by "twisting" the skin of her upper arm or by pinching her inner thigh.

TABLE 13-5 Disassociation Relaxation

The uterus, an involuntary muscle over which you have no control, will work most efficiently and effectively when the rest of your body is free from tension. The following exercises will give you further practice in conscious release. They will also give you and your partner a way to evaluate your progress.

Goals

During pregnancy, disassociation relaxation will teach you consciously to release certain sets of muscles, while contracting others, and to disassociate yourself from voluntary tension. During labor, this technique will release all voluntary muscles of your body at will, while the uterus contracts. This conserves energy and fights fatigue.

Tools

Body awareness, touch release, and concentration.

Procedure

Partner gives consistent suggestions.
Partner checks relaxation using touching.

Example

Partner: "Contraction begins."
Mother: Relaxation breath (following with a comfortable rate of breathing).
Partner: [See suggested sequence.]
Mother: Relaxation breath.

Sequence

"Contract right arm. Hold. Release."
"Contract left arm. Hold. Release."
"Contract right leg. Hold. Release."
"Contract left leg. Hold. Release."
"Contract both arms. Hold. Release."
"Contract both legs. Hold. Release."
"Contract right side (arm and leg). Hold. Release."
"Contract left side (arm and leg). Hold. Release."
"Contract right arm and right leg. Hold. Release."
"Contract left arm and left leg. Hold. Release."

For Variety

"Contract right arm and left leg."
"Release left leg. Contract right leg. Release right arm. Contract left arm."
"Release."

Source: O'Halloran, S. (1984). Pregnant and prepared: A guide to preparing for childbirth *(pp. 45–46). Wayne, NJ: Avery Publishing Group.*

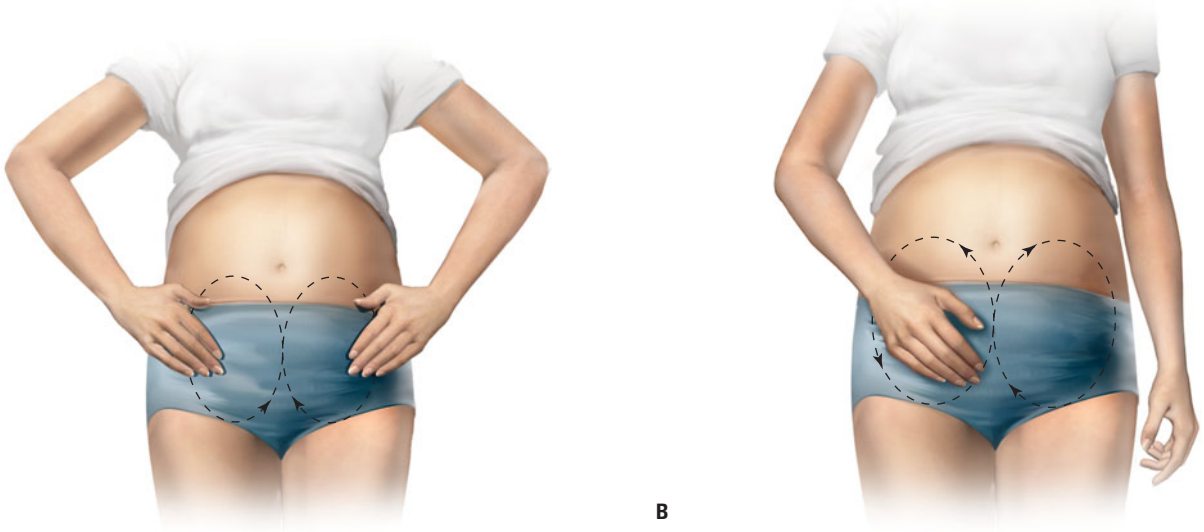


Figure 13-6 ■ Effleurage is light stroking of the abdomen with the fingertips. A. Starting at the symphysis, the woman lightly moves her fingertips up and around in a circular pattern. B. An alternative approach involves using one hand in a figure-eight pattern. This light stroking can also be done by the support person.

The suggestion can come verbally or from touch. The exercises are usually practiced each day so that they become comfortable and easy to do.

Other Relaxation Techniques

A specific type of cutaneous stimulation called abdominal **effleurage** is used before the transitional phase of labor (Figure 13-6 ■). This light abdominal stroking effectively relaxes the woman experiencing mild to moderate pain. Deep pressure over the sacrum is more effective for relieving back pain.

Additional modalities that may be used to promote relaxation in labor include guided imagery, hypnosis, meditation, music, massage, aromatherapy, therapeutic touch, biofeedback, transcutaneous electrical nerve stimulation (TENS) unit, acupressure, and acupuncture. In addition to these measures, the nurse can promote relaxation by encouraging and supporting the patient's controlled breathing.

Individualization is essential when choosing appropriate relaxation techniques. The nurse should encourage techniques that are comfortable for the woman. Some techniques that may be beneficial are as follows:

- Vocalization or "sounding" to relieve tension in pregnancy and labor.
- Massage (light touch) to facilitate relaxation.
- Breathing in any manner that seems to bring relief. No specific pattern is followed.
- Use of warm water for showers or bathing during labor.
- Visualization (imagery).
- Relaxing music and subdued lighting.

Breathing Techniques

Breathing techniques are a key element of most childbirth preparation programs. They help keep the mother and her unborn baby adequately oxygenated and help the mother relax and focus her attention appropriately (Table 13-6). Breathing techniques are best taught during the final trimester of pregnancy when the expectant mother's attention is focused on the birth experience. The nurse then supports the mother's use of breathing techniques during labor. Breathing techniques are described in detail in chapter 24 ∞.

TABLE 13-6 Goals of Breathing Techniques

- Provide adequate oxygenation of mother and baby, open maternal airways, and avoid inefficient use of muscles.
- Increase physical and mental relaxation.
- Decrease pain and anxiety.
- Provide a means of focusing attention.
- Control inadequate ventilation patterns that are related to pain and stress.
- Provide a sense of control for the mother.

CLINICAL TIP

Practice the techniques for relaxation yourself. This practice will prepare you to help expectant parents and laboring women.

Vocalization Techniques

With the increased use of analgesics and epidural anesthesia, many nurses have become unfamiliar with and may be uncomfortable about natural sounds made by laboring women. Vocalization or *sounding* during uterine contractions can be encouraged to promote relaxation and relieve tension. The nurse should encourage the woman to relax, drop her jaw to her chest, and make low-pitched sounds. Suggesting that the woman try to sound like a man or a mother bear can help her to produce the appropriate pitch. These low, moaning sounds open the glottis, helping the woman to relax, breathe freely, and feel confident and strong. In contrast, high-pitched sounds can promote tension, closure of the glottis, and a feeling of fear.

FOCUS YOUR STUDY

- Preconception counseling can be used to identify risk factors and unhealthy behaviors before a pregnancy occurs. Healthful lifestyle changes can be employed.
- Childbearing decisions include the healthcare provider, birth setting, support persons, and whether to include siblings in the birth experience.
- Prenatal education programs vary in their goals, content, leadership techniques, and method of teaching. The major childbirth preparation methods are Lamaze, Kitzinger, Bradley, and HypnoBirthing.
- Prenatal classes may be offered early or late in the pregnancy. The class content varies depending on the type of class and the individual offering it. Expectant parents tend to want information in chronologic sequence with the pregnancy.
- Breastfeeding programs in the prenatal period offer encouragement, practical instruction, and resources for the breastfeeding family.
- Siblings are now included in the whole birthing process, and classes for them are available from many sources.
- Grandparents have unique information needs that are addressed in grandparents' classes.
- Information regarding cesarean birth is included in antepartum classes to help prepare all parents for this alternative method of birth.
- Most childbirth classes include information on body-toning exercises, relaxation techniques, breathing method, and vocalization techniques.

CRITICAL THINKING IN ACTION

Source: George Dodson/Pearson Education.

Terry Dole, a 38-year-old G1 P0000, at 6 weeks' gestation, presents to you at the OB clinic for her first prenatal visit with the certified nurse-midwife (CNM). One of the first decisions facing Terry is the selection of a healthcare provider. The midwife explains the various options available to Terry at the clinic related to the differences in educational preparation, skill level, practice characteristics, and general philosophy of CNMs and obstetricians. Terry tells you that she has been married for 6 years and works as a massage therapist. You obtain the following data: BP 110/70, temperature 97.0° F, pulse 76, respirations 12, weight 140 lb, height 5'7". The physical and pelvic exams are essentially normal. The CNM asks you to teach Terry about birth plans.

1. Discuss the advantages of a birth plan.
2. Discuss the disadvantages of a birth plan.
3. Explain the role of a doula.
4. What gender differences are there in moving toward parenthood?

Physical and Psychologic Changes of Pregnancy

CHAPTER 14

> The atmosphere of approval in which I was bathed—even by strangers on the street, it seemed—was like an aura I carried with me . . . This is what women have always done.
>
> —Adrienne Rich, *Of Woman Born*

LEARNING OUTCOMES

1. Identify the anatomic and physiologic changes that occur during pregnancy.
2. Relate the physiologic and anatomic changes that occur in the body systems during pregnancy to the signs and symptoms that develop in the woman.
3. Compare subjective (presumptive), objective (probable), and diagnostic (positive) changes of pregnancy.
4. Contrast the various types of pregnancy tests.
5. Discuss the emotional and psychologic changes that commonly occur in a woman, her partner, and her family during pregnancy.
6. Summarize cultural factors that may influence a family's response to pregnancy.

Through modern technology and highly evolved research methods, we know a great deal about how pregnancy occurs and what happens to the fetus and the woman's body during gestation. Yet no matter how much we learn about this event, it never ceases to amaze us. First, it is nothing short of a miracle that the union of two microscopic entities—an ovum and a sperm—can produce a living being. Second, the woman's body must undergo extraordinary physical changes to sustain a pregnancy. A pregnant woman's body changes in size and shape, and all her organ systems modify their functions to create an environment that protects and nurtures the growing fetus.

Pregnancy is divided into three trimesters, each a 3-month period. Each trimester has its own predictable developments in both the fetus and the mother. This chapter describes both obvious and subtle physical and psychologic changes caused by pregnancy. It also discusses the various cultural factors that can affect a woman's well-being during pregnancy.

Anatomy and Physiology of Pregnancy

The changes that occur in the pregnant woman's body are caused by several factors. Many changes are the result of hormonal influences, some are caused by the growth of the fetus inside the uterus, and some are a result of the mother's physical adaptation to the changes that are occurring.

Reproductive System

Uterus

The changes in the uterus during pregnancy are phenomenal. Before pregnancy the uterus is a small, almost solid, pear-shaped organ measuring approximately 7.5 × 5 × 2.5 cm and weighing about 60 g (2 oz). At the end of pregnancy the dimensions are approximately 28 × 24 × 21 cm with an organ weight of approximately 1100 g (2.5 lb). Its capacity increases from 10 to 5000 ml (5 L) or more (Cunningham et al., 2010).

The enlargement of the uterus is primarily a result of an increase in size (hypertrophy) of the preexisting myometrial cells. Only a limited increase in cell number (hyperplasia) occurs. The amount of fibrous tissue between the muscle bands increases markedly, which adds to the strength and elasticity of the muscle wall.

The uterine walls become considerably thicker during the first few months of pregnancy than during the nonpregnant state. The initial changes are stimulated by increased estrogen and progesterone levels and not by mechanical distention (enlargement) by the fetus, placenta, and amniotic fluid. In general, the uterus enlarges more around the placental insertion site and in the upper portion of the uterus, the *fundus* (Cunningham et al., 2010). After approximately the third month, the uterine contents begin to exert intrauterine pressure. The myometrial hypertrophy continues during the first few months of pregnancy. Then the musculature begins to distend, resulting in a thinning of the muscle wall to a thickness of about 1.5 cm or less at term (38 through 41 weeks of gestation). The ease of palpating the fetus through the abdominal wall attests to this thinning.

The circulatory requirements of the uterus increase as the uterus enlarges and the fetus and placenta develop. The size and number of the blood and lymphatic vessels within the uterine layers increase greatly. By the end of pregnancy, one sixth of the total maternal blood volume is contained within the vascular system of the uterus.

Braxton Hicks contractions—irregular contractions of the uterus—occur intermittently throughout pregnancy. They may be palpated bimanually beginning about the fourth month of pregnancy. These contractions help stimulate the movement of blood through the intervillous spaces of the placenta. In late pregnancy as these contractions increase in frequency, they can become uncomfortable and may be confused with true labor contractions.

> **CLINICAL TIP**
> Beginning early in pregnancy, have the woman feel her uterus periodically so that she becomes familiar with the size and the way it feels. As her pregnancy progresses she then will be more likely to identify Braxton Hicks contractions and preterm labor should it occur.

Cervix

The major component of cervical tissue is connective tissue, which is rearranged as pregnancy progresses. At term its strength is 1/12 of its prepregnant strength, facilitating cervical changes during labor (Cunningham et al., 2010).

Estrogen stimulates the glandular tissue of the cervix, which increases in cell number and becomes hyperactive. The endocervical glands occupy about half the mass of the cervix at term, as compared with a small fraction in the nonpregnant state. They secrete a thick, tenacious mucus, which accumulates and thickens to form the **mucous plug** that seals the endocervical canal and prevents the ascent of bacteria or other substances into the uterus. This plug is expelled when cervical dilatation begins. The hyperactive glandular tissue also causes an increase in the normal physiologic mucorrhea, at times resulting in a profuse discharge. Increased vascularization causes both the softening of the cervix (**Goodell's sign**) and a blue-purple discoloration of the cervix (**Chadwick's sign**). Increased vascularization is a result of hypertrophy and engorgement of the vessels below the growing uterus.

Ovaries

The ovaries cease ovum production during pregnancy. Many follicles develop temporarily but never to the point of maturity. The cells lining these follicles, the thecal cells, become active in hormone production and have been called the interstitial glands of pregnancy.

During early pregnancy human chorionic gonadotropin (hCG) maintains the corpus luteum, which persists and produces hormones until about weeks 6 to 8 of pregnancy. The corpus luteum engulfs approximately a third of the ovary at its peak of hypertrophy. By the middle of pregnancy it has regressed to almost

complete obliteration. The corpus luteum secretes progesterone to maintain the endometrium until the placenta produces enough progesterone to maintain the pregnancy; then the corpus luteum disintegrates slowly.

Vagina

The vaginal epithelium undergoes hypertrophy, increased vascularization, and hyperplasia during pregnancy. As with the cervical changes, these changes are estrogen induced and result in a thickening of mucosa, a loosening of connective tissue, and an increase in vaginal secretions. The secretions are thick, white, and acidic (pH 3.5 to 6). The acid pH plays a significant role in preventing infections. However, it also favors the growth of yeast organisms, resulting in moniliasis, a common vaginal infection during pregnancy.

As in the uterus, the smooth muscle cells of the vagina hypertrophy, with an accompanying loosening of the supportive connective tissue. By the end of pregnancy, the vaginal wall and perineal body have become sufficiently relaxed to permit distention of the tissues and passage of the infant.

Because the blood flow to the vagina increases, it may show the same blue-purple color (Chadwick's sign) seen in the cervix.

Breasts

Soon after the woman first misses her menstrual period, estrogen- and progesterone-induced changes occur in the mammary glands. Increases in breast size and nodularity are the result of glandular hyperplasia and hypertrophy in preparation for lactation. By the end of the second month, superficial veins are prominent, nipples are more erectile, and pigmentation of the areola is obvious. Pigmentation tends to be more pronounced in women with dark complexions. Hypertrophy of Montgomery's follicles is noted within the primary areola. **Striae** (purplish stretch marks that slowly turn silver after childbirth) may develop as the pregnancy progresses. Breast changes are often most noticeable in the woman who is pregnant for the first time.

Colostrum, an antibody-rich, yellow secretion, may be expressed manually by the 12th week and may leak from the breasts during the last trimester of pregnancy. Colostrum gradually converts to mature milk during the first few days following childbirth.

Respiratory System

Pulmonary function is modified throughout pregnancy. Pregnancy induces a small degree of hyperventilation as the tidal volume (amount of air breathed with ordinary respiration) increases steadily throughout pregnancy. There is a 30% to 40% rise from nonpregnant values in the volume of air breathed each minute. Between weeks 16 and 40, oxygen consumption increases approximately 15% to 20% to meet the increased needs of the mother as well as those of the fetus and placenta. The vital capacity (maximum amount of air that can be moved in and out of the lungs with forced respiration) increases slightly, while lung compliance (elasticity) and pulmonary diffusion remain constant. Measurements of airway resistance show a marked decrease in pregnancy in response to elevated progesterone levels. The diaphragm is elevated and the subcostal angle is increased as a result of pressure from the enlarging uterus. This change causes the rib cage to flare with a decrease in the vertical diameter and increases in the anteroposterior and transverse diameters. The circumference of the chest may increase by as much as 6 cm. The increase compensates for the elevated diaphragm, and there is no significant loss of intrathoracic volume. Breathing changes from abdominal to thoracic as pregnancy progresses. Overall, pulmonary function is not impaired by pregnancy. Many women experience an increased awareness of the need to breathe, however, starting early in pregnancy. This may be perceived as dyspnea and is thought to be due to the increased tidal volume, which causes a slight decrease in blood PCO_2. Actual lung disease may be aggravated by pregnancy because of the increased need for oxygen by the woman and her fetus (Cunningham et al., 2010).

Nasal stuffiness and congestion, referred to as rhinitis of pregnancy, are not uncommon. Epistaxis (nosebleeds) may also occur. They are primarily the result of estrogen-induced edema and vascular congestion of the nasal mucosa.

Cardiovascular System

The growing uterus exerts pressure on the diaphragm, pushing the heart upward and to the left and rotating it forward. This lateral displacement makes the heart appear somewhat enlarged on x-ray examination. A systolic murmur can be heard in 90% of pregnant women, and the first and third heart sounds are louder.

Blood volume progressively increases throughout pregnancy, beginning in the first trimester, and increases rapidly until about 30 to 34 weeks, then plateaus until birth at about 40% to 50% above nonpregnant levels. This increase is due to increases in both plasma and erythrocytes (Gordon, 2007). No increase occurs in pulmonary capillary wedge pressure or in central venous pressure despite the increase in blood volume. This is due to decreases in both systemic vascular resistance and pulmonary vascular resistance, which enable the circulation to adapt to higher blood volume while maintaining normal vessel pressures. Cardiac output begins to increase early in pregnancy and peaks at 25 to 30 weeks' gestation at 30% to 50% above prepregnant levels. It generally remains elevated in the third trimester.

During pregnancy, organ systems receive additional blood flow according to their increased workload. Thus blood flow to the uterus, placenta, and breasts increases, whereas hepatic and cerebral flow remains unchanged.

The pulse rate frequently increases during pregnancy, although the amount varies from almost no increase to an increase of 10 to 15 beats per minute. The blood pressure decreases slightly during pregnancy, reaching its lowest point during the second trimester. The blood pressure then gradually increases during the third trimester and is near prepregnant levels at term (when the baby is due).

The femoral venous pressure slowly rises as the uterus exerts increasing pressure on return blood flow. There is an increased tendency toward stagnation of blood in the lower extremities, with a resulting dependent edema and tendency toward varicose vein formation in the legs, vulva, and rectum late

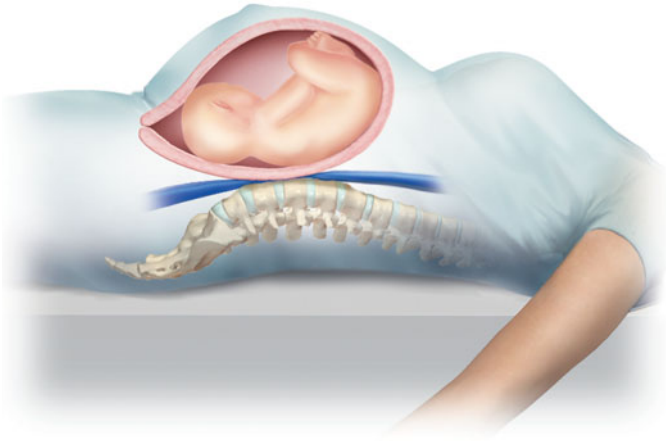

Figure 14-1 ■ Vena caval syndrome. The gravid uterus compresses the vena cava when the woman is supine. This reduces the blood flow returning to the heart and may cause maternal hypotension.

in pregnancy. In addition to the effects of increased femoral venous pressure, a reduction of plasma colloid osmotic pressure resulting from a reduction in plasma albumin further maintains the presence of fluid in the extravascular space. The pregnant woman becomes more prone to develop postural hypotension because of the increased blood volume in the lower extremities.

During pregnancy the enlarging uterus may put pressure on the vena cava when the woman is supine, resulting in **supine hypotensive syndrome**, also called **vena caval syndrome** or **aortocaval compression**. This pressure interferes with returning blood flow and produces a marked decrease in blood pressure with accompanying dizziness, pallor, and clamminess, which can be corrected by having the woman lie on her left side. Research indicates that the enlarging uterus may press on the aorta and its collateral circulation as well (Cunningham et al., 2010) (Figure 14-1 ■).

The total erythrocyte volume increases by about 30% in women who receive iron supplementation but increases only about 18% without iron supplements. This increase is necessary to transport the additional oxygen required during pregnancy. The increase in plasma volume averages about 50%. Because the plasma volume increase (50%) is greater than the erythrocyte increase (30%), however, the hematocrit, which measures the portion of whole blood that is composed of erythrocytes, decreases slightly (Gordon, 2007). This decrease is sometimes referred to as the **physiologic anemia of pregnancy** (pseudoanemia).

Iron is necessary for hemoglobin formation, and hemoglobin is the oxygen-carrying component of erythrocytes. Thus the increase in erythrocyte levels results in an increased need for iron by the pregnant woman. Even though the gastrointestinal absorption of iron is moderately increased during pregnancy, it is usually necessary to add supplemental iron to the diet to meet the expanded red blood cell and fetal needs.

Leukocyte production equals or is slightly greater than the increase in blood volume. The average cell count is 5600 to 12,200/mm^3, with an occasional woman developing a physiologic leukocytosis of 15,000/mm^3. During labor and the early postpartum period, these levels may reach 20,000 to 30,000/mm^3 or higher (Gordon, 2007). The reason for this dramatic increase remains unknown, but similar leukocyte changes occur with physiologic stress such as vigorous exercise. It probably represents the return to the circulation of mature leukocytes that had been shunted out of the circulatory system (Cunningham et al., 2010).

The platelet count does not change much in pregnancy, but the plasma fibrinogen has been known to increase by as much as 50%. The increased fibrinogen accounts for the nonpathologic rise of the sedimentation rate. Although the clotting time of the pregnant woman does not differ significantly from that of the nonpregnant woman, blood factors VII, VIII, IX, and X are increased so that pregnancy becomes a somewhat hypercoagulable state. These changes, coupled with venous stasis in late pregnancy, place the pregnant woman at increased risk of developing venous thrombosis.

Gastrointestinal System

Many of the discomforts of pregnancy are attributed to changes in the gastrointestinal system. Nausea and vomiting during the first trimester are sometimes associated with the hCG secreted by the implanted blastocyst and with a change in carbohydrate metabolism that occurs in early pregnancy. Peculiarities of taste and smell are common and can further aggravate gastrointestinal discomfort. Gum tissue may become hyperemic and softened and may bleed when only mildly traumatized. The secretion of saliva may increase or become excessive (ptyalism).

During the second half of pregnancy, numerous gastrointestinal symptoms are attributable to the pressure of the growing uterus and smooth muscle relaxation due to elevated progesterone levels. The intestines are moved laterally and posteriorly and the stomach superiorly. Heartburn (pyrosis) is caused by the reflux of acidic secretions from the stomach into the lower esophagus as a result of relaxation of the cardiac sphincter. Gastric emptying time and intestinal motility are delayed, leading to frequent complaints of bloating and constipation, which can be aggravated by the smooth muscle relaxation and increased electrolyte and water reabsorption in the large intestine. Hemorrhoids frequently develop if constipation is a problem or, in the second half of pregnancy, from pressure on vessels below the level of the uterus.

Only minor liver changes occur with pregnancy. Plasma albumin concentrations and serum cholinesterase activity decrease with normal pregnancy as with certain liver diseases.

The emptying time of the gallbladder is prolonged during pregnancy as a result of smooth muscle relaxation from progesterone. Hypercholesterolemia may follow, and it can predispose the woman to gallstone formation. Pruritus (itching) caused by retained bile salts may also occur (Cunningham et al., 2010).

Urinary Tract

During the first trimester, the growing uterus puts pressure on the bladder, producing urinary frequency until the second trimester, when the uterus becomes an abdominal organ. Near term, when the presenting part engages in the pelvis, pressure is again exerted on the bladder. This pressure can impair the

drainage of blood and lymph from the hyperemic bladder, rendering it more susceptible to infection and trauma. The bladder, normally a convex organ, becomes concave from the external pressure, and its capacity is greatly reduced.

Dilation of the kidneys and ureter may occur, most frequently on the right side above the pelvic brim, because of the lie of the uterus. This dilation is accompanied by elongation and curvature of the ureter. There appears to be no single factor accounting for this anatomic variation; instead a combination of ureteral atonia and hypoperistalsis, probably caused by pressure from the enlarging fetus with some progesterone effects, seems to be involved. The presence of amino acids and glucose in the urine in conjunction with the tendency toward ureteral atonia and stasis of urine in the ureters may increase the risk of urinary tract infection.

The glomerular filtration rate (GFR) and renal plasma flow (RPF) increase early in pregnancy. The GFR rises by as much as 50% by the beginning of the second trimester and remains elevated until birth. The increase in RPF is slightly less and decreases somewhat during the third trimester (Cunningham et al., 2010). The mechanism for these rises remains unclear.

An increased renal tubular reabsorption rate compensates for the increased glomerular activity. Amino acids and water-soluble vitamins are excreted in greater amounts than in the nonpregnant woman. Glycosuria is not uncommon or necessarily pathogenic during pregnancy but is merely a reflection of the kidneys' inability to reabsorb all of the glucose filtered by the glomeruli. However, pregnancy can be diabetogenic, so the possibility of diabetes mellitus cannot be disregarded.

The increased renal function during pregnancy results in an increased clearance of urea and creatinine and in a lowering of the blood urea and nonprotein nitrogen values. Because of this, measurement of creatinine clearance provides an accurate test of renal functioning during pregnancy.

Skin and Hair

Changes in skin pigmentation commonly occur during pregnancy. These changes are thought to be stimulated by increased estrogen, progesterone, and α-melanocyte-stimulating hormone levels.

Pigmentation of the skin increases primarily in areas that are already hyperpigmented: the areolae, the nipples, the vulva, the perianal area, and the linea alba. The linea alba refers to the midline of the abdomen from the pubic area to the umbilicus and above. During pregnancy increased pigmentation may cause this area to darken. It is then referred to as the **linea nigra** (Figure 14-2 ■). Some women also develop facial **chloasma** (or **melasma gravidarum**), the "mask of pregnancy." This is an irregular pigmentation of the cheeks, forehead, and nose that occurs in many women during pregnancy and is accentuated by sun exposure. Similar changes may occur in women who are taking oral contraceptives. Facial melasma is more prominent in dark-haired women and is occasionally disfiguring. Fortunately, it fades or at least regresses soon after birth when the hormonal influence of pregnancy has stopped.

Striae, or stretch marks, are reddish, wavy, depressed streaks that may occur over the abdomen, breasts, and thighs as pregnancy progresses. They are caused by reduced connective tissue strength due to elevated adrenal steroid levels.

Figure 14-2 ■ Linea nigra.
Source: George Dodson/Pearson Education.

Vascular spider nevi may develop on the chest, neck, face, arms, and legs. They are small, bright-red elevations of the skin radiating from a central body. They may be caused by increased subcutaneous blood flow in response to increased estrogen levels. This condition is of no clinical significance and disappears after pregnancy ends.

The rate of hair growth may decrease during pregnancy, and the number of hair follicles in the resting or dormant phase also decreases. After birth the number of hair follicles in the resting phase increases sharply, and the woman may notice increased shedding of hair for 1 to 4 months. Practically all hair is replaced within 6 to 12 months, however (Cunningham et al., 2010).

Finally, the sweat and sebaceous glands are frequently hyperactive during pregnancy. Some women may notice heavy perspiration, night sweats, and/or the development of acne even if they have never experienced these symptoms before.

Musculoskeletal System

No demonstrable changes occur in the teeth of the pregnant woman. No demineralization takes place. The fairly common occurrence of dental caries during pregnancy has led to the myth "a tooth for every pregnancy." The dental caries that may accompany pregnancy is likely to be caused by inadequate oral hygiene and dental care.

The sacroiliac, sacrococcygeal, and pubic joints of the pelvis relax in the later part of the pregnancy, presumably as a result of hormonal changes. This often causes a waddling gait. A slight separation of the symphysis pubis can often be demonstrated on radiologic examination.

As the pregnant woman's center of gravity gradually changes, the lumbodorsal spinal curve is accentuated, and the woman's

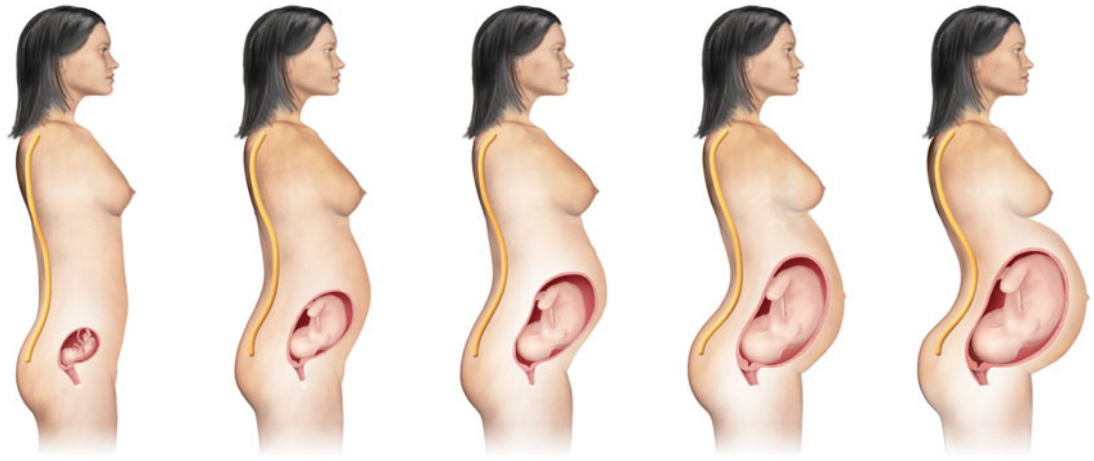

Figure 14-3 ■ Postural changes during pregnancy. Note the increasing lordosis of the lumbosacral spine and the increasing curvature of the thoracic area.

posture changes (Figure 14-3 ■). This posture change compensates for the increased weight of the uterus anteriorly and frequently results in low backache. Late in pregnancy, aches in the neck, shoulders, and upper extremities may occur because of shoulder slumping and anterior flexion of the neck accompanying the lumbodorsal lordosis. Paresthesias of the extremities may occur late in pregnancy as a result of pressure on peripheral nerves.

Often pressure of the enlarging uterus on the abdominal muscles causes the rectus abdominis muscle to separate, producing *diastasis recti.* If the separation is severe and muscle tone is not regained postpartally, subsequent pregnancies will not have adequate support, and the woman's abdomen may appear pendulous.

Eyes

Two changes generally occur in the eyes during pregnancy. First, intraocular pressure decreases, probably as a result of increased vitreous outflow. Second, a slight thickening of the cornea occurs, which is generally attributed to fluid retention. Although these changes are not readily perceived, some pregnant women experience difficulty wearing previously comfortable contact lenses (Cunningham et al., 2010). The change in the corneas generally disappears by 6 weeks postpartum.

Central Nervous System

Pregnant women frequently describe decreased attention, concentration, and memory during and shortly after pregnancy, but few studies have explored this phenomenon. One study did compare a group of pregnant women against a control group, finding a decline in memory that could not be attributed to depression, anxiety, sleep deprivation, or other physical changes of pregnancy. This memory loss disappeared soon after childbirth. Another study found that sleep problems are common in pregnancy. These include difficulty going to sleep, frequent awakenings, fewer hours of night sleep, and reduced sleep efficiency (Cunningham et al., 2010).

Metabolism

Most metabolic functions accelerate during pregnancy to support the additional demands of the growing fetus and its support system. The expectant mother must meet her own tissue replacement needs, those of the fetus, and those preparatory for labor and lactation. No other event in life induces such profound metabolic changes.

Weight Gain

Growth of the uterus and its contents, growth of the breasts, and increases in intravascular fluids account for most of the weight gain in pregnancy. In addition, extra water, fat, and protein are stored; these are usually called *maternal reserves.*

The recommended total weight gain during pregnancy for a woman of normal weight before pregnancy is 11.5 to 16 kg (25 to 35 lb); for women who were overweight before becoming pregnant, the recommended gain is 6.8 to 11.5 kg (15 to 25 lb). Obese women are advised to limit weight gain to 5 to 9 kg (11 to 20 lb). Underweight women are advised to gain 12.7 to 18.1 kg (28 to 40 lb) (Institute of Medicine [IOM], 2009). Weight may decrease slightly during the first trimester because of nausea, vomiting, and food intolerances of early pregnancy. The lost weight is soon regained, and the IOM (2009) recommends that a normal weight woman gain 0.5 to 2 kg (1.1 to 4.4 lb) during the first trimester, followed by an average gain of about 0.45 kg (1 lb) per week during the last two trimesters.

Adequate nutrition and weight gain are important during pregnancy. Maternal nutrition is discussed in detail in chapter 18 ∞.

Water Metabolism

Increased water retention is a basic chemical alteration of pregnancy. Several interrelated factors cause this phenomenon. The increased level of steroid sex hormones affects sodium and fluid retention. The lowered serum protein also influences the fluid balance, as do the increased intracapillary pressure and permeability.

The extra water is needed for the products of conception—the fetus, placenta, and amniotic fluid—and the mother's increased blood volume, interstitial fluids, and enlarged organs.

Nutrient Metabolism

The fetus makes its greatest protein and fat demands during the second half of gestation, doubling in weight in the last 6 to 8 weeks. The increased protein retention that begins in early pregnancy is initially used for hyperplasia and hypertrophy of maternal tissues, such as the uterus and breasts. Protein must also be stored during pregnancy to maintain a constant level within the breast milk and to avoid depletion of maternal tissues.

Fats are more completely absorbed during pregnancy, resulting in a marked increase in the serum lipids, lipoproteins, and cholesterol and decreased elimination through the bowel. Fat deposits in the fetus increase from about 2% at midpregnancy to almost 12% at term. The excess nitrogen and lipidemia are considered to be a preparation for lactation. In addition, the woman's body switches from glucose metabolism to lipid metabolism once glucose from food intake has been used up. This leads to an increased tendency to develop ketosis between meals and overnight. The demand for carbohydrate increases, especially during the last two trimesters. Intermittent glycosuria is not uncommon during pregnancy. When it is not accompanied by a rise in blood sugar levels, glycosuria is a physiologic entity secondary to the increased glomerular filtration rate. Fasting blood sugar levels tend to fall slightly, returning to more normal levels by the sixth postpartal month. The oral glucose tolerance test shows no change with pregnancy.

The possibility of diabetes must not be overlooked during pregnancy. Plasma levels of insulin increase during pregnancy (probably because of hormonal changes that cause increased tissue resistance) and rapid destruction of insulin takes place within the placenta. Insulin production must be increased by the mother during the second trimester, and any marginal pancreatic function quickly becomes apparent. The woman with diabetes often experiences increased exogenous insulin demands during pregnancy.

The demand for iron during pregnancy is accelerated, and the pregnant woman needs to guard against anemia. Iron is necessary for the increase in erythrocytes, hemoglobin, and blood volume, as well as for the increased tissue demands of both woman and fetus.

Iron transfer takes place at the placenta in only one direction—toward the fetus. It has been demonstrated that approximately five sixths of the iron stored in the fetal liver is assimilated during the last trimester of pregnancy. This stored iron in the fetal liver compensates in the first 4 months of neonatal life for the normal inadequate amounts of iron available in breast milk and non–iron-fortified formulas.

The progressive absorption and retention of calcium during pregnancy has been noted. The maternal plasma concentration of bound calcium decreases as the levels of bindable plasma proteins fall. Approximately 30 g of calcium is retained in maternal bone for fetal deposition late in pregnancy.

Pregnancy produces little change in the metabolism of most other minerals, other than retention of amounts needed for fetal growth.

Endocrine System

Thyroid

Pregnancy influences the thyroid gland's size and activity. Often a palpable change is noted, which represents an increase in vascularity and hyperplasia of glandular tissue. Total serum thyroxine (T_4) increases in early pregnancy, and thyroid-stimulating hormone (TSH) decreases. The elevated levels of total T_4 continue until several weeks postpartum, although the level of free serum T_4 returns to normal after the first trimester (Cunningham et al., 2010). Increased thyroxine-binding capacity is evidenced by an increase in serum protein-bound iodine (PBI), probably due to the increased levels of circulating estrogens.

The basal metabolic rate (BMR) increases by as much as 20% to 25% during pregnancy. The increased oxygen consumption is due primarily to fetal metabolic activity.

Parathyroid

The concentration of the parathyroid hormone and the size of the parathyroid glands increase, paralleling the fetal calcium requirements. Parathyroid hormone concentration reaches its highest level of approximately twofold between 15 and 35 weeks of gestation, returning to a normal or even subnormal level before childbirth.

Pituitary

During pregnancy, the pituitary gland enlarges somewhat, but it returns to normal size after birth. There is no significant change in the posterior lobe of the gland, although the anterior lobe increases in weight with each successive pregnancy.

Pregnancy is made possible by the hypothalamic stimulation of the anterior pituitary hormones: follicle-stimulating hormone (FSH), which stimulates follicle growth within the ovary, and luteinizing hormone (LH), which effects ovulation. Pituitary stimulation prolongs the corpus luteal phase of the ovary, which maintains the secretory endometrium for development of the pregnancy.

Two additional pituitary hormones, thyrotropin and adrenotropin, alter maternal metabolism to support the pregnancy. Prolactin, also an anterior pituitary secretion, is responsible for initial lactation. Its levels increase 10-fold during pregnancy and then, somewhat surprisingly, decrease after childbirth, even in breastfeeding women. (Continued lactation depends on the suckling of the infant.)

The posterior pituitary contains the mechanism for the release of oxytocin and vasopressin, which exert oxytocic, vasopressor, and antidiuretic effects. The main effects of oxytocin are the promotion of uterine contractility and the stimulation of milk ejection from the breasts. Vasopressin causes vasoconstriction, which results in increased blood pressure; it also has an antidiuretic effect and plays an important role in the regulation of water balance. Vasopressin secretion is controlled by changes in plasma osmolarity and blood volume.

Adrenals

Little structural change occurs in the adrenal glands during a normal pregnancy. Estrogen-induced increases in the levels of circulating cortisol result primarily from lowered renal excretion.

The circulating cortisol levels regulate carbohydrate and protein metabolism. A normal level resumes 1 to 6 weeks postpartum.

The adrenals secrete increased levels of aldosterone by the early part of the second trimester. The levels of secretion are even more elevated in the woman on a sodium-restricted diet. This increase in aldosterone in a normal pregnancy may be the body's protective response to the increased sodium excretion associated with progesterone (Cunningham et al., 2010).

Pancreas

The pregnant woman has increased insulin needs. The islets of Langerhans are stressed to meet this increased demand, and a latent deficiency may become apparent during pregnancy, producing symptoms of gestational diabetes (see chapter 19 ∞).

Hormones in Pregnancy

Several hormones are required to maintain pregnancy. Most of these are produced initially by the corpus luteum; production is then assumed by the placenta. (For an in-depth discussion of placental hormones, see chapter 11 ∞.)

HUMAN CHORIONIC GONADOTROPIN The trophoblast secretes hCG in early pregnancy. This hormone stimulates progesterone and estrogen production by the corpus luteum to maintain the pregnancy until the placenta is developed sufficiently to assume that function.

HUMAN PLACENTAL LACTOGEN Also called human chorionic somatomammotropin (hCS), human placental lactogen (hPL) is produced by the syncytiotrophoblast. This hormone is an antagonist of insulin; it increases the amount of circulating free fatty acids for maternal metabolic needs and decreases maternal metabolism of glucose to favor fetal growth.

ESTROGEN Secreted originally by the corpus luteum, estrogen is produced primarily by the placenta as early as the seventh week of pregnancy. Estrogen stimulates uterine development to provide a suitable environment for the fetus. It also helps to develop the ductal system of the breasts in preparation for lactation.

PROGESTERONE Progesterone, also produced initially by the corpus luteum and then by the placenta, plays the greatest role in maintaining pregnancy. It maintains the endometrium and also inhibits spontaneous uterine contractility, thus preventing early spontaneous abortion due to uterine activity. In addition, progesterone helps develop the acini and lobules of the breasts in preparation for lactation.

RELAXIN Relaxin is detectable in the serum of a pregnant woman by the time of the first missed menstrual period. Relaxin inhibits uterine activity, diminishes the strength of uterine contractions, aids in the softening of the cervix, and has the long-term effect of remodeling collagen. Its primary source is the corpus luteum, but small amounts are believed to be produced by the placenta and uterine decidua throughout pregnancy.

Prostaglandins in Pregnancy

Prostaglandins (PGs) are lipid substances that can arise from most body tissues but occur in high concentrations in the female reproductive tract and are present in the decidua during pregnancy. The exact functions of PGs during pregnancy are still unknown, although it has been proposed that they are responsible for maintaining reduced placental vascular resistance. Decreased PG levels may contribute to hypertension and preeclampsia. Prostaglandins are also believed to play a role in the complex biochemistry that initiates labor, although their specific functions are still being defined.

Signs of Pregnancy

Many of the changes women experience during pregnancy are used to diagnose the pregnancy itself. They are called the subjective (or presumptive) changes, the objective (or probable) changes, and the diagnostic (or positive) changes of pregnancy.

Subjective (Presumptive) Changes

The subjective changes of pregnancy are the symptoms the woman experiences and reports. They can be caused by other conditions (Table 14-1) and, therefore, cannot be considered proof of pregnancy. The following can be diagnostic clues when other signs and symptoms of pregnancy are also present.

Amenorrhea is the earliest symptom of pregnancy. In a healthy woman whose menstrual cycles are regular, missing one or more menstrual periods leads to the consideration of pregnancy.

Nausea and vomiting of pregnancy (NVP) are experienced by almost half of all pregnant women during the first 3 months of pregnancy and may be the result of elevated human chorionic gonadotropin (hCG) levels and changed carbohydrate me-

TABLE 14-1 Differential Diagnosis of Pregnancy—Subjective Changes

SUBJECTIVE CHANGES	POSSIBLE ALTERNATIVE CAUSES
Amenorrhea	Endocrine factors: early menopause; lactation; thyroid, pituitary, adrenal, ovarian dysfunction Metabolic factors: malnutrition, anemia, climatic changes, diabetes mellitus, degenerative disorders, long-distance running Psychologic factors: emotional shock, fear of pregnancy or sexually transmitted infection, intense desire for pregnancy (pseudocyesis), stress Obliteration of endometrial cavity by infection or curettage Systemic disease (acute or chronic), such as tuberculosis or malignancy
Nausea and vomiting	Gastrointestinal disorders Acute infections such as encephalitis Emotional disorders such as pseudocyesis or anorexia nervosa
Urinary frequency	Urinary tract infection Cystocele Pelvic tumors Urethral diverticula Emotional tension
Breast tenderness	Premenstrual tension Chronic cystic mastitis Pseudocyesis Hyperestrogenism
Quickening	Increased peristalsis Flatus ("gas") Abdominal muscle contractions Shifting of abdominal contents

tabolism. Further research is being conducted to determine other causes for nausea and vomiting. The woman may feel merely a distaste for food or may suffer extreme vomiting, which may be accompanied by dehydration and ketosis. Because these symptoms frequently occur in the early part of the day and disappear within a few hours, they are commonly called **morning sickness**. In reality, symptoms may occur at any time. This gastrointestinal disturbance usually appears about 6 weeks after the first day of the last menstrual period (LMP) and usually disappears spontaneously 6 to 12 weeks later, although it may be prolonged in some instances. Research suggests that women who experience NVP often have a more favorable pregnancy outcome than those who do not.

> "I believed that the nausea and vomiting would only occur in the morning because everyone called it morning sickness. I soon realized that it could occur at any time of the day or night. I was exhausted all the time and nauseated. Everyone told me the nausea was a sign of a healthy baby, which was reassuring I guess but I was so relieved when I started my second trimester and the nausea ended. The rest of my pregnancy was a breeze."

Excessive fatigue may be noted within a few weeks after the first missed menstrual period and may persist throughout the first trimester.

Urinary frequency is experienced during the first trimester as the enlarging uterus exerts pressure on the bladder. The increased vascularization and pelvic congestion that occur in each pregnancy can also cause frequent voiding. This symptom decreases during the second trimester, when the uterus is an abdominal organ, but reappears during the third trimester, when the presenting part descends into the pelvis.

Changes in the breasts are frequently noted in early pregnancy. Some women report significant breast changes even before missing their first menses. Engorgement of the breasts due to the hormone-induced growth of the secretory ductal system results in the subjective symptoms of tenderness and tingling, especially of the nipple area. The veins also become more visible and form a bluish pattern beneath the skin in fair-skinned women.

Quickening, or the mother's perception of fetal movement, occurs about 18 to 20 weeks after the LMP in a primigravida (a woman who is pregnant for the first time) but may occur as early as 16 weeks in a multigravida (a woman who has been pregnant more than once). Quickening is a fluttering sensation in the abdomen that gradually increases in intensity and frequency.

CLINICAL TIP

Some women suggest that it is easiest to imagine the fluttering associated with quickening by letting the outer tips of the eyelashes brush a finger and then imagining that same sensation deep inside the abdomen.

TABLE 14-2 Differential Diagnosis of Pregnancy—Objective Changes

OBJECTIVE CHANGES	POSSIBLE ALTERNATIVE CAUSES
Changes in pelvic organs	Increased vascular congestion
Goodell's sign	Estrogen-progestin oral contraceptives
Chadwick's sign	Vulvar, vaginal, cervical hyperemia
Hegar's sign	Excessively soft walls of nonpregnant uterus
Uterine enlargement	Uterine tumors
Braun von Fernwald's sign	Uterine tumors
Piskacek's sign	Uterine tumors
Enlargement of abdomen	Obesity, ascites, pelvic tumors
Braxton Hicks contractions	Hematometra, pedunculated, submucous, and soft myomas
Uterine souffle	Large uterine myomas, large ovarian tumors, or any condition with greatly increased uterine blood flow
Pigmentation of skin	Estrogen-progestin oral contraceptives
Chloasma (melasma)	Melanocyte hormonal stimulation
Linea nigra	
Nipples/areola	
Abdominal striae	Obesity, pelvic tumor
Ballottement	Uterine tumors/polyps, ascites
Pregnancy tests	Increased pituitary gonadotropins at menopause, choriocarcinoma, hydatidiform mole
Palpation for fetal outline	Uterine myomas

Objective (Probable) Changes

An examiner can perceive the objective changes that occur in pregnancy. They are more diagnostic than the subjective symptoms. However, their presence does not offer a definite diagnosis of pregnancy (Table 14-2).

Changes in the pelvic organs caused by increased vascular congestion are the only physical signs detectable within the first 3 months of pregnancy. These changes are noted on pelvic examination. There is a softening of the cervix, called Goodell's sign. Chadwick's sign is the deep red to purple or bluish coloration of the mucous membranes of the cervix, vagina, and vulva due to increased vasocongestion of the pelvic vessels. **Hegar's sign** is a softening of the isthmus of the uterus, the area between the cervix and the body of the uterus, which occurs at 6 to 8 weeks of pregnancy. This area may become so soft that on a bimanual exam there seems to be nothing between the cervix and the body of the uterus (Figure 14-4 ■).

Ladin's sign is a soft spot anteriorly in the middle of the uterus near the junction of the body of the uterus and cervix (Figure 14-5A ■). **McDonald's sign** is an ease in flexing the body of the uterus against the cervix.

The uterus assumes an irregular globular shape during the early months of pregnancy. Irregular softening and enlargement at the site of implantation, known as *Braun von Fernwald's sign,* occurs about the fifth week (Figure 14-5B ■). Occasionally an almost tumorlike, asymmetric enlargement

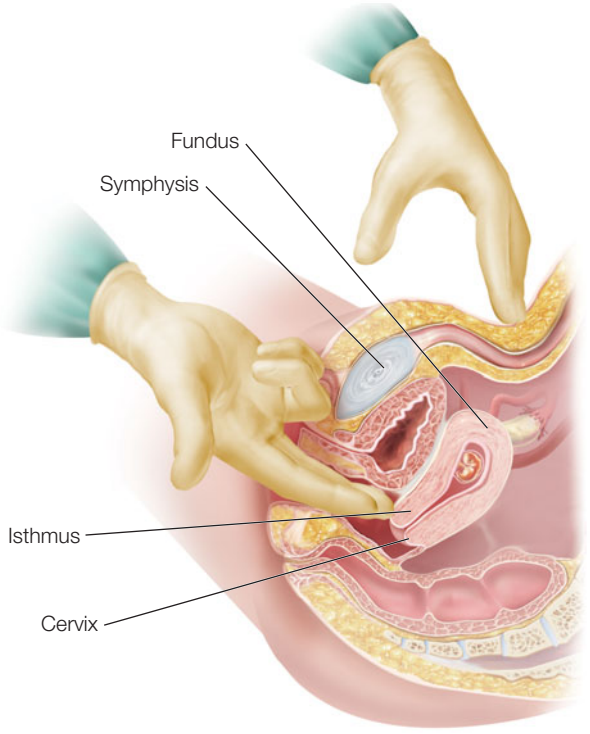

Figure 14-4 ■ Hegar's sign, a softening of the isthmus of the uterus, can be determined by the examiner during a vaginal examination.

occurs, called *Piskacek's sign* (Figure 14-5C ■). Generalized enlargement and softening of the body of the uterus are present after the eighth week of pregnancy. The fundus of the uterus is palpable just above the symphysis pubis at approximately 10 to 12 weeks' gestation and at the level of the umbilicus at 20 to 22 weeks' gestation (Figure 14-6 ■).

Enlargement of the abdomen during the childbearing years is usually regarded as evidence of pregnancy, especially if the enlargement is progressive and is accompanied by a continuing amenorrhea. It is generally more pronounced in a woman whose abdominal musculature has lost some of its tone because of previous childbirth.

As mentioned earlier, *Braxton Hicks* contractions are irregular, ordinarily painless contractions that occur at irregular intervals throughout pregnancy but are felt with abdominal palpation after week 28. As the woman approaches the end of the pregnancy, these contractions often become more uncomfortable and are then called *false labor.*

Uterine souffle may be heard when auscultating the abdomen over the uterus. It is a soft blowing sound at the same rate as the maternal pulse and is due to the increased uterine vascularization and the blood pulsating through the placenta. It is sometimes confused with the *funic souffle,* which is a soft blowing sound of blood pulsating through the umbilical arteries. The funic souffle is at the same rate as the fetal heart rate.

Changes in pigmentation of the skin and the *appearance of abdominal striae* are common manifestations in pregnancy. Facial melasma (chloasma) occurs in varying degrees after week 16. The pigmentation of the nipple and areola may darken, especially in primigravidas and dark-haired women. The Montgomery glands of the areola may become enlarged. The skin in the midline of the abdomen may develop a pigmented line, the linea nigra (Figure 14-2). As pregnancy progresses, striae appear on the abdomen and buttocks.

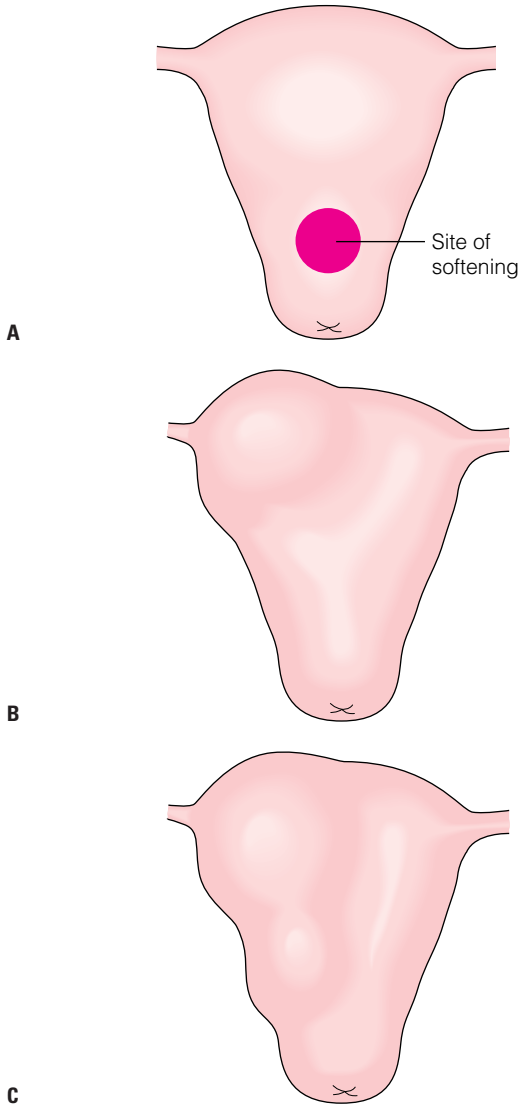

Figure 14-5 ■ Early uterine changes of pregnancy. A. Ladin's sign: a soft spot anteriorly in the middle of the uterus near the junction of the body of the uterus and the cervix. B. Braun von Fernwald's sign: irregular softening and enlargement at the site of implantation. C. Piskacek's sign: a tumorlike asymmetric enlargement.

The *fetal outline* may be identified by palpation in many pregnant women after 24 weeks of gestation, becoming easier to distinguish as term approaches. **Ballottement** is the passive fetal movement elicited by pushing up against the cervix with two fingers. This pushes the fetal body up and, as it falls back, the examiner feels a rebound.

Pregnancy tests are based on analysis of maternal blood or urine for the detection of hCG, the hormone secreted by the trophoblast. These tests are not considered positive signs of pregnancy because the similarity of hCG and the pituitary-secreted luteinizing hormone (LH) occasionally results in cross-reactions.

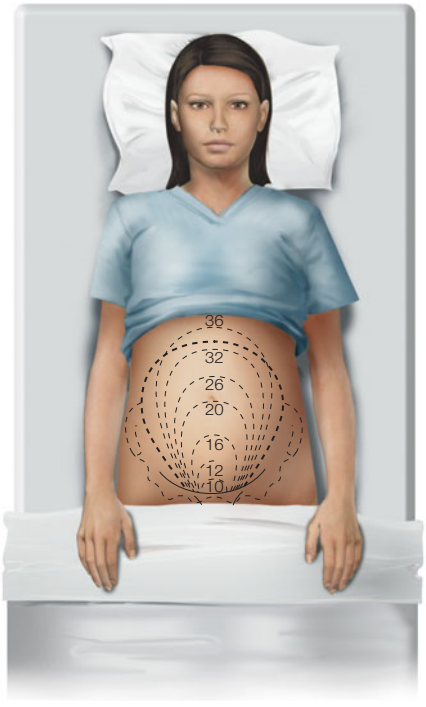

Figure 14-6 ■ Approximate height of the fundus at various weeks of pregnancy.

In addition, certain conditions other than pregnancy can cause elevated levels of hCG.

Clinical Pregnancy Tests

A variety of assay techniques are available to detect hCG in either blood or urine during early pregnancy. Companies that manufacture pregnancy tests provide instructions for performance and interpretation of the test as well as test accuracy. It is important to remember that the presence of hCG in the serum or urine is not always the result of an intrauterine pregnancy. Historically, the following two tests were commonly used urine pregnancy tests.

- *Hemagglutination-inhibition test,* an immunoassay, is based on the fact that no clumping of cells occurs when the urine of a pregnant woman is added to the hCG-sensitized red blood cells of sheep.
- *Latex agglutination test,* also an immunoassay, is based on the fact that latex particle agglutination is inhibited in the presence of urine containing hCG.

The hemagglutination-inhibition test and the latex agglutination test are approximately 95% accurate in diagnosing pregnancy and 98% accurate in determining the absence of pregnancy. The tests become positive approximately 10 to 14 days after the first missed menstrual period. The specimen used for the tests is the first early morning midstream urine because it is adequately concentrated for accuracy. The presence of protein substances (such as blood) in the specimen should be avoided because false-positive results may occur.

Several newer types of pregnancy tests are available, including the following (Buster & Carson, 2002):

- β-*Subunit radioimmunoassay* (RIA) uses an antiserum with specificity for the β-subunit of hCG in blood plasma. This is a very accurate pregnancy test that becomes positive a few days after presumed implantation, thereby permitting earlier diagnosis of pregnancy. This test is also used in the diagnosis of ectopic pregnancy or trophoblastic disease. However, because it requires several hours to perform and has only limited sensitivity, it is being replaced by other, simpler tests such as the immunoradiometric assay.
- *Immunoradiometric assay* (IRMA) uses a radioactive antibody to identify the presence of hCG in the serum. This test can identify very low concentrations of hCG and requires only about 30 minutes to perform. Because this test requires a gamma counter, many laboratories are switching to the enzyme-linked immunosorbent assays.
- *Enzyme-linked immunosorbent assay* (ELISA) does not use radioisotopes but a substance that results in a color change after binding. A blue color develops, the intensity of which is related to the amount of hCG present. This assay, which may be done on urine or blood, is sensitive and quick. It can detect hCG levels as early as 7 to 9 days after ovulation and conception, which is 5 days before the first missed period.
- *Fluoroimmunoassay* (FIA) uses an antibody tagged with a fluorescent label to detect serum hCG. The test, which takes about 2 to 3 hours to perform, is extremely sensitive and is used primarily to identify and follow hCG concentrations.

Over-the-Counter Pregnancy Tests

Home pregnancy tests (HPTs) are available over the counter at a reasonable cost. These enzyme immunoassay tests are quite sensitive and detect even low levels of hCG in urine. Home pregnancy tests are convenient, provide privacy, and allow women to diagnose pregnancy prior to visiting a provider.

Multiple brands and types of HPTs are available, which differ in use and instructions. The newer HPTs claim to be 99% accurate at the time of the missed menses and to have the ability to detect pregnancy 4 days prior to the expected period. This accuracy has been questioned by researchers. Nevertheless, an HPT with a sensitivity of 1.2–5 international units/L hCG will detect 98% of pregnancies close to the time of missed menses (Cole & Ladner, 2009).

There are many variables that may affect the accuracy of home pregnancy test results. Most HPT instructions do not meet recommended compliance with plain language guidelines, including use of wording and language at a reading level above the 6th grade level (Wallace, Zite, Homewood, 2009). Women may not comprehend the HPT instructions, which can affect the accuracy results. It is important that nurses, providers, and patients remember that the tests are not always accurate.

The false-positive rate of these tests is quite low but can also occur in certain situations such as early pregnancy loss, protein in the urine, or the presence of background hCG production. False-negative results are more common and more concerning and should be followed up in the presence of pregnancy symptoms. False-negative results typically occur when the test is completed too early or too late. If the results are negative, the woman should

repeat the test in 1 week if she has not started her menstrual period; at that time the test may become positive. Unfortunately, a false-negative result may lead to delays in beginning prenatal care and obtaining guidance, which could negatively impact the pregnancy and fetus. It is important that women using home pregnancy tests understand that a positive result merely indicates growing trophoblastic tissue and not necessarily a uterine pregnancy. If the woman delays seeking prenatal care after pregnancy is confirmed, an early ectopic pregnancy may be missed.

Diagnostic (Positive) Changes

The positive signs of pregnancy are completely objective, cannot be confused with pathologic states, and offer conclusive proof of pregnancy.

The *fetal heartbeat* can be detected with a fetoscope by approximately weeks 17 to 20 of pregnancy. With the electronic Doppler device it is possible to detect the fetal heartbeat as early as weeks 10 to 12. The fetal heart rate is between 120 and 160 beats per minute and must be counted and compared with the maternal pulse for differentiation. Auscultation of the abdomen may reveal sounds other than that of the fetal heart. The maternal pulse, emanating from the abdominal aorta, may be unusually loud, or a uterine souffle may be heard.

Fetal movement is actively palpable by a trained examiner after about 20 weeks' gestation. The movements vary from a faint flutter in the early months to more vigorous movements late in pregnancy.

Visualization of the fetus by ultrasound confirms a pregnancy. The gestational sac can be observed by 4 to 5 weeks' gestation (2 to 3 weeks after conception). Fetal parts and fetal heart movement can be seen as early as 8 weeks. Recently, ultrasound using a vaginal probe has been used to detect a gestational sac as early as 10 days after implantation (Cunningham et al., 2010).

Psychologic Response of the Expectant Family to Pregnancy

Application: Internet Pregnancy Information

Pregnancy is a developmental challenge, a turning point in a family's life accompanied by stress and anxiety whether the pregnancy is desired or not. Pregnancy confirms one's biologic capabilities to reproduce. It is evidence of one's participation in sexual activity and as such is an affirmation of one's sexuality. For beginning families, pregnancy is the transition period from childlessness to parenthood. If the pregnancy terminates in the birth of a child, the couple enters a new stage of their life together, one that is irreversible and characterized by awesome responsibilities.

The expectant couple may be unaware of the physical, emotional, and cognitive states peculiar to pregnancy. The couple may anticipate no problem from such a normal event as pregnancy and, therefore, may be confused and distressed by new feelings and behaviors that are generally considered normal.

If the expectant woman is married or has a stable partner, she no longer is only a mate but also must assume the role of mother. Her partner will also assume a parenting role. Career goals and mobility may be altered or thwarted for one or both partners. Each partner begins to see the other in a different light. Their relationship takes on a different meaning to them and within the larger family and community. Their lifestyle changes. With each pregnancy, routines and family dynamics are altered, requiring readjustment and realignment.

If a pregnant woman is without a stable partner, she will still experience changes in role identity and psychobiologic maturation. She must deal alone with the role changes, fears, and adjustments of pregnancy or seek support from family and friends. She also faces the reality of planning for the future as a single parent. Even if the pregnant woman plans to relinquish her infant, she must still deal with the adjustments of pregnancy. She is no longer a separate individual; she must consider the needs of another being who depends on her totally, at least during the pregnancy. This adjustment can be especially difficult without a good support system.

In most pregnancies, whether of a mother with a supportive partner, a single mother, or a relinquishing mother, finances are an important consideration. Traditional lore relegates to the father the role of primary breadwinner, and, indeed, finances are often a very real concern for fathers. However, in today's society even pregnant women with stable partners recognize the financial impact of a child and may feel concern about financial issues. For the single mother, finances may be a major source of concern.

Decisions about financial matters need to be made at this time. Will the woman work during the pregnancy and return to work after the baby is born? Who will provide child care if she works? Decisions may also need to be made about the division of tasks within the home. Any differences of opinion must be discussed openly and resolved so that the family can meet its members' needs.

The couple must face the realities of labor and birth. Many nonparents have little idea what labor entails. Their information is frequently based on contacts with visual or print media and on experiences related to them by family members or friends, and these tales are often fraught with myths and exaggerations. Classes in prepared childbirth can help them address this lack of information or misinformation.

Labor is threatening in many respects. Pain, disfigurement, disruption of bodily function, and even death are potential threats for the woman. The partner faces the threat of the woman's disfigurement, impairment of her health, or her death. Both fear that the baby may be ill or disfigured. The expectant couple is subject to anxiety during this period because no one can provide total reassurance about the outcome.

Pregnancy can be viewed as a developmental stage with its own distinct developmental tasks. It can be a time of support or conflict for a couple, depending on the amount of adjustment each is willing to make to maintain the family's equilibrium. Family dynamics are an important factor in adjusting to pregnancy. Family strengths include the ability of the couple to talk about issues that are important to them, to resolve conflicts and make compromises, and to seek and receive assistance and support from loved ones.

During pregnancy, the woman and her partner plan together for the first child's arrival, collecting information on how to be parents. At the same time, each continues to participate in some

separate activities with friends or family members. The availability of social support is an important factor in psychosocial well-being during pregnancy. Most pregnant women turn to their partners as their primary source of social support. In addition, the broader social network often is a major source of advice for the pregnant woman. However, evidence indicates that both sound and unsound information is given.

The expectant mother and her partner both face significant changes during pregnancy and must deal with major psychosocial adjustments (Table 14-3). Other family members, especially other children of the woman or couple, and the grandparents-to-be, must also adjust to the pregnancy.

In late pregnancy, the concerns of expectant fathers tend to focus most on the health of the unborn child and the safety of the mother. The concerns of expectant mothers center on the health of the baby and their ability to handle labor and birth. Couples typically agree on the primary concern, the health of the unborn child. Nurses can use this focus as a springboard for discussing other concerns. Couples can then come to understand the differences between their second most important concerns. A woman worries about how she will handle labor and birth but has little concern for her own safety; the father's expression of his fear for her safety can be seen as evidence that he cares enough to worry about her. This response may allow the mother to depend on him more during the vulnerable time of late pregnancy and birthing. Sharing his views gives the father a chance to express his love and concern for mother and child, encouraging the development of stronger marital and paternal relationships.

Case Study: Prenatal Education

For some couples, pregnancy is more than a developmental stage; it is a crisis. *Crisis* can be defined as a disturbance or conflict in which the individual cannot maintain a state of equilibrium. Pregnancy can be considered a *maturational crisis* because it is a common event in the normal growth and development of the family. During such a crisis, the individual or family is in disequilibrium. The period of disequilibrium and disorganization is marked by abortive attempts to solve the perceived problems. If the crisis is not resolved, it will result in maladaptive behaviors in one or more family members and possible disintegration of the family. Families who are able to resolve a maturational crisis successfully will return to normal functioning and can even strengthen the bonds in the family relationship.

Mother

Pregnancy is a condition that alters body image and also necessitates a reordering of social relationships and changes in roles of family members. The way a particular woman meets the

TABLE 14-3 Parental Reactions to Pregnancy

FIRST TRIMESTER	SECOND TRIMESTER	THIRD TRIMESTER
Mother's Reactions	**Mother's Reactions**	**Mother's Reactions**
Informs father secretively or openly. Feels ambivalent toward pregnancy, anxious about labor and responsibility of child. Is aware of physical changes; daydreams of possible miscarriage. Develops special feelings for and renewed interest in her own mother, with formation of a personal identity.	Remains regressive and introspective; projects all problems with authority figures onto partner; may become angry if she perceives his lack of interest as a sign of weakness in him. Continues to deal with feelings as a mother; shops for nursery furniture as something concrete to do. May experience anxiety or, alternately, may be extremely lackadaisical and wait until 9th month to look for furniture and clothes for baby. Feels movement and is aware of fetus and incorporates it into herself. Dreams that partner will be killed; telephones him often for reassurance. Experiences more distinct physical changes; sexual desires may increase or decrease.	Experiences more anxiety and tension, with physical awkwardness. Feels much discomfort and insomnia from physical condition. Prepares for birth, assembles layette; picks out names. Dreams often about misplacing baby or not being able to give birth; fears birth of deformed baby. Feels ecstasy and excitement; has spurt of energy during last month.
Father's Reactions	**Father's Reactions**	**Father's Reactions**
Differ according to age, parity, desire for child, economic stability. Acceptance of pregnant woman's attitude or complete rejection and lack of communication. Is aware of his sexual feelings; may develop more or less sexual arousal. Accepts, rejects, or resents mother-in-law. May develop new hobby outside of family as sign of stress.	If he can cope, will give her extra attention she needs; if he cannot cope, will develop a new time-consuming interest outside of home. May develop a creative feeling and a "closeness to nature." Many become involved in pregnancy and buy or make furniture. Feels for movement of baby, listens to heartbeat, or remains aloof, with no physical contact. May have fears and fantasies about himself being pregnant; may become uneasy with this feminine aspect in himself. May react negatively if partner is too demanding; may become jealous of physician and of physician's importance to partner and her pregnancy.	Adapts to alternative methods of sexual contact. Becomes concerned over financial responsibility. May show new sense of tenderness and concern, treats partner like doll. Daydreams about child as if older and not newborn; dreams of losing partner. Renewed sexual attraction to partner. Feels he is ultimately responsible for whatever happens.

stresses of pregnancy is influenced by her emotional makeup, her sociologic and cultural background, and her acceptance or rejection of the pregnancy. However, many women manifest similar psychologic and emotional responses during pregnancy, including ambivalence, acceptance, introversion, mood swings, and changes in body image.

Intendedness

Many pregnancies are unintended, but not all unintended pregnancies are unwanted. For some women, an unintended pregnancy has more psychologic and social advantages than disadvantages. It provides purpose and direction to life and allows a woman to test the devotion and love of her partner and family. However, an unintended pregnancy can be a risk factor for depression. Women with an unintended pregnancy may perceive life events as being more stressful than women with an intended pregnancy—another contributor to depression. Depression, in turn, can negatively impact a pregnant woman's health choices and behaviors (Messer, Dole, Kaufman, et al., 2005).

Ambivalence

Initially, even if the pregnancy is planned, the mother may experience a sense of surprise that conception has actually occurred. This may be coupled with a feeling that pregnancy is desirable "someday" but "not now." Such ambivalence may be related to feelings that the timing is somehow "wrong," worries about the need to modify existing relationships or career plans, fears about assuming a new role, unresolved emotional conflicts with the woman's own mother, and fears about pregnancy, labor, and birth. Indirect evidence of ambivalence includes complaints about prolonged or frequent depression, considerable physical discomfort, significant dissatisfaction with body shape, excessive mood swings, and difficulty accepting the life changes resulting from the pregnancy (Lederman & Weis, 2009).

Such feelings may be even more pronounced if the pregnancy is unintended or unwanted. Women who view their pregnancy as unwanted are more likely to delay prenatal care and to experience complications. The support and opinion of the woman's current partner, even if he is not the father of the child, have a major impact on pregnancy wantedness. Financial and emotional support from the partner are essential to the woman's positive attitude. Involving the partner in the prenatal care may help promote a supportive attitude. During the early months, the pregnant woman may consider the possibility of a therapeutic abortion if the pregnancy is unwanted. In the event of religious conflicts about induced abortion, the woman may experience guilt feelings about her thoughts or may tend to focus on the possibility of spontaneous abortion (miscarriage). Even when the pregnancy is planned, thoughts of abortion and miscarriage arise. Concurrently, the pregnant woman may feel guilty for having such negative thoughts and may worry that in some way these thoughts will harm the baby.

Acceptance

Acceptance of pregnancy is influenced by many factors. Lower acceptance tends to be related to an unplanned pregnancy and greater evidence of fear and conflict. The woman carrying an unplanned pregnancy tends to experience more physical discomfort and depression. When a pregnancy is well accepted, the woman demonstrates feelings of happiness and pleasure in the pregnancy. She experiences less physical discomfort and shows a high degree of tolerance for the discomforts associated with the third trimester (Lederman & Weis, 2009).

Conflicts about adapting to pregnancy are no more pronounced for older pregnant women (age 35 and older) than for younger ones. Moreover, older pregnant women tend to be less concerned about the normal physical changes of pregnancy and are confident about handling issues that arise during pregnancy and parenting. This may be because mature pregnant women have more experience with problem solving. However, mature pregnant women may have fewer pregnant peers and thus may have fewer people with whom to share concerns and expectations.

For some women, an unintended pregnancy has more psychologic and social advantages than disadvantages. It provides purpose and direction to life and allows a woman to test the devotion and love of her partner and family.

> "I didn't expect to get pregnant, but my baby seems like a gift from God. Suddenly I feel like I have a purpose in life. I know I have to do the right things so the baby will be okay. Being pregnant made me grow up in a hurry, but I don't regret it—not at all."

During the *first trimester,* evidence of pregnancy is often limited to amenorrhea and to the word of the caregiver that the pregnancy test was positive. Unless the woman has the opportunity to see the gestational sac during an ultrasound, her baby may not seem real. Consequently, she may tend to focus on herself and her pregnancy. In an effort to verify her condition, a woman may become minutely conscious of changes in her body that could validate the pregnancy.

The *second trimester* is relatively tranquil. Morning sickness generally passes, the threat of spontaneous abortion diminishes, and the woman begins to accept the reality of her pregnancy. It is not unusual for an enthusiastic primigravida to don maternity clothes at the beginning of this trimester even when it is not truly necessary. The clothing serves as a verification of her pregnant state.

The highlight of the second trimester is quickening, which generally occurs about week 20—midway through the pregnancy. Actual perception of fetal movement frequently produces dramatic changes in the woman. She now perceives her baby as a real person and generally becomes excited about the pregnancy even if she has not been before this time.

As quickening and her altered physical appearance confirm her pregnant state, the woman adjusts to the idea of change and begins to prepare for her new role and her new set of relationships—with her partner and family, the child-to-be and other children, friends, and loved ones. When the pregnancy is well accepted, the woman takes pleasure in the sensations of pregnancy and attempts to picture her baby in order to know him or her better. She may seek out other women who are pregnant or have recently given birth. She

feels well, is excited, and may exhibit the "glow" so often attributed to pregnant women.

The *third trimester* combines a sense of pride with anxiety about what is to come in order for the child to be born. During this time, the special prerogatives of pregnancy may be most marked. As her protruding abdomen proclaims her advanced pregnancy, the woman may find that others become more solicitous, that a chair may be offered in a crowded room, that others may carry her parcels. The woman may actually need this help, she may simply enjoy the attention as a privilege of pregnancy, or she may reject it if she fears that such gestures indicate she is helpless.

During the final trimester, physical discomforts again increase, and adequate rest becomes a necessity. The woman makes final preparation for the baby and may spend long periods considering names for the child. During this time she worries more about the health and safety of her unborn child and may have concerns that she will not behave well during childbirth.

The woman may feel vulnerable to rejection, loss, or insult. She may worry about a variety of things and may withdraw into the security and quiet of her home. Toward the end of this period many women report bursts of energy in which they vigorously clean and organize their homes ("nesting").

Introversion

Introversion, or turning in on oneself, is a common occurrence in pregnancy. An active, outgoing woman may become less interested in previous activities and more concerned with needs for rest and time alone. This concentration of attention permits the woman to plan, adjust, adapt, build, and draw strength in preparation for her child's birth. As she becomes more aware of herself, her partner may feel she is being overly sensitive. Her partner may perceive her introversion and passivity as exclusionary and may in turn become unable to interact with her, either verbally or physically, or to provide the affection, support, and consideration she requires. This change may result in disequilibrium and stress for the entire family. It is essential that the couple work together to establish new, mutually acceptable patterns of response to overcome these blocks to communication.

Fantasies about the unborn child are quite common among pregnant women. However, the themes of the fantasies (baby's appearance, gender, traits, impact on parents, and so forth) vary by trimester and also differ between women pregnant for the first time and women who already have children.

Mood Swings

Throughout pregnancy, the emotions of many women are characterized by mood swings, from great joy to deep despair. Frequently, the woman will become tearful with little apparent cause. When asked why she is crying, she may find it difficult or impossible to give a reason. The situation may be extremely unsettling for the partner, causing him to feel confused and inadequate. Because the man may feel unable to handle the woman's tears, he often reacts by withdrawing and ignoring the problem. Because the pregnant woman needs increased love and affection, she may perceive his reaction as unloving and nonsupportive. Once the couple understands that this behavior is characteristic of pregnancy, it becomes easier for them to deal with it more effectively—although it will be a source of stress to some extent throughout pregnancy.

Changes in Body Image

Pregnancy produces marked changes in a woman's body within a relatively short time. With these changes, women also experience changes in body image. The degree of this change is related to a certain extent to personality factors, social network responses, and attitudes toward pregnancy. Changes in body image are normal but can be very stressful for the pregnant woman. Explanation and discussion of the changes may help both the woman and her partner deal with the stress associated with this aspect of pregnancy.

> "I'm due in 2 weeks and I can't wait. These last few weeks have been hard on my self-image. I can't see my feet anymore and I feel awkward and lumbering, not graceful at all."

Psychologic Tasks of the Mother

Rubin (1984) identified four major tasks that the pregnant woman undertakes to maintain her intactness and that of her family and at the same time incorporate her new child into the family system. These tasks form the basis for a mutually gratifying relationship with her baby:

1. ***Ensuring safe passage through pregnancy, labor, and birth:*** The pregnant woman feels concern for both her unborn child and herself. She seeks competent maternity care to provide a sense of control. She may also seek knowledge from literature, observation of other pregnant women and new mothers, and discussion with others. The pregnant woman also seeks to ensure safe passage by engaging in self-care activities related to diet, exercise, alcohol consumption, and so forth. In the third trimester, as her movements slow and her body mass increases, she becomes aware of external threats in the environment—a toy on a stair, the awkwardness of an escalator—that pose a threat to her intactness and represent hazards to be overcome. She may worry if her partner is late or if she is home alone. Sleep becomes difficult, and she begins to long for the baby's birth, even though it, too, is frightening.
2. ***Seeking of acceptance of this child by others:*** The birth of a child alters a woman's primary support group, her family, and her secondary affiliative groups. The family generally makes the transition, and the woman slowly and subtly alters her secondary network to meet the needs of her pregnancy. In this adjustment the woman's partner is the most important figure. The partner's support and acceptance influence her completion of her maternal tasks and the formation of her maternal identity. If there are other children in the home, the mother also works to ensure their acceptance of the coming child. Accepting the coming change in exclusive relationships—woman and

partner or mother and first child—can be stressful, and the woman will often work to maintain some special time with her partner or older child. Achieving social acceptance of the child and of herself as mother may be more difficult for the adolescent mother or single woman. The child to come is not always wanted, and the woman often must direct her energies to changing this situation.

3. ***Seeking of commitment and acceptance of self as mother to the infant (binding-in):*** During the first trimester, the child remains a rather abstract concept. With quickening, however, the child begins to become a real person, and the mother begins to develop bonds of attachment. The mother experiences the movement of the child within her in an intimate, exclusive way, and out of this experience bonds of love form. The mother develops a fantasy image of her ideal child. This binding-in process, characterized by its strong emotional component, motivates the pregnant woman to become competent in her role and provides satisfaction for her in her role of mother (Mercer, 2004). This possessive love increases her maternal commitment to protect her fetus now and her child after she or he is born.
4. ***Learning to give of oneself on behalf of one's child:*** Childbirth involves many acts of giving. The man "gives" a child to a woman; she in turn "gives" a child to the man. Life is given to an infant; a sibling is given to older children of the family. The woman begins to develop a capacity for self-denial and learns to delay immediate personal gratification to meet the needs of another. Baby showers and baby gifts are acts of giving that help the mother's self-esteem while also helping her acknowledge the separateness and needs of the coming baby.

Accomplishment of these tasks helps the expectant woman develop her self-concept as mother. The expectant mother who was well nurtured by her own mother may view her mother as a role model and emulate her; the woman who views her own mother as a "poor mother" may worry that she will make similar mistakes (Lederman & Weis, 2009). A woman's self-concept as mother expands with actual experience and continues to grow through subsequent childbearing and childrearing. Occasionally, a woman never accepts the mother role but plays the role of babysitter or older sister.

Father

Until fairly recently, the expectant father was often viewed as a "bystander" or observer of his partner's pregnancy. He was necessary for conception, for bill paying, and for providing male guidance as his child matured. This view has changed, and the father of today is expected to fulfill the role of nurturing, caring, involved parent as well as provider. In response to societal pressures, the influence of the feminist movement, and the economic pressures that result in more women employed outside the home, shared parenting and breadwinning have become more commonplace. Many men have actively sought to be more involved in the experience of childbirth and parenting.

Expectant fathers experience many of the same feelings and conflicts experienced by expectant mothers when the pregnancy has been confirmed. Initially, expectant fathers may feel pride in their virility, which pregnancy confirms, but also have ambivalent feelings. The extent of ambivalence depends on many factors, including the father's relationship with his partner, his previous experience with pregnancy, his age, his economic stability, and whether the pregnancy was planned. The expectant father must first deal with the reality of the pregnancy and then struggle to gain recognition as a parent from his partner, family, friends, coworkers, society—and from his baby as well. The expectant mother can help her partner be a participant and not merely a helpmate to her if she has a definite sense of the experience as their pregnancy and their infant and not her pregnancy and her infant.

Men whose partners are pregnant following a previous pregnancy loss may experience a variety of emotions attributable to the loss. These emotions might include an increased sense of risk, feelings of increased concern about the outcome of the current pregnancy, the recognition that something could go wrong again, and the sense that increased vigilance is essential. These fathers may call home more often to check on the mother's condition and the baby and may also feel an increased need to be involved more actively in the current pregnancy. They wish to be acknowledged as more than just a support person; they want their important role as family protector recognized (O'Leary & Thorwick, 2006).

In general, the expectant father faces psychologic stress as he makes the transition from nonparent to parent or from parent of one to parent of two or more. Sources of stress include financial issues, unexpected events during pregnancy, concern that the baby will not be healthy and normal, worry about the pain the partner will experience in childbirth, and his role during labor and birth. Other sources of stress for expectant fathers include concern over the changing relationship with their partners, diminished sexual responsiveness in their partners or in themselves, change in relationships with their families or male friends, and their ability to parent. Most men handle the transition to fatherhood well, and generally any anxieties they feel resolve over time. Fathers' feelings of anxieties often stem from inadequate preparation and can be addressed by recognizing paternal needs and including fathers more in antepartal education (Deave, Johnson, & Ingram, 2008).

The expectant father must establish a fatherhood role just as the woman develops a motherhood role. The mother experiences biologic changes of pregnancy that aid in the transition to motherhood. Fathers may feel left out because they are unable to experience what their partner is experiencing. Fathers who are most successful at developing a fatherhood role generally like children, are excited about the prospect of fatherhood, are eager to nurture a child, have confidence in their ability to be a parent, and share the experiences of pregnancy and childbirth with their partners (Lederman & Weis, 2009).

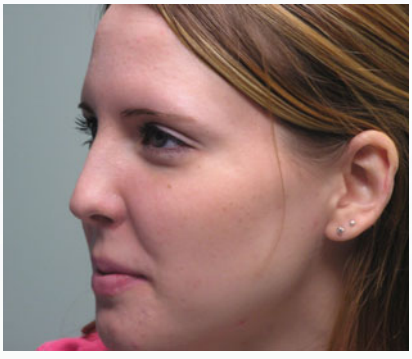
First Trimester

After the initial excitement of the announcement of the pregnancy to friends and relatives and receipt of their congratulations, an expectant father may begin to feel left out of the

Through the Eyes of a Nurse
Psychologic Changes in Pregnancy

Family's Experience

"I am dealing with a lot of shifting emotions right now. One minute I feel happy and elated, and then suddenly I am so blue. I feel like I am on an emotional roller coaster! I find myself tearful for no reason and can't even explain to my husband why I am crying. When he doesn't act supportive, I feel unloved and angry like I am the one dealing with all of these changes while my family stands by, unaffected."



Nurse's Response

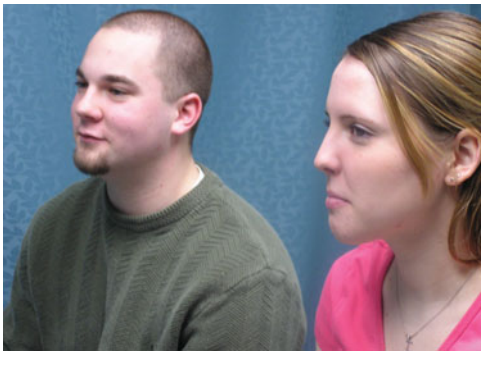
"Even though each woman is different in her reactions to pregnancy and every pregnancy is different, mood swings with extremes in emotions are common. So what you are describing is pretty typical but it can be hard to handle, and you may feel overwhelmed at times.

"During pregnancy, women experience a wide variety of responses such as ambivalence, mood swings, and changes in body image. Because your emotional well-being is so important during pregnancy, we will assess your adjustment to pregnancy at each visit, much like we routinely monitor your blood pressure, the baby's movements, and the size of your uterus.

"It might help if you express your feelings to your family and ask them for additional support when you are sad, overwhelmed, or ambivalent about the pregnancy. Also, I would be glad to talk to your husband about these changes and suggest ways for him to be supportive if you feel that would help."

Nurse's Actions and Rationale

The nurse validates the woman's feelings and provides reassurance that the feelings she is experiencing are normal. The nurse also takes the opportunity to provide teaching about the common emotional responses that occur during pregnancy. The father's actions can be a positive influence during a woman's pregnancy and postpartum so it is important to seek opportunities to provide him with interventions to ease the adjustment process for his partner.



pregnancy. He is also often confused by his partner's mood changes and perhaps bewildered by his responses to her changing body. He may resent the attention given to the woman and the need to change their relationship as she experiences fatigue and a decreased interest in sex.

During this time, his child is a "potential baby." Fathers often picture interacting with a child of 5 or 6 rather than a newborn. Even the pregnancy itself may seem unreal until the woman shows more physical signs.

Second Trimester

The father's role in the pregnancy is still vague in the second trimester, but his involvement can be increased by his watching and feeling fetal movement. It is helpful if the father, as well as the mother, has the opportunity to hear the fetal heartbeat. That requires a visit to the nurse-midwife's or physician's office. Involvement of fathers in antepartal care is increasing and may even be an expectation of their partner. For many men, seeing the infant on ultrasound is an important experience in accepting the reality of the pregnancy.

Like expectant mothers, expectant fathers need to confront and resolve some of their own conflicts about the fathering they received. A father needs to sort out those behaviors in his own fathering that he wants to imitate and those he wishes to avoid. Research indicates that a father's beliefs about the fathering role are a strong predictor of his competence in parenting (Schoppe-Sullivan, Brown, Cannon, et al., 2008).

> "I was excited about the chance to be the kind of father who was involved and available. However, I also wanted to provide adequately for my child, support my wife, and still have time to do the things I loved to do. I was surprised by how excited my father was about becoming a grandfather. He even talked to me about the regrets he had about not being around as I was growing up. I think the experience will help to bring my dad and me closer as he tries to be a great grandfather and I understand more about his struggles as a father."

The father-to-be's anxiety is lessened if both parents agree on the support role the man is to assume during pregnancy and on his projected paternal role. For example, if both see his role as that of breadwinner, the man's stress is low. However, if the man views his role as that of breadwinner and the woman expects him to be actively involved in preparations and child care, his stress increases. An open and honest discussion about the expectations each parent has about their roles will help the father-to-be to determine his transition to fatherhood (Goodman, 2005).

The woman's appearance begins to alter at this time too, and men react differently to the physical change. For some it decreases sexual interest; for others it may have the opposite effect. Both partners experience a multitude of emotions, and it continues to be important for them to communicate and accept each other's feelings and concerns. In situations in which the expectant mother's demands dominate the relationship, the expectant father's resentment may increase to the point that he is spending more time at work, involved in a hobby, or with his friends. The behavior is even more likely if the expectant father did not want the pregnancy and/or if the relationship was not a good one before the pregnancy.

Third Trimester

If the couple have communicated their concerns and feelings to one another and grown in their relationship, the third trimester is a special and rewarding time. A more clearly defined role evolves at this time for the expectant father, and it becomes more obvious how the couple can prepare together for the coming event. They may become involved in childbirth education classes and make concrete preparations for the arrival of the baby, such as shopping for a crib, car seat, and other equipment. If the expectant father has developed a detached attitude about the pregnancy before this time, however, it is unlikely that he will become a willing participant even though his role becomes more obvious.

Concerns and fears may recur. Many men are afraid of hurting the unborn baby during intercourse. The father may also begin to have anxiety and fantasies about what could happen to his partner and the unborn baby during labor and birth and feels a great sense of responsibility. The questions asked earlier in pregnancy emerge again. What kind of parents will he and his partner be? Will he really be able to help his partner in labor? Can they afford to have a baby?

Couvade

The term **couvade** traditionally referred to the observance of certain rituals and taboos by the male to signify the transition to fatherhood. This observance affirms his psychosocial and biophysical relationship to the woman and child. These taboos may have taken specific form—for example, the man may have been forbidden to eat certain foods or carry certain weapons before and immediately after the birth. More recently, the term has been used to describe the unintentional development of physical symptoms, such as fatigue, increased appetite, difficulty sleeping, depression, headache, or backache by the partner of the pregnant woman. Men who demonstrate couvade syndrome tend to have a higher degree of paternal role preparation and be involved in more activities related to this preparation.

Siblings

The introduction of a new baby into the family is often the beginning of sibling rivalry. Sibling rivalry results from children's fear of change in the security of their relationships with their parents. Some of the behaviors demonstrating feelings of sibling rivalry may even be directed toward the mother during the pregnancy as she experiences more fatigue and less patience with her toddler, for example. Parents who recognize the situation early in pregnancy and begin constructive actions can help minimize the problems of sibling rivalry.

Care Plan Activity: Preparing Siblings for New Baby

Preparation of the young child begins several weeks before the anticipated birth and is designed according to the age and experience of the child. Because they do not have a clear concept of time, young children should not be told too early about the pregnancy. From the toddler's point of view "several weeks" is an extremely long time. The mother may let the child feel the baby moving in her uterus, explaining that this is "a special place where babies grow." The child can help the parents put the baby clothes in drawers or prepare the baby's room.

Consistency is important in dealing with young children. They need reassurance that certain people, special things, and familiar places will continue to exist after the new baby arrives. The crib is an important though transient object in a child's life. If it is to be given to the new baby, the parents should thoughtfully help the child adjust to this change. Any move from crib to bed or from one room to another should precede the baby's birth by several weeks or more. If the new baby is to share a room with siblings, the parents must discuss this with the older child or children.

Some parents advocate cosleeping or bed sharing (one or both parents sleeping with their baby or young child), and so the crib is less of an issue. Cosleeping, which is common in many non-Western cultures, is on the increase in the United States. Opinion varies sharply about the advantages and risks of the practice. In 2005 the American Academy of Pediatrics (AAP) issued a policy statement recommending against cosleeping because of the increased risk of sudden infant death syndrome (SIDS). This policy statement was reaffirmed by the AAP in January 2009. The AAP stresses that the infant can be brought to the bed to be comforted or for breastfeeding but should be placed supine in a separate bed ("back to bed") to sleep. (See the discussion in chapter 37 ∞.) Parents who choose to cosleep must make decisions about the sleeping arrangements of other siblings following the birth of the baby.

If the child is ready for toilet training, it is most effectively done several months before or after the baby's arrival. Parents should know that the older, toilet-trained child may regress to wetting or soiling because he or she sees the new baby getting attention for such behavior. The older, weaned child may want to drink from the breast or bottle again after the new baby comes. If the new mother anticipates these behaviors, they will be less frustrating during her early postpartum days.

During the pregnancy, older children should be introduced to a new baby for short periods to get an idea of what a new baby is like. This introduction dispels fantasies that the new arrival will be big enough to be a playmate. Pregnant women may also find it helpful to bring their children to a prenatal visit after they have been told about the expected baby. The children are encouraged to become involved in prenatal care and to ask any questions they may have. They are also given the opportunity to hear the baby's heartbeat, either with a stethoscope or with the Doppler. This helps make the baby more real to them.

If siblings are school-age children, the pregnancy should be viewed as a family affair. Teaching about the pregnancy should be based on the child's level of understanding and interest. Overeager parents may go into lengthier and more in-depth responses than the child is able to understand. Some children are more curious than others. Books at their level of understanding can be made available in the home. Involvement in family discussions, attendance at sibling preparation classes, encouragement to feel fetal movement, and an opportunity to listen to the fetal heart supplement the learning process and help make the school-age child feel part of the pregnancy. Sibling preparation classes assist in the transition process for both parents and children. After attending the classes, children often exhibit less anxiety and increased ability to express their feelings.

Older children or adolescents may appear to have a sophisticated knowledge base, but it may be intermingled with many misconceptions. Thus the parents should make opportunities to discuss their concerns and should involve the children in preparation for the new baby.

Even after the birth, siblings need to feel that they are part of a family affair. Changes in hospital regulations allowing siblings to be present at the birth or to visit their mother and the new baby facilitate this process. Participation in special programs for siblings may help in this process. On arrival at home, siblings can share in "showing off" the new baby.

Sibling preparation for the arrival of a new baby is essential, but other factors are equally important. These include the amount of parental attention focused on the new arrival, the amount of parental attention given the older child after the birth of the new arrival, and parental skill in dealing effectively with regressive and/or aggressive behavior.

Grandparents

The first relatives told about a pregnancy are usually the grandparents. Although relationships with parents can be very complex, the expectant grandparents often become increasingly supportive of the expectant couple, even if conflicts previously existed. But it can be difficult for even sensitive grandparents to know how deeply to become involved in the childrearing process.

Because grandparenting can occur over a wide expanse of years, people's response to this role can vary considerably. Younger grandparents leading active lives may not demonstrate as much interest as the young couple would like. In other cases, expectant grandparents may give advice and gifts unsparingly. For grandparents, conflict may be related to the expectant couple's need to feel in control of their lives, or it may stem from events that signal changing roles in the grandparents' own lives (e.g., retirement, financial concerns, menopause, or death of a friend). Some parents of expectant couples may already be grandparents with a developed style of grandparenting. This influences their response to the pregnancy.

Childbearing and childrearing practices are very different for today's childbearing couple. It helps family cohesiveness for young couples to share with interested grandparents what today's practices are and why they feel they are effective. At the same time, it is important for young couples to listen to

any differences expectant grandparents want to explain. When grandparents give advice, it helps to remember that they care. When their recommendations seem effective, it is significant to grandparents that young couples do listen and follow their advice.

Occasionally young couples feel they are receiving more advice than they can tolerate. Too often they perceive parents' suggestions as criticizing their ability to prepare adequately for the childbearing process—and later as criticizing their care of the newborn. It is useful for the young couple to discuss the problem and agree on a plan of action. The role of the helping grandparents when the new baby is brought home needs to be clarified before the event to ensure a comfortable situation for all.

In some areas, classes for grandparents provide information about changes in birthing and parenting practices. These classes help familiarize grandparents with new parents' needs and may offer suggestions for ways in which the grandparents can support the childbearing woman or couple.

Cultural Values and Pregnancy

A universal tendency exists to create ceremonial rituals and rites around important life events. Thus pregnancy, childbirth, marriage, and death are often tied to ritual (Spector, 2009). The rituals, customs, and practices of a group are a reflection of the group's values. In many developed countries such as the United States, Canada, England, Germany, and so forth, populations are becoming more and more ethnically diverse as the number of immigrants continues to grow. It is not realistic or appropriate to assume that people who are new to a country or area will automatically abandon their ways and adopt the practices of the dominant culture (Dean, 2010). Consequently the identification of cultural values is useful in planning and providing culturally sensitive care.

Generalizations about cultural characteristics or cultural values are difficult because not every individual in a culture may display these characteristics. Just as variations are seen among cultures, variations are also seen within cultures. These variations are often related to social and economic factors such as class, income, and education. For example, because of their exposure to the American culture, a third-generation Chinese American family might have very different values and beliefs from those of a traditional Chinese family who has recently immigrated to America. For this reason, the nurse needs to supplement a general knowledge of cultural values and practices with a complete assessment of the individual's values and practices. The Developing Cultural Competence box summarizes the key actions a nurse can take to become more culturally aware.

DEVELOPING CULTURAL COMPETENCE

Providing Culturally Sensitive Care

Nurses who are interacting with expectant families from a different culture or ethnic group can provide more effective, culturally sensitive nursing care by:

- Critically examining their own cultural beliefs.
- Identifying personal biases, attitudes, stereotypes, and prejudices.
- Making a conscious commitment to respect and study the values and beliefs of others.
- Using sensitive, current language when describing others' cultures.
- Learning the rituals, customs, and practices of the major cultural and ethnic groups with whom they have contact.
- Including cultural assessment and assessment of the family's expectations of the healthcare system as a routine part of prenatal nursing care.
- Incorporating the family's cultural and spiritual practices into prenatal care as much as possible.
- Fostering an attitude of respect for and cooperation with alternative healers and caregivers whenever possible.
- Providing for the services of an interpreter if language barriers exist.
- Learning the language (or at least several key phrases) of at least one of the cultural groups with whom they interact.
- Recognizing that ultimately it is the woman's right to make her own healthcare choices.
- Evaluating whether the patient's healthcare beliefs have any potential negative consequences for her health.

Cultural assessment is an important aspect of prenatal care (see Figure 2-8 ∞ on page 38). Healthcare professionals are becoming increasingly aware of the importance of addressing cultural, physiologic, and psychologic needs in the prenatal assessment in order to provide culture-specific health care during pregnancy. The nurse needs to identify the main beliefs, values, and behaviors that relate to pregnancy and childbearing. This includes information about ethnic background, amount of affiliation with the ethnic group, patterns of decision making, religious preferences, language, communication style, and common etiquette practices. The nurse can also explore the woman's (or family's) expectations of the healthcare system. Once this information is gathered, the nurse can then plan and provide care that is appropriate and responsive to the family's needs. These topics are discussed in detail in chapter 2 ∞.

FOCUS YOUR STUDY

- Virtually all systems of a woman's body are altered in some way during pregnancy. Blood pressure decreases slightly during pregnancy. It reaches its lowest point in the second trimester and gradually increases to near normal levels in the third trimester. The enlarging uterus may exert pressure on the vena cava when the woman lies supine, causing a drop in blood pressure. This is called the vena caval syndrome or supine hypotension.
- A physiologic anemia may occur during pregnancy because the total plasma volume increases more than the total number of erythrocytes. This produces a drop in the hematocrit.
- The glomerular filtration rate increases during pregnancy. Glycosuria may be caused by the body's inability to reabsorb all the glucose filtered by the glomeruli.
- Changes in the skin include the development of chloasma; linea nigra; darkened nipples, areolae, and vulva; striae; and spider nevi.
- Insulin needs increase during pregnancy. A woman with a latent deficiency state may respond to the increased stress on the islets of Langerhans by developing gestational diabetes mellitus.
- The subjective (presumptive) signs of pregnancy are those symptoms experienced and reported by the woman, such as amenorrhea, nausea and vomiting, fatigue, urinary frequency, breast changes, and quickening.
- The objective (probable) signs of pregnancy can be perceived by the examiner but may be caused by conditions other than pregnancy.
- The diagnostic (positive) signs of pregnancy can be perceived by the examiner and can be caused only by pregnancy.
- During pregnancy the expectant woman may experience ambivalence, acceptance, introversion, emotional lability, and changes in body image.
- Rubin (1984) identified four developmental tasks for the pregnant woman: (1) ensuring safe passage through pregnancy, labor, and birth; (2) seeking acceptance of this child by others; (3) seeking commitment and acceptance of self as mother to the infant; and (4) learning to give of oneself on behalf of one's child.
- Fathers also face a series of adjustments as they accept their new role.
- Siblings of all ages require assistance in dealing with the birth of a new baby.
- Cultural values, beliefs, and behaviors influence a couple's response to childbearing and the healthcare system.
- A cultural assessment should focus on factors that will influence the practices of the childbearing family with regard to their health needs.

CRITICAL THINKING IN ACTION

Source: George Dodson/Pearson Education.

Twenty-two-year-old Jean Simmons is an aerobics instructor, G0, P0000 in her first trimester of pregnancy. She presents to you at the local clinic complaining of frequent nausea, urinary frequency, and fatigue. You obtain her vital signs as: BP 108/60, temperature 97° F, pulse 68, respirations 12, weight 125 lb, height 64 inches. Her urine tests negative for ketones, albumin, leukocytes, and sugar. You note that Jean has lost 3 lb since her last visit. You assist the certified nurse-midwife with a physical exam, the findings of which are essentially normal. Jean says that while she knows it could become an issue, she would like to continue working as an aerobic instructor for as long as she possibly can during the pregnancy. You identify Jean's complaints as normal discomforts of pregnancy, and proceed with prenatal education.

1. What advice would you suggest to cope with the nausea of pregnancy?
2. What advice might you suggest to cope with urinary frequency?
3. What teaching would be important relating to exercise in pregnancy?
4. What symptoms related to exercise should Jean report to her physician?

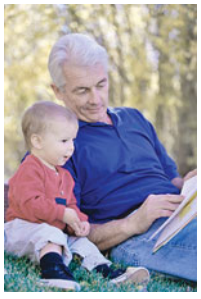
Antepartum Nursing Assessment

CHAPTER 15



The father of the late 1950s . . . Main objective: Get your wife to the hospital on time. Check her in and find the father's waiting lounge. You won't be needed until the baby is born. Fathers are really useless at this time. Try not to be nervous. Coffee is available. Lots of coffee.

More coffee, pacing, no sleep, waiting for word. What a drain on the father. . . . The baby finally comes. "It's a beautiful, healthy baby girl. Mother and baby are doing fine. You can see them now, but only for 5 minutes." What a relief. The pressure is finally off. Isn't nature wonderful?

Today's father, my grandson. Attends most of the prenatal visits. Schooled in Lamaze. Drives his wife to the hospital. Coaches her through her labor. Helps her push. His digital camera is ready. The baby is born. He cuts the cord. He sends e-mail & pictures of the baby to everyone. Isn't nature wonderful?

—*The father of one of the book authors*

LEARNING OUTCOMES

1. Summarize the essential components of a prenatal history.
2. Define common obstetric terminology found in the history of maternity patients.
3. Identify factors related to the father's health that should be recorded on the prenatal record.
4. Describe the normal physiologic changes one would expect to find when performing a physical assessment on a pregnant woman.
5. Explain the use of Nägele's rule to determine the estimated date of birth.
6. Develop an outline of the essential measurements that can be determined by clinical pelvimetry.
7. Describe areas that should be evaluated as part of the initial assessment of psychosocial factors related to a woman's pregnancy.
8. Relate the danger signs of pregnancy to their possible causes.

KEY TERMS

Abortion *318*
Antepartum *318*
Diagonal conjugate *332*
Estimated date of birth (EDB) *323*
Gestation *318*

Primipara *318*
Risk factors *320*
Stillbirth *318*
Term *318*

Today nurses are assuming a more important role in prenatal care, particularly in the area of assessment. The certified nurse-midwife has the education and skill to perform in-depth prenatal assessments with the opportunity to care for women during labor, birth, and the postpartum period. The nurse practitioner may also share the assessment responsibilities of women during their prenatal care. The primary roles of a nurse in an office or prenatal clinic are to counsel, educate, and meet the psychologic needs of the expectant family and perform other nursing care functions and assessments.

The nurse needs to establish an environment of comfort and open communication at each prenatal visit, conveying concern for the woman as an individual and being available to listen to and discuss the woman's concerns and needs. A supportive atmosphere coupled with the information found in the prenatal assessment guides in this chapter will enable the nurse to identify needed areas of education and counseling for each individual patient.

Initial Patient History

The course of a pregnancy depends on a number of factors, including the past pregnancy history (if this is not a first pregnancy), prepregnancy health of the woman, presence of disease/illness states, emotional status, and past health care. Ideally, antenatal care is a continuation of established care that the woman has been receiving to ensure a status of health outside of pregnancy. For some women, however, this may be the only health care that they have received in many years. One important method of determining the adequacy of a woman's prepregnancy care is by completing a thorough history.

Definition of Terms

AWHONN

The following terms are used in recording the obstetric history of maternity patients:

- **Antepartum:** Time between conception and onset of labor, usually used to describe the period during which a woman is pregnant; used interchangeably with *prenatal*.
- **Intrapartum:** Time from onset of labor until the birth of the infant and placenta.
- **Postpartum:** Time from birth until the woman's body returns to an essentially prepregnant condition.
- **Gestation:** The number of weeks since the first day of the last menstrual period (LMP).
- **Abortion:** Birth that occurs before 20 weeks' gestation or the birth of a fetus-newborn who weighs less than 500 g (Cunningham et al., 2010).
- **Term:** The normal duration of pregnancy (38 to 42 weeks' gestation).
- **Preterm or premature labor:** Labor that occurs after 20 weeks but before the completion of 37 weeks of gestation.
- **Postterm labor:** Labor that occurs after 42 weeks of gestation.
- **Gravida:** Any pregnancy, regardless of duration, including present pregnancy.
- **Nulligravida:** A woman who has never been pregnant.
- **Primigravida:** A woman who is pregnant for the first time.
- **Multigravida:** A woman who is in her second or any subsequent pregnancy.
- **Para:** Birth after 20 weeks' gestation, regardless of whether the infant is born alive or dead.
- **Nullipara:** A woman who has not given birth at more than 20 weeks' gestation.
- **Primipara:** A woman who has had one birth at more than 20 weeks' gestation, regardless of whether the infant is born alive or dead.
- **Multipara:** A woman who has had two or more births at more than 20 weeks' gestation.
- **Stillbirth:** A fetus born dead after 20 weeks' gestation.

The terms *gravida* and *para* refer to pregnancies, not to the fetus. Thus, traditionally, twins, triplets, and other multiple fetuses are counted as one pregnancy and one birth. This approach is confusing because it fails to identify the number of children a woman may actually have. Consequently, to provide more comprehensive data, a detailed approach is now used by many healthcare team members. Using this detailed system, *gravida* keeps the same meaning but the use of *para* changes because the detailed system counts *each infant born* rather than the number of pregnancies carried to viability (Varney, Kriebs, & Gegor, 2004). Thus in the traditional approach, twins would count as *one* pregnancy and *one* birth. In the detailed system, twins count as *one* pregnancy but *two* babies. A useful acronym for remembering the system is TPAL.

T: number of *term* infants born (number of infants born at the completion of 37 weeks' gestation or beyond)

P: number of *preterm* infants born (number of infants born after 20 weeks' but before the completion of 37 weeks' gestation, whether living or stillborn)

A: number of pregnancies ending in either spontaneous or therapeutic *abortion*

L: number of currently *living* children to whom the woman has given birth

The following examples delineate the differences between the two systems.

1. Jean Sanchez has one child born at 38 weeks' gestation and became pregnant for a second time. The second pregnancy ended in a miscarriage at 15 weeks' gestation. Using the *traditional approach* her obstetric history would be recorded as "gravida 2 para 1 ab 1." Using the *detailed approach,* her obstetric history would be recorded as "gravida 2 para 1011."
2. Tracy Hopkins is pregnant for the fourth time. At home she has a child who was born at term. Her second pregnancy ended at 10 weeks' gestation. She then gave birth to twins at 35 weeks. One of the twins died soon after birth. Using the *traditional approach* her obstetric history would be recorded as gravida 4 para 2 ab 1. Using the *detailed approach* her obstetric history would be recorded as "gravida 4 para 1212."

Occasionally a fifth digit is added to indicate the number of pregnancies that ended in multiple births (Varney et al., 2004). Thus, using the five-digit system, Tracy Hopkins would be gravida 4 para 12121. Some practice settings seem to have adopted variations of these two approaches. Consequently, to avoid confusion, it is best for practicing nurses to clarify the recording system used at their facilities (Figure 15-1 ■).

Name	Gravida	Term	Preterm	Abortions	Living Children
Jean Sanchez	2	1	0	1	1
Tracy Hopkins	4	1	2	1	2

Figure 15-1 ■ The TPAL approach provides more detailed information about the woman's pregnancy history.

Patient Profile

The patient's history is a screening tool that identifies factors that can affect the course of a pregnancy. For optimal prenatal care, the nurse should obtain the following information for each maternity patient at the initial prenatal assessment:

1. ***Current pregnancy***
   - First day of last normal menstrual period (LMP). Is this a sure date or uncertain? Within days? Does she know the last month of menses? Do her cycles normally occur every 28 days, or do her cycles tend to be longer or shorter? Does she have monthly menses? Was the LMP normal in duration and bleeding? Was she using any form of contraception?
   - Presence of cramping, bleeding, or spotting since LMP.
   - Woman's opinion about time when conception occurred and when infant is due? Was she charting her cycles?
   - Woman's attitude toward pregnancy. (Is pregnancy planned or unplanned? Wanted?)
   - Date of positive pregnancy test; date of negative pregnancy test.
   - Any pregnancy discomforts since LMP, such as nausea, vomiting, urinary frequency, fatigue, breast tenderness, constipation, fever, headaches.
2. ***Past pregnancies***
   - Number of pregnancies.
   - Number of abortions, spontaneous or therapeutic.
   - Number of living children.
   - History of previous pregnancies: length of pregnancy, length of labor and birth, type of birth (vaginal, forceps or vacuum-assisted birth, cesarean), location of birth, type of anesthesia/medication used (if any), woman's perception of the experience, complications (antepartal, intrapartal, postpartal).
   - Neonatal status of previous children: Apgar scores, birth weights, general development, complications, feeding method (breast, formula, or both). If breastfed, how long?
   - Loss of a child (miscarriage, elective or medically indicated abortion, stillbirth, neonatal death, relinquishment, death after the neonatal period). Cause of loss? What was the experience like for her? What coping skills helped? How did her partner, if involved, respond?
   - Blood type and Rh factor. (If Rh negative, was Rh immune globulin received after birth/miscarriage/abortion?)
   - Prenatal education classes, resources (books, Web sites).
3. ***Gynecologic history***
   - Date of last Pap smear; result? History of abnormal Pap results? Colposcopy? Loop electrosurgical excision procedure (LEEP)? Human papilloma virus (HPV)?
   - Previous infections: vaginal, cervical, pelvic inflammatory disease (PID), sexually transmitted.
   - Previous surgery (uterine, ovarian).
   - Age of menarche.
   - Regularity, frequency, and duration of menstrual flow.
   - History of dysmenorrhea.
   - History of infertility.
   - Sexual history.
   - Contraceptive history. (If hormonal method was used, did pregnancy immediately follow cessation of method? If not, how long after? When was contraception last used?)
4. ***Current medical history***
   - Weight (prepregnancy and current), height, body mass index (BMI) (determine recommended weight gain).
   - Blood type and Rh factor.
   - General health, including nutrition (dietary practices or problems such as vegetarianism, lactose intolerance, food allergies), regular exercise program (type, frequency, duration), monthly breast exams, eye exam, dental exam.
   - Any medication use (nonprescription, homeopathic, or herbal medications); medications taken since LMP?
   - Previous or present use of alcohol, tobacco, or caffeine (if yes, ask about amounts consumed each day); planning cessation?
   - Illicit drug use or abuse (specific drugs such as cocaine, crack, marijuana, methamphetamines); planning cessation?
   - Drug allergies, latex allergy or sensitivities: what type of reaction?
   - Potential teratogenic insults to this pregnancy, such as viral infections, medications, x-ray examinations, surgery, or cats in the home (source of toxoplasmosis).
   - Presence of chronic disease conditions, such as diabetes, hypertension, asthma, cardiovascular disease, renal problems, or thyroid disorders.
   - Infections or illnesses since LMP (flu, measles).
   - Record of immunizations (especially rubella); up to date?
   - Presence of any abnormal signs/symptoms.
5. ***Past medical history***
   - Childhood diseases (varicella).
   - Past treatment for any disease condition. Any hospitalizations? Major accidents?
   - Surgical procedures.
   - Presence of bleeding disorders or tendencies.
   - Blood transfusion history? Will she accept blood transfusion?
6. ***Family medical history***
   - Presence of diabetes, cardiovascular disease, hypertension, hematologic disorders, tuberculosis, thyroid disease.
   - Occurrence of multiple births.
   - History of congenital diseases or deformities.
   - History of mental illness.
   - Occurrence of cesarean births and cause, if known.
   - Cause of death of deceased parents or siblings.

7. *Genetic history (patient, father of child [FOC], and both families)*
   - Birth defects.
   - Recurrent pregnancy loss.
   - Stillbirth.
   - Down syndrome, mental retardation, developmental delay, chromosomal abnormalities.
   - Ethnic background (Mediterranean decent, Jewish, Asian).
   - Genetic disorders (cystic fibrosis, sickle cell disease/trait, muscular dystrophy).
8. *Religious/cultural history*
   - Does the woman wish to specify a religious preference on her chart? Does she have any spiritual beliefs or practices that might influence her health care or that of her child, such as prohibition against receiving blood products, dietary considerations, or other practices?
   - What practices are important to maintain her spiritual well-being?
   - Are there practices in her culture or that of her partner that might influence her care or that of her child?
9. *Occupational history*
   - Occupation.
   - Physical demands. (Does she stand all day, or are there opportunities to sit and elevate her legs? Does she do any heavy lifting?)
   - Exposure to lead, chemicals, or other harmful substances.
   - Opportunity for regular meals and breaks for nutritious snacks.
   - Provision for maternity or family leave.
10. *History of the FOC*
    - Presence of genetic conditions or diseases in him or in his family history.
    - Age.
    - Significant health problems.
    - Previous or present alcohol intake, drug use, or tobacco use.
    - Blood type and Rh factor.
    - Occupation.
    - Educational level; methods by which he learns best.
    - Thoughts/feelings regarding pregnancy.
11. *Personal information about the woman (social history)*
    - Age.
    - Relationship status (married? partner involved?).
    - Educational level; methods by which she learns best.
    - Race or ethnic group (to identify need for prenatal genetic screening or counseling).
    - Housing; stability of living conditions.
    - Economic level.
    - Any history of emotional or physical deprivation or abuse of herself or children. (Does she experience any abuse in her current relationship? Has she been hit, slapped, kicked, or hurt within the past year or since she has been pregnant? Is she afraid of her partner or anyone else? If yes, of whom is she afraid?)
    - History of emotional/mental health disorder (depression in general, postpartum depression, anxiety).
    - Support systems available to her.
    - Overuse or underuse of healthcare system.
    - Personal preferences about the birth (expectations of both the woman and her partner, presence of others, and so on). (See chapter 13 ∞.)
    - Plans for care of child following birth.
    - Feeding method for the baby (breast milk, formula, or both).

Obtaining Data

In many settings, nurses use standardized questionnaires to obtain the necessary data for the initial prenatal visit. The questionnaire developed by the American College of Obstetricians and Gynecologists (ACOG), for example, is commonly used in many clinical settings. The woman should fill out the questionnaire in a quiet place with a minimum of distractions and be provided ample time to complete all questions.

The nurse can review the questionnaire and obtain further information in a direct interview with the patient. This allows the pregnant woman to expand or clarify her responses to questions and allows the nurse to gather additional information or clarify data provided. The initial interview provides the nurse and the woman the opportunity to begin developing a healthy relationship. The expectant partner should be encouraged to attend the initial and subsequent prenatal visits. He or she is often able to contribute information to the history and may use this opportunity to ask questions and express concerns that may be of particular importance to him or her.

> "I didn't know what to expect when I went for my first prenatal visit. I'm clean now and wanted to be honest, but I was afraid they would yell if I told them about some of the really dumb things I did in high school—the drinking, the marijuana, the sex and stuff. I really liked the nurse-midwife who was taking care of me, so I decided to be straight with her—for the baby's sake, you know. She was great about everything and really made me feel okay."

Prenatal Risk-Factor Screening

A highly significant part of the prenatal assessment is screening for risk factors. **Risk factors** are any findings that have been shown to have a negative effect on pregnancy outcomes either for the woman or her unborn child. Many risk factors can be identified during the initial prenatal assessment, while others may be detected during subsequent visits through subjective and objective data collection. Identification of risk factors allows for education to promote change and to initiate interventions to reduce risk and avoid poor outcomes (Jordan & Murphy, 2009).

All risk factors do not threaten the pregnancy to the same degree. The nurse needs to be aware of potential risk factors and the impact that they might have on the pregnancy. It is possible that a pregnancy may begin as low risk and change to high risk because of current or developed risk factors. Risk is also assessed intrapartally and postpartally. Ideally, the initial risk as-

sessment should occur prior to pregnancy when changes can be made to decrease risks during pregnancy.

Table 15-1 identifies the major prenatal risk factors currently recognized. The table describes potential maternal and fetal/neonatal implications should the risk be present in the pregnancy. In addition to the factors listed, the perinatal health team also needs to evaluate psychosocial factors, including ethnic background; occupation; education; financial status; environment, including living arrangements and location; and the woman's and her family's concept of health, which might influence her attitude toward seeking health care. Women's health status and risk is continually evaluated at every healthcare team encounter.

TABLE 15-1 Prenatal High-Risk Factors

FACTOR	MATERNAL IMPLICATIONS	FETAL/NEONATAL IMPLICATIONS
Social-Personal		
Low income level/or low educational level	Insufficient antenatal care or late antenatal care ↑ risk preterm birth Poor nutrition ↑ risk of preeclampsia	Low birth weight Prematurity Intrauterine growth restriction (IUGR)/small for gestational age (SGA)
Poor diet	↑ Inadequate nutrition/inadequate Poor weight gain ↑ risk preterm labor/birth ↑ risk anemia ↑ risk preeclampsia	Fetal malnutrition Prematurity IUGR/SGA
Living at high altitude	↑ hemoglobin	Prematurity IUGR ↑ hemoglobin (polycythemia)
Multiparity greater than 3	↑ risk antepartum or postpartum hemorrhage	Anemia Fetal death
Weight less than 45.5 kg (100 lb)	Poor nutrition Cephalopelvic disproportion Prolonged labor	IUGR Hypoxia associated with difficult labor and birth
Weight greater than 91 kg (200 lb)	↑ risk hypertension ↑ risk cephalopelvic disproportion ↑ risk diabetes	↓ fetal nutrition/perfusion ↑ risk macrosomia
Age less than 16	Poor nutrition Insufficient/late antenatal care ↑ risk preeclampsia ↑ risk cephalopelvic disproportion	Low birth weight ↑ fetal demise
Age greater than 35	↑ risk preeclampsia ↑ risk cesarean birth Psychosocial issues	↑ risk congenital anomalies ↑ chromosomal abnormalities
Smoking one pack/day or more	↑ risk hypertension ↑ risk cancer	↓ placental perfusion → ↓ O_2 and nutrients available Low birth weight IUGR/SGA Preterm birth
Use of addicting drugs	↑ risk poor nutrition ↑ risk of infection with intravenous (IV) drugs ↑ risk HIV, hepatitis C ↑ risk abruptio placentae	↑ risk congenital anomalies ↑ risk low birth weight Neonatal withdrawal Lower serum bilirubin
Excessive alcohol consumption	↑ risk poor nutrition Possible hepatic effects with long-term consumption	↑ risk fetal alcohol syndrome (FAS)
Preexisting Medical Disorders		
Diabetes mellitus	↑ risk preeclampsia, hypertension Episodes of hypoglycemia and hyperglycemia ↑ risk cesarean birth	Low birth weight Macrosomia Neonatal hypoglycemia ↑ risk congenital anomalies ↑ risk respiratory distress syndrome
Cardiac disease	Cardiac decompensation Further strain on mother's body ↑ maternal death rate	↑ risk fetal demise ↑ perinatal mortality
Anemia: hemoglobin less than 11 g/dl less than 32% hematocrit	Iron deficiency anemia Low energy level Decreased oxygen-carrying capacity	Fetal death Prematurity Low birth weight
Hypertension	↑ vasospasm ↑ risk central nervous system (CNS) irritability ↑ risk convulsions ↑ risk cerebrovascular accident (CVA) ↑ risk renal damage	↓ placental perfusion → low birth weight Preterm birth

(continued)

TABLE 15-1 Prenatal High-Risk Factors continued

FACTOR	MATERNAL IMPLICATIONS	FETAL/NEONATAL IMPLICATIONS
Thyroid disorder Hypothyroidism Hyperthyroidism	↑ infertility ↓ basal metabolic rate (BMR), goiter, myxedema ↑ risk miscarriage ↑ risk preterm labor/birth ↑ risk preeclampsia ↑ risk postpartum hemorrhage ↑ risk preeclampsia Danger of thyroid storm	↑ spontaneous abortion ↑ risk congenital goiter ↑ risk IUGR/SGA ↑ risk anemia ↑ risk stillbirth Mental retardation → cretinism ↑ incidence congenital anomalies ↑ IUGR/SGA ↑ neonatal hyperthyroidism
Renal disease (moderate to severe)	↑ risk renal failure	↑ risk IUGR/SGA ↑ risk preterm birth
Diethylstilbestrol (DES) exposure	↑ Infertility, spontaneous abortion ↑ cervical incompetence ↑ risk breech presentation	↑ risk preterm birth
Obstetric Considerations		
Previous Pregnancy		
Stillborn	↑ emotional/psychologic distress	↑ risk IUGR/SGA ↑ risk preterm birth
Habitual abortion	↑ emotional/psychologic distress	↑ risk abortion
Cesarean birth	↑ possibility repeat cesarean birth Risk of uterine rupture	↑ risk preterm birth ↑ risk respiratory distress
Rh or blood group sensitization		Hydrops fetalis Icterus gravis Neonatal anemia Kernicterus Hypoglycemia
Current Pregnancy		
Large for gestational age (LGA)	↑ risk cesarean birth ↑ risk gestational diabetes ↑ risk operative birth	↑ risk birth injury Hypoglycemia
Gestational diabetes mellitus	↑ risk operative birth ↑ risk preeclampsia ↑ risk extensive lacerations ↑ risk primary pulmonary hypertension (PPH) ↑ risk shoulder dystocia	Macrosomia Hyperbilirubinemia ↑ risk birth injury
Rubella (first trimester)		Congenital heart disease Cataracts Nerve deafness Bone lesions Prolonged virus shedding
Rubella (second trimester)		Hepatitis Thrombocytopenia
Cytomegalovirus		IUGR Encephalopathy
Herpesvirus type 2	Severe discomfort Concern about possibility of cesarean birth, fetal infection	Neonatal herpesvirus type 2 Hepatitis with jaundice Neurologic abnormalities
Syphilis	↑ incidence abortion	↑ fetal demise Congenital syphilis
Urinary tract infection	↑ risk preterm labor Uterine irritability	↑ risk preterm birth
Abruptio placentae and placenta previa	↑ risk hemorrhage Bed rest Extended hospitalization	Fetal/neonatal anemia Intrauterine hemorrhage ↑ fetal demise
Preeclampsia/eclampsia	See hypertension	↓ placental perfusion → low birth weight
Multiple gestation	↑ risk postpartum hemorrhage ↑ risk gestational diabetes ↑ risk preeclampsia ↑ risk placenta previa	↑ risk preterm labor/birth ↑ risk stillbirth ↑ risk fetal demise ↑ risk IUGR/SGA ↑ risk malpresentation
Elevated hematocrit (greater than 41%)	Increased viscosity of blood	Fetal death rate 5 times normal rate
Spontaneous premature rupture of membranes	↑ risk uterine infection	Preterm birth Fetal demise

Initial Prenatal Assessment

The initial prenatal assessment focuses on the woman holistically by considering physical, cultural, and psychosocial factors that influence her health. During this visit she and her primary support person are also evaluating the health team that they have chosen. The establishment of the nurse-patient relationship will help the woman evaluate the health team and also provide the nurse with a basis for developing an atmosphere that is conducive to interviewing, support, and education. Because many women are excited and anxious at the first antepartal visit, the initial psychosocial-cultural assessment is of a general nature.

As part of the initial psychosocial-cultural assessment the nurse discusses with the woman any religious, cultural, or socioeconomic factors that may influence the woman's expectations of the childbearing experience. It is especially helpful if the nurse is familiar with common practices of various religious and cultural groups who reside in the community. Gathering the data in a tactful, caring way can help make the childbearing woman's experience a positive one and provides opportunity for a partnership in care to develop.

After the history is obtained, the nurse prepares the woman for the physical examination. The physical examination begins with assessment of vital signs followed by the head-to-toe examination with the pelvic examination completed last. It is important for the nurse or caregiver to provide anticipatory guidance and reassurance when completing the physical exam because this may be the patient's first gynecologic examination.

Before the examination, the woman should provide a clean urine specimen for screening. When her bladder is empty, the patient will be more comfortable during the pelvic examination, and the examiner can palpate the pelvic organs more easily. After the woman has emptied her bladder, the nurse asks her to disrobe and gives her a gown and sheet or some other protective covering to provide modesty, comfort, and warmth.

CLINICAL TIP

Use of Gloves

Gloves are worn for procedures that involve contact with body fluids such as drawing blood for laboratory work, handling urine specimens, and conducting pelvic examinations. Because of the increased incidence of latex allergies, it is becoming more common for latex-free gloves to be used. It is important to inquire about latex allergies with any patient before beginning the exam.

Thoroughness and a systematic procedure are the most important considerations when performing the physical portion of an antepartal examination (see Assessment Guide: Initial Prenatal Assessment). To promote completeness, the assessment guide is organized into three columns that address the areas to be assessed, the variations or alterations that may be observed, and nursing responses to the data. The nurse should be aware that certain organs and systems are assessed concurrently with other systems during the physical portion of the examination.

PROFESSIONALISM IN PRACTICE

Physical Exams and Scope of Practice

Increasing numbers of nurses, such as certified nurse-midwives and other advanced practice nurses are educationally prepared to perform physical examinations. The nurse who has not yet fully developed these specific assessment skills obtains the woman's vital signs, explains the procedures to allay apprehension, positions her for examination, and assists the examiner as necessary. Each nurse is responsible for operating at expected professional standards within his or her skill level, educational preparation, and knowledge base.

Initial Prenatal Assessment

DEVELOPING CULTURAL COMPETENCE

Using Cultural Information Effectively

During prenatal assessment, it is important for nurses to avoid stereotyping women based on race or ethnicity. However, race and ethnicity may provide valuable information about cultural, behavioral, environmental, and medical factors that might affect a pregnant woman's health (American College of Obstetricians and Gynecologists [ACOG], 2005a).

Nursing interventions based on assessment of the normal physical and psychosocial changes, as well as the cultural influences associated with pregnancy and patient teaching and counseling needs that have been mutually defined, are discussed further in chapter 16 ∞.

Determination of Due Date

Application: Ovulation Calculator

Childbearing families are generally eager to know the "due date," or the date around which childbirth will occur. Determination of the due date should be attempted at the initial visit. Historically, the due date has been called the *estimated date of confinement (EDC).* The concept of confinement is rather negative, however, and there is a trend among caregivers to avoid it by referring to the birth date as the *estimated date of delivery (EDD).* Childbirth educators often stress that babies are not "delivered" like a package but rather they are *born* or *birthed by the mother.* In keeping with a view that emphasizes the normality of the process, we have chosen to refer to the due date as the **estimated date of birth (EDB)** throughout this text.

It is crucial to know the first day of the woman's LMP when calculating the EDB. The LMP is sometimes not known because some women have episodes of irregular bleeding or amenorrhea or they may fail to keep track of their menstrual cycles. Thus there are other techniques to help determine how far along a woman is in her pregnancy or how many weeks' gestation she is. Other techniques that can be used include evaluating uterine size, establishing when quickening occurs (or occurred), using early ultrasound (US), and auscultating the fetal heart rate. An early ultrasound should be obtained if a precise LMP is not available to help establish an accurate EDB. See Research Evidence in Practice.

ASSESSMENT GUIDE Initial Prenatal Assessment

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
VITAL SIGNS		
Blood Pressure (BP): Less than or equal to 135/85 mmHg	High BP (essential hypertension; renal disease; pregestational hypertension, apprehension or anxiety, preeclampsia if initial assessment not done until after 20 weeks' gestation)	BP greater than 140/90 requires immediate consideration; establish woman's BP; refer to healthcare provider if necessary. Assess woman's knowledge about high BP; counsel on self-care and medical management.
Pulse: 60–90 beats/min; rate may increase10 beats/min during pregnancy	Increased pulse rate (excitement or anxiety, dehydration, infection, cardiac disorders)	Count for 1 full minute; note irregularities. Evaluate temperature, increase fluids.
Respirations: 12–22 breaths/min (or pulse rate divided by 4); pregnancy may induce a degree of hyperventilation; thoracic breathing predominant	Marked tachypnea or abnormal patterns	Assess for respiratory disease.
Temperature: 36.2°–37.6°C (97°–99.6°F)	Elevated temperature (infection)	Assess for infection process or disease state if temperature is elevated; refer to healthcare provider.
HEIGHT AND WEIGHT		
Depends on body build	Weight less than 45 kg (100 lb) or greater than 91 kg (200 lb); rapid, sudden weight gain (preeclampsia)	Evaluate need for nutritional counseling; obtain information on eating habits, cooking practices, food regularly eaten, income limitations, need for food supplements, food allergies, pica and other abnormal food habits. Note initial weight to establish baseline for weight gain throughout pregnancy. Determine body mass index (BMI) and recommended weight gain for pregnancy.
SKIN		
Color: Consistent with racial background; pink nail beds	Pallor (anemia); bronze, yellow (hepatic disease; other causes of jaundice)	Tests to perform: complete blood count (CBC), bilirubin level, urinalysis, and blood urea nitrogen (BUN).
	Bluish, reddish, mottled; dusky appearance or pallor of palms and nail beds in dark-skinned women (anemia)	If abnormal, refer to healthcare provider.
Condition: Absence of edema (slight edema of lower extremities is normal during pregnancy)	Edema (preeclampsia, normal pregnancy changes); rashes, dermatitis (allergic response)	Counsel on relief measures for slight edema. Initiate preeclampsia assessment; refer to healthcare provider.
Lesions: Absence of lesions	Ulceration (varicose veins, decreased circulation)	Further assess circulatory status; refer to healthcare provider if lesion is severe.
Spider nevi common in pregnancy	Petechiae, multiple bruises, ecchymosis (hemorrhagic disorders; abuse)	Evaluate for bleeding or clotting disorder. Provide opportunities to discuss abuse if suspected.
	Change in size or color (carcinoma)	Refer to healthcare provider.
Moles		
Pigmentation: Pigmentation changes of pregnancy include linea nigra, striae gravidarum, melasma		Assure woman that these are normal manifestations of pregnancy and explain the physiologic basis for the changes.
Café-au-lait spots	Six or more (Albright syndrome or neurofibromatosis)	Consult with healthcare provider.
NOSE		
Character of Mucosa: Redder than oral mucosa; in pregnancy nasal mucosa is edematous in response to increased estrogen, resulting in nasal stuffiness (rhinitis of pregnancy) and nosebleeds	Olfactory loss (first cranial nerve deficit)	Counsel woman about possible relief measures for nasal stuffiness and nosebleeds (epistaxis); refer to healthcare provider for olfactory loss.
MOUTH		
May note hypertrophy of gingival tissue because of estrogen	Edema, inflammation (infection); pale in color (anemia)	Assess hematocrit for anemia; counsel regarding dental hygiene habits. Refer to healthcare provider or dentist if necessary. Routine dental care appropriate during pregnancy.
NECK		
Nodes: Small, mobile, nontender nodes	Tender, hard, fixed, or prominent nodes (infection, carcinoma)	Examine for local infection; refer to healthcare provider.
Thyroid: Small, smooth, lateral lobes palpable on either side of trachea; slight hyperplasia by third month of pregnancy	Enlargement or nodule tenderness (hyperthyroidism)	Test to perform: thyroid-stimulating hormone (TSH). Listen over thyroid for bruits, which may indicate hyperthyroidism. Question woman about dietary habits (iodine intake). Ascertain history of thyroid problems; refer to healthcare provider.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial intervention.

ASSESSMENT GUIDE Initial Prenatal Assessment continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
CHEST AND LUNGS		
Chest: Symmetric, elliptic, smaller anteroposterior (AP) than transverse diameter	Increased AP diameter, funnel chest, pigeon chest (emphysema, asthma, chronic obstructive pulmonary disease [COPD])	Evaluate for emphysema, asthma, pulmonary disease (COPD).
Ribs: Slope downward from nipple line	More horizontal (COPD)	Evaluate for COPD. Evaluate for fractures.
	Angular bumps	Consult healthcare provider.
	Rachitic rosary (vitamin C deficiency)	Consult nutritionist.
Inspection and Palpation: No retraction or bulging of intercostal spaces (ICS) during inspiration or expiration; symmetric expansion	ICS retractions with inspirations, bulging with expiration; unequal expansion (respiratory disease)	Do thorough initial assessment. Refer to healthcare provider.
Tactile fremitus	Tachypnea, hyperpnea, Cheyne-Stokes respirations (respiratory disease)	Refer to healthcare provider.
Percussion: Bilateral symmetry in tone	Flatness of percussion, which may be affected by chest wall thickness	Evaluate for pleural effusions, consolidations, or tumor.
Low-pitched resonance of moderate intensity	High diaphragm (atelectasis or paralysis), pleural effusion	Refer to healthcare provider.
Auscultation: Upper lobes—bronchovesicular sounds above sternum and scapulas; equal expiratory and inspiratory phases	Abnormal if heard over any other area of chest	Refer to healthcare provider.
Remainder of Chest: Vesicular breath sounds heard; inspiratory phase longer (3:1)	Rales, rhonchi, wheezes; pleural friction rub; absence of breath sounds; bronchophony, egophony, whispered pectoriloquy	Refer to healthcare provider.
BREASTS		
Supple: Symmetric in size and contour; darker pigmentation of nipple and areola; may have supernumerary nipples, usually 5–6 cm below normal nipple line	"Pigskin" or orange-peel appearance, nipple retractions, swelling, hardness (carcinoma); redness, heat, tenderness, cracked or fissured nipple (infection)	Encourage monthly self-examination; instruct woman how to examine her own breasts (see chapter 7 ∞).
Axillary nodes nonpalpable or pellet sized	Tenderness, enlargement, hard node (carcinoma); may be visible bump (infection)	Refer to healthcare provider for evaluation of abnormal breast findings. Plan ultrasound/mammogram/ magnetic resonance imaging (MRI) of breasts.
Pregnancy Changes: 1. Size increase noted primarily in first 20 weeks. 2. Become nodular. 3. Tingling sensation may be felt during first and third trimester; woman may report feeling of heaviness. 4. Pigmentation of nipples and areolae darkens. 5. Superficial veins dilate and become more prominent. 6. Striae seen in multiparas. 7. Tubercles of Montgomery enlarge. 8. Colostrum may be present after 12th week. 9. Secondary areola appears at 20 weeks, characterized by series of washed-out spots surrounding primary areola. 10. Breasts less firm, old striae may be present in multiparas.		Discuss normalcy of changes and their meaning with the woman. Teach and/or institute appropriate relief measures. Encourage use of supportive, well-fitting brassiere.
HEART		
Normal rate, rhythm, and heart sounds	Enlargement, thrills, thrusts, gross irregularity or skipped beats, gallop rhythm or extra sounds (cardiac disease)	Complete an initial assessment. Explain normalcy pregnancy-induced changes. Refer to healthcare provider if indicated.
Pregnancy Changes: 1. Palpitations may occur due to sympathetic nervous system disturbance. 2. Short systolic murmurs that increase in held expiration are normal due to increased volume.		
ABDOMEN		
Normal appearance, skin texture, and hair distribution; liver nonpalpable; abdomen nontender	Muscle guarding (anxiety, acute tenderness); tenderness, mass (ectopic pregnancy, inflammation, carcinoma)	Assure woman of normalcy of diastasis. Provide initial information about appropriate prenatal and postpartum exercises. Evaluate woman's anxiety level. Refer to healthcare provider.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial intervention.

(continued)

ASSESSMENT GUIDE Initial Prenatal Assessment continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
Pregnancy Changes:		
1. Purple striae may be present (or silver striae on a multipara) as well as linea nigra.		
2. Diastasis of the rectus muscles late in pregnancy.		
3. Size: Flat or rotund abdomen; progressive enlargement of uterus due to pregnancy. 10–12 weeks: Fundus slightly above symphysis pubis. 16 weeks: Fundus halfway between symphysis and umbilicus. 20–22 weeks: Fundus at umbilicus. 28 weeks: Fundus three finger breadths above umbilicus. 36 weeks: Fundus just below ensiform cartilage.	Size of uterus inconsistent with length of gestation (intrauterine growth restriction [IUGR], multiple pregnancy, fetal demise, incorrect estimated date of birth (EDB), abnormal amniotic fluid, hydatidiform mole)	Reassess menstrual history regarding pregnancy dating. Evaluate increase in size using McDonald's method. Use ultrasound to establish diagnosis.
4. Fetal heart rate: 110–160 beats/min may be heard with Doppler at 10–12 weeks' gestation; may be heard with fetoscope at 17–20 weeks.	Failure to hear fetal heartbeat with Doppler (fetal demise, hydatidiform mole)	Refer to healthcare provider. Administer pregnancy tests. Use ultrasound to establish diagnosis.
5. Fetal movement palpable by a trained examiner after the 18th week.	Failure to feel fetal movements after 20 weeks' gestation (fetal demise, hydatidiform mole)	Refer to healthcare provider.
6. Ballottement: During fourth to fifth month fetus rises and then rebounds to original position when uterus is tapped sharply.	No ballottement (oligohydramnios)	Refer to healthcare provider.
EXTREMITIES		
Skin warm, pulses palpable, full range of motion; may be some edema of hands and ankles in late pregnancy; varicose veins may become more pronounced; palmar erythema may be present	Nonpalpable or diminished pulses (arterial insufficiency); marked edema (preeclampsia)	Evaluate for other symptoms of heart disease; initiate follow-up if woman mentions that her rings feel tight. Discuss prevention and self-treatment measures for varicose veins; refer to healthcare provider if indicated.
SPINE		
Normal Spinal Curves: Concave cervical, convex thoracic, concave lumbar	Abnormal spinal curves; flatness, kyphosis, lordosis	Refer to healthcare provider if indicated.
In pregnancy, lumbar spinal curve may be accentuated	Backache	May have implications for administration of spinal anesthetics; see chapter 25 ∞ for relief measures.
Shoulders and iliac crests should be even	Uneven shoulders and iliac crests (scoliosis)	Refer very young women to healthcare provider; discuss back-stretching exercise with older women.
REFLEXES		
Normal and symmetric	Hyperactivity, clonus (preeclampsia)	Evaluate for other symptoms of preeclampsia.
PELVIC AREA		
External Female Genitals: Normally formed with female hair distribution; in multiparas, labia majora loose and pigmented; urinary and vaginal orifices visible and appropriately located	Lesions, hematomas, varicosities, inflammation of Bartholin's glands; clitoral hypertrophy (masculinization)	Explain pelvic examination procedure. Encourage woman to minimize her discomfort by relaxing her hips. Provide privacy.
Vagina: Pink or dark pink, vaginal discharge odorless, nonirritating; in multiparas, vaginal folds smooth and flattened; may have episiotomy scar	Abnormal discharge associated with vaginal infections	Obtain vaginal smear. Provide understandable verbal and written instructions about treatment for woman and partner, if indicated.
Cervix: Pink color; os closed except in multiparas, in whom os admits fingertip	Eversion, reddish erosin, nabothian or retention cysts, cervical polyp; granular area that bleeds (carcinoma of cervix); lesions (herpes, human papilloma virus [HPV]); presence of string or plastic tip from cervix (intrauterine device [IUD] in uterus)	Provide woman with a hand mirror and identify genital structures for her; encourage her to view her cervix if she wishes. Refer to healthcare provider if indicated. Advise woman of potential serious risks of leaving an IUD in place during pregnancy; refer to healthcare provider for removal.
Pregnancy Changes:		
1–4 weeks' gestation: Enlargement in anteroposterior diameter		
4–6 weeks' gestation: Softening of cervix (Goodell's sign); softening of isthmus of uterus (Hegar's sign); cervix takes on bluish coloring (Chadwick's sign)	Absence of Goodell's sign (inflammatory conditions, carcinoma)	Refer to healthcare provider.
8–12 weeks' gestation: Vagina and cervix appear bluish violet in color (Chadwick's sign)	Fixed (pelvic inflammatory disease [PID]); nodular surface (fibromas)	Refer to healthcare provider.
Uterus: Pear shaped, mobile; smooth surface		
Ovaries: Small, walnut shaped, nontender (ovaries and fallopian tubes are located in the adnexal areas)	Pain on movement of cervix (PID); enlarged or nodular ovaries (cyst, tumor, tubal pregnancy, corpus luteum of pregnancy)	Evaluate adnexal areas; refer to healthcare provider. Plan ultrasound to evaluate mass.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial intervention.

ASSESSMENT GUIDE Initial Prenatal Assessment continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
PELVIC MEASUREMENTS		
Internal Measurements:	Measurement below normal	Vaginal birth may not be possible if deviations are present.
1. Diagonal conjugate at least 11.5 cm (see Figure 15-6)		
2. Obstetric conjugate estimated by subtracting 1.5–2 cm from diagonal conjugate	Disproportion of pubic arch	
3. Inclination of sacrum	Abnormal curvature of sacrum	
4. Motility of coccyx; external intertuberosity diameter greater than 8 cm	Fixed or malposition of coccyx	
ANUS AND RECTUM		
No lumps, rashes, excoriation, tenderness; cervix may be felt through rectal wall	Hemorrhoids, rectal prolapse; nodular lesion (carcinoma)	Counsel about appropriate prevention and relief measures; refer to healthcare provider for further evaluation.
LABORATORY EVALUATION		
Hemoglobin: 12–16 g/dl; women residing in areas of high altitude may have higher levels of hemoglobin	Less than 11 g/dl (anemia)	Hemoglobin less than 12 g/dl requires nutritional counseling; less than 11 g/dl requires iron supplementation.
ABO and Rh Typing: Normal distribution of blood types	Rh negative	If Rh negative, check for presence of anti-Rh antibodies. Check partner's blood type; if partner is Rh positive, discuss with woman the need for Rh immune globulin administration at 28 weeks, management during the intrapartal period, and possible need for Rh immune globulin after childbirth. (See chapter 20 ∞.)
Complete Blood Count (CBC)		
Hematocrit: 38%–47% physiologic anemia (pseudoanemia) may occur	Marked anemia or blood dyscrasias	Perform CBC and Schilling differential cell count.
Red Blood Cells (RBC): 4.2–5.4 million/microliter		
White Blood Cells (WBC): 5000–12,000/microliter	Presence of infection; may be elevated in pregnancy and with labor	Evaluate for other signs of infection.
Differential		
Neutrophils: 40%–60%		
Bands: up to 5%		
Eosinophils: 1%–3%		
Basophils: up to 1%		
Lymphocytes: 20%–40%		
Monocytes: 4%–8%		
Syphilis Tests: Serologic tests for syphilis (STS), complement fixation test, veneral disease research laboratory (VDRL) test—nonreactive	Positive reaction STS—tests may have 25%–45% incidence of biologic false-positive results; false results may occur in individuals who have acute viral or bacterial infections, hypersensitivity reactions, recent vaccinations, collagen disease, malaria, or tuberculosis	Positive results may be confirmed with the fluorescent treponemal antibody-absorption (FTA-ABS) test; all tests for syphilis give positive results in the secondary stage of the disease; antibiotic tests may cause negative test results. Refer to healthcare provider for treatment.
Gonorrhea Culture: Negative	Positive	Refer for treatment.
Urinalysis (u/a): Normal color, specific gravity; pH 4.6–8	Abnormal color (porphyria, hemoglobinuria, bilirubinemia): alkaline urine (metabolic alkalemia, *Proteus* infection, old specimen)	Repeat u/a; refer to healthcare provider.
Negative for protein, red blood cells, white blood cells, casts	Positive findings (contaminated specimen, kidney disease)	Repeat u/a; refer to healthcare provider.
Glucose: Negative (small degree of glycosuria may occur in pregnancy)	Glycosuria (low renal threshold for glucose, diabetes mellitus)	Assess blood glucose level; test urine for ketones.
Rubella Titer: Hemagglutination-inhibition (HAI) test–1:10 or above indicates woman is immune	HAI titer less than 1:10	Immunization will be given postpartum. Instruct woman whose titers are less than 1:10 to avoid children who have rubella. Educate regarding prevention measures and need for immunization after birth.
Hepatitis B Screen for hepatitis B surface antigen (HbsAg): negative	Positive	If positive, refer to physician. Infants born to women who test positive are given hepatitis B immune globulin soon after birth followed by first dose of hepatitis B vaccine.
HIV Screen: Offered to all women; encouraged for those at risk; negative	Positive	Refer to healthcare provider.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial intervention.

(continued)

ASSESSMENT GUIDE Initial Prenatal Assessment continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
LABORATORY EVALUATION (continued)		
Illicit Drug Screen: Offered to all women; negative	Positive	Refer to healthcare provider.
Sickle-Cell Screen for Patients of African Descent: Negative	Positive; test results would include a description of cells	Refer to healthcare provider.
Pap Smear: Negative	Test results that show abnormal cells with negative or positive high-risk human papilloma virus (HPV).	Refer to healthcare provider. Discuss with the woman the meaning of the findings and the importance of follow-up. Plan colposcopy if indicated by results.
Cultural Assessment	**Variations to Consider***	**Nursing Responses to Data†**
Determine the woman's fluency in written and oral English.	Woman may be fluent in language other than English.	Work with a knowledgeable translator to provide information and answer questions.
How does she prefer to be addressed? Nickname?	Some women prefer informality; others prefer to use titles.	Address the woman according to her preference. Maintain formality in introducing oneself if that seems preferred.
Determine customs and practices regarding prenatal care:	Practices are influenced by individual preference, cultural expectations, or religious beliefs.	Honor a woman's practices and provide for specific preferences unless they are contraindicated because of safety.
• Are there certain practices she expects to follow when she is pregnant?	Some women believe that they should perform certain acts related to sleep, activity, or clothing.	Have information printed in the language of different cultural groups that live in the area.
• Are there any activities she cannot do while she is pregnant?	Some women have restrictions or taboos they follow related to work, activity, sexual, environmental, or emotional factors.	Respect the woman's food preferences, help her plan an adequate prenatal diet within the framework of her preferences, and refer to a dietitian if necessary.
• Are there certain foods she is expected to eat or avoid while she is pregnant? Determine whether she has lactose intolerance or food allergies.	Foods are an important cultural factor. Some women may have certain foods they must eat or avoid; many women have lactose intolerance and have difficulty consuming sufficient calcium.	
• Is the caregiver's gender of concern to her?	Some women are comfortable only with a female caregiver.	Arrange for a female caregiver if it is the woman's preference.
• What amount or type of partner involvement in her pregnancy does she expect or want? This includes her mother, other family members, and friends.	A woman may not want her partner involved in the pregnancy. For some the role falls to the woman's mother or a female relative or friend.	Respect the woman's preferences about her partner or husband's involvement; avoid imposing personal values or expectations.
• What type of support and counseling resources are available to her?	Some women seek advice from family members, *curanderas,* tribal healers, or religious leaders.	Respect and honor the woman's sources of support.
PSYCHOLOGIC STATUS		
Excitement and/or apprehension, ambivalence	Marked anxiety (fear of pregnancy diagnosis, fear of medical facility or providers)	Establish lines of communication. Active listening is useful. Establish trusting relationship. Encourage woman to take active part in her care.
	Apathy; display of anger with pregnancy diagnosis	Establish communication and begin counseling. Use active listening techniques.
EDUCATIONAL NEEDS		
May have questions about pregnancy or may need time to adjust to reality of pregnancy		Establish educational, supporting environment that can be expanded throughout pregnancy.
SUPPORT SYSTEM		
Can identify at least two or three individuals with whom woman is emotionally intimate (partner, parent, sibling, friend)	Isolated (no telephone, unlisted number); cannot name a neighbor or friend whom she can call on in an emergency; does not perceive parents as part of her support system	Institute support system through community groups. Help woman to develop trusting relationship with healthcare professionals.
FAMILY FUNCTIONING		
Emotionally supportive Communications adequate Mutually satisfying Cohesiveness in times of trouble	Long-term problems or specific problems related to the pregnancy, potential stressors within the family, pessimistic attitudes, unilateral decision making, unrealistic expectations of the pregnancy or child	Help identify the problems and stressors, encourage communication, and discuss role changes and adaptations. Refer to counseling as indicated.
ECONOMIC STATUS		
Source of income is stable and sufficient to meet basic needs of daily living and medical needs	Limited prenatal care; poor physical health; limited use of healthcare system; unstable economic status	Discuss available resources for health maintenance and the birth. Institute appropriate referral for meeting expanding family's needs (food stamps, WIC [a federally funded nutrition program for women, infants, and children], and so forth)
STABILITY OF LIVING CONDITIONS		
Adequate, stable housing for expanding family's needs	Crowded living conditions; questionable supportive environment for newborn	Refer to appropriate community agency. Work with family on self-help ways to improve situation.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial intervention.

RESEARCH EVIDENCE IN PRACTICE

Ultrasound for Pregnancy Viability, Dating, and Location

CLINICAL QUESTIONS

Is routine diagnostic ultrasound in early pregnancy effective in identifying the viability and location of a pregnancy? Is ultrasound an accurate method of determining the baby's due date?

RESEARCH EVIDENCE

Determining whether a pregnancy is viable, and doing so early in the pregnancy, is of intense interest to many potential parents. Additionally, the determination of the location of a pregnancy can help identify mothers who may be at risk for the serious complications of an ectopic pregnancy. While ultrasound is of clear benefit for monitoring fetal well-being, it is unclear how early ultrasound may reveal a viable pregnancy and its location. Its role in determining the due dates of a pregnancy has also been questioned.

A Cochrane Collaborative Systematic Review appraised 11 randomized trials including 37,505 women to study the effectiveness of ultrasound as a diagnostic tool. One of the study questions was the use of ultrasound for accurate dating of a pregnancy. These studies were conducted over a period of 3 decades and so provide evidence of effectiveness as well as longitudinal data about long-term effects of this diagnostic method. A secondary application tested in multiple international studies involved the use of ultrasound early in pregnancy to determine viability. These studies, involving more than 1500 women, focused on the effectiveness and optimal timing of ultrasound scans to assess the location of a pregnancy (uterine vs. ectopic) and the viability of the fetus.

The routine use of diagnostic ultrasound improved gestational dating and, subsequently, reduced the rate of inductions of labor for postterm pregnancy. The earliest that ultrasound appears to be effective in confirming fetal viability is 42 days; prior to that time, ultrasound may reveal an amniotic sac but cannot confirm viability. Diagnosis of the location of the pregnancy, that is, ectopic or uterine, continues to involve a combination of clinical examination and ultrasound. The presence of an adnexal mass combined with the absence of an intrauterine gestational sac are the best indicators of an ectopic pregnancy.

WHAT QUESTIONS REMAIN UNANSWERED?

There continues to be a lack of standardization as to how early and how often ultrasounds should be conducted. What is the optimal time to begin ultrasound assessment? How often should they be conducted during a normal pregnancy?

WHAT IS BEST PRACTICE?

Routine diagnostic ultrasound can be conducted in early pregnancy to determine adequate dating of the pregnancy. Diagnostic ultrasound scans are probably not useful before 40 days of gestation, and clinical examination is still required to adequately diagnose the location of the pregnancy.

CRITICAL THINKING

How can the nurse assure the mother that routine diagnostic ultrasound is a safe and useful prenatal assessment?

Nägele's Rule

The most common method of determining the EDB is by **Nägele's rule**. To use this method, begin with the first day of the LMP, subtract 3 months, and add 7 days. The following is an example of Nagele's rule:

First day of LMP	July 20
Subtract 3 months	− 3 months
	April 20
Add 7 days	+ 7 days
EDB	April 27 (of the next year)

It is simpler to change the months to numeric terms:

July 20 becomes	07 − 20
Subtract 3 months	− 3
	04 − 20
Add 7 days	+ 7
EDB	04 − 27 (of next year)

A gestation calculator or "wheel" permits the caregiver to calculate the EDB even more quickly (Figure 15-2 ■).

Nägele's rule can be a fairly accurate determiner of EDB if a woman has a history of menses every 28 days, has an accurate LMP, and was not utilizing hormonal contraception prior to conception. Some women, however, may have cycles that

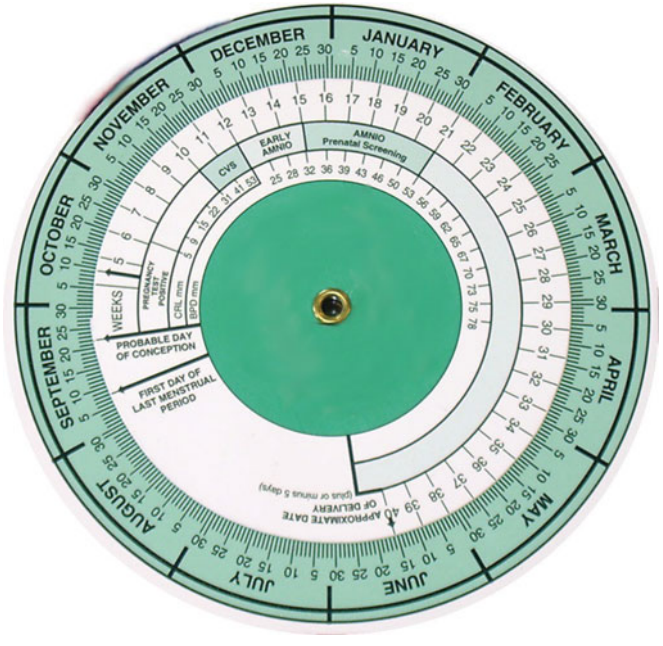

Figure 15-2 ■ The EDB wheel can be used to calculate the due date. To use it, place the arrow labeled "first day of last period" on the date of the woman's LMP. Then read the EDB at the arrow labeled 40. In this case, the LMP is September 8th and the EDB is June 17th.

last from 35 to 40 days in length, which will cause ovulation to be delayed by several days. Ovulation usually occurs 14 days before the onset of the next menses, not 14 days after the previous menses. In cases of unsure LMP, irregular menstrual cycles, breastfeeding women, amenorrhea, or hormonal contraception use, an ultrasound is done to visualize the gestational sac and obtain measurements of the embryo/fetus to determine EDB. (See the discussion of ultrasound in chapter 21 ∞.)

Thus Nägele's rule, although helpful, is not always accurate. It is of no use in calculating EDB for (1) women with markedly irregular periods that include one or more months of amenorrhea, (2) women who have amenorrhea but are ovulating and conceive while breastfeeding, or (3) women who conceive before regular menstruation is established following discontinuation of oral contraceptives or termination of a pregnancy (Varney et al., 2004). An estimation of EDB can be made using other subjective and objective findings such as fundal height, uterine size, auscultation of fetal heart tones, and timing of quickening. Despite these assessments, an ultrasound should be completed as early as possible if Nägele's rule cannot be used.

CLINICAL JUDGMENT

Case Study: Davia Mankovitz

Davia Mankovitz is a 27-year-old G1P0 who presents with her husband for her initial prenatal visit. She is at 13 weeks' gestation based on her LMP. She has a history of irregular menses. She has been trying to get pregnant for 2 years and had a visit scheduled with the infertility clinic next month to be evaluated. She and her husband are very excited about the pregnancy. She reports feeling baby movement for 3 weeks. Her fundal height today is 22 cm.

Critical Thinking

What are your initial impressions about her pregnancy status?
See www.nursing.pearsonhighered.com for possible responses.

Uterine Assessment

Physical Examination

The initial physical examination is done at the patient's first prenatal visit to evaluate for potential health concerns but also to evaluate uterine size to assist with dating the pregnancy. The exam could occur in the first, second, or third trimester depending on when the woman seeks care initially. It becomes much more difficult to accurately evaluate uterine size as the pregnancy progresses, in obese women, in multiple gestations, or if uterine fibroids are present.

Fundal Height

Fundal height may be used as an indicator of uterine size, which can assist with determining pregnancy gestation. This method cannot be used for dating purposes late in pregnancy. A tape measure is used to measure the distance in centimeters from the top of the symphysis pubis over the curve of the abdomen to the top of the uterine fundus (McDonald's method) (Figure 15-3 ■).

Fundal height in centimeters correlates well with weeks of gestation between 22 weeks and 34 weeks. At 26 weeks' gestation, for example, fundal height is probably about 26 cm. Typically, ±2 cm is considered normal. To be most accurate, fundal height should be measured by the same examiner each time. Maternal position (trunk elevation, knee flexion) may influence fundal height measurement. If the woman is very tall or very short, fundal height may also differ. In the third trimester, variations in fetal weight decrease the accuracy of fundal height measurements. Unfortunately, this method of dating a pregnancy can be quite inaccurate in the following situations:

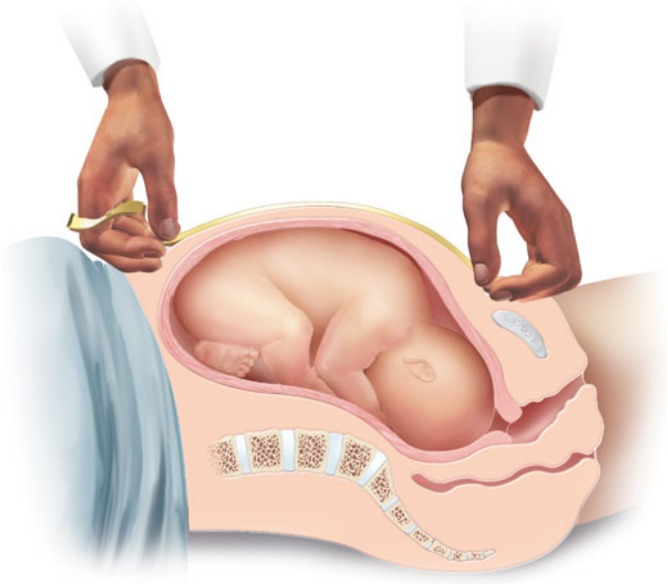

Figure 15-3 ■ A cross-sectional view of fetal position when McDonald's method is used to assess fundal height.

- Obese women (because of difficulty palpating the fundus accurately)
- Women with uterine fibroids (because uterine size may be distorted)
- Women who develop hydramnios (because the excess fluid increases uterine size, leading the examiner to conclude the fetus is larger than it is)

CLINICAL TIP

The woman should empty her bladder before measuring fundal height. A full bladder may impact the accuracy of the measurement.

Measurements of fundal height from month to month and week to week may yield other information as well. For example, a lag in the progression of fundal height may indicate intrauterine growth restriction (IUGR), or oligohydraminos, and a sudden increase in height may indicate the presence of twins, polyhydramnios, or a large for gestational age (LGA) fetus. Abnormal fundal height measurements should be assessed by ultrasound to determine possible cause.

Assessment of Fetal Development

Quickening

Fetal movements felt by the mother or perception of life—*quickening*—may give some indications that the fetus is nearing 20 weeks' gestation. Quickening may be experienced between 16 and 22 weeks' gestation, so this is not a completely accurate

method to date a pregnancy. Because multiparous women have experienced quickening before, they often report fetal movement earlier than a primigravida does. It is good to note this milestone, but it should not be used solely for determining an EDB.

CLINICAL TIP
Early fetal movement may be described by the mother as feeling butterfly movements, gas, flicking sensations, or bubbles.

Fetal Heartbeat

The ultrasonic Doppler device (Figure 15-4 ■) is the primary tool for assessing fetal heartbeat. It may detect fetal heartbeat at about 10 to 12 weeks' gestation. The normal range for fetal heart tones (FHT) is 110–160. An ultrasound should be completed if the nurse is unable to auscultate between 10 and 12 weeks, because there may be a discrepancy of EDB, twins, or a missed abortion. In the case of twins or the obese woman, it may be later before the fetal heartbeat can be detected.

> "I went with my daughter to her prenatal visit, which included an ultrasound. I was not only able to hear the heartbeat of my first grandchild, I was also able to see the baby. What a blessing to be part of this experience! It was a special moment for me as a soon-to-be grandfather."

Ultrasound

In the first trimester, transabdominal ultrasound can detect a gestational sac as early as 4 to 5 weeks after the LMP, fetal heart activity by 6 to 7 weeks, and fetal breathing movements by 10 to 11 weeks of pregnancy. Crown-to-rump measurements can be completed for assessment of fetal age until the fetal head can be defined. Crown-to-rump length can be used for gestational age from 4 days up to 12 weeks. Biparietal diameter (BPD) measurements can be made by approximately 14 weeks and are most accurate between 14 and 26 weeks, when rapid growth in biparietal diameter occurs. The BPD predicts EDB within 7 to 10 days. Both of these measurements can provide a gestational age for EDB determination or to compare with LMP dating. (See chapter 21 ∞ for an in-depth discussion of ultrasound scanning of the fetus.)

Figure 15-4 ■ Listening to the fetal heartbeat with a Doppler device.

CLINICAL TIP
An ultrasound should be ordered or completed at the initial prenatal visit if the EDB is unknown. The ultrasound is more accurate in dating the pregnancy the earlier it is completed.

Assessment of Pelvic Adequacy

By performing a series of assessments and measurements, the examiner assesses the pelvis vaginally to determine whether the size and shape are adequate for a vaginal birth. This procedure, called *clinical pelvimetry,* is typically performed by physicians and advanced practice nurses during the pelvic exam. Clinical pelvimetry should not be used to determine if a patient is appropriate to attempt a vaginal birth. All women should be allowed a trial of labor despite clinical pelvimetry findings. For a detailed description of clinical pelvimetry, refer to a nurse-midwifery text. This section provides general information about the assessment of the inlet, midpelvis, and outlet. These terms are defined in chapter 10 ∞.

Pelvic Inlet

The important anteroposterior diameters of the inlet for childbearing are the diagonal conjugate, the obstetric conjugate, and the conjugata vera, or true conjugate (Figure 15-5 ■).

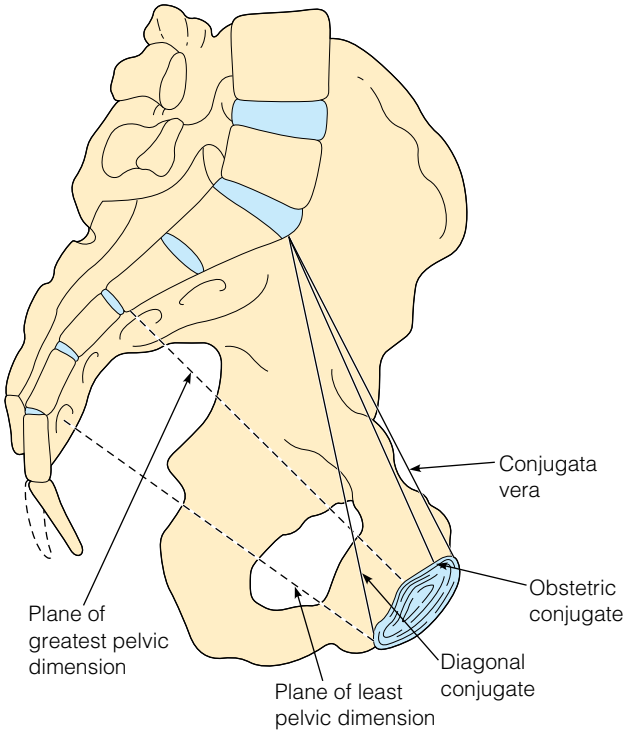

Figure 15-5 ■ Anteroposterior diameters of the pelvic inlet and their relationship to the pelvic planes.

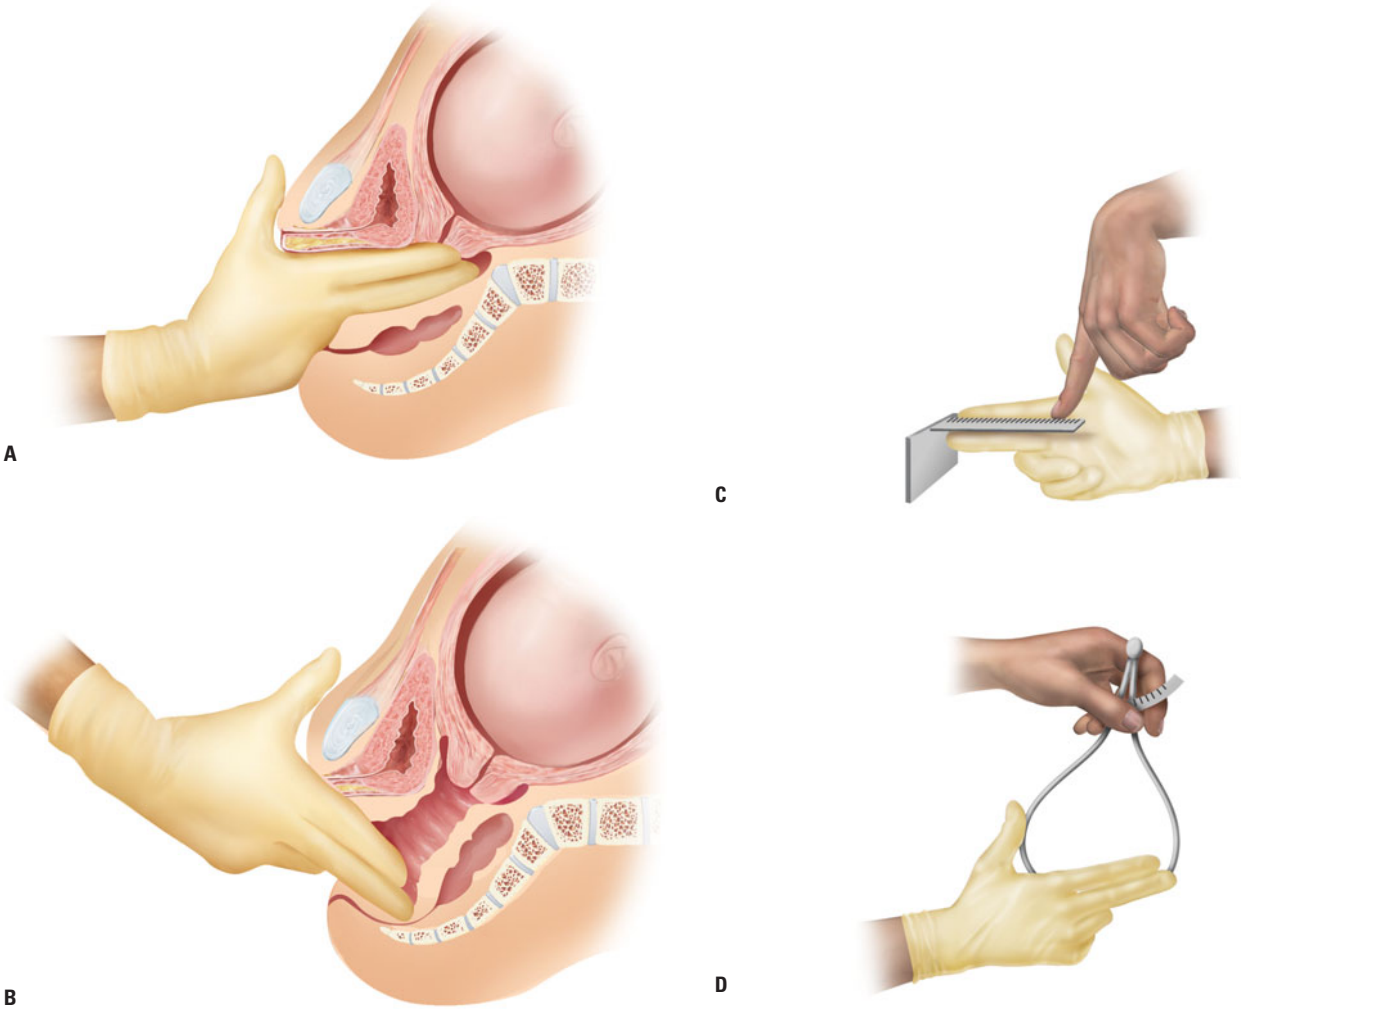

Figure 15-6 ■ Manual measurement of inlet and outlet. A. Estimation of the diagonal conjugate, which extends from the lower border of the symphysis pubis to the sacral promontory. B. Estimation of the anteroposterior diameter of the outlet, which extends from the lower border of the symphysis pubis to the tip of the sacrum. C and D. Methods that may be used to check the manual estimation of anteroposterior measurements.

Other diameters are the transverse (approximately 13.5 cm) and the oblique (averages 12.75 cm).

The anteroposterior diameters of the pelvic inlet may be assessed. To measure the **diagonal conjugate**, the distance from the lower border of the symphysis pubis to the sacral promontory, the examiner inserts a gloved hand into the vagina with index and middle finger extended. The thumb remains extended outside the vagina. The examiner then attempts to reach from the lower border of the symphysis pubis to the sacral promontory with the middle finger. The clinician should determine the length of the finger before attempting this. The diagonal conjugate can then be measured by marking the place where the proximal part of the hand makes contact with the pubis (Figure 15-6A ■). The examiner measures the distance (which normally measures at least 11.5 cm). The **obstetric conjugate** is the smallest and thus the most important anteroposterior diameter through which the fetus must pass. It extends from the middle of the sacral promontory to the upper inner point on the symphysis. Because it cannot be measured manually (but only by x-ray examination), it is estimated by subtracting 1.5 to 2 cm from the length of the diagonal conjugate. It should measure 10 cm or more in order for an average size baby (7.5 to 8 lb) to pass through without difficulty. The true conjugate extends from the upper border of the symphysis pubis to the middle of the sacral promontory. It can be determined by subtracting 1 cm from the diagonal conjugate.

Pelvic Cavity (Midpelvis)

Important midpelvic measurements include the plane of least dimension, or midplane (anteroposterior diameter, normally 11.5 to 12 cm; posterior sagittal diameter, 4.5 to 5 cm; and transverse diameter [interspinous], 10 cm). It is shown in Figure 15-5. The planes of the midpelvis cannot be accurately measured by clinical examination. An evaluation of adequacy is made based on the prominence of the ischial spines and degree of convergence of the side walls.

Location of the sacrospinous ligament, a firm ridge of tissue, makes location of the ischial spines easier. When this ligament is located, the examiner should run the fingers along it laterally toward the anterior portion of the pelvis. The spines may range from a small, firm bump like the knuckle of a finger (termed *not encroaching*) to a very prominent bone (called *encroaching*).

The sacrosciatic notch should admit two fingers. A wide notch means that the sacrum curves posteriorly, giving the anteroposterior diameter of the midpelvis a greater length. A narrow notch indicates a decreased diameter. The width of the sacrosciatic notch is more accurately evaluated through x-ray examination but can be estimated through vaginal exam. The length of the sacrospinous ligament is measured by tracing the ligament from its origin on the ischial spines to its insertion on the sacrum. It is usually 4 cm, or two to three finger breadths long.

The capacity of the cavity can be assessed by sweeping the fingers down the side walls bilaterally to evaluate the shape of the pelvic side walls. They may be termed *convergent* (closer together at the outlet than the inlet, like a funnel), *divergent* (side walls farther apart at the outlet, which typically means the pubic arch will have a wide angle), or *straight* (normal finding). The curvature, inclination, and hollowness of the sacrum help indicate the capacity of the posterior pelvis. It is estimated digitally by palpating the sacrococcygeal junction and by inching up toward the promontory. The examiner then estimates the hollowness of the sacrum. A flat or shallow sacrum has less room; a hollow sacrum is considered normal. The plane of greatest pelvic dimensions represents the largest portion of the pelvic cavity and has no obstetric significance.

Pelvic Outlet

The anteroposterior diameter of the pelvic outlet (9.5 to 11.5 cm), which extends from the lower border of the symphysis pubis to the tip of the sacrum, can be measured digitally (Figure 15-6B ■). The transverse diameter of the outlet is measured by placing the fist between the ischial tuberosities. It usually measures 8 to 10 cm (Figure 15-7 ■). The posterior sagittal diameter, the third important outlet diameter, normally measures at least 7.5 cm.

The mobility of the coccyx is determined by pressing down on it with the forefinger and middle finger during the initial vaginal examination. An immobile coccyx can decrease the diameter of the outlet.

The subpubic angle is estimated by palpating the bony structure externally with two fingers placed side by side at the border of the symphysis (Figure 15-8A ■). It should be 85 to 90 degrees. The angle is probably less if the examiner cannot separate his or her fingers.

The length and shape of the pubic rami affect the transverse diameter of the outlet. The pubic ramus is expected to be short and concave inward, as opposed to straight and long.

The height and inclination of the symphysis pubis are measured, and the contour of the pubic arch is estimated. Excessively long or angulated bone structure shortens the diameter of the obstetric conjugate. Height can be determined by placing the index finger of the gloved hand up to the superior border of the symphysis (Figure 15-8B ■). The examiner should measure the length of the first phalanx of the index finger (normally about 2.5 cm). Inclination can be determined by externally placing one finger on the top of the symphysis while the internal finger palpates the internal margin (Figure 15-8C ■). An imaginary line is drawn between the fingers, and the angle is estimated.

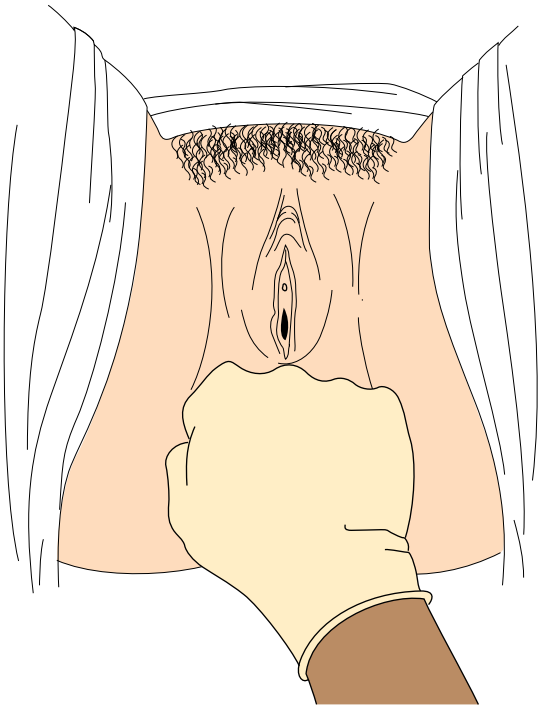

Figure 15-7 ■ Use of a closed fist to measure the outlet. Most examiners know the distance between their first and last proximal knuckles. If they do not, they can use a measuring device.

A posterior inclination with the lower border of the pubis slanting inward decreases the anteroposterior diameter. The anteroposterior sagittal diameter is the most significant diameter of the outlet because it is the shortest diameter through which the infant must pass. The examiner uses two fingers to determine the contour of the pubic arch. This provides information on the width of the angle at which these bones come together (Figure 15-8D ■). The pubic arch has obstetric importance; if it is narrow, the infant's head may be pushed backward toward the coccyx, making extension of the fetal head difficult, which may lengthen the second stage of labor.

Screening Tests

Many screening tests are routinely performed during pregnancy, either at the initial prenatal visit or at specified times during pregnancy. Tests completed at the initial visit include a Pap smear, complete blood count, HIV screening, rubella titer, ABO and Rh typing, urine culture, and hepatitis B screen, as well as testing for sexually transmitted infections such as syphilis, HIV, chlamydia, and gonorrhea. Additional tests are completed at certain gestational ages throughout the pregnancy.

Women are routinely screened for gestational diabetes mellitus (GDM). Several methods may be used. Typically, between 24 and 28 weeks' gestation a 50-g 1-hour glucose screen is completed to detect GDM. The cutoff range may vary between 130 mg/dl, 135 mg/dl, or 140 mg/dl depending on the specific laboratory. If the screen is abnormal, a 3-hour glucose tolerance test (gtt) is then completed for diagnosis (see chapter 19 ∞). A hemoglobin or hematocrit is also completed at this time to evaluate for iron deficiency anemia.

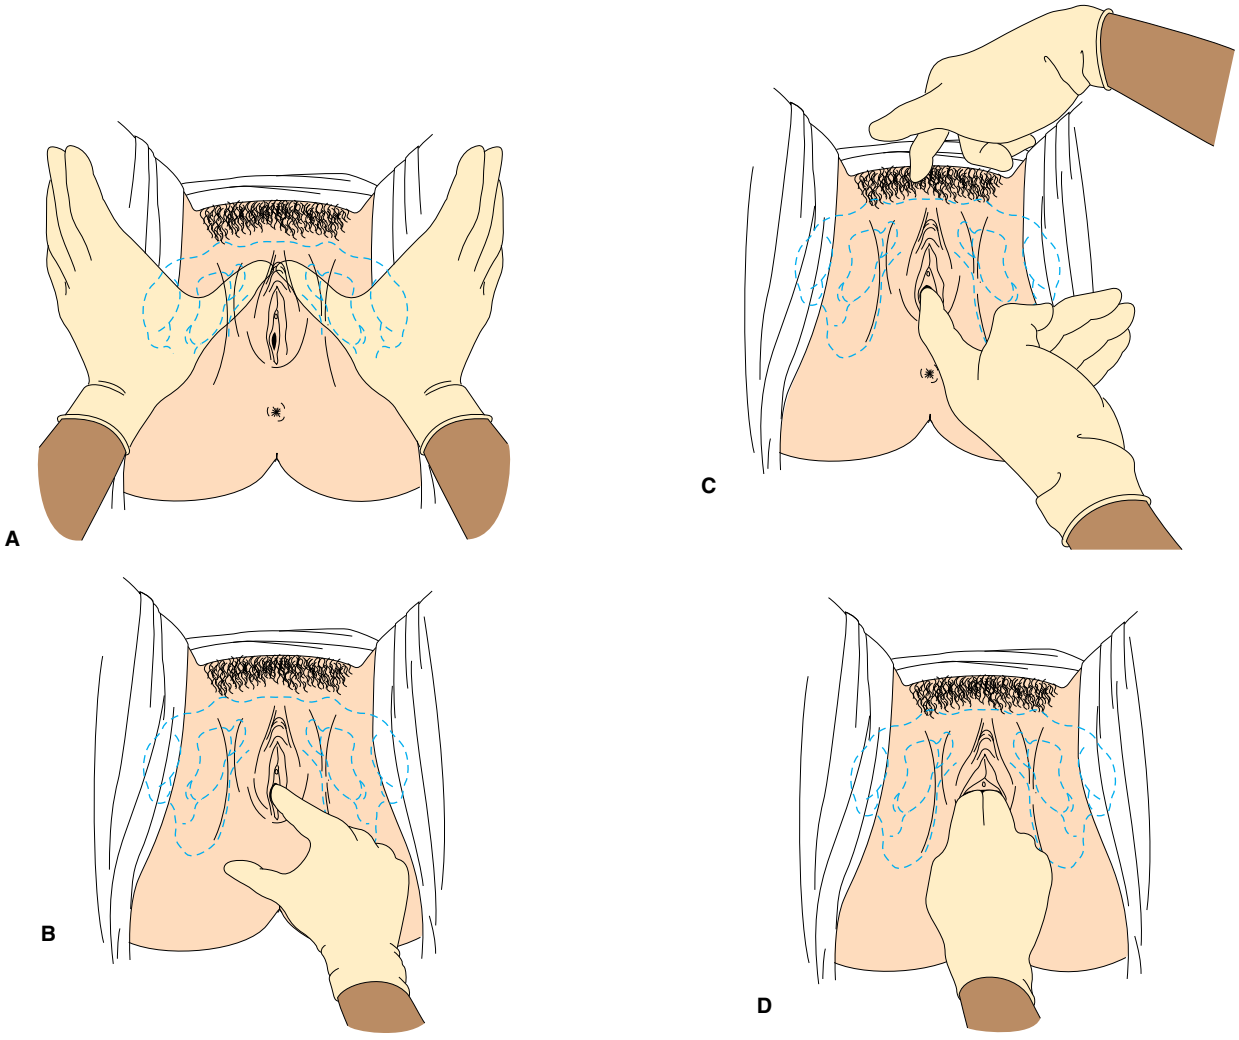

Figure 15-8 ■ Evaluation of the outlet. A. Estimation of the subpubic angle. B. Estimation of the length of the pubic ramus. C. Estimation of the depth and inclination of the pubis. D. Estimation of the contour of the subpubic angle.

Group B streptococcus (GBS) testing is completed between 35 and 37 weeks. GBS is a leading cause of serious neonatal infections. For this reason, a rectal and vaginal swab of the mother is obtained to screen for presence of the bacteria. Women with GBS in the urine at any time during the pregnancy are considered to be positive and do not need a culture completed. Intrapartum prophylaxis with antibiotics is recommended for women with positive GBS status.

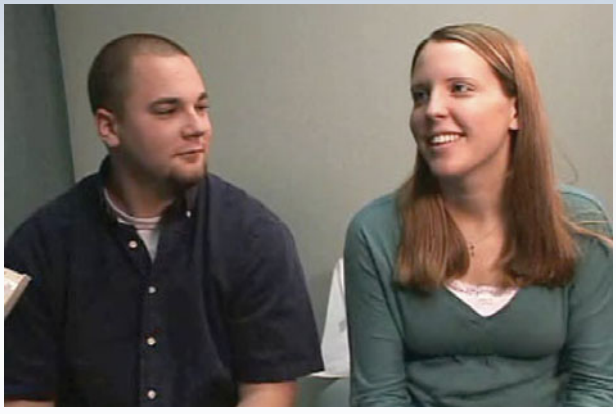
Certain screening tests should be offered to women based on risk findings that become apparent from the history and/or physical evaluation. For example, a hemoglobin electrophoresis should be performed in women of African, Southeast Asian, and Mediterranean descent to evaluate for sickle cell disease and thallasemias. Appropriate treatment and counseling can then be arranged based on the laboratory findings. Women who have not received varicella immunization or report a negative disease history should also be evaluated for varicella immunity. If they do not have documented immunity, plans should be made for the woman to be immunized after pregnancy. A tuberculin test (PPD) should also be completed on women who are considered to be high risk. High-risk populations include women who are foreign born, have a known exposure to tuberculosis, and healthcare workers who care for patients with tuberculosis. Lastly, additional tests are completed in the event of pathologic findings or known disease states. For example, a woman with known chronic hypertension should have a 24-hour urine, metabolic panel, and uric acid completed.

Additional genetic screening tests may be offered to pregnant women. Prenatal screening for cystic fibrosis (CF) is available. Originally the screening was offered before conception or in early pregnancy to Caucasian couples (including Ashkenazi Jews) because the condition is most common in these populations. However, ACOG (2005b) now recommends that cystic fibrosis carrier screening be offered to all couples regardless of ethnicity or race during preconception or early in pregnancy. It is important that families are counseled about the limitations of CF screening, including the fact that a risk of positive CF carrier status is still present after negative results because the test does not screen for all possible mutations.

Through the Eyes of a Nurse
Prenatal Testing in Pregnancy

Family's Experience

"I know there are things that can go wrong in pregnancy. Maybe I have just read too much, but I am really scared something is going to go wrong. How will you know if there is a problem?"



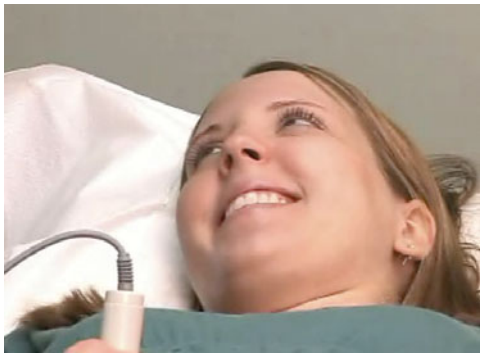
Nurse's Response

"It is not uncommon to be nervous or scared about the baby and yourself. At your first visit, you remember that we asked you a lot of medical information and questions about your medical history, the medical history of the father of the baby, and questions about your social situation and environmental factors in your everyday life. This provides us with information to determine if there are problems that you may be at risk for developing.

"The physical exam and lab tests you have had done also allow us to look for underlying or developing complications. So far, all of your test results have been normal. We will continue monitoring you and the baby throughout the pregnancy to make sure things are progressing normally and that there are no concerns."

Nurse's Actions and Rationale

The nurse validates the woman's feelings and provides reassurance that feeling concerned and worried about problems that can occur during pregnancy are normal responses. In the beginning of pregnancy, a physical examination is performed to determine a baseline physical assessment. The assessment guide in this chapter reviews the physical examination, along with laboratory tests that are commonly performed. The nurse should also assess for cultural, educational, psychologic, and financial needs or concerns. A family assessment (discussed in chapter 2 ∞) should also be performed during the pregnancy.



Women and family members should be counseled about the process of screening, interpretation of outcomes, and limitations of testing.

Universal screening for certain birth defects including neural tube defects, Down syndrome, and trisomy 18 is offered to all women during pregnancy. The goal of screening is to identify women who will benefit from diagnostic testing and to decrease the need for invasive procedures (Rappaport, 2008).

The *quadruple screen* (quad screen) is a safe, useful screening test performed on the mother's serum between 15 and 21 weeks of pregnancy. The test is used to detect levels of specific serum markers—alpha-fetoprotein (AFP), human chorionic gonadotropin (hCG), unconjugated estriol (UE), and inhibin-A (a placental hormone). Test results that reveal higher than normal AFP levels indicate an increased risk of a fetal neural tube defect, a multiple gestation, or a pregnancy that is farther along than believed. Lower than normal AFP could indicate that the woman is at risk for having a baby with Down syndrome or trisomy 18. Higher than normal levels of hCG and inhibin-A and lower than normal UE may also indicate that a woman is at increased risk of having a baby with Down syndrome. An accurate gestational age must be determined when using the quad screen. The more accurate the EDB estimation, the better the screening performance (Saller & Canick, 2008).

First trimester ultrasound assessment of the thickness (presence of fluid) in the fetal nuchal fold (called *nuchal translucency [NT]*) is a positive marker for Down syndrome and an early presenting feature of fetal chromosomal, genetic, and structural abnormalities. Ultrasound evaluation of NT combined with a serum screen of pregnancy-associated plasma protein A (PAPP-A) and free B-hCG completed between 11 and 13 weeks has an 85% detection rate for Down syndrome (Saller & Canick, 2008). These tests are generally combined with second trimester serum screening and may be called either a sequential or an integrated test depending on the sequence of evaluation. NT evaluations may not be available in all areas due to lack of NT certified sonographers (Rappaport, 2008). Neural tube defect screening should be offered in the second trimester to women who complete the first trimester screening.

It is important for healthcare professionals to provide parents with factual information about the results of screening tests that detect chromosomal defects or fetal anomalies including detection rates, false-positive results, advantages, disadvantages, limitations, risks, and benefits of diagnostic procedures (ACOG, 2007). This allows patients to make informed decisions when choosing to complete screening or diagnostic testing. The goal of screening is to identify women who might benefit from diagnostic testing based on screening results. Parents need to decide on any course of action based on their own spiritual, cultural, and personal beliefs prior to initiating diagnostic or screening testing. It is important to remember that some patients will decline genetic screening for personal reasons. This decision must be respected and supported by the nurse.

Subsequent Patient History

At subsequent prenatal visits, the nurse continues to gather data about the family's adjustment to the pregnancy and the course of the pregnancy to date. Each subsequent visit includes a chart review, history and physical examination, laboratory studies as indicated, and explanations and teaching appropriate to the woman's needs and gestational age. A chart review should be completed before starting the subsequent visit. This allows the nurse to determine the gestational age of the woman, evaluate laboratory results, and identify any problems or risks that may be present. The nurse can subsequently address important findings and investigate findings as needed. Once the chart review is completed, the nurse should obtain a basic revisit history, which should indicate complications or discomforts that the women may be experiencing. The nurse inquires about physical changes that relate directly to the pregnancy.

At prenatal visits, the nurse should evaluate the psychosocial needs of the woman and the adjustment and expectations of the support person and other children in the family. As the pregnancy progresses, the nurse assesses preparations that the family has made for the new baby and provides anticipatory guidance as needed. Taking time to address psychosocial issues is necessary in helping the nurse assess the family's success in meeting their developmental tasks.

Danger signs and signs of preterm labor that a woman should report immediately are discussed during the initial prenatal visit and reviewed at each subsequent prenatal visit (Figure 15-9 ■). Many caregivers also provide printed information on the subject written in lay terms. Table 15-2 identifies the danger signs of pregnancy and possible causes for each. Table 15-3 lists the signs of preterm labor.

The interchange between the nurse and woman will be facilitated if it takes place in a friendly, trusting environment. The nurse should give the woman sufficient time to ask questions and to voice concerns. If the nurse provides the time and

Figure 15-9 ■ The nurse reviews the danger signs in pregnancy at the initial prenatal visit and at each subsequent visit.

TABLE 15-2 Danger Signs in Pregnancy

The woman should report the following danger signs in pregnancy immediately.

DANGER SIGN	POSSIBLE CAUSE
Sudden gush of fluid from vagina	Premature rupture of membranes
Vaginal bleeding	Abruptio placentae, placenta previa
	Lesions of cervix or vagina
	"Bloody show"
	Cervical, vaginal infection
	Irritation of cervix from intercourse
Abdominal pain	Premature labor, abruptio placentae
Temperature above 38.3°C (101°F) and chills	Infection
Dizziness, blurring of vision, double vision, spots before eyes	Hypertension, preeclampsia
Persistent nausea and vomiting	Hyperemesis gravidarum
Severe headache	Hypertension, preeclampsia
Edema of hands or face	Preeclampsia
Seizures or convulsions	Preeclampsia, eclampsia
Epigastric pain	Preeclampsia, ischemia in major abdominal vessel
Dysuria	Urinary tract infection
Absent or decreased fetal movement	Maternal medication, obesity, fetal death, fetal distress

TABLE 15-3 Signs of Preterm Labor

- Painful menstrual-like cramps
- Dull low backache
- Suprapubic pain or pressure
- Pelvic pressure or heaviness
- Change in character or amount of vaginal discharge (bloody, thinner, thicker)
- Diarrhea
- Uterine contractions felt every 10 minutes for 1 hour
- Leaking of water from vagina

demonstrates genuine interest, the woman will feel more at ease bringing up questions that she may believe are silly or concerns that she has been afraid to verbalize. The nurse who has an accurate understanding of all the changes of pregnancy is most able to answer questions and provide information. See the foldout color chart, "Maternal-Fetal Development," for vivid illustrations of some of this information.

CLINICAL TIP

The woman and her partner should be encouraged to bring a list of questions or concerns to subsequent prenatal visits. This helps ensure that the needs and concerns of the woman and her family are addressed.

The nurse should be sensitive to religious, spiritual, cultural, and socioeconomic factors that may influence a family's response to pregnancy as well as to the woman's expectations of the healthcare system. The nurse can avoid stereotyping simply by asking each woman about her expectations for the antepartal period. Although many women's responses may reflect what are thought to be traditional norms, other women will have decidedly different views or may have expectations that represent a blending of beliefs or cultures.

During the prenatal period, it is essential that the nurse begin assessing the developing readiness of the woman and her partner to take on the responsibilities of parenthood successfully. Table 15-4 identifies areas for assessment and provides some sample questions the nurse might use to obtain necessary information. If the woman's responses are primarily negative, the nurse can plan interventions for the prenatal and postpartal periods.

Depression during and after pregnancy is a common problem, one that is gaining increased attention worldwide. The challenges of pregnancy and motherhood can be overwhelming for women experiencing perinatal depression (Baisch, Carey, Conway, et al., 2010). Infants of depressed women are at increased risk for delayed cognitive, neurologic, psychologic, and motor development (Gjerdingen & Yawn, 2007). Although ACOG reports that there is not sufficient evidence to recommend universal screening for depression at this time, women who have a history of depression or who are currently depressed need to be evaluated and monitored closely (ACOG, 2010).

Subsequent Prenatal Assessment

The Subsequent Prenatal Assessment Guide, which begins on page 340, provides a systematic approach to the regular physical examinations the pregnant woman should undergo for optimal prenatal care and a model for evaluating both the pregnant woman and the expectant partner, if he or she is involved in the pregnancy.

CLINICAL TIP

When assessing blood pressure, have the pregnant woman sit up with her arm resting on a table so that her arm is at the level of her heart. Expect a decrease in her blood pressure from baseline during the second trimester because of normal physiologic changes.

The woman's individual needs and the assessment of her risks should determine the frequency of subsequent visits. Generally, the recommended frequency of prenatal visits is as follows:

- Every 4 weeks for the first 28 weeks of gestation
- Every 2 weeks until 36 weeks' gestation
- After week 36, every week until childbirth

During the subsequent antepartal assessments, most women demonstrate ongoing psychologic adjustment to pregnancy and

ever-improving coping skills. However, some women may exhibit signs of psychologic problems. These signs may include one or more of the following:

- Increasing anxiety
- Depression or feelings of sadness
- Inability to establish communication
- Inappropriate responses or actions
- Denial of pregnancy
- Inability to cope with stress
- Intense preoccupation with the sex of the baby
- Failure to acknowledge quickening
- Failure to plan and prepare for the baby (for example, living arrangements, clothing, feeding methods)
- Indications of substance abuse

If the woman's behavior indicates possible psychologic problems, the nurse should provide ongoing support and counseling and also refer the woman to appropriate professionals as indicated.

DEVELOPING CULTURAL COMPETENCE

Pregnant Women Who Decline Blood Products

At the first prenatal visit, it is important to evaluate your patient's willingness to receive blood products in the event of an emergency. Some women and families decline blood products based on religious, cultural, or personal beliefs. Jehovah's Witnesses make up the largest population of individuals who typically refuse blood products. Women who are Jehovah's Witnesses have a 6 times increased risk for maternal death and have 3.1 times increased risk for serious maternal morbidity compared to the general population (Van Wolfswinkel et al., 2009).

A woman's decision to decline blood products should be respected; however, the woman needs to understand the potential consequences of this decision including increased risk of a hysterectomy or death. It is important to determine which blood products the patient will accept, obtain a healthcare proxy, obtain an advance directive, complete a blood refusal consent form, avoid anemia during the pregnancy, and provide the necessary counseling so that the patient can make informed decisions. The obstetrician and anesthesiologist (if needed) should be aware of the woman's decision. A multidisciplinary team approach is indicated to ensure that appropriate care is provided to avoid serious complications.

TABLE 15-4 Guide to Prenatal Assessment of Parenting

AREAS ASSESSED	SAMPLE QUESTIONS
I. Perception of complexities of mothering	1. Did you plan on getting pregnant? 2. How do you feel about being pregnant? 3. Why do you want this baby?
A. Desires baby for itself Positive: 1. Feels positive about pregnancy Negative: 1. Wants baby to meet own needs such as someone to love her, someone to get her out of unhappy home	
B. Expresses concern about impact of mothering role on other roles (wife, career, school) Positive: 1. Realistic expectations of how baby will affect job, career, school, and personal goals 2. Interested in learning about child care Negative: 1. Feels pregnancy and baby will make no emotional, physical, or social demands on self 2. Has no insight that mothering role will affect other roles or lifestyle	1. What do you think it will be like to take care of a baby? 2. How do you think your life will be different after you have your baby? 3. How do you feel this baby will affect your job, career, school, and personal goals? 4. How will the baby affect your relationship with your partner? 5. Have you done any reading, baby-sitting, or made any things for a baby?
C. Gives up routine habits because "not good for baby" (e.g., quits smoking, adjusts time schedule) Positive: 1. Gives up routines not good for baby (quits smoking, adjusts eating habits)	
II. Attachment	
A. Strong feelings regarding sex of baby. Why? Positive: 1. Verbalizes positive thoughts about the baby Negative: 1. Baby will be like negative aspects of self and partner	1. Why do you prefer a certain sex? (Is reason inappropriate for a baby?) 2. Note comments patient makes about baby not being normal and why patient feels this way.
B. Interested in data regarding fetus (e.g., growth and development, heart tones) Positive: 1. As above	

TABLE 15-4 Guide to Prenatal Assessment of Parenting continued

AREAS ASSESSED	SAMPLE QUESTIONS
Negative: 1. Shows no interest in fetal growth and development, quickening, and fetal heart tones 2. Expresses negative feelings about fetus by rejecting counseling regarding nutrition, rest, hygiene	
C. Fantasies about baby Positive: 1. Follows cultural norms regarding preparation 2. Time of attachment behaviors appropriate to her history of pregnancy loss Negative: 1. Bonding conditional depending on sex, age of baby, and/or labor and birth experience 2. Woman considers only own needs when making plans for baby 3. Exhibits no attachment behaviors after critical period of previous pregnancy 4. Failure to follow cultural norms regarding preparation	1. What did you think or feel when you first felt the baby move? 2. Have you started preparing for the baby? 3. What do you think your baby will look like—what age do you see your baby at? 4. How would you like your new baby to look?
III. Acceptance of child by significant others	
A. Acknowledges acceptance by significant other of the new responsibility inherent in child Positive: 1. Acknowledges unconditional acceptance of pregnancy and baby by significant others 2. Partner accepts new responsibility inherent with child 3. Timely sharing of experience of pregnancy with significant others Negative: 1. Significant others not supportively involved with pregnancy 2. Conditional acceptance of pregnancy depending on sex, race, age of baby 3. Decision making does not take in needs of fetus (e.g., spends food money on new car) 4. Takes no/little responsibility for needs of pregnancy, woman/fetus	1. How does your partner feel about this pregnancy? 2. How do your parents feel? 3. What do your friends think? 4. Does your partner have a preference regarding the baby's sex? Why? 5. How does your partner feel about being a parent? 6. What do you think he/she will be like as a parent? 7. What do you think he/she will do to help you with child care? 8. Have you and your partner talked about how the baby might change your lives? 9. Who have you told about your pregnancy?
B. Concrete demonstration of acceptance of pregnancy/baby by significant others (e.g., baby shower, significant other involved prenatal education) Positive: 1. Baby shower 2. Significant other attends prenatal class with patient	1. Note if partner attends clinic with patient (degree of interest; e.g., listens to heart tones). 2. Does your partner plan to be with you during labor and birth? 3. Is your partner contributing financially?
IV. Ensures physical well-being	
A. Concerns about having normal pregnancy, labor and birth, and baby 1. Preparing for labor and birth, attends prenatal classes, interested in labor and birth 2. Aware of danger signs of pregnancy 3. Seeks and uses appropriate health care (e.g., time of initial visit, keeps appointments, follows through on recommendations) Negative: 1. Denies signs and symptoms that might suggest complications of pregnancy 2. Verbalizes extreme fear of labor and birth—refuses to talk about labor and birth 3. Misses appointments, fails to follow instructions, refuses to attend prenatal classes	1. What have you heard about labor and birth? 2. Note data about patient's reaction to prenatal class.
B. Family/patient decisions reflect concern for health of mother and baby (e.g., use of finances, time) Positive: 1. As above	

Source: Modified and used with permission of the Minneapolis Health Dept., Minneapolis, MN.

Note: When "Negative" is not listed in a section, the reader may assume that negative is the absence of positive responses.

ASSESSMENT GUIDE Subsequent Prenatal Assessment

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
VITAL SIGNS		
Temperature: 36.2°–37.6°C (97°–99.6°F)	Elevated temperature (infection)	Evaluate for signs of infection. Refer to healthcare provider.
Pulse: 60–90/min Rate may increase 10 beats/min during pregnancy	Increased pulse rate (anxiety, cardiac disorders)	Note irregularities. Assess for anxiety and stress.
Respiration: 12–22/min	Marked tachypnea or abnormal patterns (respiratory disease)	Refer to healthcare provider.
Blood Pressure: Less than or equal to 135/85 (falls in second trimester)	Greater than 140/90 or increase of 30 mm systolic and 15 mm diastolic (preeclampsia)	Assess for edema, proteinuria, and hyperreflexia. Refer to healthcare provider. Schedule appointments more frequently.
WEIGHT GAIN		
First Trimester: .05–2 kg (1.1–4.4 lb)	Inadequate weight gain (poor nutrition, nausea, intrauterine growth restriction [IUGR])	Discuss appropriate weight gain.
Second Trimester: 5.5–6.8 kg (12–15 lb)	Excessive weight gain (excessive caloric intake, edema, preeclampsia)	Provide nutritional counseling. Assess for presence of edema or anemia. Refer to dietitian as needed.
Third Trimester: 5.5–6.8 kg (12–15 lb)		
EDEMA		
Small amount of dependent edema, especially in last weeks of pregnancy	Edema in hands, face, legs, and feet (preeclampsia)	Identify any correlation between edema and activities, blood pressure, or proteinuria: Refer to healthcare provider if indicated.
UTERINE SIZE		
See "Assessment Guide: Initial Prenatal Assessment" for normal changes during pregnancy	Unusually rapid growth (multiple gestation, hydatidiform mole, hydramnios, miscalculation of estimated date of birth [EDB])	Evaluate fetal status. Determine height of fundus (page 330). Use diagnostic ultrasound.
FETAL HEARTBEAT		
120–160/min	Absence of fetal heartbeat after 20 weeks' gestation (maternal obesity, fetal demise)	Evaluate fetal status.
Funic soufflé		
LABORATORY EVALUATION		
Hemoglobin: 12–16 g/dl Pseudoanemia of pregnancy	Less than 11 g/dl (anemia)	Provide nutritional counseling. Hemoglobin is repeated at 7 months' gestation. Women of Mediterranean heritage need a close check on hemoglobin because of the possibility of thalassemia.
Quad Marker Screen: Blood test performed at 15–21 weeks' gestation. Evaluates four factors—maternal serum alpha-fetoprotein (MSAFP), unconjugated estriol (UE), human chorionic gonadotropin (hCG), and inhibin-A: normal levels	Elevated MSAFP (neural tube defect, underestimated gestational age, multiple gestation). Lower than normal MSAFP (Down syndrome, trisomy 18). Higher than normal hCG and inhibin-A (Down syndrome). Lower than normal UE (Down syndrome)	Offered to all pregnant women. If quad screen abnormal further testing such as ultrasound or amniocentesis is offered.
Indirect Coombs Test done on Rh negative women: Negative (done at 28 weeks' gestation)	Rh antibodies present (maternal sensitization has occurred)	If Rh negative and unsensitized, Rh immune globulin given (see chapter 20 ∞). If Rh antibodies present, Rh immune globulin not given; fetus monitored closely for isoimmune hemolytic disease.
		Refer for a diagnostic 100-g oral glucose tolerance test. Discuss implications of gestational diabetes mellitus (GDM) if diagnosis is made. Refer to healthcare provider.
50-g 1-hour glucose screen (done between 24 and 28 weeks' gestation)	Plasma glucose level greater than 130–140 depending on the facility are abnormal. Be aware of your institution's guidelines	
Urinalysis: See "Assessment Guide: Initial Prenatal Assessment" for normal findings	See "Assessment Guide: Initial Prenatal Assessment" for deviations	Urinalysis and culture is completed at initial visit and at subsequent visits as indicated.
Protein: Negative	Proteinuria, albuminuria (contamination by vaginal discharge, urinary tract infection, preeclampsia)	Obtain dipstick urine sample. Refer to healthcare provider if deviations are present.
Glucose: Negative	Persistent glycosuria (diabetes mellitus)	Refer to healthcare provider.
Note: Glycosuria may be present due to physiologic alterations in glomerular filtration rate and renal threshold		
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further nursing assessment and initial intervention.

ASSESSMENT GUIDE Subsequent Prenatal Assessment continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
Screening for Group B Streptococcus (GBS):	Positive culture (maternal infection)	Explain maternal and fetal/neonatal risks (see chapter 20 ∞).
Rectal and vaginal swabs obtained at 35–37 weeks' gestation for all pregnant women		Refer to healthcare provider for therapy.
Cultural Assessment	**Variations to Consider***	**Nursing Responses to Data†**
Determine the mother's (and family's) attitudes about the sex of the unborn child.	Some women have no preference about the sex of the child; others do. In many cultures, boys are especially valued as firstborn children.	Provide opportunities to discuss preferences and expectations; avoid a judgmental attitude to the response.
Ask about the woman's expectations of childbirth. Will she want someone with her for the birth? Whom does she choose? What is the role of her partner?	Some women want their partner present for labor and birth; others prefer a female relative or friend.	Provide information on birth options but accept the woman's decision about who will attend.
	Some women expect to be separated from their partner once labor begins.	
Ask about preparations for the baby. Determine what is customary for the woman.	Some women may have a fully prepared nursery; others may not have a separate room for the baby.	Explore reasons for not preparing for the baby. Support the mother's preferences and provide information about possible sources of assistance if the decision is related to a lack of resources.
EXPECTANT MOTHER		
Psychologic Status	Increased stress and anxiety	Encourage woman to take an active part in her care.
First Trimester/Period of Adjustment: Incorporates idea of pregnancy; may feel ambivalent or anxious, especially if she must give up desired role; usually looks for signs of verification of pregnancy, such as increase in abdominal size or fetal movement	Inability to establish communication; inability to accept pregnancy; inappropriate response or actions; denial of pregnancy; inability to cope	Establish lines of communication. Discuss and provide anticipatory guidance regarding normalcy of feelings and actions. Establish a trusting relationship. Counsel as necessary. Refer to appropriate professional as needed.
Second Trimester/Period of Radiant Health: Baby becomes more real to woman as abdominal size increases and she feels movement; she begins to turn inward, becoming more introspective		
Third Trimester/ Period of Watchful Waiting: Begins to think of baby as separate being; may feel restless, uneasy, and may feel that time of labor will never come; remains self-centered and concentrates on preparing place for baby. Fears well-being for herself and baby		
Educational Needs		
Self-care Measures and Knowledge About the Following:	Inadequate information	Provide information and counseling.
Health promotion Breast care Hygiene Rest Exercise Nutrition Relief measures for common discomforts of pregnancy Danger signs in pregnancy (see Table 15-2) Signs of preterm labor (see Table 15-3)		
Sexual Activity: Woman knows how pregnancy affects sexual activity	Lack of information about effects of pregnancy and/or alternative positions during sexual intercourse	Provide counseling.
Preparation for Parenting: Appropriate preparation	Lack of preparation (denial, failure to adjust to baby, unwanted child)	Counsel. If lack of preparation is due to inadequacy of information, provide information.
Preparation for Childbirth		If couple chooses particular technique, refer to classes (see chapter 13 ∞ for description of childbirth preparation techniques).
Patient Aware of the Following:	Continued abuse of drugs and alcohol; denial of possible effect on self and baby	
1. Prepared childbirth techniques		
2. Normal processes and changes during childbirth		Encourage prenatal class attendance. Educate woman during visits based on current physical status. Provide reading list for more specific information.
3. Problems that may occur as a result of drug and alcohol use and of smoking		Review danger signs that were presented on initial visit.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further nursing assessment and initial intervention.

(continued)

ASSESSMENT GUIDE Subsequent Prenatal Assessment continued

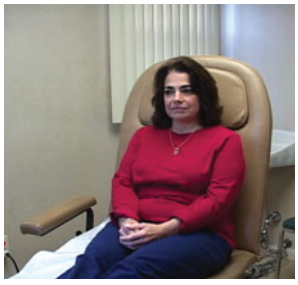
Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
Woman has met other physician or nurse-midwife who may be attending her birth in the absence of primary caregiver	Introduction of new individual at birth may increase stress and anxiety for woman and partner	Introduce woman to all members of group practice.
Impending Labor	Lack of information	Provide appropriate teaching, stressing importance of seeking appropriate medical assistance.
Patient Knows Signs of Impending Labor:		
1. Uterine contractions that increase in frequency, duration, and intensity		
2. Bloody show		
3. Expulsion of mucous plug		
4. Rupture of membranes		
EXPECTANT PARTNER		
Psychologic Status		
First Trimester: May express excitement over confirmation of pregnancy and of his virility; concerns move toward providing for financial needs; energetic, may identify with some discomforts of pregnancy and may even exhibit symptoms	Increasing stress and anxiety; inability to establish communication; inability to accept pregnancy diagnosis; withdrawal of support; abandonment of the mother	Encourage expectant partner to come to prenatal visits. Establish line of communication. Establish trusting relationship.
Second Trimester: May feel more confident and be less concerned with financial matters; may have concerns about wife's changing size and shape, her increasing introspection		Counsel. Let expectant partner know that it is normal for him to experience these feelings.
Third Trimester: May have feelings of rivalry with fetus, especially during sexual activity; may make changes in his physical appearance and exhibit more interest in himself; may become more energetic; fantasizes about child but usually imagines older child; fears mutilation and death of woman and child		Include expectant partner in pregnancy activities as he desires. Provide education, information, and support. Increasing numbers of expectant partners are demonstrating desire to be involved in many or all aspects of prenatal care, education, and preparation.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further nursing assessment and initial intervention.

FOCUS YOUR STUDY

- A complete history forms the basis of prenatal care and is reevaluated and updated as necessary throughout the pregnancy.
- The initial prenatal assessment is a careful and thorough physical examination and cultural and psychosocial assessment designed to identify variations and potential risk factors.
- Laboratory tests completed at the initial visit, such as a complete blood count, ABO and Rh typing, urinalysis/culture, Pap smear, chlamydia culture, gonorrhea culture, rubella titer, and various blood screens (such as rapid plasma reagin [RPR], HIV, and hepatitis B), provide information about the woman's health during early pregnancy and also help detect potential problems.
- The estimated date of birth (EDB) can be calculated using Nägele's rule. Using this approach, one begins with the first day of the last menstrual period, subtracts 3 months, and adds 7 days. A "wheel" may also be used to calculate the EDB.
- Accuracy of the EDB may be evaluated by physical examination to assess uterine size, measurement of fundal height, and ultrasound. Perception of quickening and auscultation of fetal heartbeat are also useful tools in confirming the gestation of a pregnancy.

- The diagonal conjugate is the distance from the lower posterior border of the symphysis pubis to the sacral promontory. The obstetric conjugate is estimated by subtracting 1.5 to 2 cm from the length of the diagonal conjugate.
- As part of the assessment of the pelvic cavity (midpelvis), the prominence of the ischial spines is assessed, the sacrosciatic notch and the length of the sacrospinous ligament are measured, and the shape of the pelvic side walls is evaluated. Finally, the hollowness of the sacrum is determined.
- The anteroposterior diameter of the pelvic outlet is determined, the mobility of the coccyx is assessed, the suprapubic angle is estimated, and the contour of the pubic arch is evaluated to assess the adequacy of the pelvic outlet.
- The nurse begins evaluating the woman psychosocially during the initial prenatal assessment. This assessment continues and is modified throughout the pregnancy.
- Cultural and ethnic beliefs may strongly influence the woman's attitudes and apparent cooperation with care during pregnancy.

CRITICAL THINKING IN ACTION



Source: George Dodson/Pearson Education.

Wendy Stodard, age 40, G3, P0020 comes to the obstetrician's office where you are working for a prenatal visit. Wendy has experienced two spontaneous abortions followed by a D & C at 14 and 15 weeks' gestation during the previous year. She has a history of *Chlamydia trachomatis* infection 3 years ago, which was treated with azithromycin. She is at 10 weeks' gestation. Wendy tells you that she is afraid of losing this pregnancy as she did previously. She says that she has been experiencing some mild nausea, breast tenderness, and fatigue, which did not occur with her other pregnancies. You assist the obstetrician with an ultrasound. The gestational sac is clearly seen, fetal heartbeat is observed, and crown-to-rump measurements are consistent with gestational age of 10 weeks. The pelvic exam demonstrates a closed cervix, and positive Goodell's, Hegar's, and Chadwick's signs. You discuss with Wendy the signs of a healthy pregnancy.

1. What signs are reassuring with this pregnancy?
2. What symptoms should be reported to the obstetrician immediately?
3. What is the frequency of antepartal visits?

See www.nursing.pearsonhighered.com for possible responses.

CHAPTER 16

The Expectant Family: Needs and Care

I don't know how I timed it, but my nursing program OB rotation finishes up right about my due date. Watching all the births during my clinicals has been really exciting. The labor and delivery nurses laugh and say my hormones should be hopping now, but I think this baby is subliminally telling me that we won't "hatch" until I take my final exam!

LEARNING OUTCOMES

1. Describe the significance of using the nursing process to promote health in the woman and her family during pregnancy.
2. Describe actions the nurse can take to help maintain the well-being of the expectant father and siblings during a family's pregnancy.
3. Discuss the significance of cultural considerations in managing nursing care during pregnancy.
4. Identify the common discomforts of pregnancy and their causes.
5. Summarize appropriate measures to alleviate the common discomforts of pregnancy.
6. Delineate self-care actions a pregnant woman and her family can take to maintain and promote well-being during each trimester of pregnancy.
7. Identify some of the concerns that an expectant couple may have about sexual activity.
8. Describe factors that have contributed to the increased incidence of pregnancy in women over age 35.
9. Compare similarities and differences in the needs of expectant women in various age groups.

KEY TERMS

Fetal alcohol syndrome (FAS) *371*
Fetal movement record (FMR) *358*
Kegel exercises *365*
Leukorrhea *353*
Lightening *357*
Pelvic tilt *363*
Ptyalism *353*

From the moment a woman finds out that she is pregnant, she faces a future marked by dramatic changes. Her appearance will be altered. Her relationships will change. She will experience a variety of unique physical changes throughout the pregnancy. Even her psychologic state will be affected. In coping with these changes she needs to make adjustments in her daily life.

Her family must also adjust to the pregnancy. Roles and responsibilities of family members will change as the woman's ability to perform certain activities changes. They too must adapt psychologically to the situation.

The expectant woman and her family will probably have many questions about the pregnancy and its impact on her and the other members of the family. In addition, the daily activities and healthcare practices of the woman become of concern when she and her family realize that what she does can affect the well-being of the unborn child.

Nurses caring for pregnant women need a clear understanding of pregnancy and the changes it brings if they are to be effective in managing nursing care. With this in mind, chapter 14 ∞ provides a database for the nurse by presenting material related to the normal physical, psychologic, social, and cultural changes of pregnancy. Chapter 15 ∞ then uses that database to begin a discussion of nursing care management by focusing on patient assessment. This chapter further addresses nursing care management as it relates to the needs of the expectant woman and her loved ones.

Nursing Care During the Prenatal Period

Nursing Diagnosis

The nurse may see a pregnant woman only once every 4 to 6 weeks during the first several months of her pregnancy. To ensure continuity of care, therefore, a written care plan that incorporates assessment data, nursing diagnoses, and patient goals is essential.

The nurse can anticipate that, for many women with a low-risk pregnancy, certain nursing diagnoses will be made more frequently than others. Nursing diagnoses will, of course, vary from woman to woman and according to the time in the pregnancy. Examples of common nursing diagnoses include the following:

- ***Constipation*** related to the physiologic effects of pregnancy
- ***Ineffective Sexuality Patterns*** related to discomfort during late pregnancy

After formulating an appropriate diagnosis, the nurse establishes related goals to guide the nursing plan and interventions.

Nursing Plan and Implementation

Once nursing diagnoses have been identified, the next step is to establish priorities of nursing care. Sometimes priorities of care are based on the most immediate needs or concerns perceived by the woman. For example, during the first trimester, a woman is probably not ready to hear about labor and birth because she is likely to have more immediate concerns, such as nausea or concerns about sexual intimacy with her partner.

At other times priorities may develop as a result of findings during a prenatal visit. For example, the nurse may stress the need for frequent rest periods for a woman who is showing signs of preeclampsia (a pregnancy complication discussed in chapter 20 ∞). However, the woman may feel well physically and find it difficult to accept the nurse's emphasis on rest. It is the responsibility of medical and nursing professionals to help the woman and her family understand the significance of a problem and to plan appropriate interventions to deal with it.

The intervention methods most used by nurses in caring for the expectant woman and her family are communication techniques and teaching-learning strategies. These intervention methods are often used in groups, such as early pregnancy classes and childbirth education classes, but the nurse in the prenatal setting also applies these techniques with individuals.

Community-Based Nursing Care

Prenatal care, especially for women with low-risk pregnancies, is community based, typically in a clinic or private office. The healthcare community recognizes the value of providing a primary care nurse in these settings to coordinate care for each childbearing family. The nurse in a clinic or health maintenance organization (HMO) may be the only source of continuity for the woman, who may see a different physician or certified nurse-midwife at each visit. The nurse can be extremely effective in working with the expectant family by answering their questions; providing them with complete information about pregnancy, appropriate prenatal self-care measures, and community resources or referral agencies; and supporting the healthcare activities of the woman and her family. Communities often have a wealth of services and educational opportunities available for pregnant women and their families, and the knowledgeable nurse can help the woman access these services. This allows the family to assume equal responsibility with healthcare providers in working toward their common goal of a positive childbearing experience.

HOME CARE Home care can be of benefit to any pregnant woman, but it is especially effective in removing barriers for women who have difficulty accessing health care. These barriers may include lack of locally available healthcare facilities, problems with transportation to the facility, or schedule conflicts with available appointment times because of employment hours or family responsibilities.

In-home nursing assessments vary according to the scope of practice of the nurse and include current history and those screening procedures typically completed in an office or clinic: vital signs, weight, urine screen, physical activity, and dietary intake. Advanced practice nurses can also assess reflexes, perform tests of fetal well-being, and even do cervical examinations. Once the assessments are completed, the nurse can determine the level of follow-up home care or telephone contact needed.

A prenatal home care visit or phone contact can also be useful for women who anticipate a short inpatient stay after childbirth. At the prenatal contact, the nurse explains the postpartum program and answers any questions the woman or her family has.

Application: Teaching Resources for Pregnant Couples

Although the use of home care for women with uncomplicated pregnancies is growing, it is most often used for women with prenatal complications that can be managed without hospitalization if effective nursing assessment and care are provided in the home (see chapters 19 and 20).

HEALTH PROMOTION EDUCATION

Throughout the prenatal period the nurse provides informal and formal teaching to the childbearing family designed to help the family carry out self-care when appropriate and to report changes that may indicate a possible health problem. The teaching is most effective if timed to coincide with the woman's (couple's) readiness and needs (Table 16-1). The nurse also provides anticipatory guidance to help the family plan for changes that will occur following childbirth. The expectant couple should discuss issues that could be possible sources of postpartal stress. Issues to be resolved beforehand may include the sharing of infant and household chores, help in the first few days, reapportionment of family finances, options for baby-sitting to allow the mother (and couple) some free time, the mother's return to work after the baby's birth, and sibling rivalry.

TABLE 16-1 Topics for Patient Teaching During Pregnancy

All Three Trimesters

- Discomforts of pregnancy (see Table 16-3)
- Nutrition and weight gain
- Sexual activity
- Sibling preparation

First Trimester

- Attitude toward pregnancy
- Exercise and rest
- Smoking; use of alcohol and other drugs
- Traveling
- Fetal growth and development
- Danger signals associated with spontaneous abortion
- Employment
- Early pregnancy classes

Second Trimester

- Concerns related to changes in body
- Fetal growth and development
- Fetal movement
- Clothing
- Care of skin and breasts
- Beginning preparation for care of the infant (equipment and room)
- Decisions about infant feeding

Third Trimester

- Exercise and rest
- Traveling
- Danger signals
- Preparation for labor and birth
- Completion of preparation in home for new baby
- Decisions about the infant (circumcision, method of feeding, and so forth)
- Decision making for the early postpartum period
- Education about psychologic and physical expectations in the early postpartum period

Care of the Pregnant Woman's Family

Relieving the expectant woman's discomforts, maintaining her physical health, and providing anticipatory guidance are important parts of nursing care management. In addition, the nurse helps meet the needs of the woman's family to better maintain the harmony and integrity of the family unit. The nurse does this by providing support and prenatal education. If the nurse is effective, family members may gain greater problem-solving ability, self-esteem, self-confidence, and ability to participate in health care.

Care of the Father

Although the father of the baby is generally present, his presence cannot be assumed. If he is not a part of the family structure, it is important to assess the woman's support system to determine what significant persons in her life will play a major role during this childbearing experience.

When the father is part of the family or support system, providing anticipatory guidance to him is a necessary part of any plan of care. He may need information about the anatomic, physiologic, and emotional changes that occur during pregnancy and postpartum, the couple's sexuality and sexual response, and the reactions that he may experience. He may wish to express his feelings about breastfeeding versus formula-feeding, the sex of the child, and other topics. If it is culturally acceptable to the couple and personally acceptable to him, the nurse refers the couple to expectant parents' classes. These classes provide valuable information about pregnancy and childbirth using a variety of teaching strategies such as discussion, films, demonstrations with educational models, and written handouts. Some classes even give fathers the opportunity to get a "feel" for pregnancy by wearing a pregnancy simulator (Figure 16-1 ■).

The nurse assesses the father's intended degree of participation during labor and birth and his knowledge of what to ex-

Figure 16-1 ■ The Empathy Belly® is a pregnancy simulator that allows males and females to experience some of the symptoms of pregnancy. The "belly," which weighs 33 lb, produces symptoms such as shortness of breath, bladder pressure, shift in the center of gravity with resulting waddling gait, increased lordosis and backache, and fatigue. It can also simulate fetal kicking movements.

Source: Used with permission from Birthways Childbirth Resource Center.

pect. If the couple prefers that his participation be minimal or restricted, the nurse supports their decision and does not try to impose personal values. Research indicates that increased focus on the father's needs during prenatal care aids his transition to fatherhood and also improves the mother's emotional status in the postpartum period (Condon, 2006). With this type of consideration and collaboration, the father is less apt to develop feelings of alienation, helplessness, and guilt during the pregnancy. Assessing and fostering progress in the father's journey to becoming a parent has significant long-term benefits for the man, his partner, and their child (Condon, 2006).

Care of Siblings and Other Family Members

In the plan for prenatal care, the nurse considers the effect of the pregnancy on any other children the couple may have. For example, the nurse may initiate a discussion about the ambivalence that older children may feel about the pregnancy. Parents who are unprepared for the older child's feelings of anger, jealousy, and rejection may respond inappropriately in their confusion and surprise. The nurse emphasizes that open communication between parents and children (or acting out feelings with a doll if the child is too young to verbalize) helps children master their feelings and may prevent them from hurting the baby when they are unsupervised. Children may feel less neglected and more secure if they know that their parents are willing to listen to their expressions of sadness or to help with their anger and aggressiveness.

Parents may be encouraged to bring their children to antepartal visits. Seeing what is involved and listening to the fetal heartbeat may make the pregnancy more real to siblings. Many agencies also provide sibling classes geared to different ages and levels of understanding. Relationship changes with in-laws should be addressed as well as the woman's or couple's expectations of the grandparents. Although some grandparents are eager to assist with child care by baby-sitting, others are not. The parents should also give some thought to the best ways of dealing with possible conflicts with the grandparents over childrearing approaches. Couples resolve these issues in different ways; however, postpartal adjustment is easier for a couple who agrees on the issues beforehand than for a couple who does not confront and resolve these issues.

Cultural Considerations in Pregnancy

As discussed in chapter 2 ∞, the increasingly diverse population in the United States, Canada, and in other countries around the world, requires a more inclusive approach—culturally competent care—to the delivery of care to people who belong to diverse and multicultural groups. The cultural competence approach allows care providers to include patients' cultural backgrounds in their care; this approach, however, does not examine the role of individual experience in people's health-related values, beliefs, and behaviors. The concept of *cultural humility* has been proposed as a more suitable goal in multicultural education. Cultural humility focuses on the process of intercultural exchange, paying explicit attention to clarifying the care provider's values and beliefs through self-reflection and self-critique—in other words, identifying the caregiver's own biases; additionally, it incorporates the characteristics of both the care provider and the patient into a mutually beneficial and balanced relationship (Community Partnership for Older Adults, 2007). Being open to cultural differences and learning from patients about their beliefs, values, and practices helps caregivers build relationships based on similarities.

By assessing each woman individually, the cultural humility approach removes the need to know the cultural features of every diverse group. Consequently, prenatal care should always include a discussion that clarifies each woman's health-related values and beliefs.

DEVELOPING CULTURAL COMPETENCE

Pregnant Women of African American Heritage

In caring for pregnant women of African American heritage, it is helpful to consider the following general points (Purnell, 2009):

- African American pregnant women may be guided by their extended family into common practices such as geophagia, the ingestion of dirt or clay, which is believed to alleviate mineral deficiencies. This practice has implications for the focus of teaching a nurse offers.
- Many African American families are matriarchal. Women are respected and heeded in decision making and often stress good behavior and firm parenting with their children, especially to keep them safe in dangerous situations.
- Three-generation extended families are common, and the grandmother is often highly respected for her wisdom. She may play a critical role in the care of the children.
- Certain taboos may exist, such as the belief in the necessity to avoid taking pictures during pregnancy to prevent stillbirths. Some women of African American descent may also believe that the purchase of infant clothing or supplies can result in a stillbirth. Thus they may appear to be unprepared for the arrival of the baby.

This conversation allows the nurse to adapt to the specific healthcare needs of each perinatal patient. Using the nursing process, the nurse can then formulate a transcultural nursing diagnosis that is focused on the cultural beliefs of the specific woman. The nursing diagnosis should reflect cultural sensitivity and build on the strengths of the patient, such as "***Anxiety*** related to culturally unusual expectations for behavior and treatment" (Mattson, 2004).

A major goal of transcultural nursing is to understand and assist people of diverse cultural groups with their healthcare needs. Culturally sensitive nurses recognize that each childbearing family, shaped by culture and life experience, has expectations of both its members and the healthcare system during pregnancy and birth.

Pregnancy and childbirth are recognized as special or transitional events in virtually all cultures (Lauderdale, 2008). Additionally, specific actions during pregnancy are often determined by cultural beliefs. According to Mattson (2004), these beliefs can be divided into three types:

- Prescriptive beliefs or requirements that describe expected behaviors

- Restrictive beliefs, which are stated negatively and limit behaviors
- Taboo beliefs, which refer to specific supernatural consequences

These activities are viewed as having the potential to impact the outcome of the pregnancy either positively or negatively. Table 16-2 describes activities that are encouraged (prescriptive) or forbidden (restrictive) or taboo by specific cultures. The table is not meant to be all-inclusive but rather to offer a few examples of cultural activities that may be important to some patients during the prenatal period.

In working with patients of another culture, the healthcare professional should be as open as possible to other beliefs. If certain activities are not harmful, there is no need to impose one's beliefs and practices on a person of another culture. If the activities are proving to be harmful, the nurse can consult or work with someone within the culture or someone aware of the cultural beliefs and values to see whether the patient's behavior can be modified (Figure 16-2 ■).

See Nursing Care Plan: Language Barriers at First Prenatal Visit.

Figure 16-2 ■ The culturally competent nurse respects the culture and values of the pregnant woman.

TABLE 16-2 Cultural Beliefs and Practices During Pregnancy

These are a few examples of cultural beliefs and practices related to pregnancy. It is important not to make assumptions about a patient's beliefs, because cultural norms vary greatly within a culture and from generation to generation. The nurse should observe the patient carefully and take the time to ask questions. Patients will benefit greatly from the nurse's increased awareness of their cultural beliefs and practices.

BELIEF OR PRACTICE	NURSING CONSIDERATION
Home Remedies	
Pregnant women of Native American background may use herbal remedies. An example is the dandelion, which contains a milky juice in its stem believed to increase breast milk flow in mothers who choose to breastfeed (Spector, 2009). Patients of Chinese descent may drink ginseng tea for faintness after childbirth or as a sedative when mixed with bamboo leaves. Some people of African heritage may use self-medication for pregnancy discomforts—for example, laxatives to prevent or treat constipation (Purnell, 2009).	Find out what medications and home remedies your patient is using, and counsel your patient regarding overall effects. It is common for individuals to avoid telling healthcare workers about home remedies; the patient may feel this will be judged unfavorably. Phrase your questions in a sensitive, accepting way. In some cases, you might want to suggest remedies that may be more effective—for example, eating high-fiber foods to reduce constipation. If the home remedy is not harmful, there is no reason to ask a patient to discontinue this practice.
Nutrition	
Some women of Italian background may believe that it is necessary to satisfy desires for certain foods in order to prevent congenital anomalies. Also, they may believe that they must eat food that they smell, or else the fetus will move "inside," which will result in a miscarriage. Pregnant women of Vietnamese descent are considered to be in a weak, cold state and must correct this by eating and drinking hot foods during the first trimester (Purnell, 2009).	Discuss the patient's beliefs and practices in regard to nutrition during pregnancy. Obtain a diet history from the patient. Discuss the importance of a well-balanced diet during pregnancy with consideration of the patient's cultural beliefs and practices.
Alternative Healthcare Providers	
Pregnant women of Mexican background may choose to seek out the care of a *partera* (midwife) for prenatal and intrapartal care. A partera speaks their language, shares a similar culture, and can care for pregnant women at home or in a birthing center instead of a hospital. Some people in Hispanic American communities may use the *curandero,* the folk healer. The curanderos are believed to have received their gift from God and may prescribe over-the-counter medications (Purnell, 2009).	Discuss the variety of choices of healthcare providers available to the pregnant woman. Contrast the benefits and risks of different settings for prenatal care and birth. Provide reassurance that the goal of health care during pregnancy and birth is a healthy outcome for mother and baby with respect for the specific cultural beliefs and practices of the patient.
Exercise	
Pregnant women of Korean descent may work hard toward the end of pregnancy to increase the chances of delivering a small baby (Purnell, 2009). Some people of European, African, and Mexican descent believe that reaching over the head during pregnancy can harm the baby.	Ask your patient whether there are any activities she is afraid to do because of the pregnancy. Assure her that reaching over her head will not harm the baby, and evaluate other activities to their effect on the pregnancy.
Spirituality	
Navajo Indians are aware of the mind-soul connection and may try to follow certain practices to have a healthy pregnancy and birth. Practices could include focus on peace and positive thoughts as well as certain types of prayers and ceremonies. A traditional healer may assist them (Purnell, 2009). Some people of European background may tend to pay more attention to spirituality in their life to alleviate fears and ensure a safe birth.	Encourage the use of support systems and spiritual aids that provide comfort for the mother.

NURSING CARE PLAN Language Barriers at First Prenatal Visit

INTERVENTION	RATIONALE
1. Nursing Diagnosis: Ineffective Health Maintenance related to alteration in verbal and written communication skills **Goal:** Patient will demonstrate understanding of health information received during prenatal visits.	
■ If no interpreter is available, refer to posters with pictures to explain routine care and procedures during the prenatal examination.	■ Posters put words into verbal images and are helpful in communicating information.
■ Provide handouts and brochures about prenatal care in the woman's native language.	■ Translated handouts provide information that the patient can refer to at home. This reinforces information discussed during the visit and helps the family understand what the woman will experience during the pregnancy and at each visit.
■ Use teaching models to demonstrate procedures. Teaching models may include plastic pelvis, knitted uterus, fetal model, breast model, birth control devices, ultrasound equipment, and so forth.	■ Visual aids help to communicate information during the examination.
■ Schedule an interpreter for subsequent prenatal visits.	■ If a family member cannot translate the health information to the patient, an independent translator is essential to ensure that information is accurately provided. When an interpreter is used (especially a family member), the nurse should be sure that the interpreter is translating information received from the woman and not simply answering the questions for her.
■ Refer the woman to prenatal classes taught in her own language, if available.	■ Prenatal classes taught in the woman's language enable her to receive health information that is easily understood, which will prove a better understanding of what she should expect during pregnancy, birth, and postpartum. Prenatal classes may also provide a social outlet for patients.
■ Involve other members of the healthcare team in planning and providing care.	■ Cultures vary in language, nonverbal expression, dietary habits, use of time, spatial expectations, and so forth. Use of medication and blood products may also be influenced by cultural beliefs. Social workers who are familiar with the patient's cultural beliefs, for example, may help the patient adjust to different healthcare practices while providing suggestions to ensure prenatal care that is more in line with the woman's cultural beliefs. Dietitians may help the woman plan meals that are aligned with her cultural practices while meeting the nutritional needs of pregnancy.
EXPECTED OUTCOME:	Effective communication occurs. The patient will gain an understanding of basic prenatal information as evidenced by using hand gestures, by pointing to pictures on posters and translated phrases on handouts, and through an interpreter, if one is available.

PROFESSIONALISM IN PRACTICE

In providing effective, culturally sensitive care, nurses can use the following strategies (College of Nurses of Ontario, 2009):

- Take actions that help break down language barriers.
- Explain the reasons for suggestions made to the woman or couple.
- Integrate folk treatments and Western medicine as much as possible.
- Enlist the family caretaker and others as needed.
- Get permission or consent to act from the right person.
- Provide printed materials in the patient's language.

Relief of the Common Discomforts of Pregnancy

Healthcare professionals often refer to the common discomforts of pregnancy as minor discomforts. These discomforts, however, are not minor to the pregnant woman.

Most of the discomforts of pregnancy are a result of physiologic and anatomic changes and are fairly specific to either the first trimester or to the second and third trimesters. Table 16-3 identifies the common discomforts of pregnancy, their possible causes, and the self-care measures that might relieve the discomfort.

TABLE 16-3 Health Promotion Education: Self-Care Measures for Common Discomforts of Pregnancy

DISCOMFORT	INFLUENCING FACTORS	SELF-CARE MEASURES
First Trimester		
Nausea and vomiting	Increased levels of human chorionic gonadotropin Changes in carbohydrate metabolism Emotional factors Fatigue	Avoid odors or causative factors. Eat dry crackers or toast before arising in morning. Have small but frequent meals. Avoid greasy or highly seasoned foods. Take dry meals with fluids between meals. Drink carbonated beverages.
Urinary frequency	Pressure of uterus on bladder in both first and third trimesters	Void when urge is felt. Increase fluid intake during the day. Decrease fluid intake *only* in the evening to decrease nocturia.
Fatigue	Specific causative factors unknown May be aggravated by nocturia due to urinary frequency	Plan time for a nap or rest period daily. Go to bed earlier. Seek family support and assistance with responsibilities so that more time is available to rest.
Breast tenderness	Increased levels of estrogen and progesterone	Wear well-fitting, supportive bra.
Increased vaginal discharge	Hyperplasia of vaginal mucosa and increased production of mucus by the endocervical glands due to the increase in estrogen levels	Promote cleanliness by daily bathing. Avoid douching, nylon underpants, and pantyhose; cotton underpants are more absorbent; powder can be used to maintain dryness if not allowed to cake.
Nasal stuffiness and nosebleed (epistaxis)	Elevated estrogen levels	May be unresponsive, but cool-air vaporizer may help; avoid use of nasal sprays and decongestants.
Ptyalism (excessive, often bitter salivation)	Specific causative factors unknown	Use astringent mouthwashes, chew gum, or suck hard candy.
Second and Third Trimesters		
Heartburn (pyrosis)	Increased production of progesterone, decreasing gastrointestinal motility and increasing relaxation of cardiac sphincter, displacement of stomach by enlarging uterus, thus regurgitation of acidic gastric contents into the esophagus	Eat small and more frequent meals. Use low-sodium antacids. Avoid overeating, fatty and fried foods, lying down after eating, and sodium bicarbonate.
Ankle edema	Prolonged standing or sitting Increased levels of sodium due to hormonal influences Circulatory congestion of lower extremities Increased capillary permeability Varicose veins	Practice frequent dorsiflexion of feet when prolonged sitting or standing is necessary. Elevate legs when sitting or resting. Avoid tight garters or restrictive bands around legs.
Varicose veins	Venous congestion in the lower veins that increases with pregnancy Hereditary factors (weakening of walls of veins, faulty valves) Increased age and weight gain	Elevate legs frequently. Wear supportive hose. Avoid crossing legs at the knees, standing for long periods, garters, and hosiery with constrictive bands.
Hemorrhoids	Constipation (see following discussion) Increased pressure from gravid uterus on hemorrhoidal veins	Avoid constipation. Apply ice packs, topical ointments, anesthetic agents, warm soaks, or sitz baths; gently reinsert into rectum as necessary.
Constipation	Increased levels of progesterone, which cause general bowel sluggishness Pressure of enlarging uterus on intestine Iron supplements Diet, lack of exercise, and decreased fluids	Increase fluid intake, fiber in the diet, and exercise. Develop regular bowel habits. Use stool softeners as recommended by physician.
Backache	Increased curvature of the lumbosacral vertebrae as the uterus enlarges Increased levels of hormones, which cause softening of cartilage in body joints Fatigue Poor body mechanics	Use proper body mechanics. Practice the pelvic-tilt exercise. Avoid uncomfortable working heights, high-heeled shoes, lifting heavy loads, and fatigue.
Leg cramps	Imbalance of calcium/phosphorus ratio Increased pressure of uterus on nerves Fatigue Poor circulation to lower extremities Pointing the toes	Practice dorsiflexion of feet to stretch affected muscle. Evaluate diet. Apply heat to affected muscles. Arise slowly from resting position.

TABLE 16-3 Health Promotion Education: Self-Care Measures for Common Discomforts of Pregnancy continued

DISCOMFORT	INFLUENCING FACTORS	SELF-CARE MEASURES
Second and Third Trimesters		
Faintness	Postural hypotension Sudden change of position causing venous pooling in dependent veins Standing for long periods in warm area Anemia	Avoid prolonged standing in warm or stuffy environments. Evaluate hematocrit and hemoglobin.
Dyspnea	Decreased vital capacity from pressure of enlarging uterus on the diaphragm	Use proper posture when sitting and standing. Sleep propped up with pillows for relief if problem occurs at night.
Flatulence	Decreased gastointestinal motility leading to delayed emptying time Pressure of growing uterus on large intestine Air swallowing	Avoid gas-forming foods. Chew food thoroughly. Get regular daily exercise. Maintain normal bowel habits.
Carpal tunnel syndrome	Compression of median nerve in carpal tunnel of wrist Aggravated by repetitive hand movements	Avoid aggravating hand movements. Use splint as prescribed. Elevate affected arm.

CLINICAL TIP

At each prenatal visit, focus your teaching on changes or possible discomforts the woman might encounter during the coming month and the next trimester. If the pregnancy is progressing normally, spend a few minutes describing her baby at this stage of development.

First Trimester

The dramatic hormonal changes of the first trimester account for many of the discomforts experienced in this period. These discomforts tend to abate by the beginning of the fourth month of pregnancy.

Nausea and Vomiting

Nausea and vomiting of pregnancy (NVP) are early, very common symptoms. These symptoms appear sometime after the first missed menstrual period and usually cease by the fourth missed menstrual period. Research indicates that approximately 70% to 85% of pregnant women experience NVP (American College of Obstetricians and Gynecologists [ACOG], 2004). Some women develop an aversion only to specific foods. Many experience nausea on arising in the morning, and others experience nausea only in the evening.

The exact cause of NVP is unknown but is believed to be multifactorial. Research has identified possible hormonal, metabolic, neurologic, and psychosomatic factors contributing to its development. Relaxation of the smooth muscle of the stomach contributes to this common discomfort (Johnson, Gregory, & Niebyl, 2007). Human chorionic gonadotropin (hCG) is often cited as a major factor because it begins to be present in the body at about the time symptoms of morning sickness usually begin, and hCG levels are subsiding when the discomfort of nausea and vomiting usually ends. Changes in carbohydrate metabolism, fatigue, and emotional factors may also play a role in the development of NVP.

HEALTH PROMOTION EDUCATION Treatment of nausea and vomiting is not always successful, but the symptoms can be reduced. To decrease the potential for development of hyperemesis gravidarum, ACOG (2004) recommends the initiation of prompt treatment for nausea and vomiting. It is beneficial for the healthcare professional to provide empathetic recognition of the pregnant woman's symptoms and distress as well as provide safe and effective treatment suggestions (Locock, Alexander, & Rozmovits, 2008; Wills & Forster, 2008).

The nurse needs to assess the onset, frequency, duration, and severity of symptoms and actual nutritional intake to be helpful in suggesting methods of relief or necessary medical care (Lacasse, Rey, Ferreira, et al., 2009; McParlin, Graham, & Robson, 2008). Physical assessment of the woman should include particular attention to skin color, texture, and turgor as well as vital signs and bowel sounds. For some women, simply avoiding the odor of certain foods or other conditions that precipitate the problem may relieve nausea. If nausea occurs most frequently during early morning, the woman may find it helpful to eat dry crackers or toast before arising and to rise from bed slowly. Rising slowly and avoiding sudden position changes throughout the day may also help prevent nausea due to hypotensive episodes. In addition, the nurse can suggest that the woman avoid brushing her teeth right after eating, because this, too, may trigger vomiting. Evidence suggests that a pregnant woman should start a multivitamin before reaching 6 weeks' gestation to reduce the effects of nausea and vomiting (ACOG, 2004).

Generally, it is helpful to eat small meals every 2 to 3 hours during the day and to avoid greasy or highly seasoned foods. Food may be salted to taste. The salt increases the palatability of the food and replaces any chloride lost when the woman vomits hydrochloric acid from the stomach. Eating dry meals and taking all liquids, including soups, between meals may help some women by avoiding overdistention of the stomach. Sudden changes in blood sugar levels can be avoided if the small meals are high in low-fat protein or complex carbohydrates. Some women find that slowly sipping herbal tea (peppermint, chamomile, or spearmint) or a carbonated beverage helps reduce nausea.

In addition to common self-care measures, certain complementary or alternative therapies may be useful. For example, many women find that acupressure applied to pressure points in the wrists is helpful (Figure 16-3 ■). ACOG (2004) reports that the

Case Study: First Trimester Patient

Figure 16-3 ■ Acupressure wristbands are sometimes used to help relieve nausea during early pregnancy.

Source: Patrick Watson/Pearson Education.

evidence supporting or refuting the use of acupressure for nausea and vomiting of pregnancy is unclear. Ginger may also relieve NVP. Ginger, long used in traditional Chinese medicine for a variety of maladies ranging from gastrointestinal problems to headaches, is a popular, effective, and safe treatment for NVP (Ozgoli, Goli, & Simbar, 2009). Pyridoxine (vitamin B_6) alone or in combination with doxylamine (Unisom), an over-the-counter antihistamine, is considered a first-line treatment. See Research Evidence in Practice.

Antihistamine H_1 receptor blockers, benzamines, and phenothiazines are considered safe and effective for treating refractory cases. In very severe cases, methylprednisolone, a steroid, may be used, but as a last resort because it poses a potential risk to the fetus (ACOG, 2004).

Although some nausea is common, the woman who suffers from extreme nausea coupled with vomiting requires further assessment. She should be advised to contact her care provider if she vomits more than once per day or shows signs of dehydration, such as dry mouth, decreased amounts of highly concentrated urine, and the like. In such cases, the physician or certified nurse-midwife (CNM) may order antiemetics. However, antiemetics should be avoided if at all possible during the first trimester because of the danger of teratogenic effects on embryo development.

Nausea and vomiting symptoms generally decrease by the 16th week of pregnancy. If they do not, hyperemesis gravidarum, which occurs in 1% to 3% of pregnancies must be considered (Johnson et al., 2007). Hyperemesis symptoms include weight loss, dehydration, and nutrition imbalance (Katz, 2008).

RESEARCH EVIDENCE IN PRACTICE: Ginger as a Treatment for the Nausea and Vomiting of Pregnancy

CLINICAL QUESTIONS

Is ginger an effective treatment for the nausea and vomiting of early pregnancy? Is the use of ginger free of side effects for mother and baby?

RESEARCH EVIDENCE

The most common unpleasant symptom that presents during early pregnancy is nausea and vomiting, particularly upon arising. This condition can have effects on family and personal life, as well as implications for work life. However, most of the medications used to treat nausea and vomiting are not safe to use in early pregnancy, and so nonpharmacologic treatments are desirable. A large number of women—more than 75% in one large study—use alternative therapies during pregnancy, frequently without informing their physicians or midwives. However, many of these therapies have not been tested for efficacy or safety.

Ginger has demonstrated a positive effect in calming the gastrointestinal system and has been posed as an alternative to traditional medications in the treatment of nausea and vomiting. It is classified as a nutritional supplement by the Food and Drug Administration and is listed as a safe herbal preparation.

Vitamin B_6 has also been proposed as a potential treatment for nausea and vomiting, and it is considered a nutritional supplement that is safe to use during pregnancy. However, neither ginger nor vitamin B_6 has been thoroughly evaluated as to its relative effectiveness, the optimal dosage for symptom control, or the most appropriate form of administration.

In one strong randomized trial, ginger was more effective than vitamin B_6 in treating the nausea and vomiting of early pregnancy, although both were effective in reducing episodes of vomiting. A separate randomized trial focused on the optimal daily dosage. Women who ingested 250 mg of ginger, administered in capsules 4 times a day, had fewer episodes of vomiting and less reported nausea than women who had smaller doses or who were given a placebo. No adverse effects were reported for mothers or babies who used either ginger or vitamin B_6.

WHAT QUESTIONS REMAIN UNANSWERED?

Is it necessary to administer the ginger in separate doses throughout the day, or could a single dose be effective? If a woman chooses to use vitamin B_6 instead of ginger, what is the optimal dosage?

WHAT IS BEST PRACTICE?

Women who are experiencing nausea and vomiting in early pregnancy can be encouraged to take 250 mg ginger capsules 4 times daily to minimize their symptoms. They can be reassured that the treatment will have no ill effects on their babies. Vitamin B_6 may also be recommended to control vomiting but with the caution that it may be less effective in controlling nausea than ginger.

CRITICAL THINKING

What are alternative ways of ingesting ginger if capsules or repetitive dosing is not effective? How can the pregnant woman's diet be modified to ingest both ginger and vitamin B_6 naturally and safely?

Urinary Frequency

Urinary frequency, a common discomfort of pregnancy, occurs early in pregnancy and again during the third trimester because of the pressure of the enlarging uterus on the bladder. Approximately 40% to 50% of pregnant women experience urinary incontinence, particularly, in the third trimester (Johnson et al., 2007). Although the glomerular filtration rate increases in pregnancy, it does not cause a significant increase in urine output. Urinary frequency is considered normal during the first and third trimesters; however, the nurse should advise the woman to contact her healthcare provider if she experiences any signs of bladder infection such as painful urination (dysuria), burning with voiding, or blood in the urine (hematuria).

HEALTH PROMOTION EDUCATION There are no methods of decreasing the frequency of urination in pregnancy. Fluid intake should never be decreased to prevent frequency. The woman should be encouraged to maintain an adequate fluid intake: at least 2000 ml per day. She should also be encouraged to empty her bladder frequently (approximately every 2 hours while awake).

Frequent bladder emptying helps decrease the incidence of leakage of urine. Because frequency often results in several trips to the bathroom each night, it is important to remind the woman to consider safety factors in the home, such as a clear path to the bathroom, the use of a night-light, and the like. The woman who leaks urine may choose to wear pantyliners during the day. If she does, she should change them as soon as they become damp to avoid perineal excoriation and to avoid contamination of the perineum from the rectal area if the pads move back and forth as she walks. Tightening of the pubococcygeus muscle, which supports internal organs and controls voiding, can help maintain good perineal tone. This procedure, known as Kegel exercise, is discussed later in this chapter.

Fatigue

Marked fatigue, often out of proportion to the woman's normal pattern, is so common in early pregnancy that it is considered a presumptive sign of pregnancy. The sleep-inducing effects of progesterone may play a role in the development of this sign (Cunningham et al., 2010). It is aggravated if the woman has to arise several times each night because of urinary frequency. Typically, it resolves soon after the end of the first trimester.

HEALTH PROMOTION EDUCATION Scheduling activities to allow for napping is helpful. Women should be encouraged to use every opportunity available to rest, including going to bed earlier in the evening. The woman's partner needs to understand that the fatigue is normal and will subside. The partner can be encouraged to assume more home responsibilities to support the woman and enable her to rest.

Breast Tenderness

Sensitivity of the breasts occurs early and continues throughout the pregnancy. Increased levels of estrogen and progesterone contribute to the soreness and tingling felt in the breasts and to the increased sensitivity of the nipples.

HEALTH PROMOTION EDUCATION A well-fitting, supportive brassiere gives the most relief for this discomfort. The qualities of a properly supportive brassiere are discussed in "Breast Care" later in this chapter.

Increased Vaginal Discharge

Increased whitish vaginal discharge, called **leukorrhea**, is common in pregnancy. It occurs as the result of hyperplasia of vaginal mucosa and increased production of mucus by the endocervical glands. In addition, the increased acidity of the secretions encourages the growth of *Candida albicans,* and the woman is thus more susceptible to monilial vaginitis.

HEALTH PROMOTION EDUCATION Cleanliness is important in preventing excoriation and vaginal infections. Daily bathing is adequate; douching is avoided during pregnancy. The woman should avoid nylon underpants and pantyhose because they retain heat and moisture in the genital area; absorbent cotton underpants should be worn to help prevent problems. The nurse can advise the pregnant woman to report any change in vaginal discharge, any irritation in the perineal area, and intense vaginal itching. These changes frequently indicate vaginal infections.

Nasal Stuffiness and Epistaxis

Once pregnancy is well established, elevated estrogen levels may produce edema of the nasal mucosa, resulting in nasal stuffiness, nasal discharge, and obstruction (rhinitis of pregnancy). *Epistaxis* (nosebleed) may also result.

HEALTH PROMOTION EDUCATION Cool air vaporizers and normal saline nose drops may be helpful. However, the problem is often unresponsive to treatment. Women experiencing these problems find it difficult to sleep and may resort to medicated nasal sprays and decongestants to relieve the problem. Such interventions may provide relief initially but can actually increase the nasal stuffiness over time. The use of any medication in pregnancy should be avoided if possible.

Ptyalism

Ptyalism is a rare discomfort of pregnancy in which excessive, often bitter, saliva is produced. Its cause has not been established, although it may be related to the ingestion of starch (Cunningham et al., 2010). Effective treatments are limited.

HEALTH PROMOTION EDUCATION Using astringent mouthwashes, chewing gum, or sucking on hard candy may minimize the problem of ptyalism. It may also be helpful to reduce or limit starch intake.

Second and Third Trimesters

It is difficult to classify discomforts as specifically occurring in the second or third trimester because their timing varies because of individual variations in women. The symptoms discussed in this section usually do not appear until the third trimester in primigravidas but may occur earlier with each succeeding pregnancy.

Heartburn (Pyrosis)

Heartburn is the regurgitation of acidic gastric contents into the esophagus. It creates a burning or irritating sensation in the esophagus and radiates upward, sometimes leaving a bad taste

Through the Eyes of a Nurse Physical Symptoms in the First Trimester of Pregnancy

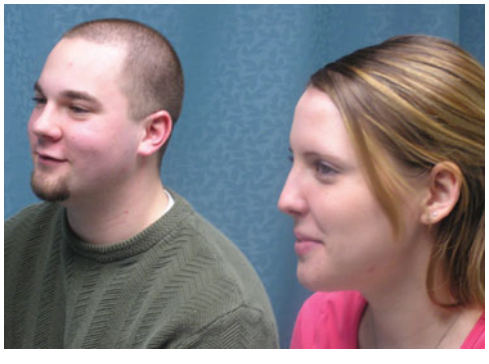
Family's Experience

"I know that each pregnancy is different and some women have nausea and some don't but I feel so sick! I have a lot of nausea and feel awful most of the time. I am not really worried because I haven't lost weight, and I only throw up occasionally, but I would like to find better ways of handling this. I eat dry crackers in the morning and during the day but that only helps a little."

Nurse's Response

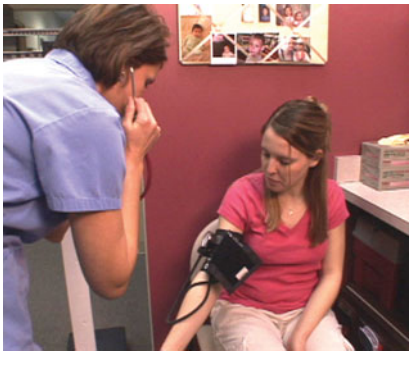
"Nausea and vomiting frequently occur in the first trimester of pregnancy as a result of changes in the gastrointestinal system as well as changes in carbohydrate metabolism. The nausea and vomiting commonly begin at 6 weeks and can continue another 6 to 12 weeks. Try small, frequent meals, avoiding hot and spicy foods. The use of antiemetic medication has been shown to reduce nausea. You might want to discuss that with your nurse-midwife. Some studies have also shown that vitamin B_6 reduces the severity of vomiting. Other studies have shown that ginger reduces nausea and vomiting, so you may want to consider taking that. We have also found that some women have found relief with acupressure bands. You can purchase these bands at any pharmacy. I would try these things and see if they help.

"We are monitoring your weight at each visit and checking your urine for ketones. You actually gained a pound and your urine is negative for ketones, so those are both good signs. Please let us know if the nausea and vomiting become so severe that you are unable to keep anything down within a 24-hour period. If you have questions or concerns, you can call us."



Nurse's Actions and Rationale

The nurse explains the physiologic process that leads to nausea and provides evidence-based information on ways of relieving or reducing nausea and vomiting (ACOG, 2004). As discussed in this chapter, interventions such as ginger, acupressure wrist bands, and vitamin B_6 are often helpful. The nurse also provides reassurance and explains how the woman will be monitored to ease the family's anxiety. Finally the nurse reassures the woman that she can call if questions arise and reviews the parameters for the woman to follow as to when to call the healthcare provider.



in the mouth. Heartburn appears to be primarily a result of the displacement of the stomach by the enlarging uterus. The increased production of progesterone in pregnancy, decreases in gastrointestinal motility, and relaxation of the cardiac (esophageal) sphincter also contribute to heartburn.

HEALTH PROMOTION EDUCATION Heartburn is aggravated by overeating, ingesting fatty and fried foods, and lying down soon after eating. The woman should, therefore, avoid these situations. The woman should be encouraged to drink an adequate amount of fluid (8 to 10 8-oz glasses) each day and to eat smaller, more frequent meals to accommodate the decreased size of her stomach. Good posture is important because it allows more room for the stomach to function. Some women choose complementary and alternative medicine (CAM) approaches to relieving their heartburn (see chapter 3 ∞ for more information about CAM).

The caregiver may recommend the liquid form of a low-sodium antacid, such as aluminum hydroxide (Amphojel) or a combination of aluminum hydroxide and magnesium hydroxide (Maalox). Because aluminum alone tends to cause constipation, and magnesium alone is associated with diarrhea, the combined approach is more desirable (Katz, 2008). Sodium bicarbonate (baking soda) and Alka-Seltzer should be avoided because of the potential for electrolyte imbalance.

If maternal heartburn is severe, not relieved by antacids, and accompanied by gastrointestinal reflux, an antisecretory agent (H_2-blocker) such as ranitidine (Zantac), cimetidine (Tagamet), or omeprazole (Losec) may be necessary. Research to date has not linked these medications with an excessive risk of birth defects, preterm birth, or intrauterine growth restriction.

Ankle Edema

Most women experience ankle edema in the last part of pregnancy because of the increasing difficulty of venous return from the lower extremities. Prolonged standing or sitting and warm weather increase the edema. It is also associated with varicose veins. Ankle edema becomes a concern only when accompanied by hypertension or proteinuria or when the edema is not postural in origin.

HEALTH PROMOTION EDUCATION The aggravating conditions just mentioned should be avoided. If the woman has to sit or stand for long periods, frequent dorsiflexion of her feet will help contract muscles, thereby squeezing the fluid back into circulation. The pregnant woman should not wear tight garters or other restrictive bands around her legs. During rest periods, the woman should elevate her legs and hips as described in the following section on varicose veins.

Varicose Veins

Varicose veins are a result of weakening of the walls of veins or faulty functioning of the valves. Poor circulation in the lower extremities predisposes the woman to varicose veins in the legs and thighs, as does prolonged standing or sitting. The weight of the gravid uterus on the pelvic veins aggravates the development of varicosities in the legs and pelvic area by preventing good venous return. Increased maternal age, excessive weight gain, a large fetus, heredity, and multiple gestation can all contribute to the problem. Symptoms may range from mildly unpleasant cosmetic effects to chronic pain and superficial thrombophlebitis.

Vulvar varicosities may also be a problem in pregnancy, although they are less common. Varicosities in the vulva and perineum cause aching and a sense of heaviness.

Treatment of varicose veins is not generally recommended during pregnancy (Cunningham et al., 2010). The woman should be aware that treatment might be needed after pregnancy because the problem will be aggravated by a succeeding pregnancy.

HEALTH PROMOTION EDUCATION Regular exercise, such as swimming, cycling, or walking, promotes venous return, which helps prevent varicosities. Avoiding factors that contribute to venous stasis is also helpful. The pregnant woman should avoid standing or sitting for prolonged periods. She should also avoid crossing her legs at the knees because of the pressure on her veins. She should not wear garters or hosiery with constricting bands, such as knee-high hose. However, supportive hose or elastic stockings may be extremely helpful. Supportive hose should be put on in the morning and should be washed daily with soap and warm water to help retain elasticity.

The pregnant woman should be encouraged to elevate her legs level with her hips when she sits. She can enhance comfort by supporting the entire leg rather than simply propping her feet up on a stool, which may lead to hyperextension of the knees. The woman who sits or stands for long periods should walk around frequently to promote venous return to the heart. She can also be encouraged to dorsiflex her feet, hold the position for 3 seconds, then release, with 8 to 10 repetitions several times each day. Venous return is most effectively promoted if the woman lies down with her feet elevated several times a day. To avoid difficulty related to pressure of the uterus on the vena cava, the woman can lie with her legs elevated on pillows and a pillow placed under one hip to displace the uterus to one side (Figure 16-4 ■).

Wearing one of the foam rubber commercial products that is placed across the perineum and held in place by a sanitary pad–type belt can provide support for vulvar varicosities (Cunningham et al., 2010). Elevation of only the legs aggravates vulvar varicosities by creating stasis of blood in the pelvic area. Therefore, it is important that the pelvic area also be elevated to promote venous drainage into the trunk of the body. More than one firm pillow under the hips may be needed to accomplish this elevation. Near the end of pregnancy, this position may be extremely awkward; the woman may best relieve uterine pressure on the pelvic veins by resting on her side. Blocks may also be placed under the foot of her bed to elevate it slightly.

Flatulence

Flatulence results from decreased gastrointestinal motility, leading to delayed emptying, and from pressure on the large intestine by the growing uterus. Air swallowing may also contribute to the problem.

HEALTH PROMOTION EDUCATION The woman should be advised to avoid gas-forming foods and to chew her food thoroughly. Regular bowel habits and exercise can also decrease flatulence.

Figure 16-4 ■ Swelling and discomfort from varicosities can be decreased by lying down with the legs and one hip elevated (to avoid compression of the vena cava).

Hemorrhoids

Hemorrhoids are varicosities of the veins in the lower end of the rectum and anus. During pregnancy, the gravid uterus presses on the veins and interferes with venous circulation. As the pregnancy progresses, the straining that accompanies constipation can contribute to the development of hemorrhoids.

Hemorrhoids may not bother some women until the second stage of labor, when the hemorrhoids appear as they push just before birth. Hemorrhoids that occur in pregnancy or at birth usually become asymptomatic after the early postpartum period.

Symptoms of hemorrhoids include itching, swelling, pain, and bleeding. Internal hemorrhoids are located above the anal sphincter and are responsible for bleeding, usually with defecation. They are not usually painful unless they protrude from the anus. External hemorrhoids are located outside the anal sphincter. They are not usually the source of bleeding or pain; however, thrombosis of the hemorrhoids can occur, and in that case they become extremely painful. The thrombosis may resolve itself in 24 hours, or the physician can treat it by incising and evacuating the blood clot. Women who have hemorrhoids before pregnancy frequently experience more difficulties with them during pregnancy.

HEALTH PROMOTION EDUCATION Relief can be achieved by gently and carefully reinserting the hemorrhoids. The woman lies on her side or in the knee to chest position. She places some lubricant on her finger and presses against the hemorrhoids, pushing them inside. She holds them in place for 1 to 2 minutes and then gently withdraws her finger. The anal sphincter should then hold them inside the rectum. The woman will find it especially helpful if she can then maintain a side-lying (Sims') position for a time, so this procedure is best done before bed or before a daily rest period.

Avoiding constipation is important in preventing or relieving the discomfort of hemorrhoids. Relief measures for existing hemorrhoid symptoms include ice packs, use of topical ointments and anesthetic agents, and warm soaks.

The woman should contact her healthcare provider if the hemorrhoids become hardened and noticeably tender to touch. Rectal bleeding that is more than spotting following defecation should also be reported.

Constipation

Conditions in pregnancy that predispose the woman to constipation include general bowel sluggishness caused by increased progesterone and steroid metabolism; displacement of the intestines, which increases with the growth of the fetus; and oral iron supplements, which most pregnant women need.

HEALTH PROMOTION EDUCATION Increased fluid intake (at least 2000 ml/day), adequate roughage or bulk in the diet, regular bowel habits, and adequate daily exercise can often maintain good bowel function in women who have not had previous problems. The addition of dietary fiber, such as Metamucil, or surface active agents, such as Colace, can decrease constipation (Johnson et al., 2007). Some women find it helpful to drink a warm beverage or glass of prune juice in the morning. Women should leave sufficient time following breakfast so that the natural action of the body will produce defecation.

In severe or preexisting cases of constipation, the woman may need a mild laxative, stool softeners, or suppositories as recommended by her caregiver.

Backache

Over 50% of pregnant women experience backache during pregnancy (Johnson et al., 2007). Backache is due primarily to the increased curvature of the lumbosacral vertebrae that occurs as the uterus enlarges and becomes heavier. Circulating steroid hormones cause a softening and relaxation of pelvic joints, contributing to the problem. If the woman does not learn how to correct this curvature, the strain on the muscles and ligaments will cause backache. Low backache can occur at any point during pregnancy.

HEALTH PROMOTION EDUCATION An exercise called the pelvic tilt can help restore proper body alignment. As the anterior pelvis is tilted upward, the curvature of the back is automatically decreased, relieving much of the discomfort. There are many exercises that can be done by the pregnant woman to relieve symptoms of low back pain (Jeffcoat, 2008). See "Exercises to Prepare for Childbirth" later in this chapter.

The use of proper posture and good body mechanics throughout pregnancy is important. The pregnant woman

Figure 16-5 ■ When picking up objects from floor level or lifting objects, the pregnant woman must use proper body mechanics.

should avoid bending over to lift or pick up items from the floor. The strain is felt in the muscles of the back. Leg muscles should be used to do the work instead. The woman can keep her back straight by bending her knees to lower her body into the squatting position (Figure 16-5 ■). She should place her feet 12 to 18 inches apart to maintain body balance. When lifting a heavy object, such as a child, she should place one foot flat on the floor, slightly in front of the other foot, and lower herself to the other knee. The object is held close to her body for lifting. This same principle of keeping the back straight and bending the knees applies when the woman sits down or gets out of a chair. Work heights that require constant bending can contribute to backache and should be adjusted as necessary.

A pendulous abdomen contributes to backache by increasing the curvature of the spine. Although maternity support belts have been typically used to decrease low back pain in pregnancy, there is inadequate evidence to conclude that wearing them is effective (Ho, Yu, Lao, et al., 2009). The use of a supportive maternity girdle is discussed later in this chapter, as is the role of high-heeled shoes in increasing the lumbosacral curvature.

Leg Cramps

Nearly half of pregnant women experience recurrent, painful muscle spasms in the lower extremities (Katz, 2008).They occur most frequently at night after the woman has gone to bed but may occur at other times. Extension of the foot can often cause leg cramps. The nurse should warn the pregnant woman not to extend the foot during childbirth preparation exercises or during rest periods.

Figure 16-6 ■ The expectant father can help relieve the woman's painful leg cramps by flexing her foot and straightening her leg.

HEALTH PROMOTION EDUCATION The woman can achieve immediate relief of the muscle spasm by stretching the muscle. With the woman lying on her back, another person can press the woman's knee down to straighten her leg while pushing her foot toward her leg (Figure 16-6 ■). The woman may also stand and put her foot flat on the floor. Massage and warm packs can be used to alleviate discomfort from leg cramps. Stretching exercises before bedtime may help prevent leg cramps.

Faintness

Many pregnant women occasionally feel faint, especially in warm, crowded areas. Faintness is caused by a combination of changes in the blood volume and postural hypotension due to venous pooling of blood in the dependent veins. Sudden change of position or standing for prolonged periods can cause this sensation, and fainting can occur.

HEALTH PROMOTION EDUCATION The nurse should first be certain that the pregnant woman understands the symptoms of faintness. These include slight dizziness, a "swirling" or "floating" sensation, and a decreased ability to hear or focus attention. If a woman feels faint from prolonged standing or from being in a warm, crowded room, she should sit down and lower her head between her knees. If this procedure does not help, the woman should be assisted to an area where she can lie down and get fresh air. When arising from a resting position, she should move slowly. Women whose jobs require standing in one place for long periods should march in place regularly to increase venous return from the legs.

Shortness of Breath

Shortness of breath occurs as the uterus rises into the abdomen and causes pressure on the diaphragm. This problem worsens in the last trimester as the enlarged uterus presses directly on the diaphragm, decreasing vital capacity. The primigravida experiences considerable relief from shortness of breath in the last few weeks of pregnancy, when **lightening** occurs, and the fetus and uterus move down in the pelvis. Because the multigravida does not usually experience lightening until labor, shortness of breath will continue throughout her pregnancy.

HEALTH PROMOTION EDUCATION During the day, sitting straight in a chair and using proper posture when standing help provide relief. If distress is great at night, the woman can sleep propped up in bed with several pillows behind her head and shoulders.

Difficulty Sleeping

From 12 weeks of pregnancy into the postpartum period, sleep disturbances are common. The pregnant woman may have difficulty falling asleep or she may wake up throughout the night, resulting in fewer overall hours of sleep. Although the pregnant woman may experience difficulty sleeping for many of the same psychologic reasons as the nonpregnant woman, many physical factors also contribute to this problem. The enlarged uterus may make it difficult to find a comfortable position for sleep, and an active fetus may aggravate the problem. The other discomforts of pregnancy such as urinary frequency, shortness of breath, and leg cramps may also be contributing factors.

HEALTH PROMOTION EDUCATION The nurse should conduct a thorough assessment of the sleep habits of the pregnant woman and offer information about habits and activities that help promote restful sleep. The pregnant woman may find it helpful to drink a warm (caffeine-free) beverage before bed and may benefit from a soothing backrub given by her partner or a family member. Pillows may be used to provide support for her back, between her legs, or for her upper arm when she lies on her side. Relaxation techniques may also help. The woman should avoid caffeine products, stimulating activity, and sleeping medication.

Restless Leg Syndrome

Approximately 25% of pregnant women develop restless leg syndrome (RLS), particularly in the second half of pregnancy. RLS is characterized by the need to move the legs and tingling or other sensations in the calves, usually as the woman falls asleep (Katz, 2008).

HEALTH PROMOTION EDUCATION RLS has been associated with iron deficiency anemia, so iron supplements may decrease leg restlessness. Also, to avoid increasing RLS symptoms, pregnant women should avoid caffeine products later in the day (Katz, 2008).

Round Ligament Pain

As the uterus enlarges during pregnancy, the round ligaments stretch, hypertrophy, and lengthen as the uterus rises up in the abdomen. Round ligament pain is attributed to this stretching.

HEALTH PROMOTION EDUCATION The woman may feel concern when she first experiences round ligament pain because it is often intense and causes a "grabbing" sensation in the lower abdomen and inguinal area. The nurse should warn women of this possible discomfort. Few treatment measures really alleviate this discomfort, but understanding the cause will help decrease anxiety. Once the caregiver has ascertained that the cause of the discomfort is not related to a medical complication such as appendicitis or gallbladder disease, the woman may find that a heating pad applied to the abdomen brings some relief. She may also benefit from bringing her knees up on her abdomen.

Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS), characterized by numbness and tingling of the hand near the thumb, occurs in about 25% to 50% of pregnant women (Johnson et al., 2007). It is caused by compression of the median nerve in the carpal tunnel of the wrist. The syndrome is commonly bilateral but may be more pronounced in the dominant hand and is characterized by numbness, tingling, or burning in the fleshy part of the palm near the thumb. The syndrome is aggravated by repetitive hand movements, such as typing/keyboarding, and may disappear following birth. Treatment involves splinting, avoiding aggravating movements, and in severe cases injecting steroids into the carpal tunnel. Surgery is indicated in severe cases.

HEALTH PROMOTION EDUCATION Although the condition is not preventable, the woman should be advised to avoid aggravating activities and use her splint as directed.

Health Promotion Education During Pregnancy

The pregnant woman is faced with the important responsibility of maintaining her health not only for her sake but also for the sake of her fetus. Nurses can help promote maternal and fetal well-being by providing expectant couples with accurate and complete information about health behaviors that can affect pregnancy and childbirth. Some women prefer to gather their own information. The nurse can refer these women to a variety of sources, including the National Women's Health Information Center, which is sponsored by the U.S. Public Health Service's Office on Women's Health.

Fetal Activity Monitoring

Many caregivers encourage pregnant women to monitor their unborn child's well-being by regularly assessing fetal activity beginning at 28 weeks' gestation. Research has documented a good positive correlation between maternal perception of fetal movement and fetal movement confirmed by ultrasound monitoring (Cunningham et al., 2010). Vigorous fetal activity generally provides reassurance of fetal well-being, whereas a marked decrease in activity or cessation of movement may indicate possible fetal compromise requiring immediate evaluation. Sound, drugs, cigarette smoking, fetal sleep state, and time of day affect fetal activity. At times, a healthy fetus may be minimally active or inactive.

A variety of methods for assessing fetal activity have been developed. They focus on having the woman keep a **fetal movement record (FMR)**, such as the Cardiff Count-to-Ten Method (Figure 16-7 ■). An FMR is a noninvasive technique that enables the pregnant woman to monitor and record fetal well-being easily and without expense. The woman's perceptions of fetal movements are influenced by her activity level, medications, and the presence of obesity (Johnson et al., 2007). Her commitment to completing a movement record may be increased when the woman understands the purpose of the as-

Sample Cardiff Count–to–Ten scoring card

Month: _____ Week of gestation at beginning of month: _____

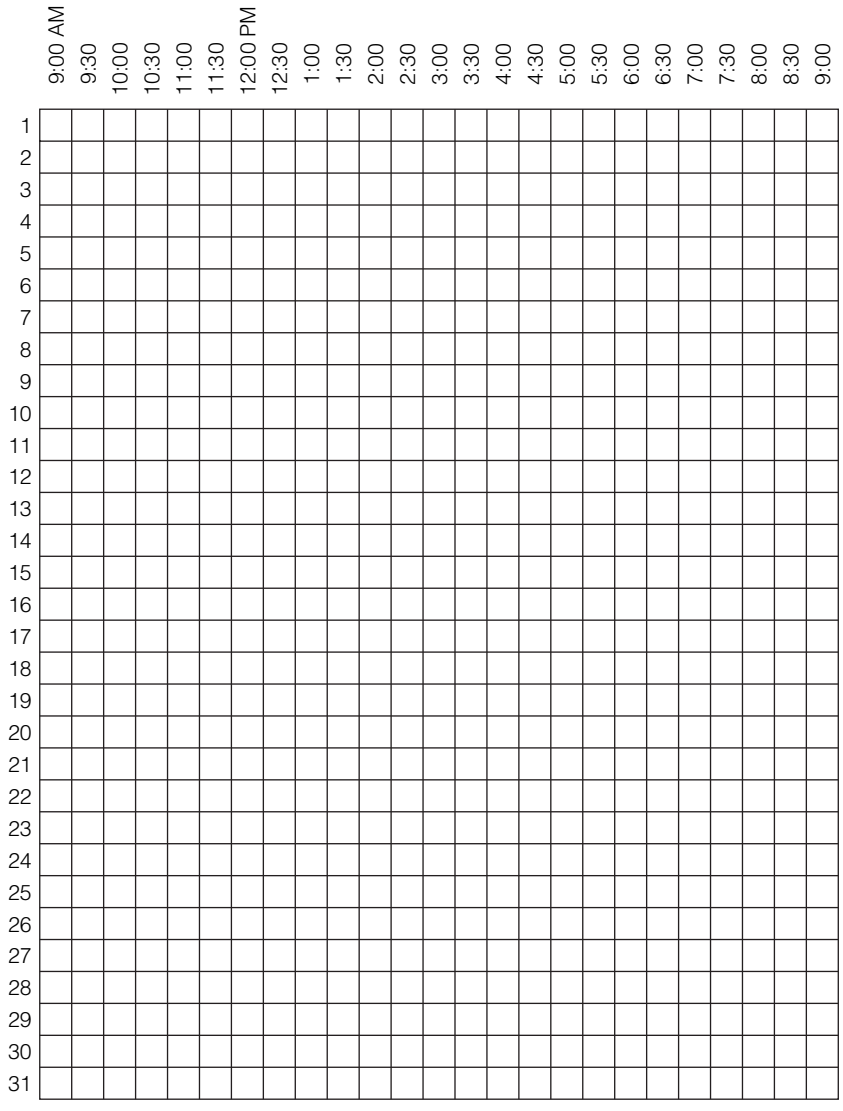


Figure 16-7 ■ An adaptation of the Cardiff Count-to-Ten scoring card for fetal movement assessment.

sessment, how to complete the form, whom to call with questions, and what to report and has the opportunity for follow-up during each visit. See Patient Teaching: What to Tell the Pregnant Woman About Assessing Fetal Activity.

> *"I like doing the fetal movement counts each day. It gives me a "time out," when I can focus on my baby and really enjoy this special time in my life."*

Breast Care

Whether the pregnant woman plans to formula-feed or breast-feed her infant, proper support of the breasts is important to promote comfort, retain breast shape, and prevent back strain, particularly if the breasts become large and pendulous. The sensitivity of the breasts in pregnancy is also relieved by good support.

A well-fitting, supportive brassiere has the following qualities:

- The straps are wide and do not stretch (elastic straps soon lose their tautness because of the weight of the breasts and frequent washing).
- The cup holds all breast tissue comfortably.
- The brassiere has tucks or other devices that allow it to expand, thus accommodating the enlarging chest circumference.
- The brassiere supports the nipple line approximately midway between the elbow and shoulder. At the same time, the brassiere is not pulled up in the back by the weight of the breasts.

Cleanliness of the breasts is important, especially as the woman begins producing colostrum. Colostrum that crusts on

PATIENT TEACHING What to Tell the Pregnant Woman About Assessing Fetal Activity

PATIENT GOALS At the completion of the teaching, the woman will be able to:

1. Discuss the types of fetal assessment methods, reasons for assessment, how to accomplish the assessment, and methods of record keeping.
2. Demonstrate the use of a fetal movement record.
3. Identify resources to call if questions arise.
4. Agree to bring the fetal movement record to each prenatal visit.

TEACHING PLAN

Content	Teaching Method
Explain that fetal movements are first around 18 weeks' gestation.	Describe procedures and demonstrate how to assess fetal movement.
From that time the fetal movements get stronger and easier to detect.	Sit beside the woman and show her how to place her hand on the fundus to feel fetal movement.
A slowing or stopping of fetal movement may be an indication that the fetus needs some attention and evaluation.	
Explain the procedure for the Cardiff Count-to-Ten method or for the Fetal Movement Record (FMR). For both methods, advise the woman to:	Provide a written teaching sheet for the woman's use at home.
■ Beginning at about 28 weeks' gestation, keep a daily record of fetal movement.	Demonstrate how to record fetal movements on the Cardiff Count-to-Ten scoring card or on FMR.
■ Try to begin counting at about the same time each day, about 1 hour after a meal if possible.	Watch the woman fill out the record as examples are provided. Encourage her to complete the record each day and bring it with her to each prenatal visit. Assure her that the record will be discussed at each prenatal visit, and questions may be addressed at the time if desired.
■ Lie quietly in a side-lying position.	
Using the Cardiff card, have the woman place an X for each fetal movement until she has recorded 10. Movement varies considerably, but most women feel fetal movement at least 10 times in 3 hours (see Figure 16-7).	
Using the FMR have the woman count 3 times a day for 20 to 30 minutes each session. If there are fewer than 3 movements in a session, have the woman count for 1 hour or more.	
Explain when to contact the care provider:	Provide the woman with a name and phone number in case she has further questions.
■ If there are fewer than 10 movements in 3 hours	
■ If overall the fetus's movement is slowing, and it takes much longer each day to note 10 movements	
■ If there are no movements in the morning	
■ If there are fewer than 3 movements in 8 hours	

Evaluation	Documentation
Evaluate learning by having the woman explain the method and by asking the woman to fill the card in using a fictitious situation. At each prenatal visit review the expectant woman's record. Review of the record provides opportunities for questions and clarification.	Document the information given to the woman, including specifics on when to contact her healthcare provider (specify if written instructions were provided in addition to verbal ones) and the type of teaching method used. Indicate if the woman practiced counting fetal movements. Document the woman's verbalization of understanding and your clarification of any information.

the nipples should be removed with warm water. The woman planning to breastfeed should not use soap on her nipples because of its drying effect.

Some women have flat or inverted nipples. True nipple inversion, which is rare, is usually diagnosed during the initial antepartal assessment. Occasionally, a nipple appears inverted at all times. In other cases, the nipple appears normal initially, but pressure on the areola with the examiner's thumb and finger causes the nipple to retract. The normal or flat nipple protrudes when this is done (Figure 16-8 ■). Breast shields designed to correct inverted nipples can be effective but some women gain little or no benefit from them (Figure 16-9 ■).

More information on breastfeeding can be found on the Web sites of La Leche League, the American Academy of Pediatrics, the National Organization of Mothers of Twins Club, and other breastfeeding-focused sites.

Clothing

Traditionally, maternity clothes have been constructed with fuller lines to allow for the increase in abdominal size during

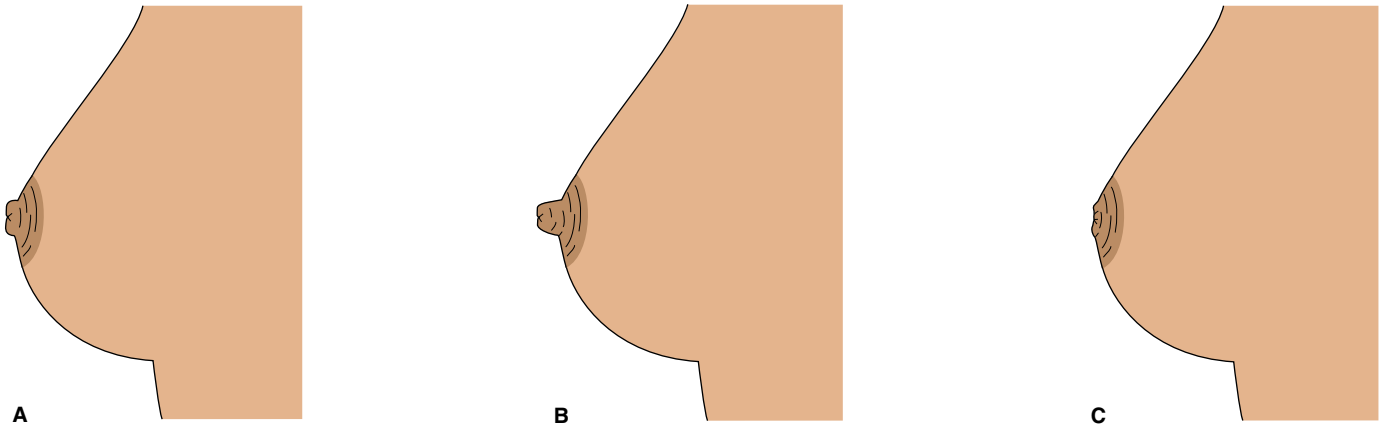

Figure 16-8 ■ A. When not stimulated, normal and inverted nipples often look alike. B. When stimulated, the normal nipple protrudes. C. When stimulated, the inverted nipple retracts. However, great variation exists; in some women, for example, one or both nipples always appear inverted, even when not stimulated.

Figure 16-9 ■ This breast shield is designed to increase the protractility of inverted nipples. Worn the last 3 to 4 months of pregnancy, they exert gentle pulling pressure at the edge of the areola, gradually forcing the nipple through the center of the shield. They may be used after birth if necessary.

Source: Photographer, Elena Dorfman.

pregnancy. Skirts and slacks have soft elastic waistbands and a stretchable panel over the abdominal area. However, maternity wear has changed in recent years and now also includes clothes that are more fitted, with little attempt to hide the pregnant abdomen. Maternity clothing is expensive, however, and is worn for a relatively short time. Women can economize by sharing clothes with friends, sewing their own garments, or buying used maternity clothing.

Clothing should be loose and nonconstricting. Women with large, pendulous abdomens may benefit from a well-fitting, supportive girdle. Without this support, the pendulous abdomen increases the curvature of the spine and is a source of backache and general discomfort. Tight leg bands on girdles should be avoided.

High-heeled shoes aggravate back discomfort by increasing the curvature of the spine. They should not be worn if the woman experiences backache or problems with her balance. Shoes should fit properly and feel comfortable.

Bathing

Daily bathing is important because of the increased perspiration and mucoid vaginal discharge that occurs during pregnancy. Practices related to cleansing the body are often influenced by cultural norms; thus a pregnant woman may choose to cleanse only some portions of her body daily or may elect to take a daily shower or tub bath. Caution is needed during tub baths because balance becomes a problem as pregnancy advances. Rubber tub mats and handgrips are valuable safety devices. Moreover, vasodilation due to the warm water may cause the woman to experience some faintness when she attempts to get out of the tub. Thus she may require assistance, especially in the third trimester. To avoid introducing infection, tub baths are contraindicated in the presence of vaginal bleeding or when the membranes are ruptured. During the first trimester, pregnant women should avoid hyperthermia associated with the use of a hot tub or whirlpool bath, such as a Jacuzzi®, because it may increase the risk for neural tube defects (Cunningham et al., 2010).

Employment

Pregnant women who have no complications can usually continue to work until they go into labor (American Academy of Pediatrics [AAP] & ACOG, 2008). Although pregnant women who are employed in jobs that require prolonged standing (more than 5 hours) do have a higher incidence of preterm birth, this has no effect on fetal growth (Saade, 2007). However, the workplace environment can affect maternal well-being as well as birth outcomes (Bell, Zimmerman, & Diehr, 2008; Cooklin, Rowe, & Fisher, 2007).

Major deterrents to employment during pregnancy include fetotoxic hazards in the environment, excessive physical strain, overfatigue, and medical- or pregnancy-related complications. In the last half of pregnancy, occupations involving balance should be adjusted to protect the mother.

Fetotoxic hazards in the environment are always a concern to the expectant couple. If the pregnant woman or the woman contemplating pregnancy is working in industry, she should contact her company physician or nurse about possible hazards in her work environment and should do her own reading and research on environmental hazards as well. Similarly, her partner can seek information about hazards in his workplace that might affect his sperm, if he has not already done this before conception.

Travel

If medical or pregnancy complications are not present, there are no restrictions on travel. Pregnant women should avoid travel if there is a history of bleeding or preeclampsia or if multiple births are anticipated.

Travel by automobile can be especially fatiguing, aggravating many of the discomforts of pregnancy. The pregnant woman needs frequent opportunities to get out of the car and walk. (A good pattern to follow is to stop every 2 hours and walk around for approximately 10 minutes.) A pregnant woman should use a seat belt, specifically a properly positioned three-point restraint. She should wear both lap and shoulder belts. The lap belt should fit snugly and be positioned under the abdomen and across the upper thighs. The shoulder belt should be positioned snugly between the breasts. Seat belts play an important role in preventing fetal and maternal mortality and morbidity with subsequent fetal death (Cunningham et al., 2010). Fetal death in car accidents is also caused by placental separation (abruptio placentae) as a result of uterine distortion. Use of the shoulder belt decreases the risk of traumatic flexion of the woman's body, thereby decreasing the risk of placental separation. Thus it clearly is important for nurses to provide information about car safety early in the prenatal period.

As pregnancy progresses, travel by airplane or train is generally recommended for long distances. Currently, occasional flying is considered safe in the absence of any obstetric or medical complications (ACOG, 2009a). However, those women who have medical or obstetric complications, such as poorly controlled diabetes, sickle cell disease, or preeclampsia, and those women with placental abnormalities or who are at risk for preterm birth are advised to avoid flying during pregnancy. Before flying, the pregnant woman should check with her particular airline to see if it has any travel restrictions. Most airlines permit pregnant women to fly up to 36 weeks' gestation. Some airlines restrict international travel earlier in pregnancy; others may require documentation of gestation (ACOG, 2009a). To avoid the development of phlebitis or blood clots, pregnant women should drink plenty of fluid to avoid dehydration and hemoconcentration; avoid caffeinated beverages, which act as diuretics, and smoking, which causes vasoconstriction; and wear support hose while flying. They should also walk about the plane at regular intervals and change positions frequently (Saade, 2007). Because of the risk of unexpected turbulence and the subsequent risk for trauma, pregnant women should wear their seat belts at all times while seated (ACOG, 2009a). The availability of medical care at her destination is an important consideration for the near-term woman who travels. A copy of the woman's medical records can be helpful to have for extensive travel (Johnson et al., 2007). Prior to international travel, pregnant women should consult with their healthcare providers about specific preventive strategies (McGovern, Boyce, & Fischer, 2007).

Activity and Rest

Exercise during pregnancy helps maintain maternal fitness and muscle tone, leads to improved self-image, increases energy, improves sleep, relieves tension, helps control weight gain, promotes regular bowel function, and is associated with improved postpartum recovery. Regular aerobic exercise maintains or improves a pregnant woman's general physical fitness and body image (Kramer, 2006). Normal participation in regular exercise can continue and, in fact, is encouraged throughout an uncomplicated pregnancy.

Exercise may play a role in the prevention of maternal and fetal complications (Gavard & Artal, 2008). For women who are morbidly obese, exercise may assist in the prevention of gestational diabetes. Exercise is also recommended by the American Diabetes Association to assist in glycemic control for women with gestational diabetes (Katz, 2008). Exercise in pregnancy may also provide long-term healthcare benefits to the woman with weight reduction and overall cardiovascular fitness (Gavard & Artal, 2008).

Application: Exercise During Pregnancy

CLINICAL JUDGMENT

Case Study: Ana Gonzalez

Ana Gonzalez, a 24-year-old G1P0, is 11 weeks pregnant when she presents for her first prenatal exam. She has been a long-distance runner for 6 years. Because of her low body fat, her menses have always been irregular, and it had not occurred to Ana that she might be pregnant. Ana says she has been told that it is fine to continue any physical activity at which one is proficient and says that she would like to continue running long distances while pregnant.

Critical Thinking

What should the nurse advise Ana about running long distances?
See www.nursing.pearsonhighered.com for possible responses.

Before beginning an exercise program, a pregnant woman should be examined by her certified nurse-midwife or physician. A pregnant woman who is already in an exercise program

can discuss her degree of participation with her caregiver. If a woman has not been physically active before her pregnancy, she should gradually increase her exercise period. However, maximum benefit of exercise for pregnant women is derived for those who have been physically fit before conception.

Women should seek the opinion of their healthcare provider about taking part in contact sports (Pivarnik & Mudd, 2009). In general, the skilled sportswoman is no longer discouraged from participating in these activities if her pregnancy is uncomplicated. However, pregnant women should not participate in physical activities that have a high risk for blunt trauma (Pivarnik & Mudd, 2009). Certain conditions do contraindicate exercise. Absolute contraindications to exercise include the following (ACOG, 2002):

- Rupture of the membranes
- Preeclampsia-eclampsia
- Incompetent cervix (cerclage)
- Persistent vaginal bleeding in the second or third trimesters
- Multiple gestation at risk for preterm labor
- History of preterm labor in the prior or current pregnancy
- Placenta previa after 26 weeks' gestation
- Chronic medical conditions that might be negatively impacted by vigorous exercise such as significant heart disease or restrictive lung disease

Research related to the effects of maternal exercise on the fetus is reassuring. Moderate exercise has not been demonstrated to increase maternal core temperature; cause fetal hyperthermia; or increase the rate of malformations such as miscarriage, retardation, or growth restriction (Katz, 2008).

The following guidelines are helpful in counseling pregnant women about exercise:

- Even mild to moderate exercise is beneficial during pregnancy. Regular exercise—at least 30 minutes of moderate exercise daily or at least most days of the week—is preferred (Penney, 2008).
- After the first trimester, women should avoid exercising in the supine position. In most pregnant women, the supine position is associated with decreased cardiac output. Because uterine blood flow is reduced during exercise as blood is shunted from the visceral organs to the muscles, the remaining cardiac output is further decreased. Similarly, women should avoid standing motionless for prolonged periods (ACOG, 2002; Penney, 2008).
- Because decreased oxygen is available for aerobic exercise during pregnancy, women should modify the intensity of their exercise based on their symptoms, should stop when they become fatigued, and should avoid exercising to the point of exhaustion. Non–weight-bearing exercises, such as swimming or cycling, are recommended because they decrease the risk of injury and provide fitness with comfort.
- As pregnancy progresses and the woman's center of gravity changes, especially in the third trimester, she should avoid exercises in which the loss of balance could pose a risk to her or her fetus. Similarly, the woman should avoid any type of exercise that has a high potential for physical contact such as basketball, soccer, and ice hockey because it could result in trauma to the woman or her fetus.
- A normal pregnancy requires an additional 300 kcal per day. Women who exercise regularly during pregnancy should be careful to ensure that they consume an adequate diet.
- To augment heat dissipation, especially during the first trimester, pregnant women who exercise should wear appropriate clothing, ensure adequate hydration, and avoid prolonged overheating (Katz, 2008). As a result of the cardiovascular changes of pregnancy, heart rate is not an accurate indicator of the intensity of exercise for pregnant women. If a pregnant woman is unable to talk or feels unable to breathe, then the exercise effort is too high (Saade, 2007).

In addition, the nurse may suggest that the woman wear a supportive bra and appropriate shoes when exercising. She should be advised to warm up and stretch to help prepare the joints for activity and cool down with a period of mild activity to help restore circulation and avoid pooling of blood. A moderate, rhythmic exercise routine involving large muscle groups such as swimming, cycling, or brisk walking is best. Jogging or running is acceptable for women already conditioned to these activities as long as they avoid exercising at maximum effort and overheating.

Warning signs include the following: pain of any kind, vaginal bleeding, uterine contractions, decreased or absent fetal movement, fluid loss from the vagina, dizziness, headache, dyspnea before exertion, and muscle weakness (ACOG, 2002). The woman should stop exercising if any of these symptoms occur and modify her exercise program. If the symptoms persist, the woman should contact her caregiver.

Adequate rest in pregnancy is important for both physical and emotional health. Women need more sleep throughout pregnancy, particularly in the first and last trimesters, when they tire easily. Without adequate rest, pregnant women have less resilience.

Finding time to rest during the day may be difficult for women who work outside the home or have small children. The nurse can help the expectant mother examine her daily schedule to develop a realistic plan for short periods of rest and relaxation.

Sleeping becomes more difficult during the last trimester because of the enlarged abdomen, increased frequency of urination, and greater activity of the fetus. Finding a comfortable position becomes difficult for the pregnant woman. Figure 16-10 ■ shows a position most pregnant women find comfortable. Progressive relaxation techniques similar to those taught in prepared childbirth classes can help prepare the woman for sleep.

Exercises to Prepare for Childbirth

Certain exercises help strengthen muscle tone in preparation for birth and promote more rapid restoration of muscle tone after birth. The woman can reduce some physical changes of pregnancy considerably by faithfully practicing prescribed body-conditioning exercises. Many body-conditioning exercises for pregnancy are taught; a few of the more common ones are discussed here.

The **pelvic tilt**, or pelvic rocking, helps prevent or reduce back strain and strengthens abdominal muscle tone. To do the pelvic tilt, the pregnant woman lies on her back and puts her feet flat on the floor. This bent position of the knees helps prevent strain and discomfort. She decreases the curvature in her back by pressing her spine toward the floor. With her back pressed to

Figure 16-10 ■ Position for relaxation and rest as pregnancy progresses.

A

B

C

D

Figure 16-11 ■ A. Starting position when the pelvic tilt is done on hands and knees. The back is flat and parallel to the floor, the hands are under the head, and the knees are directly under the buttocks. B. A prenatal yoga instructor offers pointers for proper positioning for the first part of the tilt: head up, neck long and separated from the shoulders, buttocks up, and pelvis thrust back, allowing the back to drop and release on an inhaled breath. C. The instructor helps the woman assume the correct position for the next part of the tilt. It is done on a long exhalation, allowing the pregnant woman to arch her back, drop her head loosely, push away from her hands, and draw in the muscles of her abdomen to strengthen them. Note that in this position the pelvis and buttocks are tucked under, and the buttock muscles are tightened. D. Proper posture. The knees are slightly bent but not locked, the pelvis and buttocks are tucked under, thereby lengthening the spine and helping support the weighty abdomen. With her chin tucked in, this woman's neck, shoulders, hips, knees, and feet are all in a straight line perpendicular to the floor. Her feet are parallel. This is also the starting position for doing the pelvic tilt while standing.

Source: Photographer, Elena Dorfman.

the floor, the woman tightens her buttocks and abdominal muscles as she tucks in her buttocks. The pelvic tilt can also be performed on hands and knees (Figure 16-11 ■), while sitting in a chair, or while standing with the back against a wall. The body alignment achieved when the pelvic tilt is correctly done should be maintained as much as possible throughout the day.

CLINICAL TIP

Doing the pelvic tilt on hands and knees may aggravate back strain. Teach women with a history of minor back problems to do the pelvic tilt only in the standing position.

Abdominal Exercises

A basic exercise to increase abdominal muscle tone is tightening abdominal muscles with each breath. It can be done in any position, but it is best learned while the woman lies supine. With knees flexed and feet flat on the floor, the woman expands her abdomen and slowly takes a deep breath. As she slowly exhales, she gradually pulls in her abdominal muscles until they are fully contracted. She relaxes for a few seconds and then repeats the exercise.

Partial sit-ups strengthen abdominal muscle tone and are done according to individual comfort levels. When doing a partial sit-up, the woman lies on the floor as just described (Figure 16-12 ■). The exercise is done with the knees bent and the feet flat on the floor to avoid undue strain on the lower back. She stretches her arms toward her knees as she slowly pulls her head and shoulders off the floor to a comfortable level. (If she has poor abdominal muscle tone, she may not be able to pull up very far.) She then slowly returns to the starting position, takes a deep breath, and repeats the exercise. To strengthen the oblique abdominal muscles, she repeats the process but stretches the left arm to the side of her right knee, returns to the floor, takes a deep breath, and then reaches with the right arm to the left knee.

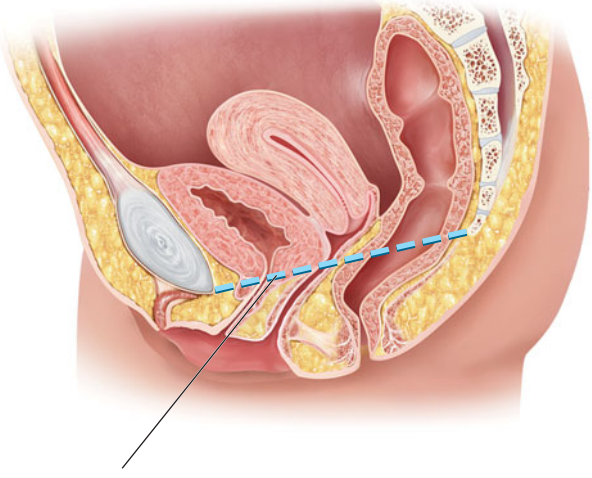
These exercises can be done approximately 5 times in a sequence, and the sequence can be repeated several times during the day as desired. It is important that the woman do the exercises slowly to prevent muscle strain and overtiring.

Figure 16-12 ■ The pregnant woman can strengthen her abdominal muscles by doing partial sit-ups.

Source: Photographer, Elena Dorfman.

Perineal Exercises

Perineal muscle tightening, also referred to as **Kegel exercises**, strengthens the pubococcygeus muscle and increases its elasticity (Figure 16-13 ■). This muscle helps support the pelvic organs, including the uterus and bladder. A strong pubococcygeus muscle



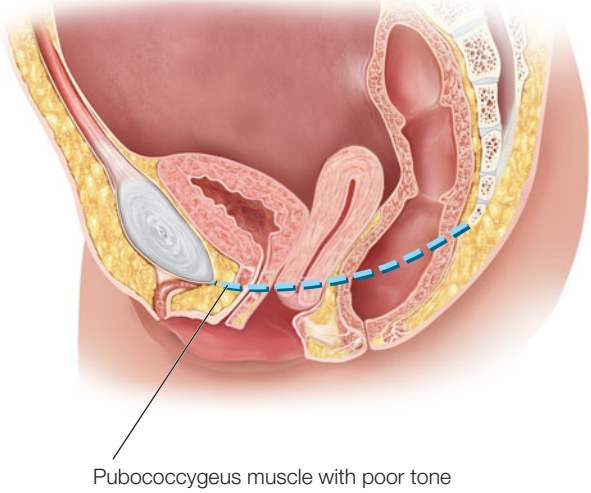


Figure 16-13 ■ Kegel exercises. The woman tightens the pubococcygeus muscle to improve support to the pelvic organs.

helps prevent stress incontinence, cystocele, rectocele, and uterine prolapse in women following childbirth.

The woman can feel the specific muscle group to be exercised by stopping urination midstream. However, doing Kegel exercises while urinating is discouraged because this practice has been associated with urinary stasis and urinary tract infection.

Childbirth educators sometimes use the following technique to teach Kegel exercises. They tell the woman to think of her perineal muscles as an elevator. When she relaxes, the elevator is on the first floor. To do the exercises, she contracts, bringing the elevator to the second, third, and fourth floors. She keeps the elevator on the fourth floor for a few seconds, and then gradually relaxes the area. If the exercise is properly done, the woman does not contract the muscles of the buttocks and thighs.

Kegel exercises can be done at almost any time. Some women use ordinary events—for instance, stopping at a red light—as a cue to remember to do the exercise. Others do Kegel exercises while waiting in a checkout line, talking on the telephone, or watching television.

Inner Thigh Exercises

The pregnant woman should assume a cross-legged sitting position whenever possible. This "tailor sit" stretches the muscles of the inner thighs in preparation for labor and birth (Figure 16-14 ■).

Sexual Activity

As a result of the physiologic, anatomic, and emotional changes of pregnancy, the couple usually has many questions and concerns about sexual activity during pregnancy. Often these questions are about possible injury to the baby or the woman during intercourse and about changes in the desire each partner feels for the other.

Figure 16-14 ■ To help prepare her inner thigh muscles for labor and birth, the pregnant woman should assume a cross-legged sitting position whenever possible during the day.

In the past, couples were frequently warned to avoid sexual intercourse during the last 6 to 8 weeks of pregnancy to prevent complications such as infection or premature rupture of the membranes. However, these fears seem to be unfounded. In a healthy pregnancy, there is no medical reason to limit sexual activity. Intercourse is contraindicated if the membranes are ruptured or if placenta previa is diagnosed (Katz, 2008).

The expectant mother may experience changes in sexual desire and response. Often these are related to the various discomforts that occur throughout pregnancy. For instance, during the first trimester, fatigue or nausea and vomiting may decrease desire, and breast tenderness may make the woman less responsive to fondling of her breasts. During the second trimester, many of the discomforts have lessened, and with the vascular congestion of the pelvis the woman may experience even greater sexual satisfaction than she experienced before pregnancy.

During the third trimester, interest in coitus may again decrease as the woman becomes more uncomfortable and fatigued. In addition, shortness of breath, painful pelvic ligaments, urinary frequency, and decreased mobility may lessen sexual desire and activity. If they are not already using them, the couple should consider coital positions other than male superior, such as side-by-side, female superior, and vaginal rear entry.

Sexual activity does not have to include intercourse. Cuddling, kissing, and being held can satisfy many of the nurturing and sexual needs of the pregnant woman. The warm, sensual feelings that accompany these activities can be an end in themselves. Her partner, however, may need to masturbate more frequently than before.

The sexual desires of men are also affected by many factors in pregnancy. These include the previous relationship with the partner, acceptance of the pregnancy, attitudes toward the partner's change of appearance, and concern about hurting the expectant mother or baby. Some men may withdraw from sexual contact because of a belief that sex with a pregnant woman is immoral. This may be especially true for the couple whose religious beliefs teach that sexual intercourse is only for procreation. Some men find it difficult to view their partners as sexually appealing while they are adjusting to the concept of her as a mother. Other men feel their partner's pregnancy is arousing and experience feelings of increased happiness, intimacy, and closeness.

The expectant couple should be aware of their changing sexual desires, the normality of these changes, and the importance of communicating these changes to each other so that they can make nurturing adaptations. The nurse has an important role in addressing the sexuality concerns of the expectant couple. The couple must feel free to express concerns about sexual activity, and the nurse must be able to respond and give anticipatory guidance in a comfortable manner. See Patient Teaching: Sexual Activity During Pregnancy.

Dental Care

No evidence suggests that pregnancy causes or accelerates the development of dental caries. Nevertheless, in spite of such discomforts as nausea and vomiting, gum hypertrophy and tenderness,

PATIENT TEACHING Sexual Activity During Pregnancy

PATIENT GOALS At the completion of the teaching, the woman will be able to:

1. Relate the changes in sexuality and sexual response that may occur during pregnancy to changes in technique, frequency, and response that may be indicated.
2. Explore personal attitudes, beliefs, and expectations about sexual activity during pregnancy.
3. Cite maternal factors that would contraindicate sexual intercourse.

TEACHING PLAN

Content	Teaching Method
Begin by explaining that the pregnant woman may experience changes in desire during the course of pregnancy. During the first trimester, discomforts such as nausea, fatigue, and breast tenderness may make intercourse less desirable for many women. In the second trimester, as symptoms decrease, desire may increase. In the third trimester, discomfort and fatigue may lead to decreased desire in the woman.	Universal statements that give permission, such as "Many couples experience changes in sexual desire during pregnancy. What kind of changes have you experienced?" are often effective in starting discussion. Depending on the woman's (or couple's) level of knowledge and sophistication, part or all of this discussion may be necessary.
Explain that men may notice changes in their level of desire, too. Among other things, this change may be related to feelings about his partner's changing appearance, his belief about the acceptability of sexual activity with a pregnant woman, or concern about hurting the woman or fetus. Some men find the changes of pregnancy erotic; others must adjust to the notion of their partners as mothers.	If the partner is present, approach him in the same nonjudgmental way used above. If not, ask the woman if she has noticed any changes in her partner or if he has expressed any concerns.
Explain that the woman may notice that orgasms are much more intense during the last weeks of pregnancy and may be followed by cramping. Because of the pressure of the enlarging uterus on the vena cava, the woman should not lie flat on her back for intercourse after about the fourth month. If the couple prefers that position, a pillow should be placed under her right hip to displace the uterus. Alternate positions such as side-by-side, female superior, or vaginal rear entry may become necessary as her uterus enlarges.	Deal with any specific questions about the physical and psychologic changes that the couple may have.
Stress that sexual activities that both partners enjoy are generally acceptable. It is not advisable for couples who favor anal sex to go from anal penetration to vaginal penetration because of the risk of introducing *Escherichia coli* into the vagina.	Discussion about various sexual activities requires that you be comfortable with your sexuality and that you be tactful.
Suggest that alternative methods of expressing intimacy and affection such as cuddling, holding and stroking each other, and kissing may help maintain the couple's feelings of warmth and closeness. If the man feels desire for further sexual release, his partner may help him masturbate to ejaculation, or he may prefer to masturbate in private. Advise the woman who is interested in masturbation as a form of gratification that the orgasmic contractions may be especially intense in later pregnancy.	The couple may be content with these approaches to meeting their sexual needs, or they may require assurance that such approaches are indeed "normal."
Stress that sexual intercourse in contraindicated once the membranes are ruptured or if bleeding is present. Women with a history of preterm labor may be advised to avoid intercourse because the oxytocin that is released with orgasm stimulates uterine contractions and may trigger preterm labor. Because oxytocin is also released with nipple stimulation, fondling the breasts may also be contraindicated in those cases.	An explanation of the contraindications accompanied by their rationale provides specific guidelines that most couples find helpful.
A discussion of sexuality and sexual activity should stress the importance of open communication so that the couple feels comfortable expressing feelings, preferences, and concerns.	Some couples are skilled at expressing their feelings about sexual activity. Others find it difficult and can benefit from specific suggestions. The nurse should provide opportunities for discussion throughout the talk. Specific handouts on sexual activity are also helpful for couples and may address topics that were not discussed.

Evaluation	Documentation
Evaluate the learning by assessing the woman's (or couple's) response to information throughout the discussion. Ask the woman to express information such as the contraindications to intercourse in her own words. Follow-up sessions and questions from the woman also provide information about teaching effectiveness.	Document the information given to the woman, including specifics on contraindications to sexual activity (specify if written instructions were provided in addition to verbal ones) and the type of teaching method used. Document the woman's verbalization of understanding and your clarification of any information.

possible ptyalism, and heartburn, it is important for pregnant women to maintain regular oral hygiene.

Ensuring a healthy oral environment is essential to overall health. Women should be advised to do the following:

- Have extensive dental work done before becoming pregnant if possible.
- Eat a healthy diet including foods high in protein; calcium; phosphorus; and vitamins C, A, and D.
- Take prenatal vitamins daily.
- Maintain good oral hygiene by brushing at least twice a day and flossing daily.
- Use an antibacterial fluoride mouth rinse.
- If morning sickness occurs, brush teeth following vomiting to prevent tooth erosion caused by stomach acids.
- Have teeth cleaned every 6 months.

Ideally, a woman should have a dental examination as part of preconception planning. If that does not occur, the pregnant woman is encouraged to have a dental checkup early in her pregnancy. She should inform her dentist of her pregnancy so that she is not exposed to teratogenic substances. Dental x-rays are permitted during pregnancy as long as the woman's abdomen is shielded with a lead apron (Guilbeau & Hurst, 2009). The second trimester is considered the most appropriate time for dental treatment because the risk of pregnancy loss tends to be lower and the woman tends to be more comfortable (Russell & Mayberry, 2008). Extensive dental care during pregnancy requires consultation between the dentist and the woman's healthcare professional.

Immunizations

Ideally, women of childbearing age should receive immunizations prior to becoming pregnant to avoid unnecessary fetal exposure (ACOG, 2009b). All women of childbearing age need to be fully aware of the risks of receiving specific immunizations if pregnancy is possible. Expectant women, especially those who intend to travel internationally, should be aware of the immunizations that are contraindicated during pregnancy. Immunizations with attenuated live viruses, such as rubella vaccine, should not be given in pregnancy because of the possible teratogenic effect of the live virus (ACOG, 2009b; Katz, 2008). The most current recommendations on vaccines related to pregnancy may be obtained from the Centers for Disease Control and Prevention Web site. Recommendations for immunizations during pregnancy are summarized in Table 16-4.

COMPLEMENTARY AND ALTERNATIVE THERAPIES

According to the National Center for Complementary & Alternative Medicine (NCCAM) (2008), the use of complementary and alternative medicine (CAM) is more common in women and in those with higher levels of education and higher incomes. Many women are electing to use CAM therapies, such as homeopathy, herbal medicine (phytomedicine), acupressure, acupuncture, biofeedback, Therapeutic Touch, massage, and chiropractic, as part of a holistic approach to their healthcare regimens. Nurses are in a unique position to bridge the gap between conventional therapies and CAM therapies. As patient advocates, nurses are able to provide patients with information needed to make informed decisions about their health and health care. Utilizing a nonjudgmental approach, the nurse should inquire about the use of CAM as part of a routine antepartal assessment. It is important that nurses working with pregnant women and their families develop a general understanding of the more commonly used therapies to be able to answer questions and provide resources as needed. See chapter 3 ∞ for an in-depth discussion of CAM.

Homeopathy

Homeopathy means "like suffering." Homeopathic medicine is based on the theory that a miniscule amount of a substance can cure symptoms in a sick person that are similar to the symptoms the substance causes in healthy people. Thus, for example, ipecac, which induces vomiting, may be used to treat a

TABLE 16-4 Recommendations for Immunization During Pregnancy

LIVE ATTENUATED VIRUS VACCINES	INACTIVATED BACTERIAL VACCINES	HYPERIMMUNE GLOBULINS
Measles—contraindicated	Pneumococcal—if indicated	Hepatitis B—postexposure prophylaxis: give along with hepatitis B vaccine initially, then vaccine alone at 1 and 6 months
Mumps—contraindicated	Meningococcal—if indicated	Rabies—postexposure prophylaxis
Rubella—contraindicated	Typhoid—not recommended	Tetanus—postexposure prophylaxis
Varicella-zoster—contraindicated		Varicella—consider for postexposure within 96 hr
Poliomyelitis—no longer recommended		
Yellow fever—high-risk areas only		
Smallpox—contraindicated		
INACTIVATED VIRUS VACCINES	**TOXOIDS**	**POOLED IMMUNE SERUM GLOBULINS**
Influenza—same as nonpregnant	Tetanus-diptheria—same as nonpregnant	Hepatitis A—postexposure prophylaxis
Rabies—same as nonpregnant		Measles—postexposure prophylaxis
Hepatitis A and B—same as nonpregnant		
Enhanced poliomyelitis (IPV-e)—risk of exposure		
Human papilloma virus (HPV)—contraindicated

person who is vomiting, such as a pregnant woman with severe nausea and vomiting.

Homeopathic therapies are available for pregnancy-related symptoms such as musculoskeletal disorders, anemia, nausea, ptyalism, pica, threatened miscarriage, and preterm labor. According to homeopathic theory, homeopathic remedies either help an individual or have no effect. However, a healing crisis or aggravation of symptoms can occur if the remedy is given in too high a potency or repeated too frequently.

Herbal Medicine

Herbal medicine uses therapies derived from plants. Many have been used for centuries in different parts of the world and are well recognized.

In the United States, herbs are categorized as dietary supplements rather than drugs. It is important for the pregnant woman to understand that herbs are considered dietary supplements and are not regulated as prescription or over-the-counter drugs through the Food and Drug Administration (FDA). Due to limited scientific evaluation of potential harmful effects on the fetus, herbal supplements should be avoided, particularly in the first trimester (Yankowitz, 2008).

In general, it is best to advise pregnant women not to ingest any herbs, except ginger, during the first trimester of pregnancy (Yankowitz, 2008). Pregnant women need to avoid certain categories of herbs such as abortifacient (abortion-inducing) herbs, herbs that induce menstruation, nervous system stimulants, stimulant laxatives, and so forth. Lists identifying common herbs that women are advised to avoid or use with caution during pregnancy and lactation are available; an example is shown in Table 16-5.

For a reliable source of information about herbs, homeopathic therapies, and other alternative options, consumers or healthcare providers can access the National Center for Complementary and Alternative Medicine Web site and the Office of Dietary Supplements Web site.

Some alternative therapies are safe and effective during pregnancy. In fact, some have been shown to be even more effective than traditional remedies. For nausea in early pregnancy, acupuncture, acupressure, ginger root (250-mg capsules 4 times a day), and vitamin B_6 (pyridoxine, 25 mg 2 or 3 times a day) work well (Cleveland Clinic, 2006). For backache, chiropractic manipulation holds the best track record, but other successful alternative therapies include yoga, massage, and reflexology that utilize light, gentle pressure. For turning a breech baby, exercise, hypnosis, and a traditional Chinese treatment called moxibustion (burning an incense-like substance on the fifth toe) have proven to be beneficial (Cleveland Clinic, 2006).

TABLE 16-5 Common Herbs to Avoid in Pregnancy*

Blue cohosh	Goldenseal
Black cohosh	Ginkgo biloba
Chamomile, Valeria	Ginseng
Comfrey	Horehound
Dong quai	Horseradish (fresh)
Ephedra (ma huang)	
Use with caution:	
Garlic	
Turmeric	

*Avoid excessive consumption relative to usual and customary food use.

Centering Pregnancy

When empowering women to choose health-promoting behaviors, it may be helpful to consider a relatively new, innovative model for prenatal care called Centering Pregnancy. Centering Pregnancy integrates the three major components of care—health assessment, education, and support—into a unified program providing complete prenatal care to women within a group setting. This model replaces the traditional one-on-one visits in an examination room with a healthcare provider. Instead, group meetings are held where mothers-to-be and their partners receive care and education and form a sense of community with other group members.

Patients begin meeting in small groups at 12 to 16 weeks' gestation and continue to meet monthly for the first 4 months, and biweekly as their due dates approach. Each group session begins with the expectant mothers taking their own blood pressure, monitoring weight gain, checking urine samples, and recording data on medical charts under their provider or nurse's guidance. The provider then reviews each group member's information and completes any further assessments that are indicated. After all assessments are completed, the group members convene in a circle to discuss topics such as nutrition, fetal development, common discomforts of pregnancy and possible remedies, exercise, relaxation, labor and birth procedures, parenting and relationship issues, contraception, and infant care (Reid, 2007). Prenatal assessment, knowledge and skills development, and support occur in an atmosphere that facilitates learning, encourages free exchange, and develops mutual support (Massey, Schindler Rising, & Ickovics, 2006). Both mothers and fathers report an increased investment in the pregnancy and self-care after attending group sessions. Studies conclude that women in group sessions are less likely to have suboptimal prenatal care and are more likely to have significantly better prenatal knowledge, feel better prepared for labor and delivery, and have greater satisfaction with their care (Ickovics et al., 2007).

Teratogenic Substances

Substances that adversely affect the normal growth and development of the fetus are called **teratogens**. Many of these effects are readily apparent at birth, but others may not be identified for years. A well-known example is the development of cervical cancer in adolescent females whose mothers took diethylstilbestrol (DES) during pregnancy.

Developmental defects may result from genetic, environmental, or unknown causes (Niebyl & Simpson, 2007). Environmental exposure to toxins may occur by inhalation, eye contact (e.g., chemical splash), ingestion and absorption through the gastrointestinal tract (e.g., foods containing pesticides or contaminated water), exposure through the skin (e.g., pesticides,

chemicals found in cosmetics, etc.), maternal-fetal transfer, and through breastfeeding (Chalupka & Chalupka, 2010).

Medications are perhaps the most likely documented teratogens, but other factors can also harm the fetus, including certain infections such as rubella, syphilis, herpes virus type 2, toxoplasmosis, and cytomegalovirus (CMV). During pregnancy, women need to have adequate information available and a realistic perspective on potential environmental hazards. Factors that are suspected to be hazardous to the general population should be avoided if possible.

Medications

The use of medications during pregnancy, including prescriptions, over-the-counter drugs, and herbal remedies, is of great concern because maternal drug and chemical exposure is thought to account for at least 10% of birth defects (Yankowitz, 2008). Over 60% of American women receive at least one prescription during pregnancy (Katz, 2008). Many pregnant women need medication for therapeutic purposes, such as the treatment of infections, allergies, or other pathologic processes. Known teratogenic agents are not prescribed and usually can be replaced by medications considered safe. Even when a woman is highly motivated to avoid taking any medications, she may have taken potentially teratogenic medications before her pregnancy was diagnosed, especially if she had an irregular menstrual cycle.

The greatest potential for gross abnormalities in the fetus occurs during the first trimester of pregnancy, when fetal organs are first developing. Many factors influence teratogenic effects, including the specific identity and dose of the teratogen, the state of embryo development, and the genetic sensitivity of the mother and fetus. For example, the commonly prescribed acne medication isotretinoin (Accutane) is associated with a high incidence of spontaneous abortion and congenital malformations if taken early in pregnancy. Valproic acid, an anticonvulsant, is associated with an increased risk of neural tube defects (Katz, 2008) and cleft lip (Niebyl & Simpson, 2007).

To provide information for caregivers and patients, the Food and Drug Administration (FDA) has developed the following classification system for medications administered during pregnancy:

Category A. Controlled studies in women have demonstrated no associated fetal risk. Few drugs fall into this category. Vitamin C is cited as a category A drug as long as its use does not exceed the recommended dietary allowance.

Category B. Either animal studies show no risk, but there are no controlled studies in women; or animal studies indicate a risk, but controlled human studies fail to demonstrate a risk. The penicillins fall into this category.

Category C. Either (1) no adequate studies, either in animals or women, are available; or (2) animal studies show teratogenic effects, but no controlled studies in women are available. Many drugs fall into this category, and the lack of information poses a problem for caregivers. Zidovudine, a drug used to decrease perinatal transmission of HIV, falls into this category.

Category D. Evidence of human fetal risk does exist, but the benefits of the drug in certain situations are thought to outweigh the risks. Examples in this category include tetracycline, vincristine, lithium, and hydrochlorothiazide.

Category X. The demonstrated fetal risks clearly outweigh any possible benefit. An example of a drug in this category is isotretinoin (Accutane), the acne medication, which can cause multiple central nervous system (CNS), facial, and cardiovascular anomalies.

If a woman has taken a drug in category D or X, she should be informed of the risks associated with that drug and of her alternatives. Similarly, a woman who has taken a drug in the safer categories can be reassured. For up-to-date information on the risks associated with specific drugs, women can contact drug information centers, either by telephone or by using online databases.

The FDA system, although useful, has been criticized because the letter system suggests a risk grading that is not necessarily accurate. More important, not all drugs in a category have the same risk level. While the FDA is working to develop a new evidence-based system, slow progress has prompted experts to recommend teratogen information databases as an alternative resource (Niebyl & Simpson, 2007; Yankowitz, 2008).

Although the first trimester is the critical period for teratogenesis, some medications are known to have teratogenic effect when taken in the second and third trimesters. For example, tetracycline taken in late pregnancy is commonly associated with staining of teeth in children and has been shown to depress skeletal growth, especially in preterm infants. Warfarin (Coumadin), a commonly prescribed anticoagulant, is associated with CNS defects following fetal exposure during the second and third trimesters (Niebyl & Simpson, 2007). Because heparin does not cross the placenta, it is safer for the fetus than warfarin and other anticoagulants.

Pregnant women should avoid all medication—prescribed, homeopathic, or over the counter—if possible. If a medication is necessary during pregnancy, the benefits must clearly outweigh the risks. If no alternative exists, it is wisest to select a well-known medication rather than a newer drug whose potential teratogenic effects may not be known. When possible, the oral form of the drug should be used, and it should be prescribed in the lowest possible therapeutic dose for the shortest time possible. Finally, the caregiver should carefully consider the multiple components of the medication.

A woman clearly has a right to the most comprehensive information available concerning medications. The nurse can assist her by suggesting appropriate references and helping her research information. Some excellent reference books on drugs and pregnancy are currently available and should be part of the library of every office and clinic that provides prenatal care. In addition, several online databases that provide information on teratogens are available for convenient reference.

The nurse should remind the woman of the need to check with her caregiver about medications she was taking when pregnancy occurred and about any nonprescription drugs she is contemplating using. Any medication with possible teratogenic effects must be avoided.

Tobacco

In the United States, smoking during pregnancy is one of the most significant, modifiable causes of poor pregnancy outcomes. Smoking during pregnancy has a strong association with low-birth-weight infants. In addition, mothers who smoke have an increased risk of infertility, spontaneous abortion, intrauterine growth restriction (IUGR), placentae previa, abruptio placentae, premature rupture of membranes, and preterm birth (ACOG, 2005; Niebyl & Simpson, 2007; Kahn, Hobbins, & Galan, 2008; Hartmann et al., 2007). Pregnant women who smoke as well as participate in other unhealthy behaviors, such as alcohol use, further increase their risk for low-birth-weight infants (Kahn et al., 2008; Martin et al., 2008). Research also links maternal smoking, both during pregnancy and afterward, with more than 3 times the risk of sudden infant death syndrome (SIDS) than that of nonsmokers (Wisner et al., 2007). Children exposed to tobacco smoke prenatally and environmentally have an increased risk of learning disabilities (Anderko, Braun, & Auinger, 2010). Maternal smoking also exposes young children to other risks of secondhand smoke including middle ear infections, acute and chronic respiratory tract illnesses, and behavioral disabilities (Niebyl & Simpson, 2007; Martin et al., 2008).

The ingredients in cigarette smoke, such as carbon monoxide, nicotine, lead, and cotinine, are toxic to the fetus. Carbon monoxide decreases availability of oxygen to maternal and fetal tissue, while nicotine decreases uteroplacental blood flow to the fetus (Niebyl & Simpson, 2007).

In response to public health education campaigns in the United States, smoking during pregnancy has decreased significantly. In fact, approximately 46% of women who smoke quit during pregnancy. Unfortunately, 60% to 80% of women who quit smoking during their pregnancy resume smoking within a year after birth (ACOG, 2005). This finding suggests that although women are aware of the potential impact of smoking on the fetus, they may be less knowledgeable about the effects of passive smoke on the baby.

Smoking cessation programs decrease the number of women who smoke in pregnancy and, therefore, the incidence of low-birth-weight infants and preterm births ((Johnson et al., 2007). Studies demonstrate that any decrease in smoking during pregnancy improves fetal outcome, and researchers continue to explore approaches designed to help women quit smoking. ACOG (2005) suggests a 5- to 15-minute intervention with women who smoke fewer than 20 cigarettes a day to be most effective. This program and other programs encourage healthcare providers to use the five As:

- *Ask* about tobacco use.
- *Advise* to quit smoking.
- *Assess* willingness to quit.
- *Assist* in attempt to quit.
- *Arrange* for follow-up care.

The nurse can play an important role in counseling women about the importance of smoking cessation during pregnancy and can be actively involved in offering smoking cessation programs.

If smoking cessation efforts are not successful in pregnant women who smoke more than 10 cigarettes per day, the healthcare provider might consider prescribing nicotine replacement therapy (NRT), which is available as gum, lozenge, patch, nasal spray, or inhaler. This approach, while still somewhat controversial, delivers less nicotine than cigarettes and avoids exposure to the other substances found in tobacco smoke (Galic & Martino, 2010). Medications such as bupropion and varenicline have been approved for smoking cessation therapy in the general population, but their safety in pregnancy has not been demonstrated (Forest, 2010). ACOG (2005) suggests that NRT or bupropion be considered for pregnant and lactating women if other efforts at cessation fail.

Application: Smoking Cessation Plan

Many educational resources are available for healthcare providers and consumers on smoking cessation programs. Organizations that might be helpful include the following:

- American Lung Association
- March of Dimes
- American Cancer Society
- Healthy Mothers, Healthy Babies

Alcohol

Application: Smoking Cessation Plan

Alcohol is now considered one of the primary teratogens in the Western world. Fetuses of women who are heavy drinkers are at increased risk for developing **fetal alcohol syndrome (FAS)**. Currently FAS, characterized by growth restriction; behavioral disturbances; craniofacial abnormalities; and brain, cardiac, and spinal defects, is the most common preventable cause of intellectual disability (mental retardation) in the United States. The Centers for Disease Control and Prevention (CDC) analysis of the 2002 Behavioral Risk Factor Surveillance System (BRFSS) survey revealed that 10% of pregnant women used alcohol, and approximately 2% engaged in binge drinking (Floyd, Ebrahim, Tsai, et al., 2006). The incidence of fetal alcohol syndrome is approximately 1 in every 100 births (Wisner et al., 2007).

The effects of moderate consumption of alcohol during pregnancy are unclear. Research suggests an increased incidence of lowered birth weight and some neurologic effects, such as attention deficit disorder. Evidence suggests that the risk of teratogenic effects increases proportionately with increased average daily intake of alcohol. Although an occasional drink during pregnancy does not carry any known risk, no safe level of drinking during pregnancy has been identified, and caregivers should recommend that pregnant women abstain from all alcohol during pregnancy (Katz, 2008). In 2005, the U.S. surgeon general issued an advisory on alcohol use in pregnancy to increase public awareness about this serious health concern (CDC, 2005).

Alcohol passes the placental barrier within minutes after consumption, with fetal blood alcohol levels becoming equivalent to maternal blood alcohol levels. The effects of alcohol consumption vary according to the stage of fetal development. During the first trimester, alcohol probably alters embryonic development; throughout pregnancy, alcohol may interfere with cell division and growth; in the third trimester, the time of most rapid brain growth, alcohol may alter CNS development and contribute to growth retardation (Cunningham et al., 2010). The risk of neurologic damage decreases with the cessation of

heavy drinking in the third trimester. Decreased consumption of alcohol in midpregnancy is associated with a lower incidence of growth restriction.

Assessment of alcohol intake is a chief part of each woman's medical history with questions asked in a direct, nonjudgmental manner. All women of childbearing age who are sexually active and not using an effective method of birth control should be advised of the tetratogenic effect of alcohol (CDC, 2005). Because the most profound impact of alcohol occurs in the first weeks after conception, however, nurses and other healthcare providers will see the most dramatic decrease in the effects of alcohol during pregnancy by increasing their teaching efforts in the period before conception. In a study of pregnant women with a positive alcohol screening assessment who received educational intervention, nearly two thirds decreased their risk of an alcohol exposed pregnancy (Floyd et al., 2006). If heavy consumption is involved, women should be referred early to an alcoholic treatment program. Because the drug disulfiram (Antabuse), which is often used in the treatment of alcoholism, is a suspected teratogen, a woman in such a program should inform her counselor if she becomes pregnant.

Caffeine

Current research reveals no evidence that moderate levels of caffeine are linked to birth defects. However, high caffeine intake may be linked to an increased rate of spontaneous abortion (Weng, Odouli, & Li, 2008). Furthermore, an increased risk of decreased birth weight has been found in infants of mothers who consume greater than 300 mg of caffeine daily (CARE Study Group, 2008). (The average cup of brewed coffee has 100 mg, a cup of tea has 50 mg, a regular cola drink has up to 40 mg, and a normal-sized chocolate bar has up to 50 mg.) Until more definitive data are available, nurses should advise women of common sources of caffeine, including coffee, tea, colas, and chocolate, and suggest they limit their caffeine intake to about 300 mg/day (Cunningham et al., 2010).

Marijuana

Research reveals that approximately 15% of pregnant women use marijuana. The prevalence of marijuana use in our society raises concerns about its effect on the fetus, but to date no teratogenic effects of marijuana use during pregnancy have been documented (Schempf, 2007; Wisner et al., 2007). Research on marijuana use in pregnancy is difficult, however, because it is an illegal drug. Unreliability of reporting, lack of a representative population, inability to determine strength or composition of the marijuana used (including the presence of herbicides), and use of other drugs at the same time are major factors complicating the research being done.

Cocaine

Research indicates that 2.8% of pregnant women use illicit substances; 1% of those women use cocaine at some point in their pregnancy (Wisner et al., 2007). A woman who uses cocaine is at increased risk for acute myocardial infarction, cardiac arrhythmias, ruptured ascending aorta, seizures, cerebrovascular accidents, hypertension, bowel ischemia, and sudden death (Cunningham et al., 2010). Cocaine use during pregnancy has been related to abruptio placentae, premature rupture of the membranes, preterm birth, low birth weight, neonatal irritability, and neonatal depression (Schempf, 2007) as well as SIDS (March of Dimes [MOD], 2009; Wisner et al., 2007). Studies indicate normal intelligence levels despite exposure in utero. However, subtle learning and behavioral problems may occur as a result of prenatal cocaine exposure (MOD, 2009; Wisner et al., 2007). Several congenital anomalies have been linked to maternal cocaine use, including genitourinary anomalies, congenital heart defects, limb reduction defects, CNS anomalies, prune belly syndrome (congenital absence of abdominal muscles), and segmental intestinal atresia (Cunningham et al., 2010).

As cocaine becomes more widely used by women of childbearing age, healthcare providers need to be alert to early signs of cocaine use. It is often difficult for a healthcare provider to face the fact that a patient may be using cocaine, but ongoing alertness and an open, nonjudgmental approach are important in early detection. Maternal urine screening for cocaine is valuable, but because cocaine is metabolized rapidly, the drug screen is negative within 24 to 48 hours after cocaine use. Thus it is probable that many expectant mothers who use cocaine are not identified. However, the newborn may also be screened to document maternal cocaine use. It is important for the nurse to promote early detection of fetal exposure to cocaine in order to provide appropriate newborn care.

Evaluation

Throughout the antepartum period, evaluation is an essential part of effective nursing care. As nurses ask questions of the pregnant woman and her family or make observations of physical changes, they are evaluating the results of previous interventions. In evaluating the effectiveness of the interventions, the nurse should not be afraid to try creative solutions if they are logical and carefully thought out. This is especially important in dealing with families from other cultures. If a practice is important to a woman and not harmful, the culturally competent nurse will not discourage it.

In completing an evaluation, the nurse must also recognize situations that require referral for further evaluation. For example, a woman who has gained 4 lb in 1 week probably does not require counseling about nutrition; she needs further assessment for preeclampsia. The nurse who has a sound knowledge of theory will recognize this and act immediately.

The ongoing and cyclic nature of the nursing process is especially evident in the prenatal setting. Throughout the course of pregnancy nurses can use certain criteria to determine the quality of care provided. In essence, nursing care has been effective if the following have been met:

- The common discomforts of pregnancy are quickly identified and are relieved or lessened effectively.
- The woman is able to discuss the physiologic and psychologic changes of pregnancy.

- The woman implements appropriate self-care measures, if they are indicated, during pregnancy.
- The woman avoids substances and situations that pose a risk to her well-being or that of her child.
- The woman seeks regular prenatal care.

Care of the Expectant Couple Over 35

Today an increasing number of women are choosing to have their first baby after age 35 (Table 16-6). In fact, in 2006, 1 in 5 women in the United States had her first child after the age of 35 (MOD, 2009). The birth rates for women between the ages of 35 and 39 (47.3 births per 1000 women) and between the ages of 40 and 44 (9.4 per 1000) are the highest in more than three decades (Martin et al., 2009). Many factors contribute to this trend, including the following:

- The availability of effective birth control methods
- The expanded roles and career options available for women
- The increased number of women obtaining advanced education, pursuing careers, and delaying parenthood until they are established professionally
- The increased incidence of later marriage and second marriage
- The high cost of living, which causes some young couples to delay childbearing until they are more secure financially
- The increased number of women in this older reproductive age group because of the baby boom between 1946 and 1964
- The increased availability of specialized fertilization procedures, which offers opportunities for women who had previously been considered infertile

There are advantages to having a first baby after the age of 35. Single women or couples who delay childbearing until they are older tend to be well educated and financially secure.

Usually their decision to have a baby was deliberately and thoughtfully made (Figure 16-15 ■). Because of their greater life experiences, they are also more aware of the realities of having a child than younger women, and they recognize what it means to have a baby at their age. This delay in family allows for women to pursue advanced educational degrees and prepare financially for the impact children will have on their lives. Some women are ready to make a change in their lives, desiring to stay home with a new baby. Those who plan to continue working are typically able to afford good child care.

TABLE 16-6 Pregnancy in Women over Age 35

- Couples who choose pregnancy at a later age are usually financially secure and have made a thoughtful, planned choice.
- If the woman has no existing health problems, her risk during pregnancy is not appreciably higher than that of the general population.
- The decreased fertility of women over age 35 may make conception more difficult.
- The incidence of Down syndrome increases somewhat in women over age 35 and significantly in those over age 40.
- The couple may choose to have amniocentesis or chorionic villus sampling to gain information about the health of their fetus.

Figure 16-15 ■ For many older couples, the decision to have a child may be a very rewarding one.

Medical Risks

In the United States and Canada over the past 30 years, the risk of death has declined dramatically for women of all ages as a result of advances in maternal health and obstetric practice. However, the risk for maternal death is significantly higher for women over age 35 and even higher for women age 40 and older. These women also are more likely to have chronic medical conditions. Preexisting medical conditions, such as hypertension or diabetes, probably play a more significant role than age in maternal well-being and the outcome of pregnancy. The incidence of low-birth-weight infants and preterm births is higher among women age 35 or older (Delbaere et al., 2007). In addition, the rate of miscarriage is significantly higher in older women. Women over age 35 who become pregnant also have an increased risk for gestational diabetes mellitus, hypertension, placenta previa, difficult labor, and newborn complications (MOD, 2009).

The cesarean birth rate is also increased in pregnant women over 35. This practice may be related to increased concern by the woman and physician about the pregnancy outcome (MOD, 2009).

The risk of conceiving a child with Down syndrome does increase with age, especially over age 35. ACOG (2007) recommends that all pregnant women, regardless of age, be screened for Down syndrome. Research has focused on the use of quadruple screening to detect Down syndrome and trisomy 18 (see chapter 15 ∞). First trimester ultrasound assessment of the thickness of fetal nuchal folds (nuchal translucency, or NT) combined with serum screens of free beta-human chorionic gonadotropin (hCG) and pregnancy-associated plasma protein A (PAPP-A), is increasing the detection of Down syndrome, trisomy 18, and trisomy 13. If the screening results are not in the normal range, follow-up testing using ultrasound and amniocentesis is often indicated (Cleveland Clinic, 2006).

Amniocentesis is routinely offered to all women over age 35 to permit the early detection of several chromosomal abnormalities, including Down syndrome. Routine genetic testing has not been offered to couples in which the only risk is advanced paternal age, because there is no sufficient evidence to determine a specific paternal age at which to start genetic testing. The chromosomal mutations that occur with age are thought to be responsible for the increased risk of the offspring of older fathers having reduced fertility and an increased risk of birth defects (Bray, Gunnel, & Smith, 2006). While the causes of stillbirth in the over-40 age group are not known, a number of studies have found that women over age 40 are about 2 to 3 times as likely as women in their 20s to have a stillborn baby (MOD, 2009; Warren & Silver, 2008). Additionally, advanced paternal age increases the risk for genetic aberrations, especially if the father is 50 or older at the time of conception (Johnson et al., 2007).

Special Concerns of the Expectant Couple over 35

No matter what their age, most expectant couples have concerns regarding the well-being of the fetus and their ability to parent. The older couple has additional concerns related to their age, especially the closer they are to 40. Some couples are concerned about whether they will have enough energy to care for a new baby. Of greater concern is their ability to deal with the needs of the older child as they, themselves, age.

> "I didn't really think I would get married but then I met Antonio and fell hard. I was 35 and he was 43, a widower with no children. We both really wanted a baby, so here I am, 36 and pregnant. How I pray that this baby will be healthy."

The financial concerns of an older couple are usually different from those of a younger couple. The older couple is generally more financially secure than the younger couple. However, when their "baby" is ready for college, the older couple may be near retirement and might not have the means to provide for their child.

While considering their financial future and future retirement, the older couple may be forced to face their own mortality. Certainly this is not uncommon in midlife, but instead of confronting this issue at 40 to 45 years of age or later, the older expectant couple may confront the issue several years earlier as they consider what will happen as their child grows.

The older couple facing pregnancy following a late or second marriage or after therapy for infertility may find themselves somewhat isolated socially. They may feel "different" because they are often the only couple in their peer group expecting their first baby. In fact, many of their peers are likely to be parents of adolescents or young adults and may be grandparents as well.

The response of older couples who already have children to learning that the woman is pregnant may vary greatly depending on whether the pregnancy was planned or unexpected. Other factors influencing their response include the attitudes of their children, family, and friends to the pregnancy; the impact on their lifestyle; and the financial implications of having another child. Sometimes couples who had previously been married to other mates will choose to have a child together. The concept of blended family applies to situations in which "her" children, "his" children, and "their" children come together as a new family group.

Healthcare professionals may treat the older expectant couple differently than they would a younger couple. Older women may be offered more medical procedures, such as amniocentesis and ultrasound, than younger women. An older woman may be prevented from using a birthing room or birthing center even if she is healthy, because her age is considered to put her at risk.

The woman who has delayed pregnancy may be concerned about the limited amount of time that she has to bear children. When pregnancy does not occur as quickly as she hoped, the older woman may become increasingly anxious as time slips away on her "biological clock." When an older woman becomes pregnant but experiences a spontaneous abortion, her grief for the loss of her unborn child is exacerbated by her anxiety about her ability to conceive again in the time remaining to her.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

In working with a woman in her 30s or 40s who is pregnant, the nurse makes the same assessments as are appropriate in caring for any woman who is pregnant. These include assessing physical status, the woman's understanding of pregnancy and the changes that accompany it, any health teaching needs that exist, the degree of support the woman has available to her, and her knowledge of infant care. In addition, the nurse explores the woman's and her partner's attitudes about the pregnancy and their expectations of the impact a baby will have on their lives.

The nursing diagnoses that are applicable to any pregnant woman apply to the pregnant woman who is over the age of 35. Examples of other nursing diagnoses that may apply include the following:

- ***Decisional Conflict*** related to unexpected pregnancy
- ***Impaired Social Interaction*** related to changes associated with pregnancy

Nursing Plan and Implementation

Once an older couple has decided to have a child, it is the nurse's responsibility to respect and support them in this decision. As with any patient, the nurse needs to discuss risks, iden-

Childbirth.org

tify concerns, and promote strengths. The woman's age should not be made an issue. To promote a sense of well-being, the nurse should treat the pregnancy as "normal" unless specific health risks are identified.

As the pregnancy continues, the nurse should identify and discuss concerns that the woman may have related to her age or to specific health problems. The older woman who has made a conscious decision to become pregnant often has carefully thought through potential problems and may actually have fewer concerns than a younger woman or one with an unplanned pregnancy.

Childbirth education classes are important in promoting adaptation to the event of childbirth for expectant couples of any age. However, older expectant couples, who are still in the minority, often feel uncomfortable in classes where the majority of participants are much younger. Because of the differences in age and life experiences, many of the needs of the older couple may not be met in the class. Consequently, classes for expectant parents over age 35 are now available in many communities. Women who are over 35 years of age and having their first baby tend to be better educated than other healthcare consumers. These patients frequently know the kind of care and services they want and are assertive in their interactions with the healthcare system. The nurse should neither be intimidated by these patients nor assume that they do not need anticipatory guidance and support. Instead, the nurse should support the couple's strengths and be sensitive to their individual needs.

A particularly difficult issue that older expectant couples face is the possibility of bearing an unhealthy child. Because of the risk of Down syndrome in these families, amniocentesis is encouraged. Chorionic villus sampling may also be suggested if available in the area. The decision to have amniocentesis can be difficult to make merely on the basis of its possible risks to the fetus. But that becomes almost a minor concern when the couple thinks of the implications of the possible findings of Down syndrome or other chromosomal abnormalities. The finding of abnormalities means that the couple may be faced with an even more difficult decision about continuing the pregnancy.

A couple's decision to have amniocentesis is usually related to their beliefs and attitudes about abortion. Generally, amniocentesis is not even considered by couples who are strongly opposed to abortion for any reason. Health professionals must respect the couple's decision, take a nonjudgmental approach, and provide them with emotional support throughout the pregnancy.

The decision to have an abortion is a painful one even when couples are not opposed to abortion on political or philosophic grounds. Even though the couple may believe that terminating a high-risk pregnancy is an option for their family, they may feel a great deal of ambivalence about amniocentesis. If the results are such that the couple elects to have an abortion, they will usually feel much grief for their loss.

Many health professionals assume that the couple who agrees to amniocentesis will also elect to have an abortion if Down syndrome or another condition is diagnosed. This is not necessarily the case. Some couples choose not to have an abortion after being informed that their unborn child has genetic abnormalities.

For couples who decide to have amniocentesis, the first few months of pregnancy are a difficult time. Amniocentesis cannot be done until 14 weeks of pregnancy, and the chromosomal studies take roughly 2 weeks to complete. Their fear that the fetus is at risk may delay the successful completion of the psychologic tasks of early pregnancy.

The nurse can support couples who decide to have amniocentesis in several ways:

- The nurse should make sure that the couple is aware of the risks of amniocentesis and why it is being performed.
- The nurse who is present during the amniocentesis procedure can offer comfort and emotional support to the expectant woman. The nurse can also provide information about the procedure as it is being performed.
- The nurse can facilitate a support group for women during the difficult waiting period between the procedure and the results.
- If the results indicate that the fetus has Down syndrome or another genetic abnormality, the nurse can ensure that the couple has complete information about the condition, its range of possible manifestations, and its developmental implications.
- The nurse can support the couple in their decision about continuing or terminating the pregnancy. It is essential that the nurse and other health professionals involved with the couple not impose their philosophic or political beliefs about abortion on the couple. The decision is the couple's, and it should be based on their belief system and a nonbiased presentation of risks and choices from caregivers.

Amniocentesis is discussed further in chapter 21 ∞.

Evaluation

Expected outcomes of nursing care include the following:

- The woman and her partner are knowledgeable about the pregnancy and make appropriate healthcare choices.
- The expectant couple is able to cope successfully with the pregnancy and its implications for the future.
- The woman receives effective health care throughout her pregnancy and during birth and the postpartum period.
- The woman and her partner develop skills in child care and parenting as necessary.

FOCUS YOUR STUDY

- Providing anticipatory guidance about childbirth, the postpartum period, and childrearing is a primary responsibility of the nurse caring for women in an antepartal setting.
- The nurse assesses the expectant father's knowledge level and intended degree of participation and then works with the couple to help ensure a satisfying experience.
- Culturally based practices and taboos may have a major impact on the childbearing family.
- The common discomforts of pregnancy occur as a result of physiologic and anatomic changes. The nurse provides the woman with information about self-care activities aimed at reducing or relieving discomfort.
- To make appropriate self-care choices and ensure healthful habits, a pregnant woman requires accurate information about a range of subjects from exercise to sexual activity, from bathing to immunization.
- Maternal assessment of fetal activity keeps the woman "in touch" with her fetus and provides ongoing assessment of fetal status.
- Teratogenic substances are substances that adversely affect the normal growth and development of the fetus.
- A pregnant woman should avoid taking nonessential medications or using over-the-counter preparations during pregnancy.
- Evidence confirms that smoking, consuming alcohol, or using social drugs during pregnancy may be harmful to the fetus.
- Childbirth among women over 35 is becoming increasingly common. It poses fewer health risks than previously believed and offers advantages for the woman or couple who makes the choice.
- A major risk for the older expectant couple relates to the increased incidence of Down syndrome in children born to women over age 35. Amniocentesis can provide information as to whether the fetus has Down syndrome. The couple can then decide whether they wish to continue the pregnancy.

CRITICAL THINKING IN ACTION

Thirty-seven-year-old Cathy Sommers, G1, P0000, presents to you, with her husband, at the OB physician's office at 32 weeks' gestation. Cathy tells you that she and her husband are practicing lawyers with their own firm. The couple delayed starting a family because it has been important to them to advance their careers and establish their firm. Cathy had an amniocentesis at 18 weeks' gestation because of her advanced maternal age, and the results ruled out chromosomal abnormalities. The couple knows that the baby is a boy, and are anticipating a vaginal birth. Cathy tells you that she is experiencing more fatigue, leg cramps, and shortness of breath when climbing stairs. The physical exam including a negative Homan's sign is within normal limits with the exception of slight ankle edema. Her weight is 150 lb, temperature 98.6°F, pulse 88, respirations 16, BP 126/70. You discuss pregnancy discomforts in the third trimester with Cathy and her husband.

1. What measures can you suggest to cope with fatigue?
2. Discuss measures to decrease leg cramps.
3. Discuss the physiologic changes underlying dyspnea.
4. Review Braxton Hicks contractions.

CHAPTER 17

Adolescent Pregnancy

I am a freshman in college, and so is my daughter. I had her when I was 15, and that forced me to grow up in a hurry. For years I've thought about being a nurse, and now is my chance. Please understand, my daughter is very precious to me, but a part of me knows that if I had it to do over, I would change so much of my life—if only I had known!

LEARNING OUTCOMES

1. Discuss the physical and psychosocial changes of adolescence.
2. Compare the three stages of adolescence: early adolescence, middle adolescence, and late adolescence.
3. Summarize the developmental tasks of adolescence and the impact that pregnancy superimposes on these tasks.
4. Describe the major factors that contribute to teenage pregnancy.
5. Identify the impact of cultural factors on the desirability of early pregnancy.
6. Identify the physical, psychologic, and sociologic risks faced by an adolescent who is pregnant.
7. Delineate characteristics of the fathers of children of adolescent mothers.
8. Discuss the reactions of the adolescent's family and social support groups to her pregnancy.
9. Formulate a plan of care to meet the needs of a pregnant adolescent.
10. Describe successful community approaches to adolescent pregnancy prevention.

KEY TERMS

Early adolescence *380*
Emancipated minors *387*
Late adolescence *380*
Middle adolescence *380*

Adolescent pregnancy is a health and social issue with no single cause or cure. For a teen, pregnancy comes at a time when her physical development and the developmental tasks of adolescence are incomplete. She may not be prepared physically, psychologically, or economically for parenthood. Thus both she and her child are at high risk for a number of adverse outcomes. Compared with women of similar socioeconomic status who postpone childbearing, teen mothers are less likely to finish high school, less likely to go to college, more likely to be single, and more likely to end up on welfare. Babies of adolescent mothers are often born prematurely and of low birth weight. In addition, children of teen mothers are at increased risk for intellectual disability (mental retardation), poverty, welfare dependency, and poor school performance. They are also more likely to grow up without a father. In addition, they suffer higher rates of abuse and neglect than would occur if their mothers had delayed childbearing (National Campaign to Prevent Teen and Unplanned Pregnancy [NCPTUP], 2010).

Each year, an estimated 750,000 U.S. adolescents ages 15 to 19 years become pregnant, and approximately 442,000 children are born to teens. Of these pregnancies, about 27% are terminated by therapeutic abortion (Alan Guttmacher Institute [AGI], 2010a). A portion of pregnancies end in miscarriage but more than half the teens who become pregnant give birth and keep their babies.

The teenage pregnancy rate dropped 40% from 1990 to 2005, from 61.8 per 1000 women to an historic low of 40.5 per 1000 women ages 15 to 19 years. Rates fell much more for younger than for older teenagers. However, the birth rate for teenagers ages 15 to 19 years rose 3% in 2006 and 1% more in 2007 to 42.5 per 1000, interrupting the long-term decline that had extended from 1991 through 2005 (NCPTUP, 2010). See Figure 17-1 ■. This increase was halted in 2008, when the birth rate for teens fell 2% to 41.5 per 1000 (Hamilton, Martin, & Ventura, 2010).

The U.S. teenage birth rate remains the highest of any industrialized nation, almost twice as high as those of England, Wales, and Canada and 8 times as high as those of the Netherlands and Japan (AGI, 2006). The incidence of sexual activity among teens in other countries is as high as in the United States. These countries may have lower adolescent pregnancy rates because of family influences, a greater openness about sexuality, better access to contraceptives, and a more comprehensive approach to sex education.

This chapter explores the incidence, risk factors, and consequences of adolescent pregnancy. It then presents the role of the nurse in meeting the special needs and concerns of pregnant adolescents and their families and concludes with a discussion of efforts to prevent adolescent pregnancy.

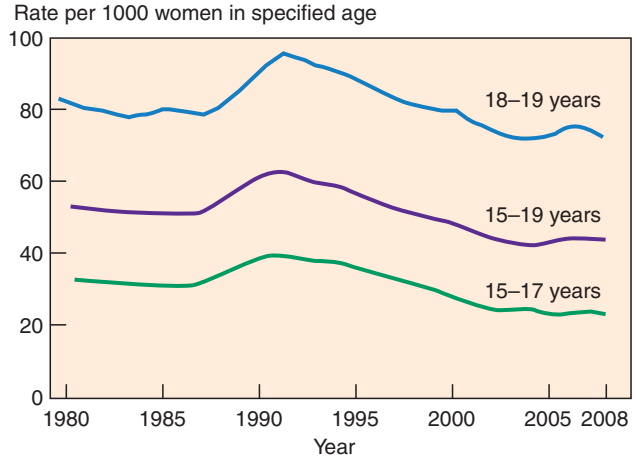

Figure 17-1 ■ Birth rates for teenagers by age: United States, final 1960–2006 and preliminary 2007 and 2008.

Overview of Adolescence

Physical Changes

Adolescence is the period of development during which an individual makes the psychologic and physiologic transition from childhood to young adulthood, usually between 13 and 20 years of age. Puberty, the period during which an individual becomes capable of reproduction, is a maturational process that can last from 1.5 to 6 years and generally coincides with adolescence. The major physical changes of puberty include a growth spurt, weight change, and the appearance of secondary sexual characteristics. *Menarche,* or the time of the first menstrual period, usually occurs in the last half of puberty, with the average age between 12 and 13.

The initial menstrual cycles are usually irregular and often anovulatory for the first 12 to 18 months; however, this is not true for all females. Some adolescents do not use contraception during this time because they falsely assume that they cannot get pregnant. Even if their initial menstrual cycles are anovulatory, there is no certainty about when the first ovulatory cycle will occur; thus, contraception is important during this time for all adolescents who are sexually active.

Psychosocial Development

Although it is well documented that the onset of puberty now occurs at a younger age than it did 50 years ago, there are no data to indicate that psychosocial development, particularly cognitive development, occurs at an earlier age. Developmental tasks of adolescence have been described by many writers and are based on a variety of classic theories. These tasks are issues that individuals may struggle with at other times in their lives, but they are especially significant during adolescence to help ensure a successful transition from childhood to adulthood. The following are major developmental tasks of this period (Steinberg, 2010):

- Developing an identity.
- Gaining autonomy and independence.
- Developing intimacy in a relationship.
- Developing comfort with one's own sexuality.
- Developing a sense of achievement.

Resolving these tasks is a developmental process that occurs over time. This developmental process is reflected in the behaviors of youths during early, middle, and late adolescence.

During adolescence, there is a need to "try on" various roles in a process of experimentation and exploration as adolescents grapple with ideas about who they want to be and how they want to live. This developmental process occurs in youths during all

stages of adolescence and is affected by many factors, including culture, religion, and socioeconomic status.

Teens work to separate themselves from their parents to establish their own identity and they begin to express themselves with music, clothing, and hairstyles. Some choose peer-identity behaviors such as body modifications (body piercing) and body art (tattoos). Although these forms of peer identity have been around for thousands of years, they are gaining popularity, especially among teens and preteens. See the discussion in chapter 4 ∞.

During **early adolescence** (age 14 and under), psychosocial development is marked by rapid physical changes that engender self-centeredness and initiate the struggle for independence. The teen at this age still sees authority as resting with the parents. She perceives her locus of control as external; that is, her destiny is controlled by others, such as parents and school authorities. However, she begins the process of "leaving the family" by spending more time with friends, especially friends of the same sex. Conformity to peer group standards is reflected in her behavior and her clothing. She may lack impulse control, which can result in risk-taking behaviors. During this phase, the adolescent has a rich fantasy life. She is also struggling to become comfortable with her changing body and body image and to fit this image with her fantasy life. Much time is spent in front of the mirror. The adolescent in this phase is very egocentric and is a concrete thinker. She has only minimal ability to see herself in the future or foresee the consequences of her behavior.

Middle adolescence (15 to 17 years) is the time for challenging authority. Experimentation with drugs, alcohol, and sex is a common method of rebellion. As the middle adolescent seeks independence, she turns increasingly to her peer group, identifying with and conforming to them in her choice of dress, makeup, hairstyle, and music. These years are often a time of great turmoil for the family as the adolescent struggles for independence and challenges the family's values and expectations.

The middle adolescent wants to be treated as an adult. However, fear of adult responsibility may cause fluctuation in behavior. At times she seems like a child; at other times she is surprisingly mature. She is beginning to move from concrete thinking to formal operational thought but is not yet able to anticipate the long-term implications of all her actions. She may even believe that she is invincible and will not suffer negative consequences from risk-taking behaviors.

In **late adolescence** (18 to 19 years), the young woman is more at ease with her individuality and decision-making ability. She can think abstractly and anticipate consequences. During this time, she becomes more confident of her personal identity. The late adolescent is capable of formal operational thought. She is learning to solve problems, to conceptualize, and to make decisions. These abilities help her see herself as having control, which leads to the ability to understand and accept the consequences of her behavior.

Table 17-1 describes successful resolution of each of the developmental tasks of adolescence and identifies high-risk factors for adolescent pregnancy.

TABLE 17-1 Developmental Tasks of Adolescence

TASKS	DESCRIPTION OF SUCCESSFUL RESOLUTION	HIGH-RISK FACTORS FOR TEEN PREGNANCY
Developing an identity	As individuals enter puberty, their physical appearance begins to change, and others begin to respond differently to them. The media present idealized images of the teenage female. Self-esteem may fluctuate, and hormonal changes create awareness of sexual desire. Adolescents experience confusion about their self-image. This is a time of experimentation until they become comfortable with whom they are.	If the young adolescent feels she cannot live up to parents' expectations or is in a dysfunctional family situation, she may adopt a negative identity. She may become rebellious and actively involved in risk-taking behaviors, such as substance abuse and early sexual activity.
Gaining independence	Adolescents gradually move away from parental control and are influenced by peers. Eventually, they develop values that help govern their behavior responsibly without extrinsic control of peers or parents.	Peer pressure is highest during early and middle adolescence. If peers are involved in antisocial behavior, this influences their behavior and all other developmental tasks. Substance abuse and sexual activity are common in these groups.
Developing emotional intimacy in relationships	Adolescents begin to develop a close emotional attachment with another individual. They can share innermost feelings and have empathy for the other. This usually begins with a friend of the same sex and eventually develops into a trusting and loving relationship with someone of the opposite sex.	Sexual activity may be an attempt to meet needs for intimacy. This is a problem for victims of neglect or abuse. Although sexual intercourse has become a common adolescent experience, emotional intimacy is not associated with the majority of dating relationships, and most teenage marriages end in divorce.
Developing comfort with their sexuality	Puberty causes a new awareness of sexual desire and new meaning about physical contact with others. Adolescents learn to express sexual feelings appropriately and comfortably in a relationship.	Many young adolescent females who become sexually involved at an early age do so for a variety of reasons that do not lead to comfort with their own sexuality, such as peer pressure, pressure from an older male partner, rebellion against parents, and sexual abuse and its consequences.
Gaining a sense of achievement	Adolescents begin to look toward the future and compare talents, work skills, and/or academic achievement with reality in preparing for adult working roles.	Those who drop out of school prematurely tend to be from economically disadvantaged backgrounds. Data show that early sexual experimentation by adolescents correlates with poor school performance whatever their background. Use of contraception is more likely among adolescent females who are high academic achievers and have a future orientation.

Factors Contributing to Adolescent Pregnancy

Teenagers rarely plan pregnancy. *Pregnancy risk taking* (sexual activity without use of pregnancy prevention measures) is believed to stem from a complex variety of factors, the most important of which are discussed next.

Socioeconomic and Cultural Factors

Nearly all young people experience pressure of some kind to be sexually active and are, therefore, at risk of pregnancy and its consequences. It is not the case that only one group of teens, only one ethnic group, or only low-income teens engage in sex and become pregnant. Sexual activity, pregnancy, and the risk for sexually transmitted infections cut across all of these groups (NCPTUP, 2007).

Poverty is both a cause and a consequence of teen pregnancy and childbearing. For many years it was believed that poverty and its manifestations, such as drop-out rates, were the *consequence* of early childbearing. However, recent research has associated poverty and social disorganization as among the *causes* of teen childbearing as well (NCPTUP, 2007). Adolescents who do not have access to middle-class opportunities tend to maintain their pregnancies, because they see pregnancy as their only option for adult status; 85% of births to unmarried teens occur to those from poor or low-income families (AGI, 2006). Not surprisingly, research indicates that the more time high school students spend without adult supervision, the greater their level of sexual activity.

In the United States, the adolescent birth rate is higher among African American and Hispanic teens than among white teens. To some degree, the higher teenage pregnancy rate in these groups reflects the impact of poverty, because a disproportionately higher number of African American and Hispanic youths live in poverty. Research has shown that minority teens are most vulnerable to early sexual activity with subsequent pregnancy (Talashek, Alba, & Patel, 2006). Pregnancy prevention programs cannot affect race or ethnicity but sometimes in collaboration with other programs they can help reduce minority poverty or minority cultural values that may contribute to sexual risk (NCPTUP, 2007).

Low educational achievement is another major risk factor for adolescent pregnancy. Teenage pregnancy is the leading reason why adolescent women drop out of school. An estimated 30% to 40% of female teenage dropouts are mothers. Teens who grow up in poor neighborhoods with inferior schools are likely to have the view that employment and educational opportunities are limited whether they are pregnant or not. Family obligations, which compete with the time and energy needed to attend school, and a lack of vocational opportunities may influence poor teens' misuse of contraception and, if they do become pregnant, their decision to carry their babies to term. Unlike middle-class teens, whose college and career plans would be inconvenienced by having a child, motherhood may become a rite of passage to adulthood for disadvantaged teens. Although many studies show discouraging results for adolescents who become pregnant, for others, pregnancy may lead the way to more responsible and mature behaviors (SmithBattle, 2007).

The younger the teen when she first gets pregnant, the more likely she is to have another pregnancy in her teens. Moreover, the likelihood of repeat pregnancies increases when the teen is living with her sexual partner and has dropped out of school. Additionally, girls whose sister had a baby in her early teens and girls whose mother and sister both gave birth as teens are significantly more likely to have a teenage pregnancy themselves (East, Reyes, & Horn, 2007).

High-Risk Behaviors

Developmentally, adolescents, especially younger ones, are not yet able to foresee the consequences of their actions. As a result, they may have a sense of invulnerability that leads to the mistaken idea that harm will not befall them. This sense of invulnerability may also result in an overly optimistic view of the outcomes of the risks associated with their actions (King-Jones, 2008).

Among American adolescents there is tremendous peer pressure to become sexually active during the teen years. Premarital sexual activity is commonplace and teenage pregnancy is more socially acceptable today than it was in the past. In fact, nearly half (46%) of all teenagers 15 to 19 have had sex at least once (AGI, 2010a).

Sexual innuendo permeates every aspect of the popular media, including music, music videos, television, and movies. Research shows that adolescents spend an average of 8 hours per day engaged in mass media including approximately 3 to 4 hours per day watching TV. Sexual content dominates many programs most popular with adolescents, and they frequently use television as a source of their sexual information (Pinkleton, Austin, Cohen, et al., 2008).

The Internet provides teens with unlimited access to information about sex as well as a steady supply of people willing to discuss it with them. These experiences and images feed the adolescent's rich fantasy life and may glamorize unprotected intercourse as proof of "true love." At the same time, media aimed at teens largely ignore issues of sexual responsibility and fail to convey the physical, emotional, financial, and social costs of pregnancy risk-taking behaviors. Of particular note is the current blend of "sex and tech" in which teens and young adults use electronic activity to send or post sexually suggestive text and images. Statistics show that 20% of teens have sent or posted nude or semi-nude pictures or videos of themselves; 39% of teens say they are sending or posting sexually suggestive messages via e-mail or phone; and 48% of teens say they have received such messages. Seventy-five percent of teens say they know that sending such messages can have serious consequences and even know that such messages are often shared with people other than the intended receiver. Another alarming outcome in the research shows that sending or posting sexually suggestive text or images has made teens personally more forward and aggressive in cyberspace than they are in their real lives (NCPTUP, 2008).

In addition to vaginal intercourse, many adolescents engage in other sexual behaviors. The incidence of oral sex is increasing. Initiation of oral sex generally occurs soon after first vaginal intercourse and up to 82% of adolescents who had engaged in vaginal intercourse went on to engage in oral sex within 6 months (Lindberg, Jones, & Santelli, 2008). The increase has occurred, especially among young and early-middle adolescents, because of the pressure to have sex coupled with the fear of pregnancy.

The question of whether "oral sex" is really "sex" has led adolescents to perceive that they are still virgins if they have not had vaginal-penile sexual activity. Adolescents believe that they are less likely to get a bad reputation, get into trouble, or feel bad about themselves if they have oral rather than vaginal sex. However, they typically underestimate the risks of contracting chlamydia, HIV, and other sexually transmitted infections (STIs).

High-risk sexual behaviors, including, for example, multiple partners and lack of contraceptive use, are of concern. Research indicates that young people ages 15 to 24 constitute 25% of the sexually experienced population in the United States. However, they account for 48% of the new cases of STIs. This is particularly worrisome because many STIs, including HIV, are asymptomatic. Thus, apparently healthy young people who are infected may not seek health care (Weinstock, Berman, & Cates, 2004).

Statistics have demonstrated an increased use of condoms among the adolescent population, probably because of widespread educational efforts related to HIV. The condom is the most common contraceptive method used at first intercourse with 66% of females and 71% of males reporting its use (AGI, 2006). Nevertheless, adolescents remain inconsistent contraceptive users. Barriers to consistent contraceptive use include denial of their status as being sexually active when they may have had intercourse only once or twice; not considering the consequences of unprotected sexual activity; and embarrassment while talking about the topic with healthcare providers, their parents, and their partners. Teens reported feeling challenged when discussing contraception, unless it was with same age and gender peers, and, therefore, they avoided discussing it with their sexual partners who "seemed so opposed to it" (Lemay, Cashman, Elfenbein, et al., 2007). Many teens lack accurate and adequate knowledge about contraceptive options. This is a common topic of sex education programs; however, debate continues about the appropriateness of such programs in schools. Proponents advocate early sex education to provide teens with the knowledge they need to avoid unwanted pregnancy and the risk of STIs. Opponents feel that sex education is the responsibility of parents and worry that sex education in the schools will promote sexual activity. However, evaluations of comprehensive sex education and HIV/STI prevention programs show that they do not increase rates of sexual initiation, do not lower the age at which youth initiate sex, and do not increase the frequency of sex or the number of sex partners among sexually active youth. Conversely, when only abstinence programs are provided, the limited education can mean that teens are less likely to get STI testing and less likely to use a condom or contraception when they do have sex. Other factors affecting the use of contraception include access or availability, cost of supplies, and concern regarding confidentiality.

Adolescent sexuality is not pathologic but a part of normal development as a human being. Emphasizing sexual health rather than discussing sex exclusively as a behavior that has only bad consequences results in more effective work with adolescents (Kelly, Lesser, & Smoots, 2005).

Psychosocial Factors

Family dysfunction and poor self-esteem are also major risk factors for adolescent pregnancy. Some young teenagers deliberately plan to get pregnant. The adolescent girl may use pregnancy for various subconscious or conscious reasons: to punish her father and/or mother, to escape from an undesirable home situation, to gain attention, or to feel that she has someone to love and to love her. In these cases, pregnancy may in a sense be the young woman's form of delinquency. Like delinquent males, pregnant adolescents often have a history of troubled family relationships, poor school achievement, and drug abuse. For others, however, pregnancy marks an important milestone that leads to positive lifestyle changes and healthier behaviors (Pinkleton et al., 2008).

More teens who become pregnant, compared with teens who have not been pregnant, have been physically, emotionally, or sexually abused. Many teens have been exposed to intimate partner violence or have lived with someone who has substance abuse, has mental illness, or is involved in criminal activity. These experiences often lead the teen herself to engage in risk-taking behaviors such as smoking and alcohol consumption and may lead to mental health problems such as depression. Children born to these mothers have a higher risk of psychologic problems, which can lead to a multigenerational risk of mental health disability (Magill & Wilcox, 2007).

Teenage pregnancy can result from an incestuous relationship. In the very young adolescent, incest or sexual abuse should be suspected as a possible cause of pregnancy. Sex at a young age with an older partner can be associated with poor reproductive health outcomes because of the younger teen's undeveloped decision-making and negotiation skills, power imbalances, and exploitation by an older partner (Manlove, Terry-Humen, & Ikramullah, 2006).Teenage pregnancy could also be caused by other nonvoluntary sexual experiences such as acquaintance rape.

International Perspective

Globally about 16 million girls ages 15 to 19 give birth each year. One in 10 babies worldwide is born to an adolescent mother with almost 95% of adolescent mothers living in developing countries. The highest birth rates are found in sub-Saharan Africa and in some parts of Latin America and south Asia. Age at marriage is an important consideration. The majority of adolescent mothers are married; in developing countries, about 90% of births to adolescent mothers occur in marriage and three out of four pregnancies are planned. Despite this, however, statistics show that 4 million adolescents become pregnant unintentionally (World Health Organization [WHO], 2008a).

Cultural factors often play a significant role in the desirability of early pregnancy. Specifically, adolescent women are more likely to welcome a pregnancy in a country where Islam is the predominant religion, where large families are desired, where social change is slow in coming, and where most childbearing occurs within marriage. Early pregnancy is less desired in countries where the reverse is true.

In the past 2 to 3 decades the rates of adolescent childbirths have dropped significantly in most regions and countries. At the same time, in most countries, educational levels for girls have risen and job opportunities have increased (WHO, 2008b). In addition, in many parts of the world, young women now have goals in their lives beyond marriage and motherhood.

Growing evidence suggests that a significant number of girls in developing countries have experienced coercive (forced) sex.

Although the actual magnitude of the problem and its implications for women's health are not well known, several negative consequences have been identified. These include unintended pregnancy and abortion, increased incidence of STIs including HIV, low self-esteem, depression, and substance abuse (Population Council, 2004).

Risks to the Adolescent Mother

Physiologic Risks

Adolescents over age 15 who receive early, thorough prenatal care are at no greater risk during pregnancy than women over 20 years. Unfortunately, many adolescents fail to seek early prenatal care. Those who do seek care may fail to cooperate with recommendations. In addition, teenage mothers are more likely to smoke than older pregnant women and less likely to gain sufficient weight during their pregnancy. Thus risks for pregnant adolescents include preterm births, low-birth-weight (LBW) infants, preeclampsia-eclampsia and its sequelae, iron deficiency anemia, and cephalopelvic disproportion (CPD). In the adolescent age group, prenatal care is the critical factor that most influences pregnancy outcome.

DEVELOPING CULTURAL COMPETENCE

Educational Level and Childbearing

Throughout the world, the higher a woman's educational level, the more likely she is to delay marriage and childbirth.

Iron deficiency anemia is a problem in all pregnant women. The adolescent who begins her pregnancy already anemic, however, is at increased risk and must be followed closely and counseled carefully regarding nutrition during pregnancy. The increased risk of CPD is a concern in adolescent pregnancy, especially with the early adolescent, because of a lack of pelvic maturity.

Teenagers 15 to 19 years old have a high incidence of STIs including herpes virus, syphilis, and gonorrhea. The incidence of chlamydial infection is also increased in this age group. The presence of such infections during a pregnancy greatly increases the risk to the fetus (see chapter 20 ∞). Other problems seen in adolescents are alcohol and drug use. By the time pregnancy is confirmed in young women, the fetus may already be harmed by these substances.

Application: Preeclampsia in an Adolescent Patient

Psychologic Risks

The most profound psychologic risk to the adolescent who maintains her pregnancy is the interruption of progress in her developmental tasks. Although adolescents have become sexually active at an earlier age and the incidence of adolescent pregnancy has decreased, the developmental tasks of this age group remain the same. Add to this the tasks of pregnancy, and the young woman has an overwhelming amount of psychologic work to do, the success of which will affect her own and her newborn's future.

Table 17-2 identifies typical behaviors of the early, middle, and late adolescent when she becomes aware of her pregnancy. In reviewing these behaviors, the nurse should realize that other factors may influence the age at which the behaviors are seen.

TABLE 17-2 Initial Reaction to Awareness of Pregnancy

AGE	ADOLESCENT BEHAVIOR	NURSING IMPLICATIONS
Early adolescent (14 and under)	Fears rejection by family and peers. Enters healthcare system with an adult, most likely mother (parents still seen as locus of control). Value system still closely reflects that of parents, so still turns to parents for decision or approval of decision. Pregnancy probably not result of intimate relationship. Is self-conscious about normal adolescent changes in body. Self-consciousness and low self-esteem likely to increase with rapid breast enlargement and abdominal enlargement of pregnancy.	Be nonjudgmental in approach to care. Focus on needs and concerns of adolescent, but if parent accompanies daughter, include parent in plan of care. Encourage both to express concerns and feelings regarding pregnancy and options: abortion, maintaining pregnancy, adoption. Be realistic and concrete in discussing implications of each option. During physical exam of adolescent, respect increased sense of modesty. Explain in simple and concrete terms physical changes that are produced by pregnancy versus puberty. Explain each step of physical exam in simple and concrete terms.
Middle adolescent (15–17 years)	Fears rejection by peers and parents. Unsure in whom to confide. May seek confirmation of pregnancy on own with increased awareness of options and services, such as over-the-counter pregnancy kits and Planned Parenthood. If in an ongoing, caring relationship with partner (peer), may choose him as confidant. Economic dependence on parents may determine if and when parents are told. Future educational plans and perception of parental support or lack of support are significant factors in decision regarding termination or maintenance of the pregnancy. Possible conflict in parental and own developing value system.	Be nonjudgmental in approach to care. Reassure the adolescent that confidentiality will be maintained. Help adolescent identify significant individuals in whom she can confide to help make a decision about the pregnancy. Be aware of state laws regarding requirement of parental notification if abortion intended. Also be aware of state laws regarding requirements for marriage: usually, minimum age for both parties is 18; 16- and 17-year-olds are, in most states, allowed to marry only with consent of parents. Encourage adolescent to be realistic about parental response to pregnancy.
Late adolescent (18–19 years)	Most likely to confirm pregnancy on own and at an earlier date due to increased acceptance and awareness of consequences of behavior. Likely to use pregnancy kit for confirmation. Relationship with father of baby, future educational plans, and own value system are among significant determinants of decision about pregnancy.	Be nonjudgmental in approach to care. Reassure the adolescent that confidentiality will be maintained. Encourage adolescent to identify significant individuals in whom she can confide. Refer to counseling as appropriate. Encourage adolescent to be realistic about parental response to pregnancy.

TABLE 17-3 The Early Adolescent's Response to the Developmental Tasks of Pregnancy

STAGE	DEVELOPMENTAL TASKS OF PREGNANCY	EARLY ADOLESCENT'S RESPONSE TO PREGNANCY	NURSING IMPLICATIONS
First trimester	Pregnancy confirmation. Seeking early prenatal care as a confirmation tool. Begins to evaluate her diet and general health habits. Initial ambivalence common. Usually supportive partner.	May delay confirmation of pregnancy until late part of first trimester or later. Reasons for delay may include lack of awareness that she is pregnant, fear of confiding in anyone, or denial. Rapid enlargement and sensitivity of breasts are embarrassing and frightening to early adolescent—may be perceived as changes of puberty. If confiding in mother, may be experiencing family turmoil in response to pregnancy.	Explain physiologic changes of pregnancy versus those associated with puberty. Explain that ambivalence is normal with any pregnancy, but recognize it as a much greater concern with adolescent pregnancy. Emphasize need for good nutrition as important for her well-being as much as infant's (prevention of preeclampsia and anemia). Use simple explanations and lots of audiovisuals. Have adolescent listen to fetal heart rate (FHR) with Doppler.
Second trimester	Changes in physical appearance begin, and fetal movement is experienced, causing pregnancy to be experienced as a reality. Begins wearing maternity clothes to accommodate the physical changes. As a result of quickening she perceives her fetus as a real baby and begins preparing for the maternal role and new relationships with her partner and members of her family.	Some teenagers may delay validation of pregnancy until now, with family turmoil occurring at this time. Abdominal enlargement and quickening may be perceived as loss of control over body image. May try to maintain prepregnant weight and wear restrictive clothing to control and conceal changing body. Becomes dependent on her own mother for support. Egocentric; unable to develop a maternal role at this time.	Continue to discuss importance of good nutrition and adequate weight gain as noted above. Discuss ways of utilizing common teenage clothing (large sweatshirts, blouses) to promote comfort but preserve adolescent image to some degree. Discuss plans being made for baby, continued educational plans, and role of teen's parents.
Third trimester	At end of second trimester begins to view fetus as separate from self. Buys baby clothes and supplies. Prepares a place for the baby. Realistic about what baby is like. Prepares to give birth to infant. Anxiety increases as labor and birth approach and has concerns about well-being of fetus.	May focus on "wanting it to be over." May have trouble individuating fetus. May have fantasies, dreams, or nightmares about childbirth. Natural fears of labor and birth greater than with older primigravida. Probably has not been in a hospital, and may associate this with negative experiences.	Assess whether adolescent is preparing for baby by buying supplies and preparing a place in the home. Childbirth education important. Provide hospital tour. Assess for discomforts of pregnancy, such as heartburn and constipation. Adolescent may be uncomfortable mentioning these and other problems.

Table 17-3 identifies the early adolescent's response to the developmental tasks of pregnancy. The early adolescent's response reflects her level of development, with pregnancy as an interruption of the normal process of development. The middle and late adolescent responds differently, reflecting her maturational progress through the developmental tasks. In addition to her maturational level, the amount of nurturing the pregnant adolescent receives is also a critical factor in the way she handles pregnancy and motherhood.

Sociologic Risks

A substantial body of research indicates that the adolescent mother is at higher risk for social and economic disadvantages than her teenage counterpart who is not pregnant and lives in the same social environment. Being forced into adult roles before completing adolescent developmental tasks causes a series of events that may result in a prolonged dependence on parents, lack of stable relationships with the opposite sex, and lack of economic and social stability. Many teenage mothers drop out of school during their pregnancy and then are less likely to complete their schooling. Similarly they are less likely to go to college, more likely to have big families, and more likely to be single. Lack of education in turn reduces the quality of jobs available. Childbearing at an early age is a strong predictor that the children of teenage mothers will live in poverty (Kirby, 2007).

Some pregnant adolescents choose to marry the father of the baby, who may also be a teen. Unfortunately, the majority of adolescent marriages end in divorce. This fact is not surprising because pregnancy and marriage interrupt the partners' "childhood" and basic education. Failure to be self-supporting logically follows lack of education and lost career goals. Lack of maturity in dealing with an intimate relationship also contributes to marital breakdown in this age group.

Dating violence is often an issue for teens, especially for younger girls dating older boys. These younger teens may interpret such actions as hitting, pushing, and making verbal threats as signs of love, caring, and a deep commitment to the relationship that will ultimately produce long-term positive results. Research suggests that up to half of teenage mothers experience domestic violence before, during, or just after their pregnancies (National Coalition Against Domestic Violence [NCADV], 2007).

In the United States, the results of teenage childbearing cost taxpayers $7 billion each year (Pinkleton et al., 2008). Simply delaying these births could result in significant savings because of the improvement in both education and occupational status of these young women.

The increased incidence of maternal complications, premature birth, and LBW babies among adolescent mothers also has an impact on society because many of these mothers are on welfare. The need for increased financial support for good prenatal care and nutritional programs remains critical.

Risks for Her Child

Children of adolescent parents are at a disadvantage in many ways because teens are not developmentally or economically prepared to be parents. In general, children of teenage mothers are at a developmental disadvantage compared with children whose mothers were older at the time of their birth. Many factors contribute to these differences, especially the adverse social and economic conditions many teenage mothers face.

These factors result in high rates of family instability, disadvantaged neighborhoods, and high rates of behavior problems. In addition, often these children do not do as well in school and are less likely to complete high school. Children born to adolescent mothers also have higher rates of abuse and neglect and are more likely to become adolescent parents themselves (Klein & The Committee on Adolescence, 2005).

Partners of Adolescent Mothers
