Cisapride	0.8 mg/kg/day divided QID. (adult dose: 10–20 mg QID)	rare cases of serious cardiac arrhythmia (FDA recommends ECG before administration) beware of drug interactions do not use in patients with liver, cardiac or electrolyte abnormalities (FDA recommends K+, Ca++, Mg++ and creatinine before administration)

are superior to placebo for relief of symptoms and healing of esophageal mucosa (152–154). However, the efficacy of H_2RAs is much greater for mild esophagitis than for severe esophagitis (155). One randomized placebo-controlled trial in infants and children with erosive esophagitis demonstrated the efficacy of H_2RA therapy (156) in 32 children who received either cimetidine 30–40 mg/kg per day or placebo. The cimetidine treated group had significant improvement in clinical and histopathology scores, but there was no improvement in the placebo group. Another randomized placebo controlled study in 24 children with mild to moderate esophagitis demonstrated that nizatidine 10 mg/kg per day was more effective than placebo for the healing of esophagitis and symptom relief (157). There are case series that provide additional support for the efficacy of H_2RAs in infants and children (158–161). Although no randomized controlled studies in children demonstrate the efficacy of ranitidine or famotidine for the treatment of esophagitis, expert opinion is that these agents appear to be as effective as cimetidine and nizatidine.

4.2.1.2 Proton Pump Inhibitors. Proton pump inhibitors (PPIs), the most effective acid suppressant medications, covalently bond and deactivate the H+, K+–ATPase pumps (162). To be activated PPIs require acid in the parietal cell canaliculus, and they are most effective when the parietal cell is stimulated by a meal following a fast (162). Optimal effectiveness is achieved when the PPI is administered one–half hour before breakfast so that peak plasma concentrations coincide with the mealtime. If given twice daily, the second dose is best administered one–half hour before the evening meal. Concomittant administration of H_2RAs can inhibit efficacy. A steady state of acid suppression is not achieved for several days. There are limited data on the pharmacology of PPIs in infants and children. In one study, doses of omeprazole of 10 to 60 mg (0.7 to 3.3 mg/kg) daily were required to normalize esophageal pH monitoring, and a starting dose of 0.7 mg/kg per day was recommended (47). In other case series reporting successful omeprazole treatment of esophagitis, doses of 0.5 or 0.6 mg/kg daily were administered for 6 to 13 weeks (163–166).

Numerous randomized controlled trials in adults have demonstrated that PPIs are superior to H_2RAs in relieving symptoms and healing esophagitis (152). PPIs are effective in patients with esophagitis refractory to high–dose H_2RA therapy (167,168), and are more effective than H_2RAs in maintaining remission of erosive esophagitis (169). There are currently no reported placebo controlled trials of PPIs in infants or children. However, one randomized controlled trial of 25 infants and children with reflux esophagitis found comparable effectiveness of omeprazole (40 mg per 1.73 m^2 surface area) and very high dose ranitidine (20 mg/kg/day) in reducing symptoms and improving histopathology and esophageal pH monitoring (170). In addition, in multiple case series of pediatric patients refractory to previous treatment regimens including H_2RAs, omeprazole appeared to be highly effective in the treatment of severe esophagitis, resulting in both symptomatic and endoscopic improvement while on treatment (47,163–166). Other proton pump inhibitors, lansoprazole, pantoprazole and rabeprazole, have been introduced recently but studies of their efficacy in infants and children have not yet been reported. Esophageal pH monitoring can be performed to assess the adequacy of the dosage but target values for either esophageal acid exposure or gastric pH that assure therapeutic efficacy are not known. Long term safety studies in adults treated with omeprazole for a mean of 6.5 years (range 1.4 to 11.2 years) show omeprazole is highly effective and safe for the control of reflux esophagitis in adults (171). Despite omeprazole therapy, 12% of the patients who did not have Barrett's esophagus at baseline developed Barrett's metaplasia during follow–up. Similar studies of the efficacy and safety of long term treatment have not been performed in pediatric patients.

One approach to acid reducing therapy, called *step-up* therapy, is to begin treatment with an H_2RA at standard dosage, following with a PPI at standard dosage and then a PPI at higher dosage if necessary to achieve improvement (47). An alternative approach, called *step-down* therapy, is to begin treatment with a PPI at higher dosage to achieve improvement, following with a PPI at standard dosage and then an H_2RA to maintain improvement. Studies in adults indicate that the step-down approach may be more cost effective (171) and has been recommended in a recently published evidence-based guideline for adult patients (172), but there are no published studies comparing these two strategies in children.

The current evidence supports the recommendation to use antisecretory therapy for the treatment of reflux esophagitis. The effectiveness of acid reducing therapy for other manifestations of GERD is not well documented in children. However, since these agents reduce esophageal acid exposure they are likely to be a useful treatment of GER-related respiratory disorders (see sections 5.5 to 5.9).

4.2.1.3 Antacids. The aim of antacids, which act by neutralizing gastric acid, is to reduce esophageal acid exposure and thereby reduce symptoms of heartburn, alleviate esophagitis and prevent acid-triggered respiratory symptoms. Intensive high-dose antacid therapy (magnesium hydroxide and aluminum hydroxide; 700 mmol/1.73 m2/day) has been shown to be as effective as cimetidine for the treatment of peptic esophagitis in children aged 2 to 42 months (173,174). However, treatment with aluminum-containing antacids significantly increases plasma aluminum levels in infants (175,176). Plasma aluminum levels measured in infants receiving these agents approach levels previously noted to cause osteopenia, microcytic anemia, and neurotoxicity in pediatric patients (177–179). There are no published studies evaluating the efficacy or safety of commercially

available antacids containing either magnesium hydroxide alone or calcium carbonate. Antacid therapy is commonly used for the short-term relief of intermittent symptoms of GER in children and adolescents. Although there appears to be little risk to this approach, it has not been formally studied. Because more convenient and safe alternatives are available, chronic antacid therapy is generally not recommended.

4.2.2 Prokinetic Therapy. Transient lower esophageal sphincter relaxations, which are prolonged relaxations unaccompanied by a swallow, are considered the most important pathophysiological mechanism of GER. Other mechanisms are free reflux and strain-induced reflux, when abdominal pressure exceeds the pressure of the lower esophageal sphincter. Although prokinetic agents appear to increase lower esophageal sphincter pressure, a number of studies have failed to demonstrate that prokinetic agents reduce the frequency of episodes of acid reflux, suggesting that they do not reduce the frequency of transient relaxations of the lower esophageal sphincter. The rationale for prokinetic therapy in the treatment of GERD is based on evidence it enhances esophageal peristalsis and accelerates gastric emptying.

Since regurgitation and vomiting are common symptoms in infants and children with reflux, even in the absence of erosive esophagitis, prokinetic agents may have a special role in the treatment of GER in infants and children with conditions where acid suppressants are unlikely to be helpful. Double blind single drug studies and randomized comparison studies of cisapride, metoclopramide, bethanecol and domperidone have been performed in infants and children with GER. Cisapride appears to be a marginally effective prokinetic agent for the treatment of GERD, whereas the effectiveness in children of other prokinetic agents is unproven.

Cisapride is a mixed serotonergic agent that facilitates the release of acetylcholine at synapses of the myenteric plexus. Six randomized controlled trials of cisapride therapy in infants less than two years of age have demonstrated improvement in symptoms or esophageal pH monitoring or both when compared to placebo (180–185). Modest improvement in clinical symptoms, with a reduction in the frequency and volume of vomiting, has been reported in four of five studies where duration of therapy was at least four weeks (180–182,184,186). Improvement occurred more often in infants who regurgitated or vomited after every meal or more than six times daily (182,184,186). One study reported complete resolution of vomiting in less than 20 percent of treated infants (182). In all studies a significant percentage of patients receiving placebo also improved, and in one study vomiting resolved in 14 percent of placebo-treated patients (182).

Randomized controlled trials using prolonged esophageal pH monitoring have demonstrated that cisapride therapy is superior to placebo in reducing esophageal acid exposure and enhancing esophageal acid clearance following reflux. All studies reported statistically significant improvement compared to baseline measurements of one or more of the following parameters: reflux index (percentage of the time that esophageal pH was less than 4), mean duration of reflux episodes, and number of episodes longer than 5 minutes (180–187). Cisapride improved symptom scores, esophageal histopathology, and pulmonary function in patients with reflux esophagitis and respiratory complications (50,180,181). This may be due to reduced esophageal acid exposure and enhanced esophageal acid clearance.

Metoclopramide is an antidopaminergic agent with cholinomimetic and mixed serotonergic effects. In adults the effects of metoclopramide on esophageal motility and clinical efficacy have been equivocal (188) and the addition of metoclopramide to ranitidine therapy for treatment of GERD resulted in no better efficacy and increased the number of adverse events (189). Four randomized controlled studies of at least two weeks duration on the efficacy of metoclopramide in the treatment of GER in children have been reported. Two of four studies reported a decrease in the frequency and volume of vomiting (190,191), whereas in two other studies metoclopramide was no better or worse than placebo (192,193). The reported effects on esophageal pH monitoring of acute and steady-state dosing of metoclopramide have also been contradictory, with both positive (187,194,195) and negative results (192,193,196). Adverse effects of metoclopramide, which are not uncommon, include central nervous system complications such as parkinsonian reactions and tardive dyskinesia, which may be irreversible (197).

Bethanechol, a direct cholinergic agonist, has been studied in two controlled trials of 6 weeks duration. In one study bethanechol was superior to placebo in reducing the frequency and volume of vomiting, but prolonged esophageal pH monitoring was not performed (198). The other study, which compared bethanechol to antacids, found no difference between the two treatments in clinical outcome or esophageal pH monitoring (199). Of three reports regarding domperidone therapy, one study found improvement in both clinical symptoms and pH score following two weeks of therapy (191), while two studies reported no improvement in either outcome measure following four and eight weeks of therapy (200,201).

In conclusion, there is evidence to support the use of cisapride when a prokinetic is indicated for the treatment of GERD in infants and children. However, because of concerns about the potential for serious cardiac arrhythmias in patients receiving cisapride, appropriate patient selection and monitoring as well as proper use, including correct dosage and avoidance of co-administration of contraindicated medications, are important (202). Despite these concerns, the use of cisapride can be considered for the treatment of selected infants with vomiting and poor weight gain, ALTE or asthma who have failed lifestyle and antisecretory therapy. In some children over

2 years of age with asthma or with recurrent vomiting that is adversely affecting lifestyle cisapride therapy may also be considered. Cisapride recently was withdrawn from the USA market due to these safety concerns and therefore in order to receive cisapride patients must be enrolled in a limited access protocol that requires repeated venipuncture and electrocardiograms, making the use of cisapride a less practical option. There is insufficient evidence that other prokinetic agents are effective in the treatment of GERD in infants and children.

4.2.3 Surface Agents. Sodium alginate forms a surface gel that decreases the regurgitation of gastric contents into the esophagus and protects the esophageal mucosa. Randomized comparison studies have demonstrated conflicting outcomes for both symptoms (203,204) and esophageal pH monitoring (205,206). The formulation utilized for most published studies is not available in the USA.

Sucralfate gel acts by adhering to peptic lesions, and protects the esophageal mucosal surface. In adults sucralfate (1 g po QID) decreases symptoms and promotes healing in patients with non-erosive esophagitis (207). The only randomized comparison study in children demonstrated that sucralfate is as effective as cimetidine for treatment of esophagitis (208). Sucralfate is an aluminum complex, and the potential adverse effects of aluminum in infants and children need to be considered. The available data are inadequate for determining the safety or efficacy of sucralfate in the treatment of GERD in children.

4.3 Surgical Treatment for GERD

Surgery is often considered for the child with GERD who has persistence of symptoms following medical management or who is unable to be weaned from medical therapy. The Nissen fundoplication is the most popular of the many surgical procedures that have been used. Recently experience with laparoscopic procedures has been reported. Results and complication rates do not appear to vary by procedure.

The literature concerning surgical treatment of GERD in children consists of a large number of descriptive papers composed of case series (209–221). The methodology for patient selection and outcome was not always well defined. Patients usually had surgery for failed medical management. There are no published randomized controlled trials. Because most series extended over many years, medical management in earlier patients was often limited to life style changes such as positional therapy and thickened feedings. Some patients received H_2RAs but few if any patients received PPIs. Most did not receive a prokinetic agent and those that did often received metoclopramide. Thus many of the patients did not receive optimal medical therapy by today's standards. Outcome measures were often vague or unspecified. The groups were heterogeneous without adjustment for co-morbid conditions. Many (if not most) of the surgically treated patients were neurologically impaired. A variety of surgical procedures were used. The addition of a pyloroplasty was variable. The outcome was sometimes defined by symptoms and at other times by postoperative tests.

Success rates (complete relief of symptoms) from 57% to 92% have been reported. Mortality related to operation in large series has ranged from 0% to 4.7%. Unrelated death rates from co-morbid conditions were 0% to 21%. The reported overall complication rates have varied between 2.2% and 45%. The most commonly reported complications include breakdown of the wrap (0.9% to 13%), small bowel obstruction (1.3% to 11%), gas bloat syndrome (1.9% to 8%), infection (1.2% to 9%), atelectasis or pneumonia (4.3% to 13%), perforation (2% to 4.3%), persistent esophageal stricture (1.4% to 9%) and esophageal obstruction (1.4% to 9%). Other complications not reported in enough detail to estimate complication rates include dumping syndrome (222,223), incisional hernia and gastroparesis. Reoperation rates were 3% to 18.9%. The results of pediatric series of laparoscopic fundoplications suggest that the results and complication rates are similar to those of the open procedure, but hospitalization is shortened (224,225).

These case series indicate overall favorable outcomes. The potential risks, benefits and costs of successful prolonged medical therapy versus surgical therapy have not been well-studied in infants or children with various symptom presentations. If chronic esophagitis is the primary indication for possible GERD surgery, an upper endoscopy with biopsy and prolonged esophageal pH monitoring study is recommended to demonstrate conclusively that esophagitis is due to GER, rather than other etiologies, such as eosinophilic esophagitis. If airway symptoms are the primary indication for surgery, review of diagnostic studies including radiographic studies, bronchoalveolar lavage, esophageal pH monitoring studies and swallowing studies may all impact on the decision to proceed with surgery, which may be beneficial in some patients even when esophageal pH monitoring is normal (226).

5. Evaluation and Management of Infants and Children with Suspected GERD

The approach to evaluation and management of infants and children with GERD depends upon the presenting symptoms or signs. The following sections discuss the evidence that supports a relationship between a particular clinical disorder and GER in pediatric patients. The approach to determining if GER is causing disease in a patient and the management of pediatric patients with specific symptom presentations is then reviewed. Recommendations are based upon the available evidence

and the consensus opinion of the GER Guidelines Guideline Committee.

5.1 Recurrent Vomiting

The diagnostic challenge for the practitioner is to distinguish between vomiting due to GER and vomiting caused by other disorders. Numerous disorders can present with recurrent vomiting that mimics GERD (see Table 3). Laboratory and radiographic investigation may be necessary to exclude other causes of vomiting. The infant with recurrent vomiting is discussed separately from the older child with recurrent vomiting.

5.1.1 The Infant with Recurrent Vomiting. In the infant with recurrent vomiting, a thorough history and physical examination (Table 4), with attention to warning signals that suggest other diagnosis (Table 5), is generally sufficient to allow the clinician to establish a diagnosis of uncomplicated GER (Figure 1). An upper GI series or other diagnostic test is not required unless gastrointestinal obstruction is suspected. Other diagnostic tests may be indicated if there are symptoms of poor weight gain, excessive crying, irritability, disturbed sleep, feeding or respiratory problems.

5.1.2 The Infant with Uncomplicated GER (Figure 1). The classical presentation of uncomplicated GER in infants is effortless, painless vomiting in a well appearing child with normal growth, often referred to as the "happy spitter'. Generally, only parental education, reassurance and anticipatory guidance are necessary for management of the infant who has uncomplicated GER. Parents are advised about potential complications, including poor weight gain, excessive crying, and feeding or respiratory problems. Some infants with cow milk allergy have symptoms that are indistinguishable from GER. Therefore, a one to two week trial of a hypoallergenic formula may be reasonable (section 4.1.1). Thickening of formula may also be considered as an option for therapy. Continuation of supine positioning is recommended. There is no evidence that pharmacological therapy affects the natural history of uncomplicated GER in infants.

Recurrent vomiting due to GER generally decreases in frequency over the first year of life and resolves by 12 months of age (8). If symptoms worsen or do not improve by 18 to 24 months of age, further evaluation is recommended, including an upper GI series and consultation with a pediatric gastroenterologist is recommended (see section 5.1.5).

5.1.3 The Infant with Recurrent Vomiting and Poor Weight Gain (Figure 2). The infant with recurrent vomiting and poor weight gain is a distinct clinical entity that is not to be confused with the happy spitter. While the history and physical examination, as well as the detection of warning signals, is identical to that described for the infant with recurrent vomiting (section 5.1.1), the finding of growth failure is a crucial factor that alters clinical management. No well-controlled studies of diagnostic or therapeutic strategies for these infants are available, and the following approach is based on expert opinion. Other causes of poor weight gain are first considered. It is recommended that the adequacy of calories being offered and ingested be assessed, by careful evaluation of the dietary history, approach to formula preparation and effectiveness of swallowing. If problems are

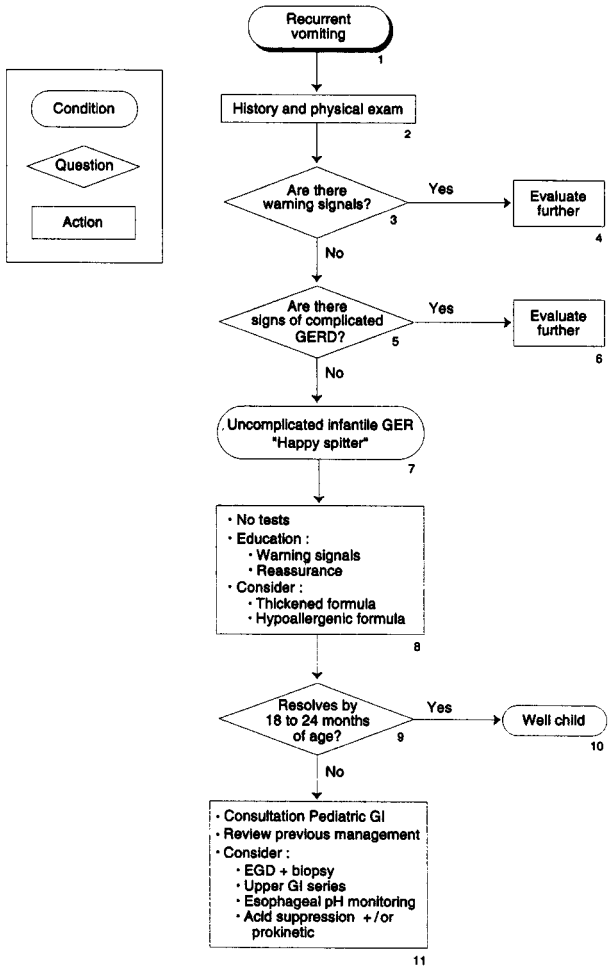

FIG. 1. An algorithm for the management of an infant with uncomplicated GER (the "happy spitter"). (Pediatric GI = pediatric gastroenterologist; EGD = esophagogastroduodenoscopy; UGI = upper gastrointestinal series radiography).

If an infant with vomiting is not gaining weight despite ingesting adequate calories then further diagnostic evaluation is necessary. Tests to uncover other causes of vomiting (such as a complete blood count, electrolytes, bicarbonate, urea nitrogen, creatinine, alanine aminotransferase, ammonia, glucose, urinalysis, urine ketones and reducing substances, and review of newborn screening for galactosemia and maple sugar urine disease) are considered. An upper GI series to evaluate anatomy is also recommended.

When no abnormalities are found, management options include medical therapy, observation in the hospital and endoscopy with biopsy. Initial medical therapeutic options include thickening of the formula, a trial of a hypoallergenic formula, acid suppression therapy, prokinetic therapy and consideration of prone positioning. Hospitalization to observe the parent-child interaction

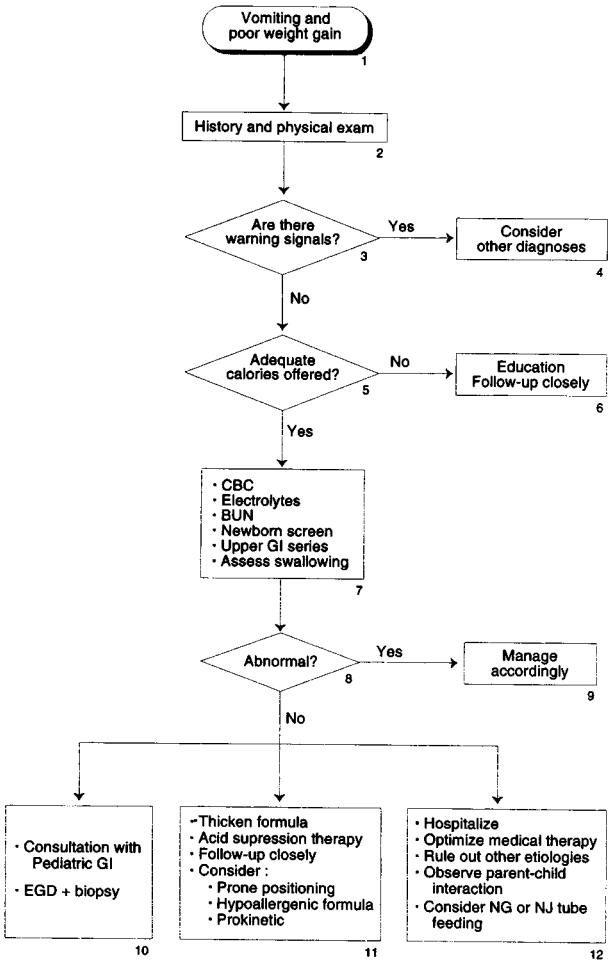

FIG. 2. An algorithm for the management of an infant with vomiting and poor weight gain. (CBC = complete blood count; BUN = blood urea nitrogen; NG = nasogastric; NJ = nasojejunal).

and to optimize medical management may be indicated in more severe cases. Endoscopy with biopsy may be useful to determine if esophagitis is present and to delineate other causes of vomiting or poor weight gain. Other options to improve caloric intake in the infant with vomiting include increasing the caloric density of the formula, and nasogastric or transpyloric tube feedings (87). Rarely surgical therapy may be indicated. Careful follow-up is necessary to assure adequate weight gain (85). If weight gain is sustained, the patient can be expected to have decreasing requirements for interventions as the amount of vomiting and regurgitation decrease with age.

5.1.4 The Infant with Recurrent Vomiting and Irritability. Vomiting, irritability and disturbed sleep in a child less than one year of age may be due to GERD. These non-specific symptoms also occur in normal infants and are associated with a wide range of conditions. Although crying is a quantifiable measure of irritability, normal infants typically fuss or cry intermittently for an average of two hours daily. Substantial individual variation occurs; some infants cry as much as six hours per day. The duration of crying typically peaks at six weeks of age (227). One parent may consider crying to be normal while another would describe the same behavior as extreme irritability. Similarly, the sleeping patterns of infants show individual and maturational variation as does the parental perceptions of normal infant sleep patterns (228).

Evidence supporting the theory that reflux causes esophageal pain and hence irritability or sleep disturbance in infancy is largely extrapolated from studies in adults (45,229,230). Very few pediatric studies address this issue. Using simultaneous video and esophageal pH monitoring, one study (46) showed an association between grimacing and reflux episodes. However, another pediatric study showed no correlation between excessive crying and esophagitis (18) and another noted no increase in irritability or back arching in infants with pathologic reflux (231). In two small studies, an association between excessive irritability and sleep disturbance in infants with abnormal pH probe studies was observed. One study found more nighttime waking, delayed onset of sleeping and greater daytime sleeping in infants with GER as compared to population norms but not when compared to a control group of infants with normal pH probe findings (232). Another study demonstrated no increase in sleep disturbances in those infants with pathologic reflux (231). One study of five infants with colic and esophagitis showed that treatment with cimetidine decreased crying from 3.7 to 1.2 hours after a week of treatment, which was significantly different from 13 children with colic who did not have esophagitis and who were not treated (233).

No studies address the best approach to evaluation of infants with vomiting and irritability or disturbed sleep. As in all infants with vomiting, other causes of vomiting need to be excluded (section 5.1.1 and Table 3). A symptom diary (234) may be useful to determine the extent to which the infant is irritable and has disturbed sleep. In addition, it is important to assure that the infant is receiving adequate feedings, since hunger may also result in irritability. Expert opinion suggests two diagnostic and treatment strategies, neither of which has been validated. The first approach is to empirically treat potential etiologies, beginning with a simultaneous or sequential two-week trial of a hypoallergenic formula and/or acid suppression (Section 5.1). If neither therapy succeeds in reducing symptoms, either esophageal pH monitoring to determine the adequacy of acid suppression (see section 3.3) or upper endoscopy with biopsy to diagnose esophagitis (see section 3.4) may be performed. If these studies are normal, and no response to empiric therapy has occurred, it is unlikely that GER is contributing to the symptoms. An alternative approach is to perform esophageal pH monitoring to determine if episodes of irritability or sleep disturbance are temporally associated with

acid reflux by calculating a symptom index (see section 3.3). One study suggested that simultaneous video monitoring was helpful (46). Time limited therapy can be initiated if episodes of GER provoke symptoms.

5.1.5 Management of the Child Over 2 Years of Age with Recurrent Regurgitation or Vomiting. No published studies describe the management of a group of otherwise normal children who have recurrent regurgitation or vomiting after the age of 2 years. These children usually vomit, or regurgitate and reswallow, between once a day and once a week. The vomiting is not associated with pain or discomfort, is not posttussive, and is non-bloody and non-bilious. Often the vomiting occurs postprandially or with exertion. This type of vomiting can be a nuisance or in some instances may disrupt a child's normal participation in childhood activities. Expert opinion suggests that in most patients an upper GI series be performed to exclude an anatomic abnormality. Some experts also recommend upper endoscopy with biopsy, although in many cases there will be no abnormalities. If vomiting persists and the child remains otherwise asymptomatic, a therapeutic trial of a prokinetic agent may be considered. If a good response to the prokinetic agent occurs, long-term therapy is an option. The small risks must be balanced with the potential improved quality of life in the individual and the family. In very unusual circumstances where the vomiting does not improve with pharmacological therapy and produces serious adverse effects on the patient's lifestyle, surgical therapy is a consideration.

5.2 Management of the Child with Heartburn or Chest Pain (Figure 3)

Heartburn or substernal burning pain may be caused by GER in the presence or absence of esophagitis (235). Other causes of chest pain include cardiac, respiratory, musculoskeletal, medication induced or infectious etiologies. In older children and adolescents the description and localization of esophageal pain is similar to adults, but in younger children symptom description and localization may be atypical. Regurgitation of sour fluid into the mouth may be present. No randomized, placebo-controlled studies evaluating the efficacy of either lifestyle or pharmacological therapy for the treatment of heartburn in children or adolescents have been published. Expert opinion suggests the use of management approaches similar to those described in adult patients. Initial interventions of lifestyle changes, avoidance of precipitating factors, accompanied by a two to four week therapeutic trial of an H_2RA or PPI are recommended (172,236–238). If no improvement occurs, the child can be referred to a pediatric gastroenterologist for upper endoscopy with biopsy. If the child improves, therapy can be administered for two to three months. If symptoms recur as therapy is discontinued, referral for upper endoscopy to determine the presence and severity of esophagitis is recommended. Because persistent symptoms of heartburn may have a substantial negative impact on a patient's quality of life, long-term therapy can be continued with either a PPI or H_2RA to provide relief from symptoms even in the absence of esophagitis (70,239). Episodic meal-induced heartburn in older children may be treated with antacids or an H_2RA, as in adults (240).

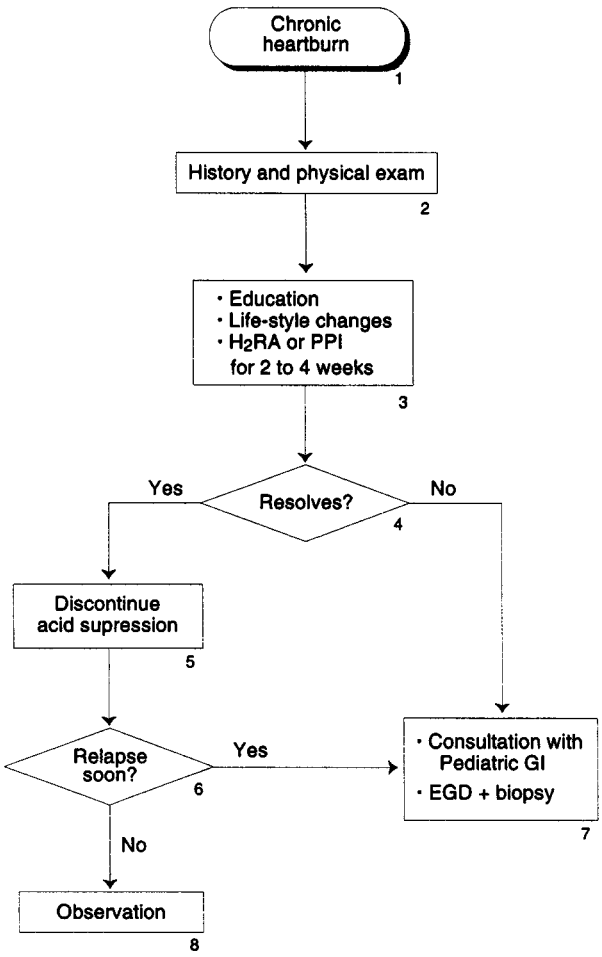

FIG. 3. An algorithm for the management of a child or adolescent with chronic heartburn. (H_2RA = histamine-$_2$ receptor antagonist; PPI = proton pump inhibitor).

5.3 The Infant or Child with Esophagitis (Figure 4)

The typical features of reflux esophagitis are described in section 3.5. Initial treatment consists of lifestyle changes and H_2RA or PPI therapy Initialtherapy. Initial treatment with a PPI results in a more rapid rate of symptom relief and healing compared to treatment with an H_2RA (152). If patients have previously been treated for GERD, medical therapy can be optimized by either the

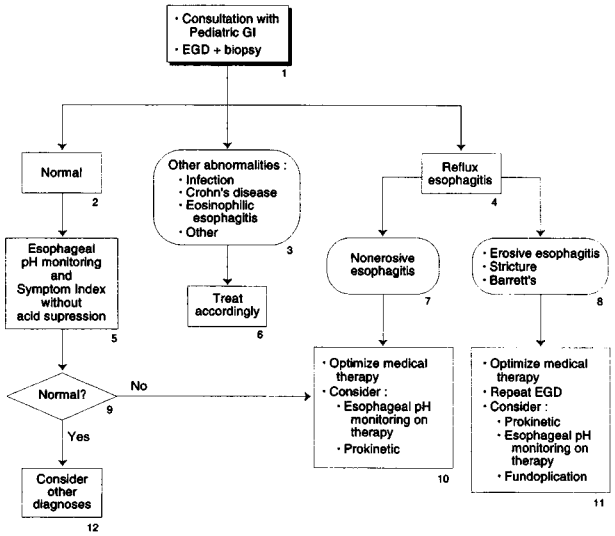

FIG. 4. An algorithm for the continued management of a child or adolescent with esophagitis.

addition of a PPI or a higher dose of PPI (47,241). In one pediatric study, cisapride alone was effective for treatment of histologic esophagitis (181). However, in adults a comparison of the efficacy of a PPI alone versus a combination of a PPI and cisapride did not show a statistically significant difference (169).

Expert opinion suggests that in infants and children with only histologic esophagitis, the efficacy of therapy can be monitored by the degree of symptom relief, whereas in patients with erosive esophagitis, repeat endoscopy is recommended to assure healing. Complete healing may prevent complications including esophageal stricture, Barrett's esophagus or esophageal adenocarcinoma, although no data are available to support this contention. High dose, long-term PPI therapy or surgical therapy may be considered when Barrett's esophagus or esophageal stricture is also present.

If patients do not respond to therapy there are two potential explanations to explore: either the diagnosis is incorrect or treatment is inadequate. The possibility of another diagnosis, such as eosinophilic esophagitis may be considered (56,57). If the clinical presentation and histopathology are consistent with a diagnosis of reflux esophagitis, then the evaluation of adherence to and adequacy of therapy is recommended. Esophageal pH monitoring while the patient is *on therapy* will determine if higher doses of acid reducing medications are needed. If the diagnosis is uncertain, esophageal pH monitoring while the patient is *off therapy* may be useful since a normal study would suggest that esophagitis is less likely to be due to GER.

When surgical therapy is considered, the potential complications of anti-reflux surgery are balanced with the nuisance, risks, effectiveness and cost of long-term pharmacological therapy. There are no studies comparing long term outcomes of medical versus surgical therapy in infants and children since the introduction of PPIs.

5.4 The Infant with Feeding Refusal or the Child with Dysphagia

Esophagitis may cause discomfort or pain (odynophagia) or difficulty (dysphagia) with eating in infants, children and adults. The older child or adult is able to describe sensations that aid in discriminating between oropharyngeal disorders and esophageal disorders. Mouth or pharyngeal pain, poor coordination of bolus formation, coughing or apnea during feeding suggests oropharyngeal anatomical or functional problems. Complaints of chest pain or food being stuck in the chest generally indicate that there is an esophageal disorder, although the sensory discrimination of the site of obstruction is often inaccurate. Reflux esophagitis appears to be one of the more common causes of these symptoms in children, being diagnosed in 12 of 16 children reported in one retrospective series (242).

In the older child or adolescent with symptoms suggestive of an esophageal cause of dysphagia or odynophagia, diagnostic evaluation usually begins with a radiographic contrast study (barium esophagram) to identify anatomic abnormalities, such as strictures or vascular rings, and motility disorders, such as achalasia. Upper endoscopy with biopsy is also usually performed. If esophagitis is present, treatment of the underlying cause of esophagitis (e.g., reflux esophagitis, pill esophagitis or eosinophilic esophagitis) generally leads to symptom resolution. There are no studies evaluating this proposed diagnostic approach in older children or adolescents; however, in a study of young adults (243), the barium esophagram revealed a cause of symptoms in 70% of patients. If the initial history is suggestive of esophagitis, upper endoscopy may be performed as the initial diagnostic test. Treatment without prior diagnostic evaluation is generally not recommended.

In infants, although case series have described an association of feeding difficulties with signs and symptoms of GER (244–246), none has demonstrated that GER is causally related to the feeding difficulties or that feeding improves following treatment. Because a large variety of disorders may contribute to infant feeding difficulties (247), empiric therapy for GER is generally not recommended in children with feeding difficulties. However, if there are other signs or symptoms suggestive of GERD (section 5.1.1) then a time-limited course of medical therapy can be considered.

5.5 The Infant with Apnea or ALTE

An apparent life-threatening event (ALTE) is defined as an episode occurring in an infant that is frightening to

the observer and characterized by a combination of apnea, change in color (cyanosis, pallor, rubor, plethora), change in muscle tone (limpness, stiffness), or choking and gagging that requires intervention by the caretaker (248). The first event usually occurs between one and two months, and rarely after 8 months of age (249,250). There is evidence that ALTEs can recur (250–252), and that infants with an ALTE are at risk for a subsequent sudden death (252–258). ALTEs can be caused by intentional suffocation, cardiac, central nervous system and infectious disorders, and can be due to upper airway obstruction or central apnea as well as GER.

In patients with ALTEs the prevalence of recurrent regurgitation or emesis is 60% to 70% (249,252), and 40% to 80% of patients have abnormal esophageal pH monitoring (259–261). Case reports have described ALTEs triggered by overt regurgitation into the oropharynx or by aspiration of refluxed gastric contents (262–264). Gross emesis or oral regurgitation has been correlated with either prolonged apnea (>20 seconds), or with shorter apnea and bradycardia, but the majority of prolonged apnea episodes in these patients were not associated with regurgitation (265). The first report of simultaneous recordings of esophageal pH, heart rate, chest wall movement and nasal airflow demonstrated that reflux could precede apnea (262). In selected patients with a history of ALTE, esophageal acid infusion has been shown to induce obstructive apnea (262) or oxygen desaturation (259), suggesting that one mechanism by which GER may trigger an ALTE is acid stimulation of laryngeal, pharyngeal, or esophageal chemoreceptors with resultant laryngospasm.

Despite these early reports and the demonstrated potential for GER to cause apnea, subsequent investigations in unselected patients with ALTE have not demonstrated a convincing temporal relationship between esophageal acidification and apnea or bradycadia (260, 261, 266-272). Although several studies reported an occasional correlation of GER with short mixed central apneas (5 to 15 sec) (266,269,271), all of the patients reported also had episodes of apnea which were unrelated to episodes of GER, suggesting a primary impairment in the regulation of respiration. The most convincing relationship between GER and episodes of obstructive or mixed apnea has been in infants in whom the episodes occurred while the patient was awake, supine and within one hour of a feeding. One study performed simultaneous recording of esophageal pH, heart rate, chest wall movement and nasal airflow to demonstrate a relationship between GER and obstructive or mixed apnea in 8 of 15 such patients (273).

At present there is no evidence that the characteristics of an ALTE or polysomnographic diagnostic study can predict which infants are at risk for future life-threatening episodes or sudden death. In one study of 182 infants with ALTE followed for two months, the coexistence of GER and ALTE did not predict the risk for a subsequent episode of prolonged apnea or bradycardia. SIDS has rarely been reported to occur in patients with a previous ALTE and documented GER (261,274); in none of these patients was a previous correlation between esophageal acidification and a cardiopulmonary event recorded.

Similarly there are no randomized studies to evaluate the usefulness of esophageal pH monitoring in infants with ALTE. In patients with frequent ALTE in which the role of GER is uncertain, esophageal pH monitoring may be useful to determine if there is a temporal association of acid reflux with ALTE. For adequate interpretation of esophageal pH monitoring in this situation, simultaneous recording of heart rate, chest wall impedance, nasal airflow and oxygen saturation is necessary to detect obstructive apnea.

The evidence suggests that infants with ALTE and GER may be more likely to respond to anti-reflux therapy when there is gross emesis or oral regurgitation at the time of the ALTE, when episodes occur in the awake infant, and when the ALTE is characterized by obstructive apnea. The effectiveness of medical therapy of GER-associated ALTEs has not been adequately studied. To reduce overt emesis and inhibit acid reflux, therapeutic options include thickened feedings and prokinetic and acid suppressant therapy. Surgical therapy has been reported to be effective in preventing recurrent ALTE and death in heterogeneous groups of patients (263,274), but there are no studies comparing surgery to medical management. Since most infants improve with medical management, surgery is considered only in severe cases. Caution should be exercised when diagnosing and treating GER as a presumptive cause of ALTE. Antireflux surgery has been performed for GER in infants with ALTE that was subsequently determined to be due to repetitive intentional suffocation (275).

5.6 The Infant or Child with Asthma (Figure 5)

Asthma affects an estimated 4.8 million children (276), 5% of whom have persistent asthma, defined as a frequency greater than 2 or 3 times weekly. Although a direct causal relationship between GER and asthma is rare, a number of animal and human studies have suggested that GER may contribute to asthma severity. Proposed pathogenetic mechanisms include direct aggravation of airway inflammation by aspiration of gastric contents, or airway hyperresponsiveness triggered by aspiration of minute amounts of acid into the lower airway (277–279). Esophageal acidification as an independent variable has minimal effect on pulmonary function (277). However, esophageal acid exposure in asthmatic patients may contribute to airway hyperresponsiveness and variable airflow obstruction (280).

Symptoms of GER are common in children with asthma (281). A high percentage of children with persis-

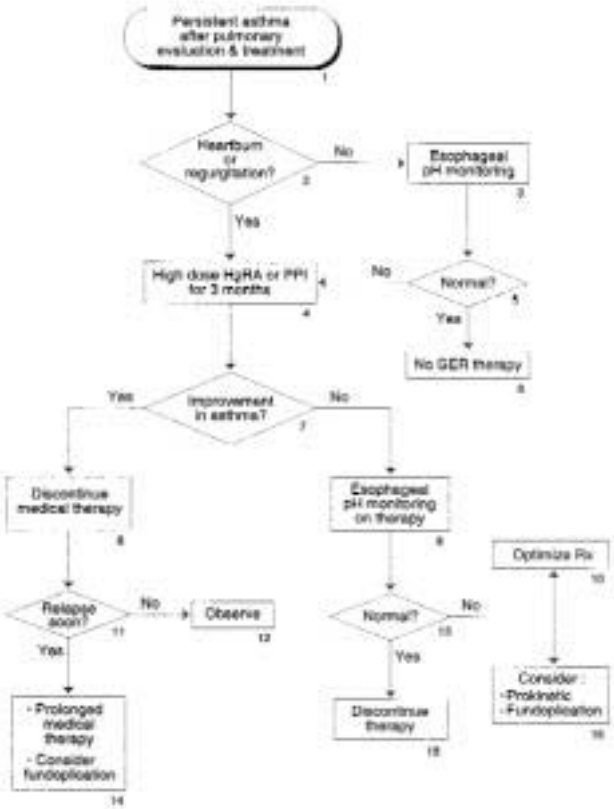

FIG. 5. An algorithm for the management of a child or adolescent with persistent asthma and suspected GER. See also Figure 3. (Rx = therapy).

tent asthma have gastroesophageal reflux detectable by abnormal esophageal pH monitoring. The reported prevalence ranges from 25% to 75%. Of 668 patients studied in 13 series, 407 or 61% were reported to have abnormal pH studies utilizing a variety of scoring techniques (48–50,65,282–290). There was a similar prevalence of GER (53%) in three studies of infants less than 2 years of age (49,282,283). Approximately 50% of patients with persistent asthma and abnormal esophageal pH monitoring have no or minimal clinical symptoms of GER, such as vomiting, regurgitation, or heartburn (48, 50,282,284,288). There is no consistent evidence that specific asthma symptoms or response to asthma therapy correlates with abnormal esophageal pH monitoring.

A number of cohort comparisons have been performed in patients with GER symptoms or positive esophageal pH probe monitoring. These studies demonstrate that prolonged medical treatment of GER improves clinical symptoms of persistent asthma and reduces required doses of bronchodilator and anti-inflammatory medications. From four case series reporting on a total of 168 patients, 63% had clinical improvement or reduced dosages of bronchodilator and anti-inflammatory medications following a variety of medical approaches (50,284, 288,291). Improvement of respiratory variables has been described in infants less than one year of age (291) and older children with or without atopy (50). Reported successful therapies have included positional therapy and thickened formula without medication (284,288), cisapride (50), and H_2RA (292). There are no studies of combined prokinetic and antisecretory therapy to treat GER in patients with asthma. Adult studies suggest that duration of therapy is very important, and aggressive acid suppression for at least 3 months may be necessary to reduce respiratory symptoms (68) (293,294). No studies address the empiric treatment of asthma in patients without GER symptoms or with normal esophageal pH monitoring.

More striking results have been reported following antireflux surgery. Eighty-five percent of 258 patients reported in 6 case series improved clinically as assessed by decreased frequency and severity of asthmatic attacks and reduced dosages of bronchodilator and anti-inflammatory medications (213,284,288,291,295,296). Although details were often not provided, it appears that all the patients had severe persistent asthma requiring frequent oral steroids or high dose inhaled steroid prior to surgery. The diagnosis of GER was most often confirmed by esophageal pH monitoring. Indications for antireflux surgery included evidence of recurrent pneumonia, failed time-limited medical antireflux management, dependence on aggressive medical management, and non-respiratory complications (persistent vomiting, vomiting with growth retardation, severe esophagitis). Subjective improvement in asthma after fundoplication was correlated with a clear history of reflux symptoms preceding the onset of asthma symptoms, a positive response to medical therapy prior to surgery, a history of recurrent pneumonia, and nocturnal attacks of asthma. Failure of medical antireflux management did not preclude a favorable response to surgical antireflux management. Adult surgical series have shown similar improvements in symptoms and reductions of medication use following surgery but without dramatic improvement in pulmonary function tests (297).

Thus there is substantial published evidence that GER is a potential contributor to symptoms of persistent asthma. The true incidence of GER in children with asthma is not known, as the reported data is from selected referred groups of patients with persistent asthma. The available evidence does not support therapy of GER in all patients with persistent asthma who fail to respond to standard asthma therapy. However, a trial of vigorous, prolonged medical therapy of GER is recommended for children when symptoms of asthma and GERD (e.g., heartburn, regurgitation) co-exist, and in infants and toddlers with chronic vomiting or regurgitation and recurrent episodes of cough and wheezing.

If a patient with persistent asthma does not have symptoms of GER, esophageal pH monitoring is recommended in selected patients who are more likely to benefit from GER therapy. This includes patients with ra-

diographic evidence of recurrent pneumonia; patients with nocturnal asthma more than once a week; and patients requiring either continuous oral corticosteroids, high-dose inhaled corticosteroids, more than two bursts per year of oral corticosteroids or those with persistent asthma unable to wean medical management. If esophageal pH monitoring demonstrates an increased frequency or duration of esophageal acid exposure, a trial of prolonged medical therapy for GER is recommended.

Currently there is insufficient pediatric evidence to establish the optimal medical therapy for GER in patients with asthma. It is recommended that a three month trial of vigorous antisecretory therapy and possibly cisapride be considered. It is recommended that outcome variables be determined prior to initiating therapy and be monitored during therapy. Outcome variables include heartburn and regurgitation; frequency of asthma symptoms (coughing, dyspnea, wheezing, and chest tightness); frequency and severity of acute exacerbations; frequency of nocturnal symptoms and breathlessness; symptom scores; quick-relief beta2-agonist use; changes in spirometry measurements (FEV1, FVC, FEV1/FVC) in older children; and subjective measures of quality of life. Antireflux surgery is considered in patients with persistent asthma and recurrent pneumonia, patients requiring prolonged medical therapy and patients with nonrespiratory complications of GER such as persistent vomiting, vomiting with growth retardation and severe esophagitis.

5.7 Recurrent Pneumonia and GER

GER-related aspiration pneumonia may arise in the absence of esophagitis. The incidence of GER and recurrent pneumonia in otherwise normal infants and children (288,290) (298) is difficult to establish due to the heterogeneity of the patients in reported studies, which include a large number of children with neurological disabilities and anatomic disorders of the upper intestinal tract. Several reports show that pediatric patients with recurrent pneumonia and GER improve after receiving medical or surgical GER therapy (296,299). In addition, many patients with idiopathic pulmonary fibrosis have GER (300), suggesting that repeated small episodes of aspiration of gastric contents can eventually cause severe compromise of pulmonary function. These clinical reports as well as clinical experience indicate that GER can cause recurrent pneumonia and chronic pulmonary fibrosis.

Before considering GER as a potential cause of recurrent pneumonia, it is important to exclude other causes, such as an anatomic abnormality, aspiration during swallowing, foreign body, cystic fibrosis or immunodeficiency (301). Determining whether GER is causing recurrent pneumonia in an individual patient is difficult but certain patient populations are prone to aspiration. The presence of neuromuscular disease (302) or a history of esophageal or laryngeal anatomic abnormalities increases the risk of aspiration during swallowing and following episodes of GER. The incidence of GER-related recurrent aspiration in otherwise normal infants and children is unknown but it appears to be rare.

Normal esophageal pH monitoring does not exclude GER as a cause of aspiration pneumonia. The addition of an upper esophageal or pharyngeal pH recording does not improve the ability of pH monitoring to determine which patients are at risk for aspiration as a complication of GER (43). Presumably, patients with even rare episodes of reflux of gastric contents into the pharynx are at risk for aspiration if airway protective reflexes are abnormal. A variety of tests may be useful to evaluate these protective mechanisms.

Flexible bronchoscopy with pulmonary lavage for lipid laden alveolar macrophages has been utilized to detect aspiration (303,304). However, lipid-laden macrophages may be present in normal individuals so their presence in pulmonary lavage lacks sensitivity and specificity for determining if the cause of pulmonary disease is aspiration. Recent efforts to improve the sensitivity and specificity utilize careful protocols that score the lipid content of over 100 macrophages, but considerable overlap exists between normal controls, patients with other causes of pulmonary disease and those with a history consistent with aspiration (305–308). If bronchoscopy with pulmonary lavage demonstrates a large percentage of lipid-laden macrophages, aspiration is more likely, but this test does not discriminate between aspiration that occurs during swallowing and that following GER. The lack of specificity of the test requires that the results be interpreted in the context of other clinical findings.

Nuclear scintigraphy can detect episodes of aspiration when follow-up images are obtained up to 24 hours after the feeding is administered. A positive test demonstrates that aspiration occurred but a negative test does not exclude the possibility that GER with aspiration occurs infrequently (section 3.5). Despite the potential utility of scintigraphy, no data are available regarding its predictive value in management of children or adults with suspected aspiration pneumonia.

Evaluation of airway protection mechanisms during feeding may also be helpful since patients who aspirate during feedings are also likely to aspirate refluxate. One study in neurologically disabled children showed that recurrent pneumonia was more likely in those with an abnormal swallowing study (309). Thus, a videofluoroscopic swallowing study (VSS) or fiberendoscopic swallowing evaluation (FEEST), particularly with neurosensory testing, may help identify at risk patients (310–313).

Often the clinician must make management decisions based on inconclusive information. If the patient has severely impaired lung function, it may be necessary to proceed with antireflux surgery in an attempt to prevent

further pulmonary damage, despite a lack of definitive proof that GER is causing pulmonary disease in the individual patient. The potential benefits of surgery are balanced with the recognition of potential complications (section 4.3). Alternatively, if minimal pulmonary disease is present, consideration of medical therapy with careful follow-up of pulmonary function can be considered. No controlled studies demonstrate the benefits of any medical therapy in preventing progression of chronic pulmonary disease caused by GER in children, but lifestyle and pharmacological agents are options.

5.8 The Infant or Child with Upper Airway Symptoms or Signs

Airway symptoms of hoarseness (314), chronic cough (315,316) and globus sensation (the sensation of a lump in the throat) (317,318) have been associated with GER in adult patients. Characteristic reflux-induced findings of airway erythema, edema, nodularity, ulceration, granuloma and cobblestoning have been described (319,320). The sensitivity and specificity of descriptive laryngoscopic findings for the identification of GER-induced disease are unknown in both pediatric and adult patients. These symptoms or signs usually occur in the absence of classical symptoms of GER such as heartburn or chest pain. In adult GER patients, increased acid exposure in the proximal esophagus (321) and pharynx (322) has been observed in those with airway symptoms of cough or frequent throat clearing. Gastropharyngeal reflux was more prevalent in a small study of children with recurrent laryngotracheitis compared to control patients (323). An increased frequency of episodes of awake GER in children with hoarseness has been suggested in one pediatric case series (324). One case report documents a temporal association of GER episodes and cough in an infant (325). Another case series suggests that GER may contribute to either the pathogenesis of subglottic stenosis or may compromise surgical results (326), while another notes increased pharyngeal reflux in children with laryngomalacia (44).

Several uncontrolled treatment studies in adults have demonstrated improvements in laryngeal symptoms and findings following aggressive medical therapy for GER, with recurrence of symptoms when treatment was discontinued (68,69,320,327,328). Improvement in symptoms of hoarseness after GER therapy was reported in one child (329). Another uncontrolled case series describes improvement in a variety of upper airway symptoms in pediatric patients following treatment of GER with a variety of therapies (330). One study demonstrates a marked reduction in cough symptoms in adults with GER following laparoscopic fundoplication (331). There are no randomized placebo controlled treatment trials evaluating the efficacy of GER therapy of laryngeal symptoms in adults or children. Adult data suggest that if a therapeutic trial is considered, it must be prolonged (longer than three months) to adequately assess efficacy (68). If there is clinical improvement, followed by a recurrence off therapy, it is reasonable to suspect a role for GER in the pathogenesis of symptoms in an individual patient.

In summary, several studies describe the presence of GER in children with either chronic or recurrent laryngeal symptoms. The evaluation of suspected GER-associated laryngeal symptoms is complicated by a lack of a uniform interpretation of laryngeal findings. Nonetheless laryngoscopy is generally indicated to rule out potential anatomic abnormalities of airway protection such as a laryngeal cleft. At this time, there is insufficient evidence and experience in children to provide recommendations for a uniform approach to diagnosis and treatment.

5.9 Other Disorders Potentially Associated with GER

Multiple case reports suggest an association between GER and a variety of other disorders. One study suggested that adolescents with GER had an increased incidence of erosion of enamel on the lingual surfaces of their teeth (332). However, another study showed no increased incidence of dental erosions in adolescents with abnormal esophageal pH monitoring (333).

GER has been suggested as a potential contributing factor in recurrent sinus disease, pharyngitis and otitis media. One uncontrolled case series of children with chronic sinusitis suggested that treatment of GER dramatically reduced the need for sinus surgery in children (334). Another demonstrated that in children with recurrent rhinopharyngitis, there was an increased number of episodes with the pharyngeal pH falling to below 6 in affected patients compared to controls (335). However, the occurrences of ear and sinus infections were similar in infants with or without GER (8). No data demonstrate an association of otitis media and GER. However, otalgia has been associated with GER in children and was reported to improve with treatment of GER (336).

Appendix A. *Summary of recommendations for diagnostic approaches and the quality of the evidence*

Section	Recommendations	Quality of evidence*
	Diagnostic approaches	
3.1	In most cases a history and physical examination are sufficient to reliably diagnose GER and initiate management.	III
3.2	The upper GI series is neither sensitive nor specific for the diagnosis of GER, but is useful for the evaluation of the presence of anatomic abnormalities, such as pyloric stenosis, malrotation and annular pancreas in the vomiting infant, as well as hiatal hernia and esophageal stricture in the older child.	III
3.3	Esophageal pH monitoring is a valid and reliable measure of acid reflux.	II-2
3.4	Endoscopy and biopsy can determine the presence and severity of esophagitis, strictures and Barrett's esophagus, as well as exclude other disorders. Esophageal biopsy is recommended when endoscopy is performed to detect inapparent esophagitis and to exclude causes of esophagitis other than GER.	II-2
3.5	The role of nuclear scintigraphy (milk scan) in the diagnosis and management of GERD in infants and children is unclear.	III
3.6	A trial of time–limited medical therapy for GER is useful for determining if GER is causing a specific symptom.	III

* Categories of the Quality of Evidence [16]
I Evidence obtained from at least one properly designed randomized controlled study.
II-1 Evidence obtained from well–designed cohort or case–controlled trials without randomization.
II-2 Evidence obtained from well–designed cohort or case–control analytic studies, preferably from more than one center or research group.
II-3 Evidence obtained from multiple time series with or without the intervention. Dramatic results in uncontrolled experiments (such as the results of the introduction of penicillin treatment in the 1940's) could also be regarded as this type of evidence.
III Opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.

Appendix B. *Summary of recommendations for treatment options and the quality of the evidence*

Section	Recommendation	Quality of evidence*
	Treatment options	
4.1.1	There is evidence to support a one to two week trial of a hypoallergenic formula in formula fed infants with vomiting.	I
4.1.1	Milk–thickening agents do not improve reflux index scores but do decrease the number of episodes of vomiting.	I
4.1.2	Esophageal pH monitoring has demonstrated that infants have significantly less GER when placed in the prone position than in the supine position.	I
4.1.2	Prone positioning is associated with a higher rate of the sudden infant death syndrome (SIDS). In infants from birth to 12 months of age with GERD, the risk of SIDS generally outweighs the potential benefits of prone sleeping. Therefore, non–prone positioning during sleep is generally recommended.	I
4.1.2	In children older than one year it is likely that there is a benefit to left side positioning and elevation of the head of the bed.	I
4.1.3	It is recommended that children and adolescents with GERD avoid caffeine, chocolate and spicy foods that provoke symptoms. Obesity, exposure to tobacco smoke and alcohol are also associated with GER.	III
4.2.1.1	Histamine–$_2$ receptor antagonists (H_2RAs) produce relief of symptoms and mucosal healing. Proton pump inhibitors (PPIs), the most effective acid suppressant medications, are superior to H_2RAs in relieving symptoms and healing esophagitis.	I
4.2.1.3	Since more convenient and safe alternatives are available (H_2RAs and PPIs), chronic antacid therapy is generally not recommended.	III
4.2	Cisapride reduces the frequency of regurgitation and vomiting. However, because of concerns about the potential for serious cardiac arrhythmias in patients receiving cisapride, appropriate patient selection and monitoring as well as proper use, including correct dosage (0.2 mg/kg/dose QID) and avoidance of co–administration of contraindicated medications, are important. Cisapride is available in the USA only through a limited–access program. Other prokinetic agents have not been shown to be effective in the treatment of GERD in children.	I
4.3	Case series indicate that surgical therapy generally results in favorable outcomes. The potential risks, benefits and costs of successful prolonged medical therapy versus fundoplication have not been well studied in infants or children with varying symptom presentations.	II-3 III

Appendix C. *Summary of recommendations for the evaluation and management of infants and children with suspected GERD and the quality of the evidence*

Section	Recommendation	Quality of evidence*
	Evaluation and management of infants and children with possible GERD	
5.1.1	In the infant with recurrent vomiting, a thorough history and physical examination with attention to warning signals is generally sufficient to allow the clinician to establish a diagnosis of uncomplicated GER.	III
5.1.2	In the infant who has uncomplicated GER, parental education, reassurance and anticipatory guidance are recommended. Generally, no other intervention is necessary. Thickening of formula and a short trial of a hypoallergenic formula are other treatment options. If symptoms worsen or do not improve by 18 to 24 months of age, re–evaluation for complications of GER is recommended.	III
5.1.3	In the vomiting infant with poor weight gain in whom adequate calories are being offered, it is recommended that tests be performed to uncover other causes of vomiting, including an upper GI series to evaluate anatomy and swallowing. Management options include thickening the formula, increasing the caloric density of the formula, acid suppression therapy, prokinetic therapy and, in selected cases, prone positioning. Further management options include endoscopy with biopsy, hospitalization, tube feedings and rarely surgical therapy.	III
5.1.4	In infants with vomiting and irritability, potentially harmful interventions are undertaken with caution because pathological findings are so infrequent. One approach to management is initial empiric therapy; an alternate approach is initial diagnostic evaluation.	III
5.1.5	In otherwise normal children who have recurrent vomiting after the age of 2 years, management options include an upper GI series and upper endoscopy with biopsy. Prokinetic therapy is also an option.	II-2 III
5.2	For the treatment of heartburn in children or adolescents, lifestyle changes accompanied by a two– to four–week therapeutic trial of an H_2RA or PPI are recommended. If symptoms persist or recur, the child can be referred to a pediatric gastroenterologist for upper endoscopy with biopsy and in some cases long–term therapy.	III
5.3	In the infant or child with esophagitis, initial treatment consists of lifestyle changes and H_2RA or PPI therapy. In patients with only histologic esophagitis, the efficacy of therapy can be monitored by the degree of symptom relief. In patients with erosive esophagitis, repeat endoscopy is recommended to assure healing.	I
5.4	In the child with dysphagia or odynophagia, a barium esophagram is recommended. If the initial history is suggestive of esophagitis, upper endoscopy may be performed as the initial diagnostic test. Treatment without prior diagnostic evaluation is not recommended. In the infant with feeding refusal, because a large variety of disorders may contribute to infant feeding difficulties, empiric therapy for GER is generally not recommended. However, if there are other signs or symptoms suggestive of GERD then a time–limited course of medical therapy can be considered.	III
5.5	In the infant with apnea or an apparent life–threatening event, if symptoms occur frequently and the role of GER is uncertain, esophageal pH monitoring may be useful to determine if there is a temporal association of acid reflux with ALTE. Therapeutic options include thickened feedings and prokinetic and acid suppressant therapy. Since most infants improve with medical management, surgery is considered only in severe cases.	II-2 III
5.6	In patients where symptoms of asthma and esophagitis co–exist, and in infants and toddlers with chronic vomiting or regurgitation and recurrent episodes of cough and wheezing, a three–month trial of vigorous acid suppressant therapy of GER is recommended. If patients with persistent asthma do not have symptoms of GER, esophageal pH monitoring is recommended in selected patients who are more likely to benefit from GER therapy.	III

Guidelines on Forgoing Life-Sustaining Medical Treatment (RE9406)

Committee on Bioethics

Most children who become ill, even those with life-threatening disorders, recover to lead satisfying lives. Nonetheless, the course of disease may at times cause health care professionals and families to consider whether continued treatment truly represents the best option. Sometimes limiting or stopping life support seems most appropriate, especially if treatment only preserves biological existence or if the overall goal of therapy has shifted to the maintenance of comfort. Based on the existing consensus in ethics and law, the following guidelines for professionals caring for children suggest elements in decisions to forgo life-sustaining medical treatment (LSMT).[1-4]

Decisions to withhold or withdraw LSMT may seriously tax the intellectual and emotional reserves of all parties. Patients, families, physicians, and other members of the medical care team should have access to and feel free to use ethics consultants or ethics committees in addition to the other resources on which they usually rely.[5,6]

PRELIMINARY NOTATIONS

Life-sustaining medical treatment encompasses all interventions that may prolong the life of patients. Although LSMT includes the dramatic measures of contemporary practice such as organ transplantation, respirators, kidney (dialysis) machines, and vasoactive drugs, it also includes less technically demanding measures such as antibiotics, insulin, chemotherapy, and nutrition and hydration provided intravenously or by tube.[7]

The term "forgo" refers to both stopping a treatment already begun as well as not starting a treatment. Although many health care professionals feel reluctant to discontinue life-sustaining treatments, most philosophical and legal commentators find no important ethical or legal distinction between not instituting a treatment and discontinuing treatment already initiated. Fear about stopping therapy may keep clinicians from beginning treatments that may help some patients, particularly when great uncertainty prevails. A better course often includes initiating interventions that, if they later prove unhelpful, may be stopped. Continuing nonbeneficial treatment harms many patients and may constitute a legal, as well as moral, wrong. Those who feel culpable and emotionally strained when faced with withdrawing treatment deserve sympathy and one should be sensitive to those upset by decisions to stop therapy. However, ethical theory and legal practice provide reasons to start or stop treatments based primarily on the relative benefits and burdens for the patient.[8]

Generally, parents give permission for the treatment of children who cannot do so themselves. (See "Decision Making for Patients Who Lack Decision-Making Capacity.") However, the American Academy of Pediatrics emphasizes that physicians and parents should give great weight to clearly expressed views of child patients regarding LSMT, regardless of the legal particulars.

For such serious matters as LSMT, the medical plan usually should conform to the values and choices of the patient and his or her family. In some circumstances, only one parent will be reasonably available before some decisions must be implemented. In other situations, although only a single parent will have actual guardianship or legal responsibility, the clinician may have moral and psychological reasons to consider the views of the other biological parent. In yet other instances, surrogates besides the parents will have decision-making authority; these may include other family members appointed guardians by a court, guardians ad litem, or representatives of child protective agencies maintaining custody of the child.

Decision-making capacity and the legal term "competency" refer to the ability of a person to make decisions at particular times under particular circumstances. One formulation of this overall capacity involves three essential elements: (1) the ability to understand and communicate information relevant to a decision; (2) the ability to reason and deliberate concerning the decision; and (3) the ability to apply a set of values to a decision that may involve conflicting elements.[9] Each potential decision maker regarding LSMT should manifest these abilities. However, children should have the opportunity to participate in decisions about LSMT to whatever extent their abilities allow.

Many decisions regarding life support for children call for the use of the "best interests" standard. This involves weighing the benefits and burdens of LSMT. The benefits may include prolongation of life (understanding that the continuation of biological existence without consciousness may not be a benefit); improved quality of life after the LSMT has been applied (including reduction of pain or disability); and increased "physical pleasure, emotional enjoyment, and intellectual satisfaction" (as cited in a ruling by the New Jersey Supreme Court).[10,p295]

The burdens of LSMT may include intractable pain; irremediable disability or helplessness; emotional suffering; invasive and/or inhumane interventions designed to sustain life; or other activities that severely detract from the patient's quality of life. (The phrase "quality of life" refers to the experience of life as viewed by the patient, ie, how the patient, not the parents or health care providers, perceives or evaluates his or her existence. The American Academy of Pediatrics specifically rejects attempts to equate quality of life with the notion of "social worth" as judged

by others. Such equations have unfortunately tainted discussions of limiting LSMT for children. Avoidance of the term quality of life would, however, ignore its widespread use.)

STATEMENT OF GENERAL PRINCIPLES

Presumption in Favor of Treatment

The American Academy of Pediatrics believes that physicians should provide life-sustaining medical care in conformity with current medical, ethical, and legal norms. Physicians should remember that two broad principles guide the implementation of therapy. First, beneficence suggests that clinicians justify the use of treatments based on the benefits they provide, not simply on the ability to employ them. The related notion of nonmaleficence reminds physicians to consider potential harm to patients. Harm includes obvious physical problems such as pain but may also include psychological, social, and economic consequences. Second, self-determination or autonomy accepts the likelihood that different persons may judge benefits differently. Our social system generally grants patients and families wide discretion in making their own decisions about health care and in continuing, limiting, declining, or discontinuing treatment, whether life-sustaining or otherwise. Medical professionals should seek to override family wishes only when those views clearly conflict with the interests of the child.

Right to Decide and To Be Informed

Whether they are child patients, parents, or other surrogates, health care decision makers have the ethical and legal right to adequate information about reasonably available diagnostic and therapeutic options (including risks, benefits, nature, and purpose of the options).

Right to Refuse Treatment

As a general rule, children who meet statutory criteria for emancipation and those who have been judged mature for purposes of medical decisions may refuse unwanted medical intervention. Most courts that have considered the issue also recognize that incompetent patients, including children, need not receive all possible treatments in each case.[10] As noted previously, society generally presumes that parents should exercise the right to refuse medical treatment when nonautonomous children cannot do so for themselves.

Decisions to Forgo Are Particular to Specific Treatment

A decision to limit, decline, discontinue, or otherwise forgo a particular treatment or procedure applies specifically to that treatment or procedure. Such decisions do not imply that any other procedures or treatments are to be forgone, without a specific decision to do so. Thus, the decision to forgo use of antibiotics in the case of suspected infection does not mean that the patient should not receive oxygen, analgesics, or range-of-motion therapy aimed at providing comfort. Similarly, a do-not-resuscitate order should never signal the abandonment of a patient. When doubts exist regarding the appropriateness of particular treatments, the parties should ask themselves if the therapies of concern further the overall treatment plan. Such a plan should encompass the general goals of treatment, including its scope and limits, and the means suited to achieving those goals.

Preservation of Respect for the Patient

The needs of the child must remain primary, and measures necessary to assure comfort must be maintained at all times. Comfort measures include appropriate nursing and hygienic care as well as analgesics.

Physicians' Obligations

Individual physicians who generally decline to participate in the limitation or withdrawal of therapy should communicate their position to patients and families as soon as that information becomes relevant. When physicians do not wish to participate in forgoing LSMT, they have a legal duty to arrange for care by another physician before removing themselves from the relationship.

Availability of Guidelines to Patients and/or Families

Educational material with substantially the same message as these guidelines should be made available, whenever relevant, to patients and/or their families.

Presumption Against Judicial Review

Families and health care professionals should work together to make decisions for patients who lack decision-making capacity. Recourse to the courts should be reserved for occasions when adjudication is clearly required by law or when concerned parties have disagreements that they cannot resolve, despite appropriate consultation, concerning matters of substantial importance.[11]

GUIDES FOR DECISION MAKING

Informing for Decision Making

Physicians have the responsibility to provide the patient, parents, or other appropriate decision makers with adequate information about applicable therapeutic and diagnostic options.

This information should include the risks, discomforts, side effects, and estimated financial and other costs of treatment alternatives, the potential benefits, and the likelihood, if known, of whether the treatment will succeed.

The physician should also provide advice about which option(s) to choose. That is, physicians should do more than offer a "menu" of choices--they should recommend what they believe is the best option for the patient under the circumstances and give any reasons, based on

medical, experiential, or moral factors, for such judgments. However, physicians should remind families that they may accept or reject the physician's recommendations.

The physician should elicit questions; provide truthful and complete answers to such questions; attempt to ascertain whether or not the decision maker understands the information and advice provided; and attempt to enhance understanding as needed.

The understanding of options by patients, parents, or other decision makers will often increase over time. Therefore, decision making should be treated as a process, rather than as an event. This implies, in part, that patients and/or their surrogates may change their minds as they develop an appreciation of the clinical situation and its meaning for their lives.

Withholding of Information From Patients, Parents, or Other Decision Makers

There is a strong presumption that all information needed to make an appropriate decision about health care (including a decision to forgo LSMT) should be provided to the patient, parents, or surrogates. Experience and study suggest that most patients, family members, or other decision makers want to hear the reality of their situation.[12,13] Open and honest communication reduces tension in the physician-patient relationship.

Information may not be withheld on the grounds that it might cause the patient or surrogate to decline a recommended treatment or to choose a treatment that the physician does not wish to provide. Nor may information be withheld because its disclosure might upset the patient, parents, or other decision maker.

Physicians may withhold information when a competent patient clearly indicates that he or she does not wish to have the information provided, and the physician has previously offered to provide such information. Some commentators believe that parents or other surrogates do not have the same prerogative to refuse information or decline participation in decision making.[14]

Physicians may withhold information if they believe the information would pose an immediate and/or serious threat to a patient's or surrogate's health or life. These circumstances will occur rarely, if ever. A physician who withholds information assumes the burden of supporting the decision not to make customary disclosures. The physician should withhold only the specific information that might produce a threat. Even when immediate full disclosure may produce harm, the physician may succeed in providing partial information gradually, until full disclosure has occurred.

When the physician purposely limits disclosure, he or she should document the reasons in the medical record.

Collaborative Physician-Patient (or Physician-Surrogate) Decision Making

When the attending physician believes the treatment no longer confers a benefit and should be forgone, the patient, parents, or other surrogate should be so informed. Children, even those of early school years, often appreciate their medical situations far better than their family members, guardians, or health care providers believe.15 In many cases, young children deserve to hear the general conclusions of decisions that will affect their continued survival. Children should not be deprived of opportunities to say goodbyes to loved ones. Well-meaning attempts to shield children from this information may result in the breakdown of open communication and trust between patients and those caring for them.

Under some circumstances, child patients and their parents will not agree on the best plan of action. Such situations defy easy rules-of-thumb. The parties must consider, among other concerns, the facts and gravity of the situation; the maturity, knowledge, and intelligence of the child; and the reasons for and strength of the feelings of other family members. The parties should consider seeking consultative help from the following: (1) child psychiatrists, family therapists, or similar professionals skilled in behavioral assessment and counseling; (2) ethics consultants or an ethics committee; (3) other sources of family support, including religious advisers; and, if necessary, (4) the courts.

Physician-Patient (or Physician-Surrogate) Disputes

Patients or surrogates may not compel a physician to provide any treatment that, in the professional judgment of that physician, is unlikely to benefit the patient.[16] However, physicians should not use their views that a treatment provides no benefit (one that they therefore do not wish to offer) as a reason for circumventing possibly difficult discussions with patients. For example, the medical judgment that cardiopulmonary resuscitation will not succeed (that resuscitation is "futile") in a patient with severely injured lungs from bronchopulmonary dysplasia or necrotizing bronchiolitis should not serve as an excuse to avoid talking about do-not-resuscitate orders. Hospitals should have policies addressing intractable differences between staff and patients or families.

If the patient or surrogate makes a decision that the physician cannot accept in good conscience, the physician should arrange transfer of the patient's care to another physician or hospital willing to accept the decision.

If the physician can make no such arrangements, action by the physician to continue or forgo treatment without extensive consultation seems unwise. Such disputes deserve careful consideration of their ethical, legal, and administrative implications. Only in the rare situations in which extended counseling efforts fail, and no physician or facility will accept the patient, should physicians or hospitals refer these cases to the courts.

Consultation With Family

Professionals who care for children should strongly encourage their patients to discuss LSMT with their families and with other close friends and advisers well in advance of the need for decisions. However, when requested to do so, medical professionals should respect the privacy and confidentiality of patients legally entitled to make their own decisions (emancipated minors or those judged mature), including decisions about LSMT. Physicians should honor the desire of patients and parents to prevent disclosure of medically related information to members of the extended family in all but the most unusual circumstances.

DECISION MAKING FOR PATIENTS WHO LACK DECISION-MAKING CAPACITY

The following sections delineate concerns about decision-making capacity and standards to be applied when patients lack such capacity. Many medical professionals who care for children, as a matter of course, take the views of the children about treatment seriously. However, the gravity of decisions about LSMT requires careful, explicit attention to the wishes and feelings of the children, regardless of the legal status of the patients.

Definitions

The definition of emancipated minor varies somewhat from state to state. Generally, legislation defines emancipated minors as those who have graduated from high school, members of the armed forces, those who are married, those who are pregnant or parents, or those who live apart and are financially independent from their parents.

The legal notion of mature minor varies even more. Many courts and some legislatures recognize that individual children, beginning at approximately age 14 years, may be assessed sufficiently mature to make decisions, including some medical ones, for themselves.

The substituted judgment standard refers to situations in which surrogates can make inferences about the preferences of previously competent patients. When such a patient's wishes are known or can be deduced, surrogates should replicate the decision that the patient would have made under the circumstances. Thus, this legal standard applies for children who are emancipated or considered mature.

Presumption of Capacity: Decision-Making Capacity in General

In the case of conscious and alert emancipated minors or those judged mature minors, the ethical and legal presumption of capacity should govern, unless countervailing evidence arises to call the presumption into question.

The professional staff may question a patient's capacity if they suspect or diagnose conditions such as delirium, dementia, depression, mental retardation, psychosis, intoxication, stupor, or coma. Lack of decision-making capacity can be transient and specific to a particular decision. Therefore, patients who suffer from any of these conditions may not lack capacity at all times for all purposes, and the staff may need to reassess decision-making capacity from time to time.

Refusal of specific treatment that most patients would agree to does not alone mean the patient lacks decision-making capacity, but such refusals may serve as a basis for inquiring into the patient's decision-making capacity.

Standards for Decision Making for Patients Lacking Decision-Making Capacity

A surrogate must make health care decisions for patients who lack decision-making capacity.

The substituted judgment standard should be used for children who are emancipated or mature when their wishes are known or may be deduced.

The best interests standard serves as the basis for decisions for patients who have never achieved decision-making capacity, including infants and young children. This standard does not easily apply to patients in whom a permanently unconscious state has been reliably diagnosed. It is difficult to claim that their continued life benefits them, although we cannot say with certainty that they suffer any burden. Physicians and families should also consider whether continued treatment conforms with respect for the meaning of human life and accords with the interests of others, such as family members and other loved ones.

Formal Assessment of Capacity

As a rule, the attending physician should assess and document the capacity of a patient to make or assist in making decisions about forgoing treatment. Formal developmental, psychiatric, or other consultation may help determine the patient's abilities and the appropriateness of the child's participation in making decisions.

Advance Directives

Legal uncertainty surrounds the status of "living wills" or durable power-of-attorney documents executed by minors, even those recognized as emancipated or mature. Thus, in most situations, children will not have formal advance directive documents even under the Federal Patient Self-Determination Act.[17] However, physicians and others should accord considerable weight to the feelings minor children may have expressed before losing the capacity to communicate clearly regarding LSMT. If the patient has executed a living will or any other form of advance directive for health care, that document should serve as strong evidence of the patient's wishes.

Pediatricians should encourage parents of dying children to plan alternatives to calling emergency medical personnel if the family does not desire resuscitation.

DOCUMENTATION OF DECISIONS AND ENTRY OF ORDERS

The American Academy of Pediatrics recommends explicit documentation, in the form of clear orders and explanatory progress notes in the medical record, to encourage involved health care providers to adhere closely to the goals of treatment agreed on by the patient, parents, or other decision maker, and the patient's physician.

Orders

Physicians should encourage hospitals to develop and maintain written policies permitting the forgoing of life-supporting treatment of patients, including children, in appropriate circumstances. Such policies should state that when it has been determined that a particular LSMT is to be forgone, the attending physician or a designee must write an order in the patient's medical record. Telephone orders alone are not acceptable under most circumstances. The attending physician has the responsibility to elicit and consider the views of other members of the professional staff regarding treatment limitations before entering orders limiting LSMT. He or she should discuss the meaning of any order limiting treatment with the staff and ensure that all involved understand such orders and their implications.

Progress Notes

At the time an order limiting LSMT is written, the attending physician should write a companion entry in the progress notes including the following information: diagnosis, prognosis, patient's or other decision-maker's wishes, the content of discussions with involved parties, any disagreements or unresolved issues, and the recommendations of the treating team and consultants.

Acceptable Orders

Each situation deserves individual consideration. This usually requires detailed orders appropriate to the specific case. However, physicians may indicate the following orders to facilitate communication.

No Specified Limits on Therapy

These patients will receive all medically appropriate interventions, including treatment of cardiopulmonary arrest. All patients are assumed to be in this category unless it is otherwise noted in the patient's orders and explained in progress notes.

Limited Therapy

These patients receive medically indicated treatment but have specific interventions, diagnostic or therapeutic, forgone as noted in the patient's orders and explained in progress notes. For example, one may omit cardiopulmonary resuscitation, provide all reasonable therapies for respiratory disease, but forgo tracheal intubation and/or mechanical ventilation, or provide "comfort measures only," such as nursing care plus appropriate analgesia and sedation. Interventions already begun may be withdrawn. Forgoing specific measures does not preclude initiation or continuation of other indicated diagnostic tests or therapies.

ACKNOWLEDGMENTS

This document draws extensively on a framework developed by Meisel and others.[1] The American Academy of Pediatrics statement focuses on the special issues that pertain to children and clarification of substantive matters beyond the largely procedural approach in that article.

Guidelines for Home Care of Infants, Children, and Adolescents With Chronic Disease (RE9530)

AMERICAN ACADEMY OF PEDIATRICS

Committee on Children With Disabilities

Many infants, children, and adolescents with long-term, serious health problems require frequent and/or prolonged hospitalizations that separate them from their home environment. Hospitalization interferes with the ability to form the normal, interpersonal family and community relationships that are important for normal growth and development. Caring for a child at home may be a desirable alternative to hospital-based care.

Caring for a child at home, with all the necessary assistance, is more supportive of the family's traditional caretaking and nurturing role, but home care should be initiated only when consonant with the best interests of the child and family and if adequate resources and support are available. Combining the benefits of home care with appropriate medical treatment and support requires the development of innovative programs among hospitals, physicians, parents, home care professionals, and communities.

Although many home health care programs for patients with chronic disease exist, objective data about their efficiency, risks, benefits, and costs are limited. Where documentation exists,[1,2] home care can be shown to be a successful, cost-effective method of health care delivery. Careful planning and coordination of family, hospital, home care providers, and community resources, however, are essential for successful home health care programs, and guidelines for program development and assessment are needed.

The goal of a home health care program for infants, children, or adolescents with chronic conditions is the provision of comprehensive, cost-effective health care within a nurturing home environment that maximizes the capabilities of the individual and minimizes the effects of the disabilities. This may be established to prevent hospitalization or reduce the length of hospitalization.

PROGRAM DEVELOPMENT

Comprehensive planning should minimize physical and emotional risk to the patient, adverse effects on the family members, or unforeseen financial burdens. Because of the many factors to be considered, planning should be done by a multidisciplinary Home Health Care Team. This team should include (when available): parents; a primary care pediatrician; other physicians (eg, hospital physicians, subspecialists, other community physicians); nurses; occupational, physical, respiratory, and speech therapists; child development specialists; educational specialists; nutritionists; social workers; teachers; home care providers (eg, home health aide and equipment provider); case managers; and insurers. The team must initially develop the Home Health Care Program, which provides comprehensive care recommendations (the treatment plan) and arrangements based on each individual patient's demonstrated needs (the resources to be utilized, including equipment and service providers). Many of the resources used in the Home Health Care Program may be an extension of existing hospital services.

After the Home Health Care Program is established, each child and family identified for the program needs an Individualized Home Care Plan (IHCP). The family (or other primary caregivers) and the primary care pediatrician must play a major role in developing, implementing, and monitoring the plan, with appropriate subspecialists, when necessary, identified early in this process. A home care service coordinator to support and coordinate the IHCP should be selected (jointly by the team and the family) for each patient. The coordinator, working in conjunction with the primary care pediatrician, works closely with the family, identifying and assisting with their needs in caring for the child at home, including family training about illness, treatment, and advocacy, and assisting families in developing service coordination skills. This family oriented advocate could be an appropriately trained parent of a child with chronic illness who has experience in home care-related issues and concerns. Every effort should be made to identify a single care coordinator for the child and family, even if this requires serving the needs of several programs/systems. If this is not possible, it is essential that a communication system be developed with unique and shared responsibilities delineated for each care coordinator.

IMPLEMENTATION

Patient Selection

Eligibility for home health care should be based on a comprehensive analysis of the Home Health Care Program capabilities, whether the child's therapeutic needs can be met by home care, the potential benefits and risks, and the available resources. Families should not face excessive pressure to enroll their children in a home care program if this move would be detrimental to the child or family. The patient should participate in the development of the IHCP to the extent possible, with the following factors considered for patient selection.

1. Patient Factors. Underlying any potential for home care in chronic disease is the patient's medical stability vis-a-vis the capacity of the Home Health Care Program to provide backup and emergency care. Previous experience with home care in similar situations should be reviewed. As part of the initial discharge planning process, plans should be made to explore home care as an option to begin when the patient's condition is as stable as possible.
2. Family and Home Factors. If possible, each family should have at least two members trained and fully able to care for the child in the home. In some situations, two or more trained adults are essential to assure medical safety. The family should provide evidence of sufficient parental/family involvement, proven capability in performing medical and nursing tasks, and an appropriate home situation (eg, physical environment, safety, and geographic location) for the child's medical safety to be reasonably assured. Respite services should be part of the plan as well as emergency staffing in case the care provider is ill. Specialized day care should be explored as well.
3. Community Factors. A primary care pediatrician or other provider should be involved in the development of the IHCP before hospital discharge, be knowledgeable about the plan, and agree to participate by providing primary medical care. This physician oversees the medical aspects of the plan after hospital discharge, communicates with the attending physician at the hospital and other involved physicians, and reviews the safety of the plan. The service coordinator must assure the availability of appropriate home health care providers, equipment, and other special needs (eg, oxygen suppliers). Essential equipment must either be portable or available at each site that the child attends. Reasonable contingency plans for emergencies (eg, power and equipment backup for those with life-support devices and appropriate transportation), including clear delineation of the unique and shared medical care responsibilities among physicians on the team, must be available. The "team leader," generally the primary care pediatrician, should be identified.
4. Home Care Trial. In order to identify any omissions or lack of clarity in the IHCP, a successful trial of care by the future home health care providers within the hospital setting (using emergency backup by the regular hospital staff) is recommended before discharge. Family members should use equipment and supplies that will be used at home first in the hospital so that they can become familiar and proficient with their use. Any differences between hospital use and home use should be addressed before hospital discharge. The trial should enable the family and other regular caregivers to develop self-confidence and avoid overdependency upon hospital staff.

IHCP DEVELOPMENT

Careful review of the patient's status and needs in the hospital should be made by each professional participating in the patient's care. Each discipline should formulate goals and objectives for the patient and develop daily program components to meet these goals in the home. Thereafter, a meeting should occur to formulate an integrated daily IHCP with specific responsibilities delineated, including the establishment of financial responsibility. This plan includes the following: 1) designation of a home care service coordinator, 2) involvement of a primary care physician who will provide "the medical home," 3) family access to a telephone, 4) specific physician orders for medications, treatments, medical follow-up, and medical tests as appropriate, 5) a plan for monitoring the home care plan that includes designation of the "team leader" and specific responsibilities of the service coordinator and primary care physician, 6) a mechanism for making adjustments to the plan when needed, 7) a defined backup system for medical emergencies, 8) regular or special educational services for school-aged children and early intervention services for eligible infants and toddlers, and 9) criteria procedures for transition from home care, when appropriate.

Educational Services

Planning for early intervention and/or educational services should stress the importance of educating children in an environment with peers that promotes and maintains socialization. With school systems providing education in the least restrictive environment, the child's Individual Educational Plan should incorporate therapeutic and nursing care that is coordinated with the daily IHCP. A child should not be denied necessary home care services because he or she is entitled to school-based services.

Equipment and Supplies

Equipment and supplies that are appropriate for use in the home must be selected and secured according to each patient's needs. Community suppliers must guarantee continuous availability, maintenance, emergency repair, and replacement of this equipment. Financial reimbursement to the family for necessary equipment, supplies, and maintenance should not be denied because the care of the patient is transferred from the hospital to the home. Any need for equipment changes, including manufacturer recalls, should be arranged in conjunction with the service coordinator and the family. Equipment performance should be documented and tracked by the manufacturer.

Child and Caregiver Training

Critical components of the IHCP are education and training for the family and other caregivers, including the child to the greatest extent possible, professional and paraprofessional health care providers, school personnel (if the child will be attending school), and all emergency personnel. Before discharge from the hospital, the family rather than the hospital staff should provide as much of the child's care as possible. The family must learn to recognize and record changes in the child's condition that would require consultation and/or modification of care. The patient, especially if an adolescent, should be encouraged to take responsibility for self-care to the extent appropriate. Although it may require time, restraint, and patience, the hospital staff should assume a supportive, rather than primary, role in this stage of the child's care. The plan should also incorporate outreach education for staff at local hospitals and community-based home care providers.

Cost

The Home Health Care Team should evaluate the projected cost of the child's IHCP and the available methods of financial support and resolve funding problems before hospital discharge of the patient. There should be continuing review and dialogue among the Home Health Care Team, insurers, and public programs to help assure the financial coverage of home care. Creative financing approaches include negotiated

arrangements among a diversity of health care and social service funding sources.

Effects of Home Care on the Child and the Family

During the development of the child's IHCP, a number of issues related to the potential effects of having a severely ill child at home need to be explored with the family, including issues of privacy, physical burdens of care, impact upon other family members such as siblings, time demands of home care, role of the parents in coordinating care, and the social and financial aspects including issues of confidentiality. Assessment should include impact of home care on family dynamics, activities, and schedules including work-related responsibilities. Discussions with the family should explore possible approaches to these issues before discharge, and the family should feel comfortable with their choices.

PROGRAM MAINTENANCE

Before discharge and at intervals during the child's home care program, there should be a coordinated review of the patient's and family's needs, how the family is managing, the progress toward the home care goals, and other available relevant information. The service coordinator and the family should conduct the program review, soliciting input from all involved providers. This is particularly important since the child's and family's needs will likely change over time, both medically and socially. The type and frequency of the child's specialized therapy should be reviewed, and any new issues that arise should be evaluated. Home care case management conferences are recommended at periodic intervals. They should include all community-based providers and case managers.

PROGRAM EVALUATION AND OUTCOME

A review of all patients in the Home Health Care Program and an assessment of data from similar programs should be done by the Home Health Care Team on an ongoing basis. Feedback data for review should be obtained from several sources (eg, the child, the parents, the community, local care providers, and school personnel). Sharing experiences will lead to the continued refinement of the Home Health Care Program. Principles of program review should include the analysis and improvement of key clinical and social outcomes, with evaluation of the ultimate value of the care provided. Follow-up and outcome assessments need to be based on the following: 1) survival, 2) the need for subsequent hospitalizations and other morbidity, 3) developmental progress, 4) course of the underlying disease, 5) actual utilization of resources as compared with expected utilization, 6) financial experience (cash flow and continued availability of benefits), and 7) effects on family members, including siblings. As with all elements of family-centered care, input from family members into this process is essential.

ALTERNATIVES

The use of intermediate or chronic care facilities may be considered as an alternative to home care. The choice of home care or alternative care must be based upon a thorough evaluation of the needs and wishes of the family and the expected course of the illness. Most effective care planning requires the development of a continuum of care options and the evaluation of alternate types of care. The home is one community-based alternative. Components comprise a spectrum of care that may be required over time depending on changing circumstances.

CONCLUSION

Home health care programs for infants, children, or adolescents with chronic disease may offer the advantages of supporting the child's growth and development in a more nurturing family environment without compromising comprehensive health care delivered in a cost-effective manner. Since the number of children with chronic diseases that may be appropriate for home care is increasing (eg, technology-dependent children, children with human immunodeficiency virus infection), this issue affects all pediatricians. Careful analysis, shared experience, and future controlled studies will help support the appropriateness and cost-effectiveness of home health care programs in the care of patients with chronic disease. The central role of the family in this process must be recognized and continuously supported, with appropriate ongoing assistance as the needs of the child and family change over time.

CLINICAL REPORT

Guidelines for Monitoring and Management of Pediatric Patients During and After Sedation for Diagnostic and Therapeutic Procedures: An Update

Guidance for the Clinician in Rendering Pediatric Care

AMERICAN ACADEMY OF PEDIATRICS
AMERICAN ACADEMY OF PEDIATRIC DENTISTRY
Charles J. Coté, MD, Stephen Wilson, DMD, MA, PhD, the Work Group on Sedation

ABSTRACT

The safe sedation of children for procedures requires a systematic approach that includes the following: no administration of sedating medication without the safety net of medical supervision; careful presedation evaluation for underlying medical or surgical conditions that would place the child at increased risk from sedating medications; appropriate fasting for elective procedures and a balance between depth of sedation and risk for those who are unable to fast because of the urgent nature of the procedure; a focused airway examination for large tonsils or anatomic airway abnormalities that might increase the potential for airway obstruction; a clear understanding of the pharmacokinetic and pharmacodynamic effects of the medications used for sedation, as well as an appreciation for drug interactions; appropriate training and skills in airway management to allow rescue of the patient; age- and size-appropriate equipment for airway management and venous access; appropriate medications and reversal agents; sufficient numbers of people to carry out the procedure and monitor the patient; appropriate physiologic monitoring during and after the procedure; a properly equipped and staffed recovery area; recovery to presedation level of consciousness before discharge from medical supervision; and appropriate discharge instructions. This report was developed through a collaborative effort of the American Academy of Pediatrics and the American Academy of Pediatric Dentistry to offer pediatric providers updated information and guidance in delivering safe sedation to children.

INTRODUCTION

Invasive diagnostic and minor surgical procedures on pediatric patients outside the traditional operating room setting have increased in the last decade. As a consequence of this change and the increased awareness of the importance of providing analgesia and anxiolysis, the need for sedation for procedures in physician offices, dental offices, subspecialty procedure suites, imaging facilities, emergency departments, and ambulatory surgery centers has also markedly increased.[1–37] In recognition of this need for both elective and emergency use of sedation in nontraditional settings, the American Academy of Pediatrics (AAP) and American Academy

of Pediatric Dentistry (AAPD) have published a series of guidelines for the monitoring and management of pediatric patients during and after sedation for a procedure.[38–42] The purpose of this updated statement is to unify the guidelines for sedation used by medical and dental practitioners, add clarifications regarding monitoring modalities, provide new information from medical and dental literature, and suggest methods for further improvement in safety and outcomes. With the revision of this document, the Joint Commission on Accreditation of Healthcare Organizations, the American Society of Anesthesiologists (ASA), the AAP, and the AAPD will use similar language to define sedation categories and the expected physiologic responses.[41–44]

This revised statement reflects the current understanding of appropriate monitoring needs both during and after sedation for a procedure.[4,5,12,19,21,22,26,45–53] The monitoring and care outlined in these guidelines may be exceeded at any time on the basis of the judgment of the responsible practitioner. Although intended to encourage high-quality patient care, adherence to these guidelines cannot guarantee a specific patient outcome. However, structured sedation protocols designed to incorporate the principles in this document have been widely implemented and shown to reduce morbidity.[29,32–34,37,54,55] These guidelines are proffered with the awareness that, regardless of the intended level of sedation or route of administration, the sedation of a pediatric patient represents a continuum and may result in respiratory depression and loss of the patient's protective reflexes.[43,56–59]

Sedation of pediatric patients has serious associated risks, such as hypoventilation, apnea, airway obstruction, laryngospasm, and cardiopulmonary impairment.[2,6,22,45,46,54,60–69] These adverse responses during and after sedation for a diagnostic or therapeutic procedure may be minimized, but not completely eliminated, by a careful preprocedure review of the patient's underlying medical conditions and consideration of how the sedation process might affect or be affected by these conditions.[54] Appropriate drug selection for the intended procedure as well as the presence of an individual with the skills needed to rescue a patient from an adverse response are essential. Appropriate physiologic monitoring and continuous observation by personnel not directly involved with the procedure allow for accurate and rapid diagnosis of complications and initiation of appropriate rescue interventions.[46,51,54]

The sedation of children is different from the sedation of adults. Sedation in children is often administered to control behavior to allow the safe completion of a procedure. A child's ability to control his or her own behavior to cooperate for a procedure depends both on his or her chronologic and developmental age. Often, children younger than 6 years and those with developmental delay require deep levels of sedation to gain control of their behavior.[57] Therefore, the need for deep sedation should be anticipated. Children in this age group are particularly vulnerable to the sedating medication's effects on respiratory drive, patency of the airway, and protective reflexes.[46] Studies have shown that it is common for children to pass from the intended level of sedation to a deeper, unintended level of sedation.[56,59,70] For older and cooperative children, other modalities, such as parental presence, hypnosis, distraction, topical local anesthetics, and guided imagery, may reduce the need for or the needed depth of pharmacologic sedation.[31,71–81]

The concept of rescue is essential to safe sedation. Practitioners of sedation must have the skills to rescue the patient from a deeper level than that intended for the procedure. For example, if the intended level of sedation is "minimal," practitioners must be able to rescue the patient from "moderate sedation"; if the intended level of sedation is "moderate," practitioners must have the skills to rescue the patient from "deep sedation"; and if the intended level of sedation is "deep," practitioners must have the skills to rescue the patient from a state of "general anesthesia." The ability to rescue means that practitioners must be able to recognize the various levels of sedation and have the skills necessary to provide appropriate cardiopulmonary support if needed. Sedation and anesthesia in a nonhospital environment (private physician or dental office or freestanding imaging facility) may be associated with an increased incidence of "failure to rescue" the patient should an adverse event occur, because the only backup in this venue may be to activate emergency medical services (EMS).[46,82] Rescue therapies require specific training and skills.[46,54,83,84] Maintenance of the skills needed to perform successful bag-valve-mask ventilation is essential to successfully rescue a child who has become apneic or developed airway obstruction. Familiarity with emergency airway management procedure algorithms is essential.[83–87] Practitioners should have an in-depth knowledge of the agents they intend to use and their potential complications. A number of reviews and handbooks for sedating pediatric patients are available.[32,48,55,88–93] These guidelines are intended for all venues in which sedation for a procedure might be performed (hospital, surgical center, freestanding imaging facility, dental facility, or private office).

There are other guidelines for specific situations and personnel that are beyond the scope of this document. Specifically, guidelines for the delivery of general anesthesia and monitored anesthesia care (sedation or analgesia), outside or within the operating room by anesthesiologists or other practitioners functioning within a department of anesthesiology, are addressed by policies developed by the ASA and by individual departments of anesthesiology.[94] Also, guidelines for the sedation of patients undergoing mechanical ventilation in a critical

care environment or for providing analgesia for patients postoperatively, patients with chronic painful conditions, and hospice care are also beyond the scope of this document.

DEFINITION OF TERMS USED IN THIS REPORT

- Pediatric patients: all patients through 21 years of age, as defined by the AAP.
- Must/shall: an imperative need or duty that is essential, indispensable, or mandatory.
- Should: the recommended need and/or duty.
- May/could: freedom or liberty to follow a suggested or reasonable alternative.
- Medical supervision/medical personnel: a currently licensed practitioner of medicine, surgery, or dentistry trained in the administration of medications used for procedural sedation and the management of complications associated with these medications.
- Encouraged: a suggested or reasonable action to be taken.
- ASA physical status classification: guidelines for classifying the baseline health status according to the ASA (see Appendix 1).
- Minimal sedation (formerly anxiolysis): a drug-induced state during which patients respond normally to verbal commands; although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.
- Moderate sedation (formerly conscious sedation or sedation/analgesia): a drug-induced depression of consciousness during which patients respond purposefully to verbal commands (eg, "open your eyes," either alone or accompanied by light tactile stimulation, such as a light tap on the shoulder or face, not a sternal rub). For older patients, this level of sedation implies an interactive state; for younger patients, age-appropriate behaviors (eg, crying) occur and are expected. Reflex withdrawal, although a normal response to a painful stimulus, is not considered as the only age-appropriate purposeful response (ie, it must be accompanied by another response, such as pushing away the painful stimulus, to confirm a higher cognitive function). With moderate sedation, no intervention is required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained. However, in the case of procedures that may themselves cause airway obstruction (eg, dental or endoscopic), the practitioner must recognize an obstruction and assist the patient in opening the airway. If the patient is not making spontaneous efforts to open their airway to relieve the obstruction, then the patient should be considered to be deeply sedated.
- Deep sedation (deep sedation/analgesia): a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully (see discussion of reflex withdrawal above) after repeated verbal or painful stimulation (eg, purposefully pushing away the noxious stimuli). The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained. A state of deep sedation may be accompanied by partial or complete loss of protective airway reflexes.
- General anesthesia: a drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive-pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

GOALS OF SEDATION

The goals of sedation in the pediatric patient for diagnostic and therapeutic procedures are to (1) guard the patient's safety and welfare; (2) minimize physical discomfort and pain; (3) control anxiety, minimize psychological trauma, and maximize the potential for amnesia; (4) control behavior and/or movement to allow the safe completion of the procedure; and (5) return the patient to a state in which safe discharge from medical supervision, as determined by recognized criteria, is possible (Appendix 2).

These goals can best be achieved by selecting the lowest dose of drug with the highest therapeutic index for the procedure. It is beyond the scope of this document to specify which drugs are appropriate for which procedures; however, the selection of the fewest number of drugs and matching drug selection to the type and goal of the procedure are essential for safe practice.[53,88,91–93,95–97] For example, analgesic medications such as opioids are indicated for painful procedures. For nonpainful procedures, such as computed tomography or MRI, sedatives/hypnotics are preferred. When both sedation and analgesia are desirable (eg, fracture reduction), either single agents with analgesic/sedative properties or combination regimens are commonly used. Anxiolysis and amnesia are additional goals that should be considered in selection of agents for particular patients. However, the potential for an adverse outcome may be increased when 3 or more sedating medications are administered.[45,98] Knowledge of each drug's time of onset, peak response, and duration of action is essential. Although the concept of titration of drug to effect is critical, one must know whether the previous dose has taken full

effect before administering additional drug. Such management will improve safety and outcomes. Drugs with long durations of action (eg, chloral hydrate, intramuscular pentobarbital, phenothiazines) will require longer periods of observation even after the child achieves currently used recovery and discharge criteria.[45,99,100] This concept is particularly important for infants and toddlers transported in car safety seats who are at risk of resedation after discharge because of residual prolonged drug effects with the potential for airway obstruction.[45,46]

GENERAL GUIDELINES

Candidates

Patients who are in ASA classes I and II (Appendix 1) are frequently considered appropriate candidates for minimal, moderate, or deep sedation. Children in ASA classes III and IV, children with special needs, and those with anatomic airway abnormalities or extreme tonsillar hypertrophy present issues that require additional and individual consideration, particularly for moderate and deep sedation.[51] Practitioners are encouraged to consult with appropriate subspecialists and/or an anesthesiologist for patients at increased risk of experiencing adverse sedation events because of their underlying medical/surgical conditions.

Responsible Person

The pediatric patient shall be accompanied to and from the treatment facility by a parent, legal guardian, or other responsible person. It is preferable to have 2 or more adults accompany children who are still in car safety seats if transportation to and from a treatment facility is provided by one of the adults.[101]

Facilities

The practitioner who uses sedation must have immediately available facilities, personnel, and equipment to manage emergency and rescue situations. The most common serious complications of sedation involve compromise of the airway or depressed respirations resulting in airway obstruction, hypoventilation, hypoxemia, and apnea. Hypotension and cardiopulmonary arrest may occur, usually from inadequate recognition and treatment of respiratory compromise. Other rare complications may also include seizures and allergic reactions. Facilities that provide pediatric sedation should monitor for, and be prepared to treat, such complications.

Back-up Emergency Services

A protocol for access to back-up emergency services shall be clearly identified with an outline of the procedures necessary for immediate use. For nonhospital facilities, a protocol for ready access to ambulance service and immediate activation of the EMS system for life-threatening complications must be established and maintained. It should be understood that the availability of EMS services does not replace the practitioner's responsibility to provide initial rescue in managing life-threatening complications.

On-Site Monitoring and Rescue Equipment

An emergency cart or kit must be immediately accessible. This cart or kit must contain equipment to provide the necessary age- and size-appropriate drugs and equipment to resuscitate a nonbreathing and unconscious child. The contents of the kit must allow for the provision of continuous life support while the patient is being transported to a medical facility or to another area within a medical facility. All equipment and drugs must be checked and maintained on a scheduled basis (see Appendices 3 and 4 for suggested drugs and emergency life support equipment to consider before the need for rescue occurs). Monitoring devices, such as electrocardiography (ECG) machines, pulse oximeters (with size-appropriate oximeter probes), end-tidal carbon dioxide monitors, and defibrillators (with size-appropriate defibrillator paddles), must have a safety and function check on a regular basis as required by local or state regulation.

Documentation

Documentation before sedation shall include, but not be limited to, the guidelines that follow.

1. Informed consent: the patient record shall document that appropriate informed consent was obtained according to local, state, and institutional requirements.[102]
2. Instructions and information provided to the responsible person: the practitioner shall provide verbal and/or written instructions to the responsible person. Information shall include objectives of the sedation and anticipated changes in behavior during and after sedation. Special instructions shall be given to the responsible adult for infants and toddlers who will be transported home in a car safety seat regarding the need to carefully observe the child's head position to avoid airway obstruction. Transportation in a car safety seat poses a particular risk for infants who have received medications known to have a long half-life, such as chloral hydrate, intramuscular pentobarbital, or phenothiazine.[45,46,100,103] Consideration for a longer period of observation shall be given if the responsible person's ability to observe the child is limited (eg, only 1 adult who also has to drive). Another indication for prolonged observation would be a child with an anatomic airway problem or a severe underlying medical condition. A 24-hour telephone number for the practitioner or his or her associates shall be provided to all patients and their families. Instructions shall include limitations of activities and appropriate dietary precautions.

Dietary Precautions

Agents used for sedation have the potential to impair protective airway reflexes, particularly during deep sedation. Although a rare occurrence, pulmonary aspiration may occur if the child regurgitates and cannot protect his or her airway. Therefore, it is prudent that, before sedation, the practitioner evaluate preceding food and fluid intake. It is likely that the risk of aspiration during procedural sedation differs from that during general anesthesia involving tracheal intubation or other airway manipulation.[104,105] However, because the absolute risk of aspiration during procedural sedation is not yet known, guidelines for fasting periods before elective sedation should generally follow those used for elective general anesthesia. For emergency procedures in children who have not fasted, the risks of sedation and the possibility of aspiration must be balanced against the benefits of performing the procedure promptly (see below). Additional research is needed to better elucidate the relationships between various fasting intervals and sedation complications.

Before Elective Sedation

Children receiving sedation for elective procedures should generally follow the same fasting guidelines as those for general anesthesia (Table 1). It is permissible for routine necessary medications to be taken with a sip of water on the day of the procedure.

Before Emergency Sedation

The practitioner must always balance the possible risks of sedating nonfasted patients with the benefits and necessity for completing the procedure. In this circumstance, the use of sedation must be preceded by an evaluation of food and fluid intake. There are few published studies with adequate statistical power to provide guidance to the practitioner regarding safety or risk of pulmonary aspiration of gastric contents during procedural sedation.[104–109] When protective airway reflexes are lost, gastric contents may be regurgitated into the airway. Therefore, patients with a history of recent oral intake or with other known risk factors, such as trauma, decreased level of consciousness, extreme obesity, pregnancy, or bowel motility dysfunction, require careful evaluation before administration of sedatives. When proper fasting has not been ensured, the increased risks of sedation must be carefully weighed against its benefits, and the lightest effective sedation should be used. The use of agents with less risk of depressing protective airway reflexes may be preferred.[110] Some emergency patients requiring deep sedation may require protection of the airway before sedation.

TABLE 1 **Appropriate Intake of Food and Liquids Before Elective Sedation**

Ingested Material	Minimum Fasting Period, h
Clear liquids: water, fruit juices without pulp, carbonated beverages, clear tea, black coffee	2
Breast milk	4
Infant formula	6
Nonhuman milk: because nonhuman milk is similar to solids in gastric emptying time, the amount ingested must be considered when determining an appropriate fasting period	6
Light meal: a light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time; both the amount and type of foods ingested must be considered when determining an appropriate fasting period	6

Source: American Society of Anesthesiologists. Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures—a report of the American Society of Anesthesiologists. Available at: www.asahq.org/publicationsAndServices/NPO.pdf.

Use of Immobilization Devices

Immobilization devices such as papoose boards must be applied in such a way as to avoid airway obstruction or chest restriction. The child's head position and respiratory excursions should be checked frequently to ensure airway patency. If an immobilization device is used, a hand or foot should be kept exposed, and the child should never be left unattended. If sedating medications are administered in conjunction with an immobilization device, monitoring must be used at a level consistent with the level of sedation achieved.

Documentation at the Time of Sedation

1. Health evaluation: before sedation, a health evaluation shall be performed by an appropriately licensed practitioner and reviewed by the sedation team at the time of treatment for possible interval changes. The purpose of this evaluation is to not only document baseline status but also determine if patients present specific risk factors that may warrant additional consultation before sedation. This evaluation will also screen out patients whose sedation will require more advanced airway or cardiovascular management skills or alterations in the doses or types of medications used for procedural sedation.

   A new concern for the practitioner is the widespread use of medications that may interfere with drug absorption or metabolism and, therefore, enhance or shorten the effect time of sedating medications. Herbal medicines (eg, St John's wort or echinacea), may alter drug pharmacokinetics through inhibition of the cytochrome P450 system, resulting in prolonged drug effect and altered (increased or decreased) blood drug concentrations.[111–116] Kava may increase the effects of sedatives by potentiating

γ-aminobutyric acid inhibitory neurotransmission, and valerian may itself produce sedation that apparently is mediated through modulation of γ-aminobutyric acid neurotransmission and receptor function.[117,118] Drugs such as erythromycin, cimetidine, and others may also inhibit the cytochrome P450 system, resulting in prolonged sedation with midazolam as well as other medications competing for the same enzyme systems.[119–122] Medications used to treat HIV infection, some anticonvulsants, and some psychotropic medications may also produce clinically important drug-drug interactions.[123–125] Therefore, carefully obtaining a drug history is a vital part of the safe sedation of children. The clinician should consult various sources (a pharmacist, textbooks, online services, or handheld databases) for specific information on drug interactions.[126]

The health evaluation should include:

- obtaining age and weight
- obtaining a health history, including (1) allergies and previous allergic or adverse drug reactions; (2) medication/drug history, including dosage, time, route, and site of administration for prescription, over-the-counter, herbal, or illicit drugs; (3) relevant diseases, physical abnormalities, and neurologic impairment that might increase the potential for airway obstruction, such as a history of snoring or obstructive sleep apnea[127,128]; (4) pregnancy status; (5) a summary of previous relevant hospitalizations; (6) history of sedation or general anesthesia and any complications or unexpected responses; and (7) relevant family history, particularly that related to anesthesia
- a review of systems with a special focus on abnormalities of cardiac, pulmonary, renal, or hepatic function that might alter the child's expected responses to sedating/analgesic medications
- determination of vital signs, including heart rate, blood pressure, respiratory rate, and temperature (for some children who are very upset or noncooperative, this may not be possible, and a note should be written to document this occurrence)
- a physical examination, including a focused evaluation of the airway (tonsillar hypertrophy, abnormal anatomy [eg, mandibular hypoplasia]) to determine if there is an increased risk of airway obstruction[54,129,130]
- a physical status evaluation (ASA classification [see Appendix 1])
- obtaining name, address, and telephone number of the child's medical home

For hospitalized patients, the current hospital record may suffice for adequate documentation of presedation health; however, a brief note shall be written documenting that the chart was reviewed, positive findings were noted, and a management plan was formulated. If the clinical or emergency condition of the patient precludes acquiring complete information before sedation, this health evaluation should be obtained as soon as is feasible.

2. Prescriptions: when prescriptions are used for sedation, a copy of the prescription or a note describing the content of the prescription should be in the patient's chart along with a description of the instructions that were given to the responsible person. *Prescription medications intended to accomplish procedural sedation must not be administered without the benefit of direct supervision by trained medical personnel.* Administration of sedating medications at home poses an unacceptable risk, particularly for infants and preschool-aged children traveling in car safety seats.[46]

Documentation During Treatment

The patient's chart shall contain a time-based record that includes the name, route, site, time, dosage, and patient effect of administered drugs. Before sedation, a "time out" should be performed to confirm the patient's name, procedure to be performed, and site of the procedure.[43] During administration, the inspired concentrations of oxygen and inhalation sedation agents and the duration of their administration shall be documented. Before drug administrations, special attention must be paid to calculation of dosage (ie, mg/kg). The patient's chart shall contain documentation at the time of treatment that the patient's level of consciousness and responsiveness, heart rate, blood pressure, respiratory rate, and oxygen saturation were monitored until the patient attained predetermined discharge criteria (see Appendix 2). A variety of sedation-scoring systems are available and may aid this process.[70,100] Adverse events and their treatment shall be documented.

Documentation After Treatment

The time and condition of the child at discharge from the treatment area or facility shall be documented; this should include documentation that the child's level of consciousness and oxygen saturation in room air have returned to a state that is safe for discharge by recognized criteria (see Appendix 2). Patients receiving supplemental oxygen before the procedure should have a similar oxygen need after the procedure. Because some sedation medications are known to have a long half-life and may delay a patient's complete return to baseline or pose the risk of resedation,[45,103,131,132] some patients might benefit from a longer period of less-intense observation (eg, a step-down observation area) before discharge from medical supervision.[133] Several scales to evaluate recovery have been devised and validated.[70,134,135] A re-

cently described and simple evaluation tool may be the ability of the infant or child to remain awake for at least 20 minutes when placed in a quiet environment.[100]

CONTINUOUS QUALITY IMPROVEMENT

The essence of medical error reduction is a careful examination of index events and root-cause analysis of how the event could be avoided in the future.[136–140] Therefore, each facility should maintain records that track adverse events such as desaturation, apnea, laryngospasm, the need for airway interventions including jaw thrust or positive pressure ventilation, prolonged sedation, unanticipated use of reversal agents, unintended or prolonged hospital admission, and unsatisfactory sedation/analgesia/anxiolysis. Such events can then be examined for assessment of risk reduction and improvement in patient satisfaction.

PREPARATION AND SETUP FOR SEDATION PROCEDURES

Part of the safety net of sedation is to use a systematic approach so as to not overlook having an important drug, piece of equipment, or monitor immediately available at the time of a developing emergency. To avoid this problem, it is helpful to use an acronym that allows the same setup and checklist for every procedure. A commonly used acronym that is useful in planning and preparation for a procedure is **SOAPME**:

S (suction)—size-appropriate suction catheters and a functioning suction apparatus (eg, Yankauer-type suction)

O (oxygen)—adequate oxygen supply and functioning flow meters/other devices to allow its delivery

A (airway)—size-appropriate airway equipment (nasopharyngeal and oropharyngeal airways, laryngoscope blades [checked and functioning], endotracheal tubes, stylets, face mask, bag-valve-mask or equivalent device [functioning])

P (pharmacy)—all the basic drugs needed to support life during an emergency, including antagonists as indicated

M (monitors)—functioning pulse oximeter with size-appropriate oximeter probes[141,142] and other monitors as appropriate for the procedure (eg, noninvasive blood pressure, end-tidal carbon dioxide, ECG, stethoscope)

E (equipment)—special equipment or drugs for a particular case (eg, defibrillator)

SPECIFIC GUIDELINES FOR INTENDED LEVEL OF SEDATION

Minimal Sedation

Minimal sedation (formerly anxiolysis) is a drug-induced state during which patients respond normally to verbal commands. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected. Children who have received minimal sedation generally will not require more than observation and intermittent assessment of their level of sedation. Some children will become moderately sedated despite the intended level of minimal sedation; should this occur, the guidelines for moderate sedation will apply.[56]

Moderate Sedation

Moderate sedation (formerly conscious sedation or sedation/analgesia) is a drug-induced depression of consciousness during which patients respond purposefully to verbal commands or light tactile stimulation (see "Definition of Terms Used in This Report"). No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained. The caveat that loss of consciousness should be unlikely is a particularly important aspect of the definition of moderate sedation. The drugs and techniques used should carry a margin of safety wide enough to render unintended loss of consciousness highly unlikely. Because the patient who receives moderate sedation may progress into a state of deep sedation and obtundation, the practitioner should be prepared to increase the level of vigilance corresponding to what is necessary for deep sedation.[56]

Personnel

The Practitioner

The practitioner responsible for the treatment of the patient and/or the administration of drugs for sedation must be competent to use such techniques, provide the level of monitoring provided in these guidelines, and manage complications of these techniques (ie, to be able to rescue the patient). Because the level of intended sedation may be exceeded, the practitioner must be sufficiently skilled to provide rescue should the child progress to a level of deep sedation. The practitioner must be trained in, and capable of providing, at the minimum, bag-valve-mask ventilation to be able to oxygenate a child who develops airway obstruction or apnea. Training in, and maintenance of, advanced pediatric airway skills is required; regular skills reinforcement is strongly encouraged.

Support Personnel

The use of moderate sedation shall include provision of a person, in addition to the practitioner, whose responsibility is to monitor appropriate physiologic parameters and to assist in any supportive or resuscitation measures if required. This individual may also be responsible for assisting with interruptible patient-related tasks of short duration.[44] This individual must be trained in and capable of providing pediatric basic life support. The support person shall have specific assignments in the event of an emergency and current knowledge of the emergency cart inventory. The practitioner and all ancillary personnel should participate in periodic reviews and practice drills of the facility's emergency protocol to ensure proper function of the equipment and coordination of staff roles in such emergencies.

Monitoring and Documentation

Baseline

Before administration of sedative medications, a baseline determination of vital signs shall be documented.

For some children who are very upset or noncooperative, this may not be possible, and a note should be written to document this happenstance.

During the Procedure

The practitioner shall document the name, route, site, time of administration, and dosage of all drugs administered. There shall be continuous monitoring of oxygen saturation and heart rate and intermittent recording of respiratory rate and blood pressure; these should be recorded in a time-based record. Restraining devices should be checked to prevent airway obstruction or chest restriction. If a restraint device is used, a hand or foot should be kept exposed. The child's head position should be checked frequently to ensure airway patency. A functioning suction apparatus must be present.

After the Procedure

The child who has received moderate sedation must be observed in a suitably equipped recovery facility (ie, the facility must have functioning suction apparatus as well as the capacity to deliver more than 90% oxygen and positive-pressure ventilation [eg, bag and mask with oxygen capacity as described previously]). The patient's vital signs should be recorded at specific intervals. If the patient is not fully alert, oxygen saturation and heart rate monitoring shall be used continuously until appropriate discharge criteria are met (see Appendix 2). Because sedation medications with a long half-life may delay the patient's complete return to baseline or pose the risk of resedation, some patients might benefit from a longer period of less-intense observation (eg, a step-down observation area in which multiple patients can be observed simultaneously) before discharge from medical supervision (see also "Documentation" for instructions to families).[45,103,131,132] A recently described and simple evaluation tool may be the ability of the infant or child to remain awake for at least 20 minutes when placed in a quiet environment.[100] Patients who have received reversal agents, such as flumazenil or naloxone, will also require a longer period of observation, because the duration of the drugs administered may exceed the duration of the antagonist, which can lead to resedation.

Deep Sedation

Deep sedation is a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully after repeated verbal or painful stimulation (see "Definition of Terms Used in This Report"). The state and risks of deep sedation may be indistinguishable from those of general anesthesia.

Personnel

There must be 1 person available whose only responsibility is to constantly observe the patient's vital signs, airway patency, and adequacy of ventilation and to either administer drugs or direct their administration. At least 1 individual must be present who is trained in, and capable of, providing advanced pediatric life support and who is skilled in airway management and cardiopulmonary resuscitation; training in pediatric advanced life support is required.

Equipment

In addition to the equipment previously cited for moderate sedation, an ECG monitor and a defibrillator for use in pediatric patients should be readily available.

Vascular Access

Patients receiving deep sedation should have an intravenous line placed at the start of the procedure or have a person skilled in establishing vascular access in pediatric patients immediately available.

Monitoring

A competent individual shall observe the patient continuously. The monitoring shall include all parameters described for moderate sedation. Vital signs, including oxygen saturation and heart rate, must be documented at least every 5 minutes in a time-based record. The use of a precordial stethoscope or capnograph for patients who are difficult to observe (eg, during MRI or in a darkened room) to aid in monitoring adequacy of ventilation is encouraged.[143] The practitioner shall document the name, route, site, time of administration, and dosage of all drugs administered. The inspired concentrations of inhalation sedation agents and oxygen and the duration of administration shall be documented.

Postsedation Care

The facility and procedures followed for postsedation care shall conform to those described for moderate sedation.

SPECIAL CONSIDERATIONS

Local Anesthetic Agents

All local anesthetic agents are cardiac depressants and may cause central nervous system excitation or depression. Particular attention should be paid to dosage in small children.[64,66] To ensure that the patient will not receive an excessive dose, the maximum allowable safe dosage (eg, mg/kg) should be calculated before administration. There may be enhanced sedative effects when the highest recommended doses of local anesthetic drugs are used in combination with other sedatives or narcotics (see Tables 2 and 3 for limits and conversion tables of commonly used local anesthetics).[64,144–157] In general, when administering local anesthetic drugs, the practitioner should aspirate frequently to minimize the likelihood that the needle is in a blood vessel; lower doses should be used when injecting into vascular tissues.[158]

TABLE 2 **Commonly Used Local Anesthetic Agents: Doses, Duration, and Calculations**

Local Anesthetic	Maximum Dose With Epinephrine, mg/kg[a]		Duration of Action, min[b]
	Medical	Dental	
Esters			
Procaine	10.0	6	60–90
Chloroprocaine	20.0	12	30–60
Tetracaine	1.5	1	180–600
Amides			
Lidocaine	7.0	4.4	90–200
Mepivacaine	7.0	4.4	120–240
Bupivacaine	3.0	1.3	180–600
Levobupivacaine	3.0	2	180–600
Ropivacaine	3.0	2	180–600
Articaine		7	60–230

Maximum recommended doses and duration of action are shown. Note that lower doses should be used in very vascular areas.

[a] These are maximum doses of local anesthetics combined with epinephrine; lower doses are recommended when used without epinephrine. Doses of amides should be decreased by 30% for infants younger than 6 months. When lidocaine is being administered intravascularly (eg, during intravenous regional anesthesia), the dose should be decreased to 3 to 5 mg/kg; long-acting local anesthetic agents should not be used for intravenous regional anesthesia.

[b] Duration of action depends on concentration, total dose, and site of administration; use of epinephrine; and the patient's age.

TABLE 3 **Local Anesthetic Percent Concentration: Conversion to mg/mL**

Concentration, %	mg/mL
3.0	30.0
2.5	25.0
2.0	20.0
1.0	10.0
0.5	5.0
0.25	2.5
0.125	1.25

Pulse Oximetry

The new-generation pulse oximeters are less susceptible to motion artifacts and may be more useful than older oximeters that do not contain the updated software.[159–163] Oximeters that change tone with changes in hemoglobin saturation provide immediate aural warning to everyone within hearing distance. It is essential that any oximeter probe is properly positioned; clip-on devices are prone to easy displacement, which may produce artifactual data (underestimation or overestimation of oxygen saturation).[141,142]

Capnography

Expired carbon dioxide monitoring is valuable to diagnose the simple presence or absence of respirations, airway obstruction, or respiratory depression, particularly in patients sedated in less-accessible locations, such as MRI or computerized axial tomography devices or darkened rooms.[47,49,50,143,164–173] The use of expired carbon dioxide monitoring devices is encouraged for sedated children, particularly in situations where other means of assessing the adequacy of ventilation are limited. Several manufacturers have produced nasal cannulae that allow simultaneous delivery of oxygen and measurement of expired carbon dioxide values.[164,165] Although these devices can have a high degree of false-positive alarms, they are also very accurate for the detection of complete airway obstruction or apnea.[166,168,173]

Adjuncts to Airway Management and Resuscitation

The vast majority of sedation complications can be managed with simple maneuvers, such as providing supplemental oxygen, opening the airway, suctioning, and using bag-mask-valve ventilation. Occasionally, endotracheal intubation is required for more prolonged ventilatory support. In addition to standard endotracheal intubation techniques, a number of new devices are available for the management of patients with abnormal airway anatomy or airway obstruction. Examples include the laryngeal mask airway (LMA), the cuffed oropharyngeal airway, and a variety of kits to perform an emergency cricothyrotomy.

The largest clinical experience in pediatrics is with the LMA, which is available in a variety of sizes and can even be used in neonates. Use of the LMA is now being introduced into advanced airway training courses, and familiarity with insertion techniques can be life-saving.[174,175] The LMA can also serve as a bridge to secure airway management in children with anatomic airway abnormalities.[176,177] Practitioners are encouraged to gain experience with these techniques as they become incorporated into pediatric advanced life support courses.

An additional emergency device with which to become familiar is the intraosseous needle. Intraosseous needles are also available in several sizes and can be life-saving in the rare situation when rapid establishment of intravenous access is not possible. Familiarity with the use of these adjuncts for the management of emergencies can be obtained by keeping current with resuscitation courses, such as Pediatric Advanced Life Support and Advanced Pediatric Life Support or other approved programs.

Patient Simulators

Advances in technology, particularly patient simulators that allow a variety of programmed adverse events such as apnea, bronchospasm, laryngospasm, response to medical interventions, and printouts of physiologic parameters, are now available. The use of such devices is encouraged to better train medical professionals to respond more appropriately and effectively to rare events.[178–180]

Monitoring During MRI

The powerful magnetic field and the generation of radio frequency emissions necessitate the use of special equipment to provide continuous patient monitoring throughout the MRI procedure. Pulse oximeters capable of continuous function during scanning should be used in any sedated or restrained pediatric patient. Thermal injuries can result if appropriate precautions are not

taken; avoid coiling the oximeter wire and place the probe as far from the magnetic coil as possible to diminish the possibility of injury. Electrocardiogram monitoring during MRI has been associated with thermal injury; special MRI-compatible ECG pads are essential to allow safe monitoring.[181–184] Expired carbon dioxide monitoring is strongly encouraged in this setting.

Nitrous Oxide

Inhalation sedation/analgesia equipment that delivers nitrous oxide must have the capacity of delivering 100% and never less than 25% oxygen concentration at a flow rate appropriate to the size of the patient. Equipment that delivers variable ratios of nitrous oxide to oxygen and that has a delivery system that covers the mouth and nose must be used in conjunction with a calibrated and functional oxygen analyzer. All nitrous oxide-to-oxygen inhalation devices should be calibrated in accordance with appropriate state and local requirements. Consideration should be given to the National Institute of Occupational Safety and Health Standards for the scavenging of waste gases.[185] Newly constructed or reconstructed treatment facilities, especially those with piped-in nitrous oxide and oxygen, must have appropriate state or local inspections to certify proper function of inhalation sedation/analgesia systems before any delivery of patient care.

Nitrous oxide in oxygen with varying concentrations has been successfully used for many years to provide analgesia for a variety of painful procedures in children.[15,186–210] The use of nitrous oxide for minimal sedation is defined as the administration of nitrous oxide (50% or less) with the balance as oxygen, without any other sedative, narcotic, or other depressant drug before or concurrent with the nitrous oxide to an otherwise healthy patient in ASA class I or II. The patient is able to maintain verbal communication throughout the procedure. It should be noted that although local anesthetics have sedative properties, for purposes of this guideline, they are not considered sedatives in this circumstance. If nitrous oxide in oxygen is combined with other sedating medications, such as chloral hydrate, midazolam, or an opioid, or if nitrous oxide is used in concentrations more than 50%, the likelihood for moderate or deep sedation increases.[211,212] In this situation, the clinician must be prepared to institute the guidelines for moderate or deep sedation as indicated by the patient's response.[213]

APPENDIX 1 ASA Physical Status Classification

Class I	A normally healthy patient
Class II	A patient with mild systemic disease (eg, controlled reactive airway disease)
Class III	A patient with severe systemic disease (eg, a child who is actively wheezing)
Class IV	A patient with severe systemic disease that is a constant threat to life (eg, a child with status asthmaticus)
Class V	A moribund patient who is not expected to survive without the operation (eg, a patient with severe cardiomyopathy requiring heart transplantation)

APPENDIX 2 Recommended Discharge Criteria

1. Cardiovascular function and airway patency are satisfactory and stable.
2. The patient is easily arousable, and protective reflexes are intact.
3. The patient can talk (if age appropriate).
4. The patient can sit up unaided (if age appropriate).
5. For a very young or handicapped child incapable of the usually expected responses, the presedation level of responsiveness or a level as close as possible to the normal level for that child should be achieved.
6. The state of hydration is adequate.

APPENDIX 3 Drugs That May Be Needed to Rescue a Sedated Patient

Albuterol for inhalation
Ammonia spirits
Atropine
Diphenhydramine
Diazepam
Epinephrine (1:1000, 1:10 000)
Flumazenil
Glucose (25% or 50%)
Lidocaine (cardiac lidocaine, local infiltration)
Lorazepam
Methylprednisolone
Naloxone
Oxygen
Fosphenytoin
Racemic epinephrine
Rocuronium
Sodium bicarbonate
Succinylcholine

The choice of emergency drugs may vary according to individual or procedural needs.
Source: American Society of Anesthesiologists, Task Force on Sedation and Analgesia by Non-anesthesiologists. *Anesthesiology.* 2002;96:1004–1017

APPENDIX 4 Emergency Equipment That May Be Needed to Rescue a Sedated Patient

- Intravenous equipment
  - Assorted intravenous catheters (eg, 24-, 22-, 20-, 18-, and 16-gauge)
  - Tourniquets
  - Alcohol wipes
  - Adhesive tape
  - Assorted syringes (eg, 1, 3, 5, and 10 mL)
  - Intravenous tubing
    - Pediatric drip (60 drops per mL)
    - Pediatric burette
    - Adult drip (10 drops per mL)
    - Extension tubing
    - 3-way stopcocks
  - Intravenous fluid
    - Lactated Ringer solution
    - Normal saline solution
    - $D_5$0.25 normal saline solution
  - Pediatric intravenous boards
  - Assorted intravenous needles (eg, 25-, 22-, 20-, and 18-gauge)
  - Intraosseous bone marrow needle
  - Sterile gauze pads
- Airway Management Equipment
  - Face masks
    - Infant, child, small adult, medium adult, large adult
  - Breathing bag and valve set
  - Oropharyngeal airways
    - Infant, child, small adult, medium adult, large adult
  - Nasopharyngeal airways
    - Small, medium, large
  - LMAs (1, 1.5, 2, 2.5, 3, 4, and 5)
  - Laryngoscope handles (with extra batteries)
  - Laryngoscope blades (with extra light bulbs)
    - Straight (Miller) No. 1, 2, and 3
    - Curved (Macintosh) No. 2 and 3
  - Endotracheal tubes
    - 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 5.5, and 6.0 uncuffed and 6.0, 7.0, and 8.0 cuffed
  - Stylettes (appropriate sizes for endotracheal tubes)
  - Surgical lubricant
  - Suction catheters (appropriate sizes for endotracheal tubes)
  - Yankauer-type suction
  - Nasogastric tubes
  - Nebulizer with medication kits
  - Gloves (sterile and nonsterile, latex-free)

The choice of emergency equipment may vary according to individual or procedural needs. The practitioner is referred to the SOAPME acronym described in the text in preparation for sedating a child for a procedure.

Guidelines for Pediatric Cancer Centers

ABSTRACT. Since the American Academy of Pediatrics published guidelines for pediatric cancer centers in 1986 and 1997, significant changes in the delivery of health care have prompted a review of the role of tertiary medical centers in the care of pediatric patients. The potential effect of these changes on the treatment and survival rates of children with cancer led to this revision. The intent of this statement is to delineate personnel and facilities that are essential to provide state-of-the-art care for children and adolescents with cancer. This statement emphasizes the importance of board-certified pediatric hematologists/oncologists, pediatric subspecialty consultants, and appropriately qualified pediatric medical subspecialists and pediatric surgical specialists overseeing the care of all pediatric and adolescent cancer patients and the need for facilities available only at a tertiary center as essential for the initial management and much of the follow-up for pediatric and adolescent cancer patients. ***Pediatrics*** **2004;113:1833–1835;** ***cancer, pediatrics, hematology, oncology, cancer center.***

INTRODUCTION

A pediatric cancer center must have the staff and facilities to ensure that the pediatric patient with cancer will receive the best care that is available for his or her diagnosis. The medical staff at such a center is composed of the primary care pediatrician, pediatric medical subspecialists, and pediatric surgical specialists—hematologists/oncologists, surgeons, urologists, neurologists, neurosurgeons, orthopedic surgeons, radiation oncologists, pathologists, child life specialists, and diagnostic radiologists. These physicians and nurse practitioners, pediatric nurses, social workers, pharmacists, nutritionists, and other allied health professionals serve as a multidisciplinary team committed to the care of the child or adolescent with cancer.

In the United States, the oncologic care of the child or adolescent with cancer should be coordinated by a pediatric hematologist/oncologist who is board certified in the subspecialty of pediatric hematology and oncology by the American Board of Pediatrics. Other subspecialists should be similarly board certified when applicable.

Oncologic care should be provided in a pediatric center that has the following personnel, facilities, and capabilities.

Personnel

- Communication with the primary pediatrician, which is essential in the provision of family-centered supportive care
- Board-certified pediatric hematologists/oncologists
- Pediatric oncology nurses who are certified in chemotherapy, knowledgeable about pediatric protocols, and experienced in the management of complications of therapy
- Board-certified radiologists with specific expertise in the diagnostic imaging of infants, children, and adolescents
- Board-certified surgeons with expertise in pediatric general surgery
- Surgical specialists with pediatric expertise (ie, training and certification, if available) in neurosurgery, urology, orthopedics, ophthalmology, otolaryngology, dentistry, and gynecology
- A board-certified radiation oncologist trained and experienced in the treatment of infants, children, and adolescents
- A board-certified pathologist with special training in the pathology of hematologic malignancies and solid tumors of children and adolescents
- Board-certified pediatric subspecialists available to participate actively in all areas of the care of the child with cancer, including anesthesiology, intensive care, infectious diseases, cardiology, neurology, endocrinology and metabolism, genetics, gastroenterology, child and adolescent psychiatry, nephrology, and pulmonology
- Pediatric physical and mental rehabilitation services including pediatric physiatry
- Pediatric (oncology) social worker(s), pediatric psychologists, child life specialists, and access to family support group services
- Pediatric nutrition experts with the capability of preparing, administering, and monitoring total parenteral nutrition

Facilities

- An immediately accessible and fully staffed, onsite pediatric intensive care unit
- Up-to-date diagnostic imaging facilities to perform radiography, computed tomography, magnetic resonance imaging, ultrasonography, radionuclide imaging, and angiography; positron-emission tomography scanning and other emerging technologies are desirable

- Up-to-date radiation-therapy equipment with facilities for treating pediatric patients
- A hematopathology laboratory capable of performing cell-phenotype analysis using flow cytometry, immunohistochemistry, molecular diagnosis, and cytogenetics and access to blast colony assays and polymerase chain reaction-based methodology
- Access to hemodialysis and/or hemofiltration and apheresis for collection and storage of hematopoietic progenitor cells

Capabilities

- A clinical chemistry laboratory with the capability to monitor antibiotic and antineoplastic drug levels
- A blood bank capable of providing a full range of products including irradiated, cytomegalovirus-negative, and leucodepleted blood components
- A pharmacy capable of accurate, well-monitored preparation and dispensing of antineoplastic agents and investigational agents
- Capability of providing sufficient isolation of patients from airborne pathogens, which could include high-efficiency particulate air (HEPA) filtration or laminar flow and positive/negative pressure rooms
- Access to stem cell transplant services
- Educational and training programs for health care professionals including the primary care physician
- Coordination of services including home health, pain management, palliative, and end-of-life care
- A regularly scheduled multidisciplinary pediatric tumor board
- An established program designed to provide long-term, multidisciplinary follow-up of successfully treated patients at the original treatment center or by a team of health care professionals who are familiar with the potential adverse effects of treatment for childhood cancer
- Membership or affiliation with the Children's Oncology Group to provide access to state-of-the-art clinical trials; availability of support for coordination to track patients' progress and maintain clinical trials data
- Capability of providing parent, caregiver, and patient education
- Full-time access to translation services to ensure accurate translation and effective communication among all health care professionals and the patient and family
- An ongoing program of assessment of care for continuing quality improvement and safety
- A formal program for cancer education for the family and instruction on self-management

ROLE OF CENTERS IN DIAGNOSIS AND TREATMENT

Approximately 12 000 new cases of cancer are diagnosed in children younger than 20 years annually in the United States.[1,2] Cancer remains the second most frequent cause of death, after injury, in children older than 3 months.[3]

Great progress has been made in the development of successful treatment programs for children and adolescents with cancer. These improvements have been possible because of the availability of pediatric cancer treatment centers with collective expertise in the clinical management of children with cancer and the existence of a network of experienced investigators and allied health professionals who recognize the central importance of randomized clinical trials as the best available method for identifying more successful treatment strategies and who have the resources to evaluate new treatment modalities as they become available.

The importance of comprehensive, multidisciplinary treatment in improving patient outcome in a cost-effective manner has been well documented for children with acute lymphoblastic leukemia,[4] non–Hodgkin lymphoma,[5,6] brain tumors,[7,8] rhabdomyosarcoma,[5,8] Wilms' tumor,[9,10] and Ewing sarcoma.[5] Almost 80% of these children can be treated successfully if modern diagnostic and therapeutic approaches are initiated expeditiously.[2] Early detection, accurate diagnosis, and appropriate treatment depend on a multidisciplinary treatment approach to children and adolescents with cancer, an approach that is uniquely available at a pediatric cancer center. The roles of specialized nursing, pharmacy, rehabilitation, and paramedical personnel and access to increasingly complex equipment and facilities are critical to improving long-term survival and quality of life.

The center-based pediatric hematologist/oncologist is the coordinator for the diagnosis and treatment of most children and adolescents with cancer. Pediatric hematology/oncology is an established specialty with specific training requirements that lead to subspecialty board eligibility. Because most pediatric tumors show a striking response to specific regimens of intensive chemotherapy, pediatric hematologists/oncologists are necessarily resolute in carrying out therapies that can have devastating morbidity and appreciable mortality. For these therapies to be administered safely, a pediatric hematologist/oncologist who is trained and experienced in the management of children and adolescents with cancer and who has extensive knowledge of the relevant drug indications and toxicities must coordinate this care.

The pediatric hematologist/oncologist must be assisted by skilled nurses, social workers, pharmacists, nutritionists, and psychologists who specialize in pediatric oncology. Professional organizations such as the Association of Pediatric Oncology Nurses and Association of Pediatric Oncology Social Workers facilitate the professional growth and education of these individuals. Diagnostic radiologists and radiation oncologists with specific training and interest in pediatric oncology should be available at the pediatric cancer center. Principles of surgery that are unique to childhood tumors have evolved, and in fields such as general (pediatric) surgery, urology, neurology, and orthopedics, the presence of surgeons whose sole (or major) effort is directed toward pediatric oncology has become indispensable in achieving maximum survival.

A pathologist experienced in pediatric oncology is an essential member of the multidisciplinary team at the pediatric cancer center. State-of-the-art diagnosis of many pediatric hematologic malignancies and tumors requires immunochemistry and/or molecular techniques. Because solid tumors in children and adolescents are rare in the experience of most pathologists, an incorrect histologic diagnosis may be given when initial surgical management occurs at a nonspecialized hospital. Ideally, the diagnostic biopsy should be performed at the cancer center, at which the facilities are available to order and obtain all the special studies that would be appropriate and would obviate the need for subjecting the patient to repeat procedures.

PRACTICE OF PEDIATRIC ONCOLOGY OUTSIDE RECOGNIZED CENTERS

The clinical results in children with cancer have been shown to be superior when specialized diagnostic, supportive, and specific care is given at a pediatric cancer center.[4–10] After diagnosis has been established and the treatment plan has been determined by the pediatric cancer center, certain aspects of care may be continued in the office of a primary care pediatrician for selected children. When such a plan for shared treatment is undertaken, it must be with the understanding that the child will be referred back to the pediatric cancer center if complications develop or there is recurrence of the tumor. For many children, the facilities and expertise available at the pediatric cancer center are required for all aspects of therapy. However, it must be emphasized that the primary care pediatrician should retain an important supportive role for the patient with cancer and his or her family, which requires excellent regular communication between the oncologist and the pediatrician.

SUMMARY

On the basis of the effectiveness of pediatric cancer centers in treating children and adolescents with cancer, the American Academy of Pediatrics recommends the following:

- Children and adolescents with newly suspected and/or recurrent malignancy should be referred to a pediatric cancer center for prompt and accurate diagnosis and management.
- Children and adolescents with newly diagnosed and/or recurrent malignancies should have their treatment coordinated by a board-certified pediatric hematologist/oncologist; treatment should be prescribed and initiated at a pediatric cancer center but may be continued at a center not specialized in the care of the pediatric oncology patient under the continuing oversight of the center's multidisciplinary team.
- Multidisciplinary team members should have pediatric expertise within their specialty area.

AMERICAN ACADEMY OF PEDIATRICS

Section on Cardiology and Cardiac Surgery

Guidelines for Pediatric Cardiovascular Centers

ABSTRACT. Pediatric cardiovascular centers should aim to provide high-quality therapeutic outcomes for infants and children with congenital and acquired heart diseases. This policy statement describes critical elements and organizational features of centers in which high-quality outcomes have the greatest likelihood of occurring. Center elements include noninvasive diagnostic modalities, cardiac catheterization, cardiovascular surgery, and cardiovascular intensive care. These elements should be organizationally united in centers in which pediatric cardiac physician specialists and specialized pediatric staff work together to achieve and surpass existing quality-of-care benchmarks.

ABBREVIATIONS. AAP, American Academy of Pediatrics; ECMO, extracorporeal membrane oxygenator; ICU, intensive care unit; ICAEL, Intersocietal Commission for the Accreditation of Echocardiography Laboratories; VAD, ventricular assist device.

INTRODUCTION

This policy statement supersedes "Guidelines for Pediatric Cardiology Diagnostic and Treatment Centers" published by the American Academy of Pediatrics (AAP) in 1991.[1] The objective of the 1991 statement was to describe the clinical and physical environment in which the pediatric patient with heart disease could undergo accurate and safe diagnostic and therapeutic procedures. Over the past decade, there have been changes in technology and clinical practice that render many aspects of the 1991 guidelines incomplete or obsolete. Recognizing the broadened scope of interaction between medical and surgical disciplines, this revised policy statement redesignates the pediatric cardiology center as the "pediatric cardiovascular center." The aim of this statement is to describe the configuration and critical elements of the pediatric cardiovascular center in which high-quality outcomes have the greatest likelihood of occurring.

CENTER CONFIGURATION

A pediatric cardiovascular center should be able to provide all of the sophisticated diagnostic services and the full range of treatments, interventions, and surgeries needed to produce high-quality outcomes in all pediatric patients with congenital and acquired heart diseases. Physicians and staff should function as a team and should include adequate numbers of qualified pediatric cardiologists, pediatric cardiovascular surgeons, pediatric cardiovascular anesthesiologists, pediatric intensive care physicians, and/or neonatologists with special expertise in the care of cardiac patients, and additional pediatric specialists required for the overall care of patients. Diagnostic elements should include a fully equipped pediatric echocardiography laboratory, a pediatric cardiac catheterization and electrophysiology laboratory, and appropriate additional facilities and capabilities for comprehensive laboratory and noninvasive diagnostic evaluations of critically ill children. Therapeutic components should include a pediatric cardiac catheterization laboratory equipped for interventional cardiology and transcatheter radiofrequency ablations, a cardiac operating suite suitable for surgical treatment of all pediatric cardiovascular patients, an extracorporeal membrane oxygenator (ECMO), and a cardiac intensive care unit (ICU) or pediatric ICU and/or neonatal ICU equipped and staffed to care for pediatric cardiovascular patients.

Pediatric cardiology practices, which do not have the configuration and the elements of a pediatric cardiovascular center, may provide triage and emergency care, care of strictly medical cardiovascular conditions, and ongoing joint management (together with a center) of patients after surgery or catheter interventions at the center. This statement does not make specific recommendations regarding such practices.

NONINVASIVE DIAGNOSTIC ELEMENTS

A pediatric echocardiographic laboratory is principal among a center's noninvasive diagnostic elements. Existing data suggest that pediatric patients are not optimally served in laboratories primarily geared for adult echocardiography[2,3]; thus, most pediatric cardiology programs should have dedicated pediatric echocardiography laboratories. The AAP endorses accreditation by the Intersocietal Commission for the Accreditation of Echocardiography Laboratories (ICAEL) and adherence to the guidelines promulgated by the American College of Cardiology and the American Heart Association[4] as means to ensure pediatric echocardiography laboratory standards are met. For ICAEL accreditation of pediatric transthoracic, transesophageal, or fetal echocardiography, a laboratory must show that it has state-of-the-art equipment and facilities suitable for children, follows good technique in recording and reporting examinations, and is staffed by physicians and technicians trained in pediatric echocardiography. The ICAEL mandates that the laboratory and its mobile or satellite locations are supervised by a medical

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

director (pediatric cardiologist) and a technical director (pediatric echocardiography technician) and sets standards for training and experience of these individuals. The medical director and other physicians who interpret echocardiograms and/or perform fetal or transesophageal echocardiography and technicians who staff the laboratory or its peripheral sites must meet the American Society of Echocardiography's guidelines for appropriate training[5–7] and must also satisfy ICAEL requirements for ongoing experience.

Pediatric cardiovascular centers should adhere to American Heart Association guidelines for exercise testing in pediatric patients.[8] Because equipment and expertise appropriate for pediatric patients are needed, in most clinical settings, establishment of a pediatric exercise laboratory separate from existing adult laboratories is appropriate. Pediatric exercise laboratories must have a knowledgeable physician director and staff with competence in exercise testing and interpretation in young patients with disorders of varying severity.[9] Pediatric resuscitative equipment must be immediately available to the laboratory.

Additional essential noninvasive elements of a pediatric cardiovascular center, which should be directed by a pediatric cardiologist, include electrocardiography, holter monitoring, transient arrhythmia monitoring, and pacemaker evaluation. Proper application of these tests requires appropriate physician expertise and personnel familiar with the unique requirements of pediatric patients.

Pediatric cardiovascular centers should also have access to tilt-table testing and additional imaging capabilities, such as magnetic resonance imaging and computed tomography. This equipment may be shared with adult patient departments. However, if shared, a pediatric cardiologist with expertise in the pediatric cardiovascular applications of these modalities should collaborate with other specialists to ensure diagnostic-quality pediatric cardiovascular studies.

CARDIAC CATHETERIZATION

The American College of Cardiology and the Society for Cardiac Angiography and Interventions have developed catheterization laboratory standards (including recommendations for pediatric catheterization laboratories).[10] The AAP endorses these standards with respect to the recommendations regarding pediatric cardiac catheterization laboratories.

Cardiac catheterization continues to be a definitive diagnostic modality that provides hemodynamic, anatomic, and electrophysiologic data critical for patient care. Transcatheter therapeutic interventions have become common but more complicated.[11,12] Furthermore, transcatheter radiofrequency ablation has become the standard definitive treatment of pathologic tachycardias. Because of the expanded role of cardiac catheterization, high-quality catheterization services are more important than they were in the past.

A number of factors help to ensure high-quality pediatric cardiac catheterization care. A board-certified pediatric cardiologist who has additional fellowship training (or qualifying experience) in pediatric catheterization and interventional procedures should direct the pediatric catheterization laboratory. The pediatric catheterization laboratory director should have responsibility for all aspects of the administration and function of the laboratory (including quality assessment and quality improvement activities). In addition to technicians trained in pediatric catheterization, staffing of every procedure should include a minimum of 1 board-certified (or board-eligible) pediatric cardiologist and 1 pediatric nurse with training and experience in pediatric airway management and sedation.

The pediatric catheterization laboratory should have biplane imaging equipment with a moveable C-arm, immediate replay capabilities (preferably digital), a physiologic recorder, a blood gas analyzer, a pulse oximeter, an infant warming device, pacing catheters and an external pacemaker, a defibrillator and an emergency cart, and a comprehensive inventory of pediatric catheters, devices, and expendables. There should be an appropriate ICU available to care for patients before and after cardiac catheterization, and interventional procedures require the availability of in-hospital pediatric cardiac surgery backup.

Each cardiac catheterization program should strive to achieve high-quality outcomes with low morbidity and mortality. Data should be gathered prospectively to document quality of care. There should be systematic review of all case outcomes and procedural complications at regular catheterization quality assurance conferences. Recent studies of pediatric catheterization demonstrate that catheterization-related mortality rates much less than 1% are achievable (with mortality essentially confined to emergency cases in neonates and high-risk interventional cases). In addition, an incidence of major complications (defined as potentially life-threatening events) less than 3% is also attainable.[13,14] Another study showed that fewer than 4% of transcatheter interventional procedures should require surgical intervention because of complications.[15] Furthermore, in radiofrequency ablation procedures, data show that permanent complete heart block rates less than 2% are common.[16] All pediatric cardiac catheterization laboratories should strive to achieve and exceed these benchmarks.

In pediatric cardiac catheterization and intervention, data relating outcomes and laboratory or operator case volume are not currently available. However, data indicate that coronary interventional outcomes are improved if operators exceed a certain number of individual cases annually.[17] Given the wide range of procedures performed and the variety of rare diagnoses treated in pediatric cardiology, pediatric cardiology centers performing a small number of catheterizations should restrict the activity to 1 or 2 cardiologists so that operators maintain their clinical skills.

CARDIOVASCULAR SURGERY

In 1991, the American College of Surgeons published guidelines for minimal standards in cardiac

surgery, including recommendations with respect to hospitals operating on children with congenital heart disease.[18] These recommendations are outdated.

In the current era, hospital mortality rates less than 1% are achievable for simpler forms of congenital heart disease (eg, atrial septal defect, ventricular septal defect, coarctation of the aorta), and significant postoperative morbidity among such patients has been rare.[19–22] For more complex lesions, risks are greater. However, for lesions such as tetralogy of Fallot, complete atrioventricular canal defect, and transposition of the great arteries without additional complicating defects or conditions, hospital mortality rates less than 5% are attainable.[19,23–25] Patients who have more complex disease or who are more ill experience higher morbidity and mortality but have usually been best served in experienced surgical environments with consistent excellent outcomes among patients with more complicated illness. Furthermore, to offer patients a full range of surgical treatments, centers have offered pediatric cardiac transplant (as centers certified by the United Network for Organ Sharing) or have been closely affiliated with a certified transplant center. All pediatric cardiovascular centers should strive to achieve and surpass these benchmarks and should provide or have available heart replacement services.

A major objective of this statement is to describe the surgical environment associated with high-quality outcomes. Surgical outcomes are enhanced by early patient referral, definitive anatomic and physiologic diagnosis, and optimal preoperative and postoperative care. Parental counseling and planning of the timing and nature of surgical intervention should be accomplished by a team skilled in the care and treatment of pediatric heart disease and responsible for the care of the patient. Team members should include cardiac surgeons, cardiologists, anesthesiologists, intensive care physicians, neonatologists, nurses, and perfusionists.

Expert, experienced congenital heart surgeons are required for staffing a pediatric cardiovascular surgical program. Surgical training (after cardiac surgery residency) requires 2 years of pediatric cardiac surgery fellowship and additional years working as a junior staff surgeon in a pediatric and congenital heart program with high volume and demonstrated high-quality outcomes.

A dedicated team of anesthesiologists, perfusionists, operating room nurses, and technicians should be available to support all pediatric cardiovascular surgical procedures. Anesthesiologists should have pediatric and pediatric cardiac anesthetic training and experience with expertise in dealing with the problems arising from complicated interactions between the cardiac pathophysiology, surgical procedures, and anesthetic techniques. Perfusionists should be dedicated to the pediatric cardiovascular surgery program and have training, knowledge, and experience with small body perfusion, ECMO, and ventricular assist devices (VADs), including set up, delivery, and maintenance of these systems. Operating room nurses should be dedicated pediatric cardiovascular operating room nurses with training, knowledge, and experience in pediatric cardiac operative techniques and requirements. Likewise, technicians should be appropriately trained and experienced permanent members of the operating team.

One or more operating rooms should be specifically designated and designed for pediatric cardiovascular procedures. Each room should be large and should include a positive-pressure climate control system capable of maintaining humidity at 55% and changing room temperature by 20°F within 15 to 20 minutes. The operating room is best located near the postoperative ICU. The operating room should be equipped with a cardiopulmonary bypass machine, which can deliver precise volumes at low flows against varying impedance with minimal blood trauma. Anesthetic equipment should be suitable for the smallest patients and appropriate also for adult patients.

Clinical data on patients who undergo cardiac surgery should be recorded prospectively in a comprehensive database. A quality assurance program responsible for monitoring and evaluating surgical outcomes should be in place. This program should also review individual deaths and major complications.

CARDIOVASCULAR INTENSIVE CARE

Although cardiac intensive care may be required for patients before surgery, before or after cardiac catheterization, and for medical conditions, the highest level of care is most often required for patients after cardiac surgery. Thus, the ICU providing care for cardiovascular patients should be a cardiac unit organized specifically to provide postoperative care for pediatric heart patients or it should be a pediatric ICU that satisfies AAP guidelines for level I pediatric ICUs[26] (currently being revised) and/or a subspeciality neonatal ICU that satisfies guidelines for perinatal care.[27] Pediatric ICUs and subspeciality neonatal ICUs should be organized to routinely provide postoperative care for pediatric heart patients.

The ICU should be equipped and staffed to provide the following services 24 hours a day, 7 days a week: respiratory support, using the full range of mechanical ventilators and gases (such as nitric oxide and carbon dioxide); complete hemodynamic and cardiac rhythm monitoring and recording; cardiac pacing; open- and closed-chest resuscitation and operating; and ECMO and VADs. Blood gas and basic biochemistry laboratory determinations, radiologic services, echocardiography, and cardiac catheterization should also be available 24 hours a day, 7 days a week.

The ICU staff should include a medical director who should have fellowship training, experience, and specific expertise in the postoperative care of pediatric heart patients. Physicians with primary responsibility for cardiovascular patient care should provide in-house supervision of the unit 24 hours a day, 7 days a week. Coverage by pediatric cardiac surgeons and pediatric cardiologists capable of performing complete echocardiographic assessments

and cardiac catheterization should be available 24 hours a day, 7 days a week. In addition, pediatric subspecialty physicians and surgeons with expertise in critical disease of all other organ systems should be readily available for consultation. ICU nurses should have training and experience in the postoperative intensive care of pediatric heart patients. The nursing staff should be dedicated to the ICU and sufficient to provide 1-to-1 coverage of all high-acuity patients. Appropriate additional staff, such as respiratory therapy technicians, should also be available 24 hours a day, 7 days a week.

RELATIONSHIP OF THE PEDIATRIC CARDIOVASCULAR CENTER TO THE HEALTH CARE ENVIRONMENT

Pediatric cardiovascular centers are established and constituted to provide high-quality cardiac care for pediatric patients. Centers are usually components of pediatric tertiary health care systems. As such and by definition, centers should support and complement related tertiary pediatric programs and centers.

Even more importantly, pediatric cardiovascular centers serve patients within family, school, and community environments. To deliver high-quality cardiac care, centers should partner with primary health care systems and practitioners in cardiovascular disease. Center physicians, particularly pediatric cardiologists, should maintain ongoing dialogue with pediatricians and other primary care practitioners regarding individual patient care plans and problems; case management should be a joint project. In addition, center physicians, in cooperation with the primary care practice team, should be responsible for education of and communication with families and school and community authorities regarding all aspects of patients' cardiovascular care. Other personnel in pediatric cardiovascular centers, such as nurse practitioners, social workers, and patient care representatives, may also be instrumental in these relationships and activities.

QUALITY OF CARE

Existing evidence suggests that certain practices promote high-quality outcomes. Thus, pediatric cardiovascular centers should strive to 1) participate in a regional health care network, 2) use modern information technology, and 3) maintain adequate case volumes to achieve and demonstrate high-quality therapeutic outcomes.

Early experience with regional networks for perinatal and neonatal care and pioneering efforts in regionalizing infant cardiac care by 11 pediatric cardiac centers in 6 states (the New England Regional Infant Cardiac Program) suggest that participation in a regional network of health care providers results in improved outcomes for mothers, infants, and children with heart disease.[28–30] Furthermore, the Northern New England Cardiovascular Disease Study Group has shown that regional intervention, including feedback of outcome data, training in continuous quality improvement techniques, and site visits to other medical centers, improves hospital mortality rates associated with coronary artery bypass surgery.[31] In pediatric cardiology, the Pediatric Cardiac Care Consortium has demonstrated the feasibility of quality improvement as the result of participation in a physician-directed clinical database.[32] Moreover, in many areas of health care, regionalization has been shown to improve access while decreasing costs, numbers of hospital beds, and inpatient days and average length of stay.[33–35]

Improvements in quality of care have been linked to information technology and automated information and decision support systems. There is evidence to suggest that the number of preventable errors can be decreased by use of better information systems that disseminate knowledge about drugs and make drug and patient information readily accessible in a timely manner.[36] Furthermore, computerized drug order entry systems have been shown to decrease the number of errors[37]; computerized laboratory data can alert clinicians to abnormal lab values[38]; and the use of a computerized physician order entry, in which physicians enter and transmit medication orders online, can prevent medication errors attributable to misinterpretation of handwritten orders.[39]

Finally, pediatric heart surgery is one of several classes of procedures for which lower mortality rates have been demonstrated at high-volume hospitals.[40] The relation of in-hospital mortality rates to case volume for congenital heart surgery has been examined in studies using statewide administrative data.[41–44] All have shown a significant correlation between improvement in severity-adjusted mortality rate and increasing institutional case volume. However, institutional case volume explains only a relatively small fraction of the variability in outcomes among pediatric heart surgery programs, and uncommon outcomes such as mortality are difficult to measure with statistical precision for smaller programs. Thus, although "high volume" ensures a certain degree of quality, there is no consistent relationship between quality and "low volume." It is probable that a number of low-volume centers have consistent and excellent results, but the identifiers of these centers have not been elucidated. Quality indicators other than in-hospital mortality rates must be developed to aid in the validation of quality, especially in smaller centers.

CONCLUSION

The quality of outcomes in pediatric cardiovascular centers is the most important measure of center activity. Although outcome assessment in pediatric cardiovascular surgery and intervention is currently rudimentary, basic outcome benchmarks are available and have been incorporated into the guidelines in this statement. Additional outcomes research is ongoing, and future guidelines will require modification to accommodate the results of this research. Nevertheless, the AAP recommends that pediatric cardiovascular centers document and analyze their individual outcomes, strive to achieve and surpass existing quality benchmarks, and commit to contin-

uous quality improvement methodology in all of their programs.

Guidelines for Preventing Opportunistic Infections Among Hematopoietic Stem Cell Transplant Recipients

Recommendations of CDC, the Infectious Disease Society of America, and the American Society of Blood and Marrow Transplantation

Summary

CDC, the Infectious Disease Society of America, and the American Society of Blood and Marrow Transplantation have cosponsored these guidelines for preventing opportunistic infections (OIs) among hematopoietic stem cell transplant (HSCT) recipients. The guidelines were drafted with the assistance of a working group of experts in infectious diseases, transplantation, and public health. For the purposes of this report, HSCT is defined as any transplantation of blood- or marrow-derived hematopoietic stem cells, regardless of transplant type (i.e., allogeneic or autologous) or cell source (i.e., bone marrow, peripheral blood, or placental or umbilical cord blood). Such OIs as bacterial, viral, fungal, protozoal, and helminth infections occur with increased frequency or severity among HSCT recipients. These evidence-based guidelines contain information regarding preventing OIs, hospital infection control, strategies for safe living after transplantation, vaccinations, and hematopoietic stem cell safety. The disease-specific sections address preventing exposure and disease for pediatric and adult and autologous and allogeneic HSCT recipients. The goal of these guidelines is twofold: to summarize current data and provide evidence-based recommendations regarding preventing OIs among HSCT patients. The guidelines were developed for use by HSCT recipients, their household and close contacts, transplant and infectious diseases physicians, HSCT center personnel, and public health professionals. For all recommendations, prevention strategies are rated by the strength of the recommendation and the quality of the evidence supporting the recommendation. Adhering to these guidelines should reduce the number and severity of OIs among HSCT recipients.

INTRODUCTION

In 1992, the Institute of Medicine (*1*) recommended that CDC lead a global effort to detect and control emerging infectious agents. In response, CDC published a plan (*2*) that outlined national disease prevention priorities, including the development of guidelines for preventing opportunistic infections (OIs) among immunosuppressed persons. During 1995, CDC published guidelines for preventing OIs among persons infected with human immunodeficiency virus (HIV) and revised those guidelines during 1997 and 1999 (*3–5*). Because of the success of those guidelines, CDC sought to determine the need for expanding OI prevention activities to other immunosuppressed populations. An informal survey of hematology, oncology, and infectious disease specialists at transplant centers

and a working group formed by CDC determined that guidelines were needed to help prevent OIs among hematopoietic stem cell transplant (HSCT)* recipients.

The working group defined OIs as infections that occur with increased frequency or severity among HSCT recipients, and they drafted evidence-based recommendations for preventing exposure to and disease caused by bacterial, fungal, viral, protozoal, or helminthic pathogens. During March 1997, the working group presented the first draft of these guidelines at a meeting of representatives from public and private health organizations. After review by that group and other experts, these guidelines were revised and made available during September 1999 for a 45-day public comment period after notification in the *Federal Register*. Public comments were added when feasible, and the report was approved by CDC, the Infectious Disease Society of America, and the American Society of Blood and Marrow Transplantation. The pediatric content of these guidelines has been endorsed also by the American Academy of Pediatrics. The hematopoietic stem cell safety section was endorsed by the International Society of Hematotherapy and Graft Engineering.

The first recommendations presented in this report are followed by recommendations for hospital infection control, strategies for safe living, vaccinations, and hematopoietic stem cell safety. Unless otherwise noted, these recommendations address allogeneic and autologous and pediatric and adult HSCT recipients. Additionally, these recommendations are intended for use by the recipients, their household and other close contacts, transplant and infectious diseases specialists, HSCT center personnel, and public health professionals.

Using These Guidelines

For all recommendations, prevention strategies are rated by the strength of the recommendation (Table 1) and the quality of the evidence (Table 2) supporting the recommendation. The principles of this rating system were developed by the Infectious Disease Society of America and the U.S. Public Health Service for use in the guidelines for preventing OIs among HIV-infected persons (*3–6*). This rating system allows assessments of recommendations to which adherence is critical.

BACKGROUND

HSCT is the infusion of hematopoietic stem cells from a donor into a patient who has received chemotherapy, which is usually marrow-ablative. Increasingly, HSCT has been used to treat neoplastic diseases, hematologic disorders, immunodeficiency syndromes, congenital enzyme deficiencies, and autoimmune disorders (e.g., systemic lupus erythematosus or multiple sclerosis) (*7–10*). Moreover, HSCT has become standard treatment for selected conditions (*7,11,12*). Data from the International Bone Marrow Transplant Registry and the Autologous Blood and Marrow Transplant Registry indicate that approximately 20,000 HSCTs were performed in North America during 1998 (Statistical

*For this report, HSCT is defined as any transplantation of blood- or marrow-derived hematopoietic stem cells, regardless of transplant type (e.g., allogeneic or autologous) or cell source (e.g., bone marrow, peripheral blood, or placental/umbilical cord blood). In addition, HSCT recipients are presumed immunocompetent at ≥24 months after HSCT if they are not on immunosuppressive therapy and do not have graft-versus-host disease (GVHD), a condition that occurs when the transplanted cells recognize that the recipient's cells are not the same cells and attack them.

Center of the International Bone Marrow Transplant Registry and Autologous Blood and Marrow Transplant Registry, unpublished data, 1998).

HSCTs are classified as either allogeneic or autologous on the basis of the source of the transplanted hematopoietic progenitor cells. Cells used in allogeneic HSCTs are harvested from a donor other than the transplant recipient. Such transplants are the most effective treatment for persons with severe aplastic anemia (*13*) and offer the only curative therapy for persons with chronic myelogenous leukemia (*12*). Allogeneic donors might be a blood relative or an unrelated donor. Allogeneic transplants are usually most successful when the donor is a human lymphocyte antigen (HLA)-identical twin or matched sibling. However, for allogeneic candidates who lack such a donor, registry organizations (e.g., the National Marrow Donor Program) maintain computerized databases that store information regarding HLA type from millions of volunteer donors (*14–16*). Another source of stem cells for allogeneic candidates without an HLA-matched sibling is a mismatched family member (*17,18*). However, persons who receive allogeneic grafts from donors who are not HLA-matched siblings are at a substantially greater risk for graft-versus-host disease (GVHD) (*19*). These persons are also at increased risk for suboptimal graft function and delayed immune system recovery (*19*). To reduce GVHD among allogeneic HSCTs, techniques have been developed to remove T-lymphocytes, the principal effectors of GVHD, from the donor graft. Although the recipients of T-lymphocyte–depleted marrow grafts generally have lower rates of GVHD, they also have greater rates of graft rejection, cytomegalovirus (CMV) infection, invasive fungal infection, and Epstein-Barr virus (EBV)-associated posttransplant lymphoproliferative disease (*20*).

The patient's own cells are used in an autologous HSCT. Similar to autologous transplants are syngeneic transplants, among whom the HLA-identical twin serves as the donor. Autologous HSCTs are preferred for patients who require high-level or marrow-ablative chemotherapy to eradicate an underlying malignancy but have healthy, undiseased bone marrows. Autologous HSCTs are also preferred when the immunologic antitumor effect of an allograft is not beneficial. Autologous HSCTs are used most frequently to treat breast cancer, non-Hodgkin's lymphoma, and Hodgkin's disease (*21*). Neither autologous nor syngeneic HSCTs confer a risk for chronic GVHD.

Recently, medical centers have begun to harvest hematopoietic stem cells from placental or umbilical cord blood (UCB) immediately after birth. These harvested cells are used primarily for allogeneic transplants among children. Early results demonstrate that greater degrees of histoincompatibility between donor and recipient might be tolerated without graft rejection or GVHD when UCB hematopoietic cells are used (*22–24*). However, immune system function after UCB transplants has not been well-studied.

HSCT is also evolving rapidly in other areas. For example, hematopoietic stem cells harvested from the patient's peripheral blood after treatment with hematopoietic colony-stimulating factors (e.g., granulocyte colony-stimulating factor [G-CSF or filgastrim] or granulocyte-macrophage colony-stimulating factor [GM-CSF or sargramostim]) are being used increasingly among autologous recipients (*25*) and are under investigation for use among allogeneic HSCT. Peripheral blood has largely replaced bone marrow as a source of stem cells for autologous recipients. A benefit of harvesting such cells from the donor's peripheral blood instead of bone marrow is that it eliminates the need for general anesthesia associated with bone marrow aspiration.

GVHD is a condition in which the donated cells recognize the recipient's cells as nonself and attack them. Although the use of intravenous immunoglobulin (IVIG) in the

routine management of allogeneic patients was common in the past as a means of producing immune modulation among patients with GVHD, this practice has declined because of cost factors (*26*) and because of the development of other strategies for GVHD prophylaxis (*27*). For example, use of cyclosporine GVHD prophylaxis has become commonplace since its introduction during the early 1980s. Most frequently, cyclosporine or tacrolimus (FK506) is administered in combination with other immunosuppressive agents (e.g., methotrexate or corticosteroids) (*27*). Although cyclosporine is effective in preventing GVHD, its use entails greater hazards for infectious complications and relapse of the underlying neoplastic disease for which the transplant was performed.

Although survival rates for certain autologous recipients have improved (*28,29*), infection remains a leading cause of death among allogeneic transplants and is a major cause of morbidity among autologous HSCTs (*29*). Researchers from the National Marrow Donor Program reported that, of 462 persons receiving unrelated allogeneic HSCTs during December 1987–November 1990, a total of 66% had died by 1991 (*15*). Among primary and secondary causes of death, the most common cause was infection, which occurred among 37% of 307 patients (*15*).*

Despite high morbidity and mortality after HSCT, recipients who survive long-term are likely to enjoy good health. A survey of 798 persons who had received an HSCT before 1985 and who had survived for >5 years after HSCT, determined that 93% were in good health and that 89% had returned to work or school full time (*30*). In another survey of 125 adults who had survived a mean of 10 years after HSCT, 88% responded that the benefits of transplantation outweighed the side effects (*31*).

Immune System Recovery After HSCT

During the first year after an HSCT, recipients typically follow a predictable pattern of immune system deficiency and recovery, which begins with the chemotherapy or radiation therapy (i.e., the conditioning regimen) administered just before the HSCT to treat the underlying disease. Unfortunately, this conditioning regimen also destroys normal hematopoiesis for neutrophils, monocytes, and macrophages and damages mucosal progenitor cells, causing a temporary loss of mucosal barrier integrity. The gastrointestinal tract, which normally contains bacteria, commensal fungi, and other bacteria-carrying sources (e.g., skin or mucosa) becomes a reservoir of potential pathogens. Virtually all HSCT recipients rapidly lose all T- and B-lymphocytes after conditioning, losing immune memory accumulated through a lifetime of exposure to infectious agents, environmental antigens, and vaccines. Because transfer of donor immunity to HSCT recipients is variable and influenced by the timing of antigen exposure among donor and recipient, passively acquired donor immunity cannot be relied upon to provide long-term immunity against infectious diseases among HSCT recipients.

During the first month after HSCT, the major host-defense deficits include impaired phagocytosis and damaged mucocutaneous barriers. Additionally, indwelling intravenous catheters are frequently placed and left in situ for weeks to administer parenteral medications, blood products, and nutritional supplements. These catheters serve as another portal of entry for opportunistic pathogens from organisms colonizing the skin (e.g., coagulase-negative *Staphylococci*, *Staphylococcus aureus*, *Candida* species, and *Enterococci*) (*32,33*).

*Presently, no updated data have been published.

Engraftment for adults and children is defined as the point at which a patient can maintain a sustained absolute neutrophil count (ANC) of >500/mm^3 and sustained platelet count of ≥20,000, lasting ≥3 consecutive days without transfusions. Among unrelated allogeneic recipients, engraftment occurs at a median of 22 days after HSCT (range: 6–84 days) (*15*). In the absence of corticosteroid use, engraftment is associated with the restoration of effective phagocytic function, which results in a decreased risk for bacterial and fungal infections. However, all HSCT recipients and particularly allogeneic recipients, experience an immune system dysfunction for months after engraftment. For example, although allogeneic recipients might have normal total lymphocyte counts within ≥2 months after HSCT, they have abnormal CD4/CD8 T-cell ratios, reflecting their decreased CD4 and increased CD8 T-cell counts (*27*). They might also have immunoglobulin G ($IgG)_2$, IgG_4, and immunoglobulin A (IgA) deficiencies for months after HSCT and have difficulty switching from immunoglobulin M (IgM) to IgG production after antigen exposure (*32*). Immune system recovery might be delayed further by CMV infection (*34*).

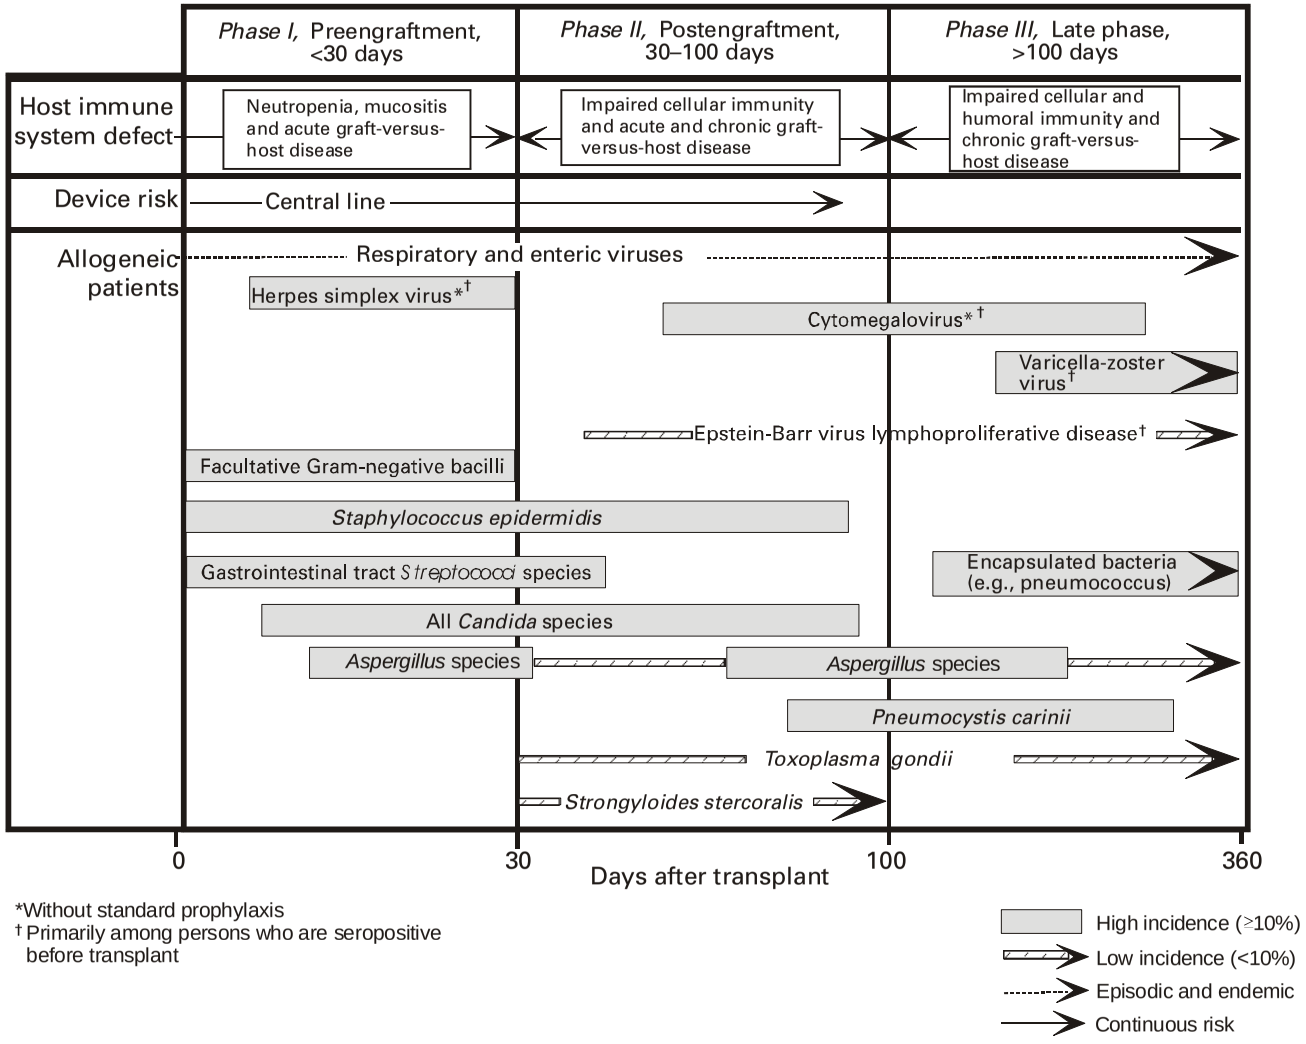
During the first ≥2 months after HSCT, recipients might experience acute GVHD that manifests as skin, gastrointestinal, and liver injury, and is graded on a scale of I–IV (*32,35,36*). Although autologous or syngeneic recipients might occasionally experience a mild, self-limited illness that is acute GVHD-like (*19,37*), GVHD occurs primarily among allogeneic recipients, particularly those receiving matched, unrelated donor transplants. GVHD is a substantial risk factor for infection among HSCT recipients because it is associated with a delayed immunologic recovery and prolonged immunodeficiency (*19*). Additionally, the immunosuppressive agents used for GVHD prophylaxis and treatment might make the HSCT recipient more vulnerable to opportunistic viral and fungal pathogens (*38*).

Certain patients, particularly adult allogeneic recipients, might also experience chronic GVHD, which is graded as either limited or extensive chronic GVHD (*19,39*). Chronic GVHD appears similar to autoimmune, connective-tissue disorders (e.g., scleroderma or systemic lupus erythematosus) (*40*) and is associated with cellular and humoral immunodeficiencies, including macrophage deficiency, impaired neutrophil chemotaxis (*41*), poor response to vaccination (*42–44*), and severe mucositis (*19*). Risk factors for chronic GVHD include increasing age, allogeneic HSCT (particularly those among whom the donor is unrelated or a non-HLA identical family member) (*40*), and a history of acute GVHD (*24,45*). Chronic GVHD was first described as occurring >100 days after HSCT but can occur 40 days after HSCT (*19*). Although allogeneic recipients with chronic GVHD have normal or high total serum immunoglobulin levels (*41*), they experience long-lasting IgA, IgG, and IgG subclass deficiencies (*41,46,47*) and poor opsonization and impaired reticuloendothelial function. Consequently, they are at even greater risk for infections (*32,39*), particularly life-threatening bacterial infections from encapsulated organisms (e.g., *Stre. pneumoniae*, *Ha. influenzae*, or *Ne. meningitidis*). After chronic GVHD resolves, which might take years, cell-mediated and humoral immunity function are gradually restored.

Opportunistic Pathogens After HSCT

HSCT recipients experience certain infections at different times posttransplant, reflecting the predominant host-defense defect(s) (Figure). Immune system recovery for HSCT recipients takes place in three phases beginning at day 0, the day of transplant.

FIGURE. Phases of opportunistic infections among allogeneic HSCT recipients



Phase I is the preengraftment phase (<30 days after HSCT); phase II, the postengraftment phase (30–100 days after HSCT); and phase III, the late phase (>100 days after HSCT). Prevention strategies should be based on these three phases and the following information:

- **Phase I, preengraftment.** During the first month posttransplant, HSCT recipients have two critical risk factors for infection — prolonged neutropenia and breaks in the mucocutaneous barrier resulting from the HSCT preparative regimens and frequent vascular access required for patient care. Consequently, oral, gastro-intestinal, and skin flora are sources of infection. Prevalent pathogens include *Candida* species, and as neutropenia continues, *Aspergillus* species. Additionally, herpes simplex virus (HSV) reactivation can occur during this phase. During preengraftment, the risks for infection are the same for autologous or allogeneic patients, and OIs can appear as febrile neutropenia. Although a recipient's first fever during preengraftment is probably caused by a bacterial pathogen, rarely is an organism or site of infection identified. Instead, such infections are usually treated preemptively or empirically (*48*) until the neutropenia resolves (*49*). Growth factors can be administered during phase I to decrease neutropenia duration and complications (e.g., febrile neutropenia) (*50*).

- **Phase II, postengraftment.** Phase II is dominated by impaired cell-mediated immunity for allogeneic or autologous recipients. Scope and impact of this defect for allogeneic recipients are determined by the extent of GVHD and its immunosuppressive therapy. After engraftment, the herpes viruses, particularly CMV, are critical pathogens. At 30–100 days after HSCT, CMV causes pneumonia, hepatitis, and colitis and potentiates superinfection with opportunistic pathogens, particularly among patients with active GVHD. Other dominant pathogens during this phase include *Pneumocystis carinii* and *Aspergillus* species.

- **Phase III, late phase.** During phase III, autologous recipients usually have more rapid recovery of immune system function and, therefore, a lower risk for OIs than do allogeneic recipients. Because of cell-mediated and humoral immunity defects and impaired reticuloendothelial system function, allogeneic patients with chronic GVHD and recipients of alternate donor allogeneic transplants are at risk for certain infections during this phase. Alternate donors include matched unrelated, UCB, or mismatched family-related donors. These patients are at risk for infections that include CMV, varicella-zoster virus (VZV), EBV-related posttransplant lymphoproliferative disease, community-acquired respiratory viruses (CRV), and infections with encapsulated bacteria (e.g., *Ha. influenzae* and *Stre. pneumoniae*). Risk for these infections is approximately proportional to the severity of the patient's GVHD during phases II and III. Patients receiving mismatched allogeneic transplants have a higher attack rate and severity of GVHD and, therefore, a higher risk for OIs during phases II and III than do patients receiving matched allogeneic HSCTs. In contrast, patients undergoing autologous transplantation are primarily at risk for infection during phase I.

Preventing infections among HSCT recipients is preferable to treating infections. However, despite recent technologic advances, more research is needed to optimize health outcomes for HSCT recipients. Efforts to improve immune system reconstitution, particularly among allogeneic transplant recipients, and to prevent or resolve the immune dysregulation resulting from donor-recipient histoincompatibility and GVHD remain

substantial challenges for preventing recurrent, persistent, or progressive infections among HSCT patients.

BACTERIAL INFECTIONS

General Recommendations

Preventing Exposure

Because bacteria are carried on the hands, health-care workers (HCWs) and others in contact with HSCT recipients should routinely follow appropriate hand-washing practices to avoid exposing recipients to bacterial pathogens (AIII).

Preventing Disease

Preventing Early Disease (0–100 Days After HSCT). Routine gut decontamination is not recommended for HSCT candidates (51–53) (DIII). Because of limited data, no recommendations can be made regarding the routine use of antibiotics for bacterial prophylaxis among afebrile, asymptomatic neutropenic recipients. Although studies have reported that using prophylactic antibiotics might reduce bacteremia rates after HSCT (51), infection-related fatality rates are not reduced (52). If physicians choose to use prophylactic antibiotics among asymptomatic, afebrile, neutropenic recipients, they should routinely review hospital and HSCT center antibiotic-susceptibility profiles, particularly when using a single antibiotic for antibacterial prophylaxis (BIII). The emergence of fluoquinolone-resistant coagulase-negative *Staphylococci* and *Es. coli* (51,52), vancomycin-intermediate *Sta. aureus* and vancomycin-resistant *Enterococcus* (VRE) are increasing concerns (54). Vancomycin should not be used as an agent for routine bacterial prophylaxis (DIII). Growth factors (e.g., GM-CSF and G-CSF) shorten the duration of neutropenia after HSCT (55); however, no data were found that indicate whether growth factors effectively reduce the attack rate of invasive bacterial disease.

Physicians should not routinely administer IVIG products to HSCT recipients for bacterial infection prophylaxis (DII), although IVIG has been recommended for use in producing immune system modulation for GVHD prevention. Researchers have recommended routine IVIG* use to prevent bacterial infections among the approximately 20%–25% of HSCT recipients with unrelated marrow grafts who experience severe

*Since November 1997, the United States has had a shortage of intravenous immunoglobulin (IVIG) (**Source:** CDC. Availability of immune globulin intravenous for treatment of immune deficient patients—United States, 1997–1998. MMWR 1999:48[8];159–162). Physicians who have difficulty obtaining IVIG should contact the following sources:

- American Red Cross Customer Service Center, (800) 261-5772;
- Alpha Therapeutic Corporation, (800) 421-0008;
- Baxter Healthcare Corporation, (847) 940-5955;
- Bayer Pharmaceutical Division, (800) 288-8370;
- Aventis Behring Customer Support, (800) 683-1288;
- Novartis Pharmaceuticals Corporation, (973) 781-8300, or the IVIG Emergency Hotline, (888) 234-2520; or
- Immune Deficiency Foundation, (800) 296-4433.

Physicians who are unable to obtain IVIG for a licensed indication from one of these sources should contact the Product Shortage Officer at the Food and Drug Administration's Center for Biologics Evaluation and Research, Office of Compliance, (301) 827-6220, for assistance.

hypogamma-globulinemia (e.g., IgG < 400 mg/dl) within the first 100 days after transplant (CIII). For example, recipients who are hypogammaglobulinemic might receive prophylactic IVIG to prevent bacterial sinopulmonary infections (e.g., from *Stre. pneumoniae*) (*8*) (CIII). For hypogammaglobulinemic allogeneic recipients, physicians can use a higher and more frequent dose of IVIG than is standard for non-HSCT recipients because the IVIG half-life among HSCT recipients (generally 1–10 days) is much shorter than the half-life among healthy adults (generally 18–23 days) (*56–58*). Additionally, infections might accelerate IgG catabolism; therefore, the IVIG dose for a hypogammaglobulinemic recipient should be individualized to maintain trough serum IgG concentrations >400–500 mg/dl (*58*) (BII). Consequently, physicians should monitor trough serum IgG concentrations among these patients approximately every 2 weeks and adjust IVIG doses as needed (BIII) (Appendix).

Preventing Late Disease (>100 Days After HSCT). Antibiotic prophylaxis is recommended for preventing infection with encapsulated organisms (e.g., *Stre. pneumoniae*, *Ha. influenzae*, or *Ne. meningitidis*) among allogeneic recipients with chronic GVHD for as long as active chronic GVHD treatment is administered (*59*) (BIII). Antibiotic selection should be guided by local antibiotic resistance patterns. In the absence of severe demonstrable hypogammaglobulinemia (e.g., IgG levels < 400 mg/dl, which might be associated with recurrent sinopulmonary infections), routine monthly IVIG administration to HSCT recipients >90 days after HSCT is not recommended (*60*) (DI) as a means of preventing bacterial infections.

Other Disease Prevention Recommendations. Routine use of IVIG among autologous recipients is not recommended (*61*) (DII). Recommendations for preventing bacterial infections are the same among pediatric or adult HSCT recipients.

Recommendations Regarding *Stre. pneumoniae*

Preventing Exposure

Appropriate care precautions should be taken with hospitalized patients infected with *Stre. pneumoniae* (*62,63*) (BIII) to prevent exposure among HSCT recipients.

Preventing Disease

Information regarding the currently available 23-valent pneumococcal polysaccharide vaccine indicates limited immunogenicity among HSCT recipients. However, because of its potential benefit to certain patients, it should be administered to HSCT recipients at 12 and 24 months after HSCT (*64–66*) (BIII). No data were found regarding safety and immunogenicity of the 7-valent conjugate pneumococcal vaccine among HSCT recipients; therefore, no recommendation regarding use of this vaccine can be made.

Antibiotic prophylaxis is recommended for preventing infection with encapsulated organisms (e.g., *Stre. pneumoniae* , *Ha. influenzae* , and *Ne. meningitidis*) among allogeneic recipients with chronic GVHD for as long as active chronic GVHD treatment is administered (*59*) (BIII). Trimethoprim-sulfamethasaxole (TMP-SMZ) administered for *Pneumocystis carinii* pneumonia (PCP) prophylaxis will also provide protection against pneumococcal infections. However, no data were found to support using TMP-SMZ prophylaxis among HSCT recipients solely for the purpose of preventing *Stre. pneumoniae* disease. Certain strains of *Stre. pneumoniae* are resistant to TMP-SMZ and penicillin. Recommendations for preventing pneumococcal infections are the same for allogeneic or autologous recipients.

As with adults, pediatric HSCT recipients aged ≥2 years should be administered the current 23-valent pneumococcal polysaccharide vaccine because the vaccine can be effective (BIII). However, this vaccine should not be administered to children aged <2 years because it is not effective among that age population (DI). No data were found regarding safety and immunogenicity of the 7-valent conjugate pneumococcal vaccine among pediatric HSCT recipients; therefore, no recommendation regarding use of this vaccine can be made.

Recommendations Regarding *Streptococci viridans*

Preventing Exposure

Because *Streptococci viridans* colonize the oropharynx and gut, no effective method of preventing exposure is known.

Preventing Disease

Chemotherapy-induced oral mucositis is a potential source of *Streptococci viridans* bacteremia. Consequently, before conditioning starts, dental consults should be obtained for all HSCT candidates to assess their state of oral health and to perform any needed dental procedures to decrease the risk for oral infections after transplant (*67*) (AIII).

Generally, HSCT physicians should not use prophylactic antibiotics to prevent *Streptococci viridans* infections (DIII). No data were found that demonstrate efficacy of prophylactic antibiotics for this infection. Furthermore, such use might select antibiotic-resistant bacteria, and in fact, penicillin- and vancomycin-resistant strains of *Streptococci viridans* have been reported (*68*). However, when *Streptococci viridans* infections among HSCT recipients are virulent and associated with overwhelming sepsis and shock in an institution, prophylaxis might be evaluated (CIII). Decisions regarding the use of *Streptococci viridans* prophylaxis should be made only after consultation with the hospital epidemiologists or infection-control practitioners who monitor rates of nosocomial bacteremia and bacterial susceptibility (BIII).

HSCT physicians should be familiar with current antibiotic susceptibilities for patient isolates from their HSCT centers, including *Streptococci viridans* (BIII). Physicians should maintain a high index of suspicion for this infection among HSCT recipients with symptomatic mucositis because early diagnosis and aggressive therapy are currently the only potential means of preventing shock when severely neutropenic HSCT recipients experience *Streptococci viridans* bacteremia (*69*).

Recommendations Regarding *Ha. influenzae* type b

Preventing Exposure

Adults with *Ha. influenzae* type b (Hib) pneumonia require standard precautions (*62*) to prevent exposing the HSCT recipient to Hib. Adults and children who are in contact with the HSCT recipient and who have known or suspected invasive Hib disease, including meningitis, bacteremia, or epiglottitis, should be placed in droplet precautions until 24 hours after they begin appropriate antibiotic therapy, after which they can be switched to standard precautions. Household contacts exposed to persons with Hib disease and who also have contact with HSCT recipients should be administered rifampin prophylaxis according to published recommendations (*70,71*); prophylaxis for household contacts of

a patient with Hib disease are necessary if all contacts aged <4 years are not fully vaccinated (BIII) (Appendix). This recommendation is critical because the risk for invasive Hib disease among unvaccinated household contacts aged <4 years is increased, and rifampin can be effective in eliminating Hib carriage and preventing invasive Hib disease (*72–74*). Pediatric household contacts should be up-to-date with Hib vaccinations to prevent possible Hib exposure to the HSCT recipient (AII).

Preventing Disease

Although no data regarding vaccine efficacy among HSCT recipients were found, Hib conjugate vaccine should be administered to HSCT recipients at 12, 14, and 24 months after HSCT (BII). This vaccine is recommended because the majority of HSCT recipients have low levels of Hib capsular polysaccharide antibodies ≥4 months after HSCT (*75*), and allogeneic recipients with chronic GVHD are at increased risk for infection from encapsulated organisms (e.g., Hib) (*76,77*). HSCT recipients who are exposed to persons with Hib disease should be offered rifampin prophylaxis according to published recommendations (*70*) (BIII) (Appendix).

Antibiotic prophylaxis is recommended for preventing infection with encapsulated organisms (e.g., *Stre. pneumoniae*, *Ha. influenzae*, or *Ne. meningitidis*) among allogeneic recipients with chronic GVHD for as long as active chronic GVHD treatment is administered (*59*) (BIII). Antibiotic selection should be guided by local antibiotic-resistance patterns. Recommendations for preventing Hib infections are the same for allogeneic or autologous recipients. Recommendations for preventing Hib disease are the same for pediatric or adult HSCT recipients, except that any child infected with Hib pneumonia requires standard precautions with droplet precautions added for the first 24 hours after beginning appropriate antibiotic therapy (*62,70*) (BIII). Appropriate pediatric doses should be administered for Hib conjugate vaccine and for rifampin prophylaxis (*71*) (Appendix).

VIRAL INFECTIONS

Recommendations Regarding Cytomegalovirus

Preventing Exposure

HSCT candidates should be tested for the presence of serum anti-CMV IgG antibodies before transplantation to determine their risk for primary CMV infection and reactivation after HSCT (AIII). Only Food and Drug Administration (FDA) licensed or approved tests should be used. HSCT recipients and candidates should avoid sharing cups, glasses, and eating utensils with others, including family members, to decrease the risk for CMV exposure (BIII).

Sexually active patients who are not in long-term monogamous relationships should always use latex condoms during sexual contact to reduce their risk for exposure to CMV and other sexually transmitted pathogens (AII). However, even long-time monogamous pairs can be discordant for CMV infections. Therefore, during periods of immunocompromise, sexually active HSCT recipients in monogamous relationships should ask partners to be tested for serum CMV IgG antibody, and discordant couples should use latex condoms during sexual contact to reduce the risk for exposure to this sexually transmitted OI (CIII).

After handling or changing diapers or after wiping oral and nasal secretions, HSCT candidates and recipients should practice regular hand washing to reduce the risk for CMV exposure (AII). CMV-seronegative recipients of allogeneic stem cell transplants from CMV-seronegative donors (i.e., R-negative or D-negative) should receive only leukocyte-reduced or CMV-seronegative red cells or leukocyte-reduced platelets (<1 x 10^6 leukocytes/unit) to prevent transfusion-associated CMV infection (*78*) (AI). However, insufficient data were found to recommend use of leukocyte-reduced or CMV-seronegative red cells and platelets among CMV-seronegative recipients who have CMV-seropositive donors (i.e., R-negative or D-positive).

All HCWs should wear gloves when handling blood products or other potentially contaminated biologic materials (AII) to prevent transmission of CMV to HSCT recipients. HSCT patients who are known to excrete CMV should be placed under standard precautions (*62*) for the duration of CMV excretion to avoid possible transmission to CMV-seronegative HSCT recipients and candidates (AIII). Physicians are cautioned that CMV excretion can be episodic or prolonged.

Preventing Disease and Disease Recurrence

HSCT recipients at risk for CMV disease after HSCT (i.e., all CMV-seropositive HSCT recipients, and all CMV-seronegative recipients with a CMV-seropositive donor) should be placed on a CMV disease prevention program from the time of engraftment until 100 days after HSCT (i.e., phase II) (AI). Physicians should use either prophylaxis or preemptive treatment with ganciclovir for allogeneic recipients (AI). In selecting a CMV disease prevention strategy, physicians should assess the risks and benefits of each strategy, the needs and condition of the patient, and the hospital's virology laboratory support capability.

Prophylaxis strategy against early CMV (i.e., <100 days after HSCT) for allogeneic recipients involves administering ganciclovir prophylaxis to all allogeneic recipients at risk throughout phase II (i.e., from engraftment to 100 days after HSCT). The induction course is usually started at engraftment (AI), although physicians can add a brief prophylactic course during HSCT preconditioning (CIII) (Appendix).

Preemptive strategy against early CMV (i.e., <100 days after HSCT) for allogeneic recipients is preferred over prophylaxis for CMV-seronegative HSCT recipients of seropositive donor cells (i.e., D-positive or R-negative) because of the low attack rate of active CMV infection if screened or filtered blood product support is used (BII). Preemptive strategy restricts ganciclovir use for those patients who have evidence of CMV infection after HSCT. It requires the use of sensitive and specific laboratory tests to rapidly diagnose CMV infection after HSCT and to enable immediate administration of ganciclovir after CMV infection has been detected. Allogeneic recipients at risk should be screened ≥1 times/week from 10 days to 100 days after HSCT (i.e., phase II) for the presence of CMV viremia or antigenemia (AIII).

HSCT physicians should select one of two diagnostic tests to determine the need for preemptive treatment. Currently, the detection of CMV pp65 antigen in leukocytes (antigenemia) (*79,80*) is preferred for screening for preemptive treatment because it is more rapid and sensitive than culture and has good positive predictive value (*79–81*). Direct detection of CMV-DNA (deoxyribonucleic acid) by polymerase chain reaction (PCR) (*82*) is very sensitive but has a low positive predictive value (*79*). Although CMV-DNA PCR is less sensitive than whole blood or leukocyte PCR, plasma CMV-DNA PCR is useful

during neutropenia, when the number of leukocytes/slide is too low to allow CMV pp65 antigenemia testing.

Virus culture of urine, saliva, blood, or bronchoalveolar washings by rapid shell-vial culture (*83*) or routine culture (*84,85*) can be used; however, viral culture techniques are less sensitive than CMV-DNA PCR or CMV pp65 antigenemia tests. Also, rapid shell-viral cultures require ≥48 hours and routine viral cultures can require weeks to obtain final results. Thus, viral culture techniques are less satisfactory than PCR or antigenemia tests. HSCT centers without access to PCR or antigenemia tests should use prophylaxis rather than preemptive therapy for CMV disease prevention (*86*) (BII). Physicians do use other diagnostic tests (e.g., hybrid capture CMV-DNA assay, Version 2.0 [*87*] or CMV pp67 viral RNA [ribonucleic acid] detection) (*88*); however, limited data were found regarding use among HSCT recipients, and therefore, no recommendation for use can be made.

Allogeneic recipients ≤100 days after HSCT (i.e., during phase II) should begin preemptive treatment with ganciclovir if CMV viremia or any antigenemia is detected or if the recipient has ≥2 consecutively positive CMV-DNA PCR tests (BIII). After preemptive treatment has been started, maintenance ganciclovir is usually continued until 100 days after HSCT or for a minimum of 3 weeks, whichever is longer (AI) (Appendix). Antigen or PCR tests should be negative when ganciclovir is stopped. Studies report that a shorter course of ganciclovir (e.g., for 3 weeks or until negative PCR or antigenemia occurs) (*89–91*) might provide adequate CMV prevention with less toxicity, but routine weekly screening by pp65 antigen or PCR test is necessary after stopping ganciclovir because CMV reactivation can occur (BIII).

Presently, only the intravenous formulation of ganciclovir has been approved for use in CMV prophylactic or preemptive strategies (BIII). No recommendation for oral ganciclovir use among HSCT recipients can be made because clinical trials evaluating its efficacy are still in progress. One group has used ganciclovir and foscarnet on alternate days for CMV prevention (*92*), but no recommendation can be made regarding this strategy because of limited data. Patients who are ganciclovir-intolerant should be administered foscarnet instead (*93*) (BII) (Appendix). HSCT recipients receiving ganciclovir should have ANCs checked ≥2 times/week (BIII). Researchers report managing ganciclovir-associated neutropenia by adding G-CSF (*94*) or temporarily stopping ganciclovir for ≥2 days if the patient's ANC is <1,000 (CIII). Ganciclovir can be restarted when the patient's ANC is ≥1,000 for 2 consecutive days. Alternatively, researchers report substituting foscarnet for ganciclovir if a) the HSCT recipient is still CMV viremic or antigenemic or b) the ANC remains <1,000 for >5 days after ganciclovir has been stopped (CIII) (Appendix). Because neutropenia accompanying ganciclovir administration is usually brief, such patients do not require antifungal or antibacterial prophylaxis (DIII).

Currently, no benefit has been reported from routinely administering ganciclovir prophylaxis to all HSCT recipients at >100 days after HSCT (i.e., during phase III). However, persons with high risk for late CMV disease should be routinely screened biweekly for evidence of CMV reactivation as long as substantial immunocompromise persists (BIII). Risk factors for late CMV disease include allogeneic HSCT accompanied by chronic GVHD, steroid use, low CD4 counts, delay in high avidity anti-CMV antibody, and recipients of matched unrelated or T-cell–depleted HSCTs who are at high risk (*95–99*). If CMV is still detectable by routine screening ≥100 days after HSCT, ganciclovir should be continued until CMV is no longer detectable (AI). If low-grade CMV antigenemia (<5 positive cells/slide) is detected on routine screening, the antigenemia test should be repeated in 3 days

(BIII). If CMV antigenemia indicates ≥5 cells/slide, PCR is positive, or the shell-vial culture detects CMV viremia, a 3-week course of preemptive ganciclovir treatment should be administered (BIII) (Appendix). Ganciclovir should also be started if the patient has had ≥2 consecutively positive viremia or PCR tests (e.g., in a person receiving steroids for GVHD or who received ganciclovir or foscarnet at <100 days after HSCT). Current investigational strategies for preventing late CMV disease include the use of targeted prophylaxis with antiviral drugs and cellular immunotherapy for those with deficient or absent CMV-specific immune system function.

If viremia persists after 4 weeks of ganciclovir preemptive therapy or if the level of antigenemia continues to rise after 3 weeks of therapy, ganciclovir-resistant CMV should be suspected. If CMV viremia recurs during continuous treatment with ganciclovir, researchers report restarting ganciclovir induction (*100*) or stopping ganciclovir and starting foscarnet (CIII). Limited data were found regarding the use of foscarnet among HSCT recipients for either CMV prophylaxis or preemptive therapy (*92,93*).

Infusion of donor-derived CMV-specific clones of CD8+ T-cells into the transplant recipient is being evaluated under FDA Investigational New Drug authorization; therefore, no recommendation can be made. Although, in a substantial cooperative study, high-dose acyclovir has had certain efficacy for preventing CMV disease (*101*), its utility is limited in a setting where more potent anti-CMV agents (e.g., ganciclovir) are used (*102*). Acyclovir is not effective in preventing CMV disease after autologous HSCT (*103*) and is, therefore, not recommended for CMV preemptive therapy (DII). Consequently, valacyclovir, although under study for use among HSCT recipients, is presumed to be less effective than ganciclovir against CMV and is currently not recommended for CMV disease prevention (DII).

Although HSCT physicians continue to use IVIG for immune system modulation, IVIG is not recommended for CMV disease prophylaxis among HSCT recipients (DI). Cidofovir, a nucleoside analog, is approved by FDA for the treatment of AIDS-associated CMV retinitis. The drug's major disadvantage is nephrotoxicity. Cidofovir is currently in FDA phase 1 trial for use among HSCT recipients; therefore, recommendations for its use cannot be made.

Use of CMV-negative or leukocyte-reduced blood products is not routinely required for all autologous recipients because most have a substantially lower risk for CMV disease. However, CMV-negative or leukocyte-reduced blood products can be used for CMV-seronegative autologous recipients (CIII). Researchers report that CMV-seropositive autologous recipients be evaluated for preemptive therapy if they have underlying hematologic malignancies (e.g., lymphoma or leukemia), are receiving intense conditioning regimens or graft manipulation, or have recently received fludarabine or 2-chlorodeoxyadenosine (CDA) (CIII). This subpopulation of autologous recipients should be monitored weekly from time of engraftment until 60 days after HSCT for CMV reactivation, preferably with quantitative CMV pp65 antigen (*80*) or quantitative PCR (BII).

Autologous recipients at high risk who experience CMV antigenemia (i.e., blood levels of ≥5 positive cells/slide) should receive 3 weeks of preemptive treatment with ganciclovir or foscarnet (*80*), but CD34+-selected patients should be treated at any level of antigenemia (BII) (Appendix). Prophylactic approach to CMV disease prevention is not appropriate for CMV-seropositive autologous recipients. Indications for the use of CMV prophylaxis or preemptive treatment are the same for children or adults.

Recommendations Regarding EBV

Preventing Exposure

All transplant candidates, particularly those who are EBV-seronegative, should be advised of behaviors that could decrease the likelihood of EBV exposure (AII). For example, HSCT recipients and candidates should follow safe hygiene practices (e.g., frequent hand washing [AIII] and avoiding the sharing of cups, glasses, and eating utensils with others) (*104*) (BIII), and they should avoid contact with potentially infected respiratory secretions and saliva (*104*) (AII).

Preventing Disease

Infusion of donor-derived, EBV-specific cytotoxic T-lymphocytes has demonstrated promise in the prophylaxis of EBV-lymphoma among recipients of T-cell–depleted unrelated or mismatched allogeneic recipients (*105,106*). However, insufficient data were found to recommend its use. Prophylaxis or preemptive therapy with acyclovir is not recommended because of lack of efficacy (*107,108*) (DII).

Recommendations Regarding HSV

Preventing Exposure

HSCT candidates should be tested for serum anti-HSV IgG before transplant (AIII); however, type-specific anti-HSV IgG serology testing is not necessary. Only FDA-licensed or -approved tests should be used. All HSCT candidates, particularly those who are HSV-seronegative, should be informed of the importance of avoiding HSV infection while immunocompromised and should be advised of behaviors that will decrease the likelihood of HSV exposure (AII). HSCT recipients and candidates should avoid sharing cups, glasses, and eating utensils with others (BIII). Sexually active patients who are not in a long-term monogamous relationship should always use latex condoms during sexual contact to reduce the risk for exposure to HSV as well as other sexually transmitted pathogens (AII). However, even long-time monogamous pairs can be discordant for HSV infections. Therefore, during periods of immunocompromise, sexually active HSCT recipients in such relationships should ask partners to be tested for serum HSV IgG antibody. If the partners are discordant, they should consider using latex condoms during sexual contact to reduce the risk for exposure to this sexually transmitted OI (CIII). Any person with disseminated, primary, or severe mucocutaneous HSV disease should be placed under contact precautions for the duration of the illness (*62*) (AI) to prevent transmission of HSV to HSCT recipients.

Preventing Disease and Disease Recurrence

Acyclovir. Acyclovir prophylaxis should be offered to all HSV-seropositive allogeneic recipients to prevent HSV reactivation during the early posttransplant period (*109–113*) (AI). Standard approach is to begin acyclovir prophylaxis at the start of the conditioning therapy and continue until engraftment occurs or until mucositis resolves, whichever is longer, or approximately 30 days after HSCT (BIII) (Appendix). Without supportive data from controlled studies, routine use of antiviral prophylaxis for >30 days after HSCT to prevent HSV is not recommended (DIII). Routine acyclovir prophylaxis is not indicated for

HSV-seronegative HSCT recipients, even if the donors are HSV-seropositive (DIII). Researchers have proposed administration of ganciclovir prophylaxis alone (*86*) to HSCT recipients who required simultaneous prophylaxis for CMV and HSV after HSCT (CIII) because ganciclovir has in vitro activity against CMV and HSV 1 and 2 (*114*), although ganciclovir has not been approved for use against HSV.

Valacyclovir. Researchers have reported valacyclovir use for preventing HSV among HSCT recipients (CIII); however, preliminary data demonstrate that very high doses of valacyclovir (8 g/day) were associated with thrombotic thrombocytopenic purpura/hemolytic uremic syndrome among HSCT recipients (*115*). Controlled trial data among HSCT recipients are limited (*115*), and the FDA has not approved valacyclovir for use among recipients. Physicians wishing to use valacyclovir among recipients with renal impairment should exercise caution and decrease doses as needed (BIII) (Appendix).

Foscarnet. Because of its substantial renal and infusion-related toxicity, foscarnet is not recommended for routine HSV prophylaxis among HSCT recipients (DIII).

Famciclovir. Presently, data regarding safety and efficacy of famciclovir among HSCT recipients are limited; therefore, no recommendations for HSV prophylaxis with famciclovir can be made.

Other Recommendations

HSV prophylaxis lasting >30 days after HSCT might be considered for persons with frequent recurrent HSV (CIII) (Appendix). Acyclovir can be used during phase I for administration to HSV-seropositive autologous recipients who are likely to experience substantial mucositis from the conditioning regimen (CIII). Antiviral prophylaxis doses should be modified for use among children (Appendix), but no published data were found regarding valacyclovir safety and efficacy among children.

Recommendations Regarding VZV

Preventing Exposure

HSCT candidates should be tested for the presence of serum anti-VZV IgG antibodies (AIII). However, these tests are not 100% reliable, particularly among severely immunosuppressed patients. Researchers recommend that a past history of varicella accompanied by a positive titer is more likely to indicate the presence of immunity to VZV than a low positive titer alone. All HSCT candidates and recipients, particularly those who are VZV-seronegative, should be informed of the potential seriousness of VZV disease among immunocompromised persons and advised of strategies to decrease their risk for VZV exposure (*116–122*) (AII).

Although researchers report that the majority of VZV disease after HSCT is caused by reactivation of endogenous VZV, HSCT candidates and recipients who are VZV-seronegative, or VZV-seropositive and immunocompromised, should avoid exposure to persons with active VZV infections (*123*) (AII). HCWs, family members, household contacts, and visitors who are healthy and do not have a reported history of varicella infection or who are VZV-seronegative should receive VZV vaccination before being allowed to visit or have direct contact with an HSCT recipient (AIII). Ideally, VZV-susceptible family

members, household contacts, and potential visitors of immunocompromised HSCT recipients should be vaccinated as soon as the decision is made to perform HSCT. The vaccination dose or doses should be completed ≥4 weeks before the conditioning regimen begins or ≥6 weeks (42 days) before the HSCT is performed (BIII).

HSCT recipients and candidates undergoing conditioning therapy should avoid contact with any VZV vaccine recipient who experiences a rash after vaccination (BIII). When this rash occurs, it usually appears 14–21 days after VZV vaccination (median: 22 days; range: 5–35 days) (personal communication from Robert G. Sharrar, M.D., Merck & Co., Inc.). However, to date, no serious disease has been reported among immunocompromised patients from transmission of VZV vaccine virus, and the VZV vaccine strain is susceptible to acyclovir.

All HSCT recipients with VZV disease should be placed under airborne and contact precautions (*62*) (AII) to prevent transmission to other HSCT recipients. Contact precautions should be continued until all skin lesions are crusted. Airborne precautions should be instituted 10 days after exposure to VZV and continued until 21 days after last exposure or 28 days postexposure if the patient received varicella-zoster immunoglobulin (VZIG)* (*62*) (AI) because a person infected with VZV can be infectious before the rash appears.

Preventing Disease

VZIG. VZV-seronegative HSCT recipients should be administered VZIG as soon as possible but ideally within 96 hours after close or household contact with a person having either chickenpox or shingles if the HSCT recipient is not immunocompetent (i.e., allogeneic patient <24 months after HSCT, ≥24 months after HSCT and on immunosuppressive therapy, or having chronic GVHD) (AII). Researchers report VZIG administration for VZV exposure as described for HSCT recipients who were VZV-seropositive before HSCT (CIII).

Because of the high morbidity of VZV-associated disease among severely immunocompromised HSCT recipients and until further data are published, HSCT physicians should administer VZIG to all VZV-seronegative HSCT recipients or candidates undergoing conditioning therapy who are exposed to a VZV vaccinee having a varicella-like rash (BIII). Researchers also report VZIG administration for this situation for VZV-seropositive HSCT recipients and candidates undergoing conditioning therapy (CIII). These recommendations are made because the vaccinee might be unknowingly incubating wild-type varicella, particularly during the first 14 days after varicella vaccination, and because vaccine-strain VZV has been rarely transmitted by VZV vaccinees with vesicular rashes postvaccination (*121*).

If VZV-seronegative HSCT recipients or candidates undergoing conditioning therapy are closely exposed to varicella >3 weeks after receiving VZIG, they should be administered another dose of VZIG (*120*) (BIII). Researchers also recommend VZIG administration for this condition for VZV-seropositive HSCT recipients and candidates undergoing conditioning therapy (CIII).

*VZIG is distributed by FFF Enterprises, Inc., under contract with the American Red Cross, except in Massachusetts where it is distributed by the Massachusetts Public Health Biologic Laboratories (now a unit of the University of Massachusetts) (*19*). FFF Enterprises, Inc., can be contacted at

FFF Enterprises, Inc.

Temecula, CA 92591
Phone: (800) 522-4448

Antiviral Drugs. Any HSCT recipient or candidate undergoing conditioning therapy who experiences a VZV-like rash (particularly after exposure to a person with wild-type varicella or shingles) should receive preemptive intravenous acyclovir until ≥2 days after all lesions have crusted (BIII) (Appendix). Any HSCT recipient or candidate undergoing conditioning therapy who experiences a VZV-like rash after exposure to a VZV vaccinee with a rash should be administered intravenous acyclovir preemptively to prevent severe, disseminated VZV disease (BII). Acyclovir should be administered until 2 days after all lesions have crusted.

Long-term acyclovir prophylaxis to prevent recurrent VZV infection (e.g., during the first 6 months after HSCT) is not routinely recommended (*124–126*) (DIII); however, this therapy could be considered for use among HSCT recipients with severe, long-term immunodeficiency (CIII). When acyclovir resistance occurs among patients, HSCT physicians should use foscarnet for preemptive treatment of VZV disease (*127*) (BIII). Researchers report valacyclovir use for preventing HSV among HSCT recipients (CIII). However, preliminary data demonstrate that very high doses of valacyclovir (8 g/day) were associated with thrombotic thrombocytopenic purpura/hemolytic uremic syndrome among HSCT recipients (*115*). Controlled trial data regarding HSCT recipients are limited (*115*), and the FDA has not approved valacyclovir for use among HSCT recipients. Physicians wishing to use valacyclovir among HSCT recipients with renal impairment should exercise caution and decrease doses as needed (BIII) (Appendix). No data were found demonstrating safety and efficacy of preemptive treatment of famciclovir against herpes zoster among HSCT recipients. Consequently, no recommendation for its use can be made.

Live-Attenuated VZV Vaccine. VZV vaccine use is contraindicated among HSCT recipients <24 months after HSCT (*128*) (EIII). Use of VZV vaccine among HSCT recipients is restricted to research protocols for recipients ≥24 months after HSCT who are presumed immunocompetent. Further research is needed to determine the safety, immunogenicity, and efficacy of VZV vaccine among HSCT recipients.

Other Recommendations

An inactivated VZV vaccine has been used investigationally among HSCT recipients (*129*); however, more studies are needed before a recommendation regarding its use can be made. Recommendations for VZV prevention are the same for allogeneic or autologous recipients. Recommendations for preventing VZV disease among pediatric or adult HSCT recipients are the same, except that appropriate dose adjustments for VZIG should be made for pediatric HSCT recipients (AIII) (Appendix).

Recommendations Regarding CRV Infections: Influenza, Respiratory Syncytial Virus, Parainfluenza Virus, and Adenovirus

Preventing Exposure

Preventing CRV exposure is critical in preventing CRV disease (*130,131*). To prevent nosocomial CRV transmission, HSCT recipients and their HCWs should always follow HSCT infection control guidelines (AIII). To minimize the risk for CRV transmission, HCWs and visitors with upper respiratory infection (URI) symptoms should be restricted from

contact with HSCT recipients and HSCT candidates undergoing conditioning therapy (AIII). At a minimum, active clinical surveillance for CRV disease should be conducted on all hospitalized HSCT recipients and candidates undergoing conditioning therapy; this clinical surveillance should include daily screening for signs and symptoms of CRV (e.g., URI or lower respiratory infection [LRI]) (AIII). Viral cultures of asymptomatic HSCT candidates are unlikely to be useful. HSCT recipients with URI or LRI symptoms should be placed under contact precautions to avoid transmitting infection to other HSCT candidates and recipients, HCWs, and visitors until the etiology of illness is identified (*62*) (BIII). Optimal isolation precautions should be modified as needed after the etiology is identified (AIII). HSCT recipients and candidates, their family members and visitors, and all HCWs should be informed regarding CRV infection control measures and the potential severity of CRV infections among HSCT recipients (*130–140*) (BIII). Physicians have routinely conducted culture-based CRV surveillance among HSCT recipients; however, the cost effectiveness of this approach has not been evaluated.

Influenza vaccination of family members and close or household contacts is strongly recommended during each influenza season (i.e., October–May) starting the season before HSCT and continuing ≥24 months after HSCT (*141*) (AI) to prevent influenza exposure among the recipients or candidates. All family members and close or household contacts of HSCT recipients who remain immunocompromised ≥24 months after HSCT should continue to be vaccinated annually as long as the HSCT recipient's immunocompromise persists (*141*) (AI). Seasonal influenza vaccination is strongly recommended for all HCWs of HSCT recipients (*142,143*) (AI).

If HCWs, family members, or other close contacts of HSCT recipients receive influenza vaccination during an influenza A outbreak, they should receive amantadine or rimantadine chemoprophylaxis for 2 weeks after influenza vaccination (BI) while the vaccinee experiences an immunologic response to the vaccine. Such a strategy is likely to prevent transmission of influenza A to HCWs and other close contacts of HSCT recipients, which could prevent influenza A transmission to HSCT recipients themselves. However, if a nosocomial outbreak occurs with an influenza A strain that is not contained in the available influenza vaccine, all healthy family members, close and household contacts, and HCWs of HSCT recipients and candidates should be administered influenza A chemoprophylaxis with amantadine or rimantadine until the end of the outbreak (*141*) (BIII).

In 1999, two neuroaminidase inhibitors (zanamivir and oseltamivir) were approved for treatment of influenza, but are not currently approved for prophylaxis. To date, experience is limited regarding use of zanamivir or oseltamivir in the treatment or prophylaxis of influenza among HSCT settings. However, HCWs, family members, or other close contacts can be offered a neuroaminidase inhibitor (e.g., zanamivir or oseltamivir) using the same strategies outlined previously, if a) rimantadine or amantadine cannot be tolerated, b) the outbreak strain of influenza A is amantadine or rimantadine-resistant, or c) the outbreak strain is influenza B (*144–147*) (BI). Zanamivir can be administered to persons aged ≥12 years, and oseltamivir can be administered to persons aged ≥18 years. Patients with influenza should be placed under droplet and standard precautions (AIII) to prevent transmission of influenza to HSCT recipients. HCWs with influenza should be excused from patient care until they are no longer infectious (AIII).

Preventing Disease

HSCT physicians should determine the etiology of a URI in an HSCT recipient or candidate undergoing conditioning therapy, if possible, because respiratory syncytial

virus (RSV), influenza, parainfluenza, and adenovirus URIs can progress to more serious LRI, and certain CRVs can be treated (BIII). Appropriate diagnostic samples include nasopharyngeal washes, swabs or aspirates, throat swabs, and bronchoalveolar lavage (BAL) fluid. HSCT candidates with URI symptoms at the time conditioning therapy is scheduled to start should postpone their conditioning regimen until the URIs resolve, if possible, because certain URIs might progress to LRI during immunosuppression (*131,133,137,138*) (BIII).

Recommendations Regarding Influenza. Life-long seasonal influenza vaccination is recommended for all HSCT candidates and recipients, beginning during the influenza season before HSCT and resuming ≥6 months after HSCT (*142*) (BIII). Influenza vaccinations administered to HSCT recipients <6 months after HSCT are unlikely to be beneficial and are not recommended (*142*) (DII). HSCT recipients <6 months after HSCT should receive chemoprophylaxis with amantadine or rimantadine during community or nosocomial influenza A outbreaks (BIII). These drugs are not effective against influenza B. Additionally, antiviral-resistant strains of influenza can emerge during treatment with amantadine or rimantadine and transmission of resistant strains can occur (*148,149*). During such outbreaks, HSCT recipients 6–24 months after HSCT, or >24 months after HSCT and still substantially immunocompromised (i.e., receiving immunosuppressive therapy, have had a relapse of their underlying disease, or have GVHD) and who have not yet received a current influenza vaccination, should be vaccinated against influenza immediately (BIII). Additionally, to allow sufficient time for the patient to experience an immunologic response to influenza vaccine, chemoprophylaxis with amantadine or rimantadine can be used for these HSCT recipients for 2 weeks after vaccination during a nosocomial or community influenza A outbreak (CIII). Influenza A chemoprophylaxis with amantadine or rimantadine has been recommended for all influenza A-exposed HSCT recipients <24 months after HSCT or ≥24 months after HSCT and substantially immunocompromised regardless of vaccination history, because of their likely suboptimal immunologic response to influenza vaccine (*142,143*). However, no recommendation regarding such chemoprophylaxis can be made because of lack of data.

To prevent severe disease, early preemptive therapy with amantadine or rimantadine has been reported for HSCT recipients with unexplained acute URI or LRI symptoms during a community or nosocomial outbreak of influenza A (*141*). However, the effectiveness in preventing influenza-related complications and the safety of this strategy have not been evaluated among HSCT recipients. Therefore, data are insufficient to make a recommendation.

Neuroaminidase inhibitors (zanimivir and oseltamivir), intravenous and aerosol ribavirin, and combination drug therapy (e.g., rimantadine or amantadine with ribavirin or interferon) (*143,150–153*) have been proposed for investigational, preemptive treatment to prevent severe influenza disease among HSCT recipients. However, because of lack of data, no recommendation for use of these strategies among HSCT recipients can be made.

Recommendations Regarding RSV. Respiratory secretions of any hospitalized HSCT candidate or recipient who experiences signs or symptoms of CRV infection should be tested promptly by viral culture and rapid diagnostic tests for RSV (BIII). If two diagnostic samples taken ≥2 days apart do not identify a respiratory pathogen despite persistence

of respiratory symptoms, BAL and further testing are advised (BIII). This testing is critical because of the high morbidity and case fatality of RSV disease among HSCT recipients (*154,155*). HSCT recipients, particularly those who are preengraftment and at highest risk for severe RSV pneumonia, should have their illness diagnosed early (i.e., during RSV URI), and their illness should be treated aggressively to prevent fatal RSV disease (BIII).

Although a definitive, uniformly effective preemptive therapy for RSV infection among HSCT recipients has not been identified, certain strategies have been proposed, including use of aerosolized ribavirin (*155,156*), RSV antibodies (i.e., passive immunization with high RSV-titered IVIG or RSV immunoglobulin) in combination with aerosolized ribavirin (*137,157*), and RSV monoclonal antibody (*158*). Clinical trials are currently underway to evaluate the efficacy of these strategies. No recommendation regarding the optimal method for RSV prevention and preemptive therapy can be made because of limited data. Further, current data do not support use of intravenous ribavirin for preemptive therapy for RSV pneumonia among HSCT recipients (*60*) (DIII), and no commercially licensed vaccines against RSV are currently available.

Recommendations Regarding Parainfluenza Virus and Adenovirus. Immunoprophylaxis, chemoprophylaxis, and preemptive treatment for parainfluenza virus and adenovirus infections among HSCT recipients have been proposed (*159,160*). However, no recommendation can be made in these guidelines because of insufficient data. No commercially licensed vaccines against parainfluenza or adenovirus are currently available.

Other Disease Prevention Recommendations

The recommendations for preventing CRV infections and their recurrence are the same for allogeneic or autologous recipients. Generally, these recommendations apply to children or adults (*161–164*), but with appropriate adjustments in antiviral drug and influenza vaccine doses for children (Appendix).

For pediatric HSCT recipients and candidates aged >6 months, annual seasonal influenza vaccination is recommended HSCT (BIII). Children aged <9 years who are receiving influenza vaccination for the first time require two doses administered ≥1 months apart (AI). Healthy children who receive influenza vaccination for the first time might not generate protective antibodies until 2 weeks after receipt of the second dose of influenza vaccine. Therefore, during an influenza A outbreak, pediatric recipients aged <9 years, ≥6 months after HSCT, and receiving their first influenza vaccination, should be administered ≥6 weeks of influenza A chemoprophylaxis after the first dose of influenza vaccine (*141*) (BIII) (Appendix). Amantadine and rimantadine are not FDA-approved for children aged <1 year (*141,161*) (DIII).

To prevent RSV disease, researchers report substituting RSV-IVIG for IVIG during RSV season (i.e., November–April) for pediatric recipients (i.e., children aged <18 years) who receive routine IVIG therapy (*164*) (i.e., those with hypogammaglobulinemia) (CIII) (Appendix). Other researchers report that pediatric recipients with RSV can be considered for preemptive therapy (e.g., during URI or early LRI) with aerosolized ribavirin (CIII), although this therapy remains controversial (*164*) (Appendix). Droplet and contact precautions for the duration of illness are required for pediatric recipients for the duration of adenovirus (*62*) (AIII).

FUNGAL INFECTIONS

General Recommendations

Preventing Exposure

Limited data were found that demonstrate to what extent preventing fungal exposures is effective in preventing infection and disease. However, HSCT recipients and candidates undergoing conditioning therapy have been advised to avoid contact with certain areas and substances, including foods, that might increase a patient's risk for fungal exposures (CII). Specific precautions have included avoiding areas of high dust exposure (e.g., excavation sites, areas of building construction or renovation, chicken coops, and caves), occupations involving soil, and foods that contain molds (e.g., blue cheese).

Preventing Disease

Growth factors (e.g., GM-CSF and G-CSF) shorten the duration of neutropenia after HSCT (*165*); however, no data were found that indicate which growth factors effectively reduce the attack rate of invasive fungal disease. Therefore, no recommendation for use of growth factors solely for prophylaxis against invasive fungal disease can be made.

Topical antifungal drugs, which are applied to the skin or mucosa (e.g., nystatin or clotrimazole), might reduce fungal colonization in the area of application. However, these agents have not been proven to prevent generation of locally invasive or disseminated yeast infections (e.g., candidiasis) or mold infections (e.g., aspergillosis) and are not recommended for their prophylaxis (DII). Performing fungal surveillance cultures is not indicated for asymptomatic HSCT recipients (*166,167*) (DII), but cultures should be obtained from symptomatic HSCT recipients (BIII).

Recommendations Regarding Yeast Infections

Preventing Exposure

Invasive candidiasis is usually caused by dissemination of endogenous *Candida* species that have colonized a patient's gastrointestinal tract (*168*). Consequently, methods of preventing exogenous yeast exposure usually do not prevent invasive yeast infections after HSCT. However, because *Candida* species can be carried on the hands, HCWs and others in contact with HSCT recipients should follow appropriate hand-washing practices to safeguard patients from exposure (AIII).

Preventing Disease

Allogeneic recipients should be administered fluconazole prophylaxis to prevent invasive disease with fluconazole-susceptible *Candida* species during neutropenia, particularly among centers where *Can. albicans* is the predominant cause of invasive fungal disease preengraftment (AI) (Appendix). Because candidiasis occurs during phase I (*169*), fluconazole (400 mg/day by mouth or intravenously) should be administered (*169,170*) from the day of HSCT until engraftment (AII). However, fluconazole is not effective against

certain *Candida* species, including *Can. krusei* (*171*) and *Can. glabrata* and is, therefore, not recommended for their prevention (DI). Further studies are needed to determine the optimal duration of fluconazole prophylaxis. Preliminary studies have reported that low-dose fluconazole prophylaxis (100–200 mg/day by mouth) among neutropenic patients has variable efficacy in preventing candidiasis (*172*). Therefore, this therapy is not recommended for HSCT recipients (DII). Oral, nonabsorbable antifungal drugs, including oral amphotericin B (500 mg suspension every 6 hours), nystatin, and clotrimazole troches, might reduce superficial colonization and control local mucosal candidiasis, but have not been demonstrated to reduce invasive candidiasis (CIII).

Other Recommendations

HSCT candidates with candidemia or invasive candidiasis can safely receive transplants (*173*) if a) their infection was diagnosed early and treated immediately and aggressively with amphotericin B or alternatively with appropriate doses of fluconazole if the organism is susceptible; and b) evidence of disease control is reported (e.g., by serial computed tomography scans) before the transplant (BIII). Such patients should continue receiving therapeutic doses of an appropriate antifungal drug throughout phase I (BII) and until a careful review of clinical, laboratory, and serial computed tomography scans verifies resolution of candidiasis (BII).

Because autologous recipients generally have an overall lower risk for invasive fungal infection than allogeneic recipients, certain autologous recipients do not require routine antiyeast prophylaxis (DIII). However, researchers recommend administering antiyeast prophylaxis to a subpopulation of autologous recipients with underlying hematologic malignancies (e.g., lymphoma or leukemia) and who have or will have prolonged neutropenia and mucosal damage from intense conditioning regimens or graft manipulation, or have received fludarabine or 2-CDA recently (BIII). Recommendations regarding preventing invasive yeast infections among pediatric or adult HSCT recipients are the same, except that appropriate dose adjustments for prophylactic drugs should be made for pediatric recipients (Appendix).

Recommendations Regarding Mold Infections

Preventing Exposure

Nosocomial mold infections among HSCT recipients result primarily from respiratory exposure to and direct contact with fungal spores (*174*). Ongoing hospital construction and renovation have been associated with an increased risk for nosocomial mold infection, particularly aspergillosis, among severely immunocompromised patients (*175–177*). Therefore, whenever possible, HSCT recipients who remain immunocompromised should avoid hospital construction or renovation areas (AIII). When constructing new HSCT centers or renovating old ones, hospital planners should ensure that rooms for HSCT patients have an adequate capacity to minimize fungal spore counts through use of

- high-efficiency (>90%) particulate air (HEPA) filtration (*140,178,179*) (BIII);
- directed room airflow (i.e., positive air pressure in patient rooms in relation to corridor air pressure) so that air from patient rooms flows into the corridor (*180*) (BIII);

- correctly sealed rooms, including correctly sealed windows and electrical outlets (*140*) (BIII);
- high rates of room air exchange (i.e., >12 air changes/hour) (*140,178*) (BIII); and
- barriers between patient care and renovation or construction areas (e.g., sealed plastic) that prevent dust from entering patient care areas and that are impermeable to *Aspergillus* species (*175,179*) (BIII).

Additionally, HSCT centers should be cleaned with care, particularly after hospital renovation or construction, to avoid exposing HSCT recipients and candidates to mold spores (*174,176*) (BIII).

Preventing Disease

No regimen has been reported to be clearly effective or superior in preventing aspergillosis, and therefore, no recommendation can be made. Further studies are needed to determine the optimal strategy for aspergillosis prevention. Moderate-dose (0.5 mg/kg/day) amphotericin B (*181–184*), low-dose (0.1–0.25 mg/kg/day) amphotericin B (*185–187*), intranasal amphotericin B spray (*188*), lipid formulations of amphotericin B (*182,189*), and aerosolized amphotericin B (*190*) have been administered for aspergillosis prophylaxis, but data are limited regarding the safety and efficacy of these formulations among HSCT recipients. Additionally, itraconazole capsules are not recommended for fungal prophylaxis among HSCT recipients (*191*) (DII) for three reasons. First, itraconazole capsules are poorly absorbed gastrointestinally, particularly among patients who are fasting (*192*) or receiving cytotoxic agents (*193*). Second, persons taking itraconazole capsules do not achieve steady-state serum levels for 2 weeks (*188,194*), and when achieved, these levels are lower than the average *Aspergillus* species minimum inhibitory concentration (MIC) among HSCT recipients (*195*). Third, itraconazole has adverse interactions with other drugs (e.g., antiepileptics, rifampin, oral hypoglycemics, protease inhibitors, vinca alkaloids, cyclosporine, methylprednisolone, and warfarin-like anticoagulants) (*196*). Trials assessing the efficacy of the recently licensed cyclodextrin oral solution and intravenous formulations of itraconazole in preventing invasive fungal disease among HSCT recipients are in progress; however, no recommendations regarding its use for *Aspergillus* species infection prophylaxis can be made. For HSCT recipients whose respiratory specimens are culture positive for *Aspergillus* species, acute invasive aspergillosis should be diagnosed presumptively (*197*) and treated preemptively and aggressively (e.g., with intravenous amphotericin) (AIII).

The risk for aspergillosis recurrence has been high among allogeneic recipients with preexisting invasive aspergillosis. Previously, allogeneic HSCTs were avoided among persons with uncontrolled, proven aspergillosis. However, HSCT center personnel have recently reported successful allogeneic or autologous HSCT among a limited number of persons who have had successfully treated, prior invasive pulmonary aspergillosis (*198–200*). Because of limited data, no recommendations regarding strategies for preventing aspergillosis recurrence can be made.

PROTOZOAL AND HELMINTHIC INFECTIONS

Recommendations Regarding PCP

Preventing Exposure

Although a possible cause of PCP is reactivation of latent infection among immunocompromised persons, cases of person-to-person transmission of PCP have been reported (*201–206*). Generally, standard precautions should be used for patients with PCP (*62*) (BIII), but researchers have reported patients with PCP being isolated (*201,204*) and contact precautions being used if evidence existed of person-to-person transmission in the institution (CIII). This subject remains controversial, and until further data are published, HSCT recipients should avoid exposure to persons with PCP (*62*) (CIII).

Preventing Disease and Disease Recurrence

Physicians should prescribe PCP prophylaxis for allogeneic recipients throughout all periods of immunocompromise (*207*) after engraftment. Prophylaxis should be administered from engraftment until 6 months after HSCT (AII) for all patients, and >6 months after HSCT for the duration of immunosuppression for those who a) are receiving immunosuppressive therapy (e.g. prednisone or cyclosporine) (AI), or b) have chronic GVHD (BII). However, PCP prophylaxis can be initiated before engraftment if engraftment is delayed (CIII). Researchers report an additional 1- to 2-week course of PCP prophylaxis before HSCT (i.e., day –14 to day –2) (CIII).

Preferred PCP prophylaxis is TMP-SMZ (AII); however, if TMP-SMZ is administered before engraftment, the associated myelosuppression could delay engraftment, and patients might experience sensitivity to the drug. Every effort should be made to keep such patients on the drug, including assessment of desensitization therapy, although data regarding this technique among HSCT recipients are limited. For patients who cannot tolerate TMP-SMZ, physicians can choose to use alternative PCP prophylaxis regimens (e.g., dapsone) (*208*) (BIII). Use of aerosolized pentamidine (*209*) is associated with the lowest PCP prevention rates and should only be used if other agents cannot be tolerated. Atovaquone is a possible alternative drug for PCP prophylaxis among dapsone-intolerant persons with HIV infection (*210*); however, no recommendation regarding use of atovaquone among HSCT recipients can be made because of lack of data. Although data are limited, concomitant use of leucovorin (folinic acid) and TMP-SMZ is not recommended (*211,212*) (DIII). A patient's history of PCP should not be regarded as a contraindication to HSCT (*213*) (DIII).

Recurrent PCP among HSCT recipients is rare; however, patients with continued immunosuppression should remain on PCP prophylaxis until their immunosuppression is resolved (AI). The regimen recommended for preventing toxoplasmosis recurrence among HSCT recipients (i.e., TMP-SMZ) will also prevent PCP recurrence.

Other Recommendations

PCP prophylaxis should be considered for autologous recipients who have underlying hematologic malignancies (i.e., lymphoma or leukemia), are receiving intense conditioning regimens or graft manipulation, or have recently received fludarabine or 2-CDA

(*207,214*) (BIII). PCP prophylaxis should be administered ≥6 months after HSCT if substantial immunosuppression or immunosuppressive therapy (e.g., steroids) persists (CIII). Use of PCP prophylaxis among other autologous recipients is controversial (CIII). Generally, indications for PCP prophylaxis are the same among children or adults, but pediatric doses should be used (Appendix).

Recommendations Regarding *Toxoplasma gondii*

Preventing Exposure

All HSCT recipients should be provided information regarding strategies to reduce their risk for *Toxoplasma* species exposure. Researchers report that potential donors for allogeneic HSCT be tested for *To. gondii* antibodies (*215,216*) by using FDA-licensed or -approved screening tests that include IgG antibody testing because *To. gondii* has been reported to be transmitted by leukocyte transfusion (*217*) and HSCT (*218,219*) (CIII).

Preventing Disease and Disease Recurrence

Because most toxoplasmosis among HSCT recipients is caused by disease reactivation, researchers report that candidates for allogeneic HSCT can be tested for IgG antibody to determine whether they are at risk for disease reactivation after HSCT (*215,216,218*) (CIII). However, the value of such testing is controversial because a limited number of patients who were seronegative for *To. gondii* pretransplant experienced the infection posttransplant (*220*). If testing is performed, only FDA-licensed or -approved screening tests should be used.

Researchers recommend toxoplasmosis prophylaxis for seropositive allogeneic recipients with active GVHD or a prior history of toxoplasmic chorioretinitis (*221,222*), but data demonstrating efficacy are limited (CIII). The optimal prophylactic regimen for toxoplasmosis among HSCT recipients has not been determined, but a proposed drug is TMP-SMZ (BII), although allogeneic recipients have experienced break-through clinical disease despite TMP-SMZ prophylaxis (*218*). For patients who are TMP-SMZ–intolerant, a combination of clindamycin, pyramethamine, and leucovorin can be substituted for *To. gondii* prophylaxis (Appendix). After therapy for toxoplasmosis, HSCT recipients should continue receiving suppressive doses of TMP-SMZ or an alternate regimen for the duration of their immunosuppression (BIII) (Appendix).

Other Recommendations

Recipients of autologous transplants are at negligible risk for toxoplasmosis reactivation (*218*). No prophylaxis or screening for toxoplasmosis infection is recommended for such patients (DIII). Indications for toxoplasmosis prophylaxis are the same among children or adults, but pediatric doses should be used among children (Appendix).

Recommendations Regarding *Strongyloides stercoralis*

Preventing Exposure

Allogeneic recipients should avoid contact with outhouses and cutaneous exposure to soil or other surfaces that might be contaminated with human feces (*223*) (AIII). Allogeneic recipients who work in settings (e.g., hospitals or institutions) where they could be

exposed to fecal matter should wear gloves when working with patients or in areas with potential fecal contamination (AIII).

Preventing Disease and Disease Recurrence

Travel and residence histories should be obtained for all patients before HSCT to determine any exposures to high-risk areas (e.g., such moist temperate areas as the tropics, subtropics, or the southeastern United States and Europe) (*223*) (BIII). HSCT candidates who have unexplained peripheral eosinophilia or who have resided in or traveled to areas endemic for strongyloidiasis, even during the distant past, should be screened for asymptomatic strongyloidiasis before HSCT (BIII). Serologic testing with an enzyme-linked immunosorbent assay is the preferred screening method and has a sensitivity and specificity of >90% (*223,224*) (BIII). FDA-licensed or -approved screening tests should be used. Although stool examinations for strongyloidiasis are specific, the sensitivity obtained from ≥3 stool examinations is 60%–70%; the sensitivity obtained from concentrated stool exams is, at best, 80% (*223*). A total of ≥3 stool examinations should be performed if serologic tests are unavailable or if strongyloidiasis is clinically suspected in a seronegative patient (BIII).

HSCT candidates whose screening tests before HSCT are positive for *Strongyloides* species, and those with an unexplained eosinophilia and a travel or residence history indicative of exposure to *Strongyloides stercoralis* should be empirically treated before transplantation (*225,226*), preferably with ivermectin (BIII), even if seronegative or stool-negative (Appendix).

To prevent recurrence among HSCT candidates with parasitologically confirmed strongyloidiasis, cure after therapy should be verified with ≥3 consecutive negative stool examinations before proceeding with HSCT (AIII). Data are insufficient to recommend a drug prophylaxis regimen after HSCT to prevent recurrence of strongyloidiasis. HSCT recipients who had strongyloidiasis before or after HSCT should be monitored carefully for signs and symptoms of recurrent infection for 6 months after treatment (BIII).

Other Recommendations

Hyperinfection strongyloidiasis has not been reported after autologous HSCT; however, the same screening precautions should be used among autologous recipients (BIII). Indications for empiric treatment for strongyloidiasis before HSCT are the same among children or adults except for children weighing <15 kg, for whom the preferred drug is thiabendazole (BIII) (Appendix).

Recommendations Regarding *Trypanosoma cruzi*

Preventing Exposure

HSCT physicians should be aware that *Trypanosoma cruzi*, the etiologic agent of Chagas' disease, can be transmitted congenitally, through blood transfusion (*227*), and possibly through HSCT. Additionally, treatment for persons infected with *Tr. cruzi* is not always effective, even during the acute stage of infection (*227*). Therefore, potential donors who were born, received a blood transfusion, or ever lived for ≥6 months in a Chagas' disease endemic area (e.g., parts of South and Central America and Mexico) should be screened serologically for anti-*Tr. cruzi* serum IgG antibody (*228*) (BIII). Persons who lived <6 months in a Chagas'-endemic area but who had high-risk living

conditions (e.g., having had extensive exposure to the Chagas' disease vector — the reduviid bug — or having lived in dwellings with mud walls, unmilled logs and sticks, or a thatched roof) should also be screened for evidence of *Tr. cruzi* infection (BIII). Because Chagas' disease can be transmitted congenitally, researchers report that any person with extensive multigenerational maternal family histories of cardiac disease (e.g., cardiomegaly and arrhythmias) should be screened serologically for serum IgG anti-*Tr. cruzi* antibodies (*227*) (CIII). To decrease the risk for misdiagnosis by false-positive or false-negative serologic tests, *Tr. cruzi* screening should consist of ≥2 conventional serologic tests (e.g., enzyme immunoassay, indirect hemagglutination, indirect fluorescent antibody) or ≥1 conventional serologic tests, followed by a confirmatory serologic test (e.g., radioimmunoprecipitation assay) (*229*) (BIII). Persons with active Chagas' disease should not serve as HSCT donors (DIII). Researchers also recommend deferral of HSCT donation for a past history of Chagas' disease (CIII).

Preventing Disease

HSCT candidates who are at risk for being infected with *Tr. cruzi* should be screened for serum IgG anti-*Tr. cruzi* antibody (*228*) (BIII). *Tr. cruzi* seropositivity is not a contraindication to HSCT (*228,230*). However, if an acute illness occurs in a *Tr. cruzi*-seropositive HSCT recipient, particularly during neutropenia, *Tr. cruzi* reactivation should be included in the differential diagnosis (*230*) (BIII). Researchers have proposed use of beznidazole or nifurtimox for preemptive therapy or prophylaxis of recurrent *Tr. cruzi* among seropositive HSCT recipients (*230,231*), but insufficient data were found to make a recommendation.*

Other Recommendations

Recommendations are the same for autologous or allogeneic recipients. However, recurrence of Chagas' disease is probably less likely to occur among autologous recipients because of the shorter duration of immunosuppression. Recommendations are the same among children or adults.

HOSPITAL INFECTION CONTROL

Room Ventilation

HSCT center personnel should follow published guidelines for hospital room design and ventilation (*140,180*) (BIII). HSCT centers should also prevent birds from gaining access to hospital air-intake ducts (*140,174*) (AII). All allogeneic recipients should be placed in rooms with >12 air exchanges/hour (*232,233*) and point-of-use HEPA filters that are capable of removing particles ≥0.3 µm in diameter (*140,178,180,233*) (AIII). Correct filtration is critical in HSCT centers with ongoing construction and renovation (*179*). When portable HEPA filters are used as adjuncts to the primary ventilation system, they must be placed centrally in patient rooms so that space is available around all surfaces to allow free air circulation (BIII). The need for environmental HEPA filtration for autologous recipients has not been established. However, HEPA-filtered rooms should

*For additional information regarding the epidemiology of Chagas' disease, contact CDC/National Center for Infectious Diseases/Division of Parasitic Diseases, (770) 488-7760.

be evaluated for autologous recipients if they experience prolonged neutropenia, a substantial risk factor for nosocomial aspergillosis (CIII).

A laminar air flow (LAF) room contains filtered air that moves in parallel, unidirectional flow — the air enters the room from one wall and exits the room on the opposite wall (*232*). Although LAF has been demonstrated to protect patients from infection during aspergillosis outbreaks related to hospital construction (*234,235*), the value of routine LAF room use for all HSCT recipients is doubtful because substantial overall survival benefit has not been reported (*236*). During 1983, LAF rooms were preferred for allogeneic recipients with aplastic anemia and HLA-identical sibling donors because use of regular rooms was associated with a mortality rate that was approximately four times higher than for those recipients treated in LAF rooms (*237*). However, the survival of aplastic anemia HSCT recipients during the late 1990s exceeds that reported during the early 1980s, and no studies have been done to determine whether HSCT recipients with aplastic anemia still have an improved survival rate when treated in an LAF room. Therefore, HSCT centers need not construct LAF rooms for each HSCT recipient. Use of LAF rooms, if available, is optional (CII).

Hospital rooms should have directed airflow so that air intake occurs at one side of the room and air exhaust occurs at the opposite side (*140*) (BIII). Each hospital room should also be well-sealed (e.g, around windows and electrical outlets) (*140*) (BIII). To provide consistent positive pressure in the recipient's room, HSCT centers should maintain consistent pressure differentials between the patient's room and the hallway or anteroom at >2.5 Pa (i.e., 0.01 inches by water gauge) (*232,233*) (BIII). Generally, hospital rooms for HSCT recipients should have positive room air pressure when compared with any adjoining hallways, toilets, and anterooms, if present.

Anterooms should have positive air pressure compared with hallways (*180*). An exception is the HSCT recipient with an active disease that has airborne transmission (e.g., pulmonary or laryngeal *Mycobacteria tuberculosis* [TB] or measles). These HSCT patients should be placed in negative isolation rooms (*62*) (BIII), and a room with an anteroom is recommended for such patients (*180*) (BIII).

Whenever possible, HSCT centers should have self-closing doors to maintain constant pressure differentials among the HSCT recipients' room and anterooms, if available, and hallways (*233*) (BIII). To enable the nursing staff to observe the HSCT recipient even when the doors are closed, windows can be installed in either the door or the wall of the HSCT recipient's room (*233*) (CIII).

HSCT centers should provide backup emergency power and redundant air-handling and pressurization systems to maintain a constant number of air exchanges and room pressurization in the center when the central ventilation system is shut off for maintenance and repair (*238*) (BIII). Additionally, infection control personnel should work with maintenance personnel to develop protocols to protect HSCT centers at all times from bursts of mold spores that might occur when air-handling systems are restarted after routine maintenance shut-downs (BIII).

Construction, Renovation, and Building Cleaning

Construction and Renovation

Hospital construction and renovation have been associated with an increased risk for nosocomial fungal infection, particularly aspergillosis, among severely immunocompromised patients (*175,176*). Therefore, persons responsible for HSCT center

construction or renovation should consult published recommendations regarding environmental controls during construction (*239,240*) (AIII).

Whenever possible, HSCT recipients, HCWs, and visitors should avoid construction or renovation areas (*240*) (AIII). Also, equipment and supplies used by HSCT recipients or their HCWs should not be exposed to construction or renovation areas (*240*). When planning for construction or renovation, the HSCT center should include plans for intensified aspergillosis-control measures (AIII). Construction and renovation infection control planning committees should include engineers, architects, housekeeping staff, infection control personnel, the director of the HSCT center, the administration, and safety officers (*241*) (BIII).

When constructing new HSCT centers, planners should ensure that patient rooms will have adequate capacity to minimize fungal spore counts by following room ventilation recommendations. During outdoor construction and demolition, the intake air should be sealed (BIII), if possible; if not, filters should be checked frequently. Additionally, to protect HSCT patient care areas during fire drills and emergencies, weather stripping should be placed around stairwell doors, or alternatively, the stairwell air should be filtered to the level of safety of the adjacent hospital air (BIII). False ceilings should be avoided whenever possible (*174*) (BII). If use of false ceilings cannot be avoided, the area above false ceilings should be vacuumed routinely to minimize dust and, therefore, fungal exposure to patients (*174*) (BIII).

During hospital construction or renovation, hospitals should construct rigid, dustproof barriers with airtight seals (*242*) between patient care and construction or renovation areas to prevent dust from entering patient care areas; these barriers (i.e., sealed drywall) should be impermeable to *Aspergillus* species (*140,175,176,179,240*) (BIII). If impervious barriers cannot be created around the construction or renovation area, patients should be moved from the area until renovation or construction is complete and the area has been cleaned appropriately (*176*) (BIII). HSCT centers should direct pedestrian traffic occurring near construction or renovation areas away from patient care areas to limit the opening and closing of doors or other barriers that might cause dust dispersion, entry of contaminated air, or tracking of dust into patient areas (*140*), particularly those in the HSCT center (*176*) (BIII). If possible, specific corridors, entrances, and exits should be dedicated to construction use only (*240*). An elevator to which patients do not have access also should be dedicated to construction use only (*240*). Construction workers, whose clothing might be contaminated with *Aspergillus* species spores, should use the construction elevator and avoid contact with patients, patient care areas, other elevators, and nonconstruction areas (BIII).

Hospital construction or renovation areas should have negative air pressure relative to that in adjacent patient care areas, if no contraindications exist for such pressure differential (*140,176,179,240,242*) (BIII). Ideally, air from the construction or renovation areas should be exhausted to the outside of the hospital (*176*) (BIII) or if recirculated, it should be HEPA-filtered first (BIII).

Researchers have proposed that HSCT recipients wear the N95 respirator to prevent mold exposure during transportation near hospital construction or renovation areas (CIII) because the N95 respirators are regarded as effective against any aerosol. However, to be maximally effective, N95 respirators must be fit-tested and all users must be trained. With correct personnel fit-testing and training, N95 respirators reliably reduce aerosol exposure by 90%. Without fit-testing and training, aerosol exposure would be reduced but not necessarily by 90% (*243*). For patients who cannot use or tolerate an

N95 respirator, researchers have proposed using the powered air purifying respirator (*244,245*), which can be used by patients in wheelchairs. Limitations of the powered air purifying respirator include its cost and that it is not appropriate for young children and infants. General limitations of using respirators are that no commercially available respirator, including N95, has been tested specifically for its efficacy in reducing exposure to *Aspergillus* species in hospital construction or renovation areas, and no studies have been done that assess the usefulness and acceptability of using respirators among HSCT recipients. Standard surgical masks provide negligible protection against mold spores and are not recommended for this indication (DIII).

Newly constructed or renovated areas should be cleaned before patients are allowed to enter them (*140,176*) (AIII). Decontamination of fungal-contaminated areas that cannot be extracted and replaced should be done using copper-8-quinolate (*179*) (BIII). Also, areas above false ceilings located under or adjacent to construction areas should be vacuumed (*174*) (BIII). Additionally, the ventilation, direction of airflow, and room pressurization should be tested and correctly adjusted before patients are allowed to enter (BIII).

Cleaning

HSCT centers should be cleaned ≥1 times/day with special attention to dust control (BIII). Exhaust vents, window sills, and all horizontal surfaces should be cleaned with cloths and mop heads that have been premoistened with an FDA- or Environmental Protection Agency (EPA)-registered hospital disinfectant (BIII). Thorough cleaning during and after any construction activity, including minor renovation projects, is critical (BIII).

HSCT center personnel should prohibit exposures of patients to such activities as vacuuming or other floor or carpet vacuuming that could cause aerosolization of fungal spores (e.g., *Aspergillus* species) (*140*) (AIII). Accordingly, doors to patient rooms should be closed when vacuuming HSCT center corridors. All vacuum cleaners used in the HSCT center should be fitted with HEPA filters. An FDA- or EPA-registered disinfectant (*246,247*) should be used daily for environmental disinfection and when wet vacuuming is performed in the HSCT center (BIII). If an HSCT center provides care for infants, phenolic disinfectants can be used to clean the floors only if the compound is diluted according to the product label; but phenolic compounds should not be used to clean basinets or incubators (*246*) (DIII).

Water leaks should be cleaned up and repaired as soon as possible but within 72 hours to prevent mold proliferation in floor and wall coverings, ceiling tiles, and cabinetry in and around all HSCT patients care areas (BIII). If cleanup and repair are delayed ≥72 hours after the water leak, the involved materials should be assumed to contain fungi and handled accordingly. Use of a moisture meter to detect water penetration of walls should be used whenever possible to guide decision-making (*238*) (BIII). For example, if the wall does not have <20% moisture content ≥72 hours after water penetration, it should be removed (BIII). Design and selection of furnishings should focus on creating and maintaining a dust-free environment. Flooring and finishes (i.e., wall coverings, window shades, and countertops) used in HSCT centers should be scrubbable, nonporous, easily disinfected, and they should collect minimal dust (BIII).

Isolation and Barrier Precautions

HSCT center personnel should follow published guidelines for hospital isolation practices, including CDC guidelines for preventing nosocomial infections (*62,140,248*) (AIII).

However, the efficacy of specific isolation and barrier precautions in preventing nosocomial infections among HSCT recipients has not been evaluated.

HSCT recipients should be placed in private (i.e., single-patient) rooms (BIII). If contact with body fluids is anticipated, standard precautions should be followed (AIII). These precautions include hand washing and wearing appropriate gloves, surgical masks or eye and face protection, and gowns during procedures and activities that are likely to generate splashes or sprays of blood, body fluids, secretions or excretions, or cause soiling of clothing (*62*). When indicated, HSCT recipients should also be placed on airborne, droplet, or contact precautions in addition to standard precautions (*62*) (AIII). Careful observation of isolation precautions is critical in preventing transmission of infectious agents among HSCT recipients, HCWs, visitors, and other HSCT recipients. Physicians are cautioned that HSCT recipients might have a prolonged or episodic excretion of organisms (e.g., CMV).

Researchers have proposed that HSCT recipients wear surgical mask and gloves when exiting their hospital rooms before engraftment (CIII). All HSCT recipients who are immunocompromised (phases I–III of immune system recovery) and candidates undergoing conditioning therapy should minimize the time spent in crowded areas of the hospital (e.g., waiting areas and elevators) (BIII) to minimize potential exposure to persons with CRV infections.

Hand Hygiene

Hand washing is the single-most critical and effective procedure for preventing nosocomial infection (*62*). All persons, but particularly HCWs, should wash their hands before entering and after leaving the rooms of HSCT recipients and candidates undergoing conditioning therapy (*62,249*) or before and after any direct contact with patients regardless of whether they were soiled from the patient, environment, or objects (AI). HSCT recipients should be encouraged to practice safe hand hygiene (e.g., washing hands before eating, after using the toilet, and before and after touching a wound) (BIII). Hand washing should be done with an antimicrobial soap and water (AIII); alternatively, use of hygienic hand rubs is another acceptable means of maintaining hand hygiene (*250,251*). If gloves are worn, HCWs should put them on in the patient's room after hand washing and then discard them in the same patient's room before washing hands again after exiting the room. When worn, gloves should always be changed between patients or when soiled before touching a clean area (e.g., change gloves after touching the perineum and before going to a "clean" area) (AIII). Appropriate gloves should be used by all persons when handling potentially contaminated biological materials (AII). Items worn on the hands and fingers (e.g., rings or artificial nails [*248,252*]) and adhesive bandage strips, can create a nidus for pathogenic organisms that is difficult to clean. Thus, HCWs should avoid wearing such items whenever possible (BII).

Equipment

All HSCT center personnel should sterilize or disinfect and maintain equipment and devices using only EPA-registered compounds as directed by established guidelines (*140,180,246,247,253–256*) (AIII). HSCT center personnel should monitor opened and unopened wound-dressing supplies (e.g., adhesive bandages [*257,258*] and surgical and elastic adhesive tape [*259*]) to detect mold contamination and prevent subsequent cutaneous transmission to patients (BII).

Monitoring should consist of discarding all bandages and wound dressings that are out of date, have damaged packaging, or are visually contaminated by construction debris or moisture (BIII). When arm boards are used to provide support for intravenous lines, only sterile dressing materials should be used (*260*), and arm boards should be changed frequently (e.g., daily) (BIII). Additionally, unsterile tongue depressors inserted into a piece of foam tubing should not be used as splints for intravenous and arterial catheter sites because these have been associated with an outbreak of fatal invasive nosocomial *Rhizopus microsporus* among preterm (i.e., very low-birth–weight) infants (*261*) (DII). HSCT centers should not install carpeting in hallways outside (DII) or in patient rooms (DIII) because contaminated carpeting has been associated with outbreaks of aspergillosis among HSCT recipients (*262,263*).

Plants, Play Areas, and Toys

Although to date, exposure to plants and flowers has not been conclusively reported to cause fungal infections among HSCT recipients, most researchers strongly recommend that plants and dried or fresh flowers should not be allowed in the rooms of hospitalized HSCT candidates undergoing conditioning therapy and HSCT recipients (phases I–III of immune system recovery) because *Aspergillus* species have been isolated from the soil of potted ornamental plants (e.g., cacti), the surface of dried flower arrangements, and fresh flowers (*140,174,178,264*) (BIII).

Play areas for pediatric HSCT recipients and candidates undergoing conditioning therapy should be cleaned and disinfected ≥1 times/week and as needed (BIII). Only toys, games, and videos that can be kept clean and disinfected should be allowed in the HSCT center (BIII). HSCT centers should follow published recommendations for washing and disinfecting toys (*265*) (BIII). All HSCT center toys, games, and videos should be routinely and thoroughly washed or wiped down when brought into the HSCT center and thereafter ≥1 times/week and as needed by using a nontoxic FDA- or EPA-registered disinfectant (*246,247,265*) followed by a water rinse (BIII). Cloth or plush toys should be washed in a hot cycle of a washing machine or dry-cleaned ≥1 times/week and as needed (BIII). Alternatively, machine washing in a cold cycle is acceptable if laundry chemicals for cold water washing are used in proper concentration (*265*). Hard plastic toys should be scrubbed with warm soapy water using a brush to clean crevices, rinsed in clean water, immersed in a mild bleach solution, which should be made fresh daily, for 10–20 minutes, rinsed again, and allowed to air dry (*246*). Alternatively, hard plastic toys can be washed in a dishwasher or hot cycle of a washing machine (BIII). Broviac dolls* should be disassembled upon completion of play and washed with a nontoxic FDA- or EPA-registered disinfectant (*246,247*), rinsed with tap water, and allowed to air dry before other children are allowed to play with them (BIII). Toys that cannot be washed, disinfected, or dry-cleaned after use should be avoided (BIII). Infants, toddlers, and children who put toys in their mouths should not share toys (*265*) (DIII). For children in isolation, researchers recommend the following:

- Disposable play items should be offered whenever possible (BIII).
- Before returning a washable toy used in an isolation room to the pediatric play room for use by another child, it should be cleaned again as previously described (BIII).

*Broviac dolls are used to demonstrate medical procedures (e.g., insertion of catheters) to children to lessen their fears.

- When a child is taken out of isolation, toys, games, and videos used during the period of isolation and that might serve as fomites for infection should be thoroughly disinfected with a nontoxic FDA- or EPA-registered disinfectant (*246,247,265*) (BIII). After use in isolation rooms, cloth or plush toys should be placed in a plastic bag and separated from unused toys. All cloth or plush toys used in isolation rooms should be washed in a washing machine or dry-cleaned before being used in a nonisolation room (BIII). Toys that cannot be disinfected or dry-cleaned after use in an isolation room should be discarded (BIII).

Water-retaining bath toys have been associated with an outbreak of *Pseudomonas aeruginosa* in a pediatric oncology ward (*266*); therefore, these toys should not be used by immunocompromised HSCT recipients and candidates (DII). Occupational and physical therapy items should be cleaned and disinfected as previously described (BIII). Soil-based materials (e.g., clay or potting soil) should be avoided (BIII).

HCWs

HSCT center personnel should have a written comprehensive policy regarding their immunizations and vaccinations, and that policy should meet current CDC, Advisory Committee on Immunization Practices, and Healthcare Infection Control Practices Advisory Committee recommendations (*267*) (BIII). Immunizations are needed to prevent transmission of vaccine-preventable diseases to HSCT recipients and candidates undergoing conditioning therapy. All HCWs with diseases transmissible by air, droplet, and direct contact (e.g., VZV, infectious gastroenteritis, HSV lesions of lips or fingers, and URIs) should be restricted from patient contact and temporarily reassigned to other duties (AI). HSCT center personnel should follow published recommendations regarding the duration of work restrictions for HCWs with infectious diseases (*268,269*) (BIII). HSCT center HCWs with bloodborne viruses (e.g., HIV or hepatitis B or C viruses) should not be restricted from patient contact (DIII) as long as they do not perform procedures that pose a high risk for injury that could result in patient exposure to the HCW's blood or body fluids. Work exclusion policies should be designed to encourage HCWs to report their illnesses or exposures (AII).

HSCT Center Visitors

Hospitals should have written policies for screening HSCT center visitors, particularly children, for potentially infectious conditions. Such screening should be performed by clinically trained HCWs (BII). Visitors who might have communicable infectious diseases (e.g., URIs, flu-like illnesses, recent exposure to communicable diseases, an active shingles rash whether covered or not, a VZV-like rash within 6 weeks of receiving a live-attenuated VZV vaccine, or a history of receiving an oral polio vaccine within the previous 3–6 weeks) should not be allowed in the HSCT center or allowed to have direct contact with HSCT recipients or candidates undergoing conditioning therapy (AII). No absolute minimum age requirement for HSCT center visitors exists; however, all visitors must be able to understand and follow appropriate hand washing and isolation precautions (AIII). The number of HSCT center visitors at any one time should be restricted to a number that permits the nursing staff to perform appropriate screening for contagious diseases and adequate instruction and supervision of hand washing, glove and mask use, and biosafety precautions (BIII).

Patient Skin and Oral Care

To optimize skin care, HSCT recipients should take daily showers or baths during and after transplantation (BIII), using a mild soap (BIII). Skin care during neutropenia should also include daily inspection of skin sites likely to be portals of infection (e.g., the perineum and intravascular access sites) (BIII). HSCT recipients and candidates undergoing conditioning therapy should maintain good perineal hygiene to minimize loss of skin integrity and risk for infection (BIII). To facilitate this precaution, HSCT center personnel should develop protocols for patient perineal care, including recommendations for gentle but thorough perineal cleaning after each bowel movement and thorough drying of the perineum after each urination (BIII). Females should always wipe the perineum from front to back after using the toilet to prevent fecal contamination of the urethra and urinary tract infections (AIII). Moreover, to prevent vaginal irritation, menstruating immunocompromised HSCT recipients should not use tampons (DIII) to avoid the risk for cervical and vaginal abrasions. Additionally, the use of rectal thermometers, enemas, suppositories, and rectal exams are contraindicated among HSCT recipients to avoid skin or mucosal breakdown (DIII).

All HSCT candidates and their caregivers should be educated regarding the importance of maintaining good oral and dental hygiene for at least the first year after HSCT to reduce the risk for oral and dental infections (AIII). For example, HSCT candidates should be informed that establishment of the best possible periodontal health before HSCT is a substantial step in avoiding short- and long-term oral infections and that maintenance of safe oral hygiene after HSCT can minimize the severity of infections and facilitate healing of mucositis, particularly before engraftment (BIII).

All HSCT candidates should receive a dental evaluation and relevant treatment before conditioning therapy begins (*270,271*) (AIII). Likely sources of dental infection should be vigorously eliminated (*271*) (AIII). For example, teeth with moderate to severe caries should be restored; ill-fitting dental prostheses should be repaired; and teeth compromised by moderate to severe periodontal disease should be extracted (*271*). Ideally, 10–14 days should elapse between the completion of tissue-invasive oral procedures and onset of conditioning therapy to allow for adequate healing and monitoring for postsurgical complications (AIII).

HSCT recipients with mucositis and HSCT candidates undergoing conditioning therapy should maintain safe oral hygiene by performing oral rinses 4–6 times/day with sterile water, normal saline, or sodium bicarbonate solutions (*270*) (AIII). HSCT recipients and candidates should brush their teeth ≥2 times/day with a soft regular toothbrush (*270*) (BIII). If the recipient cannot tolerate these brushings, use of an ultrasoft toothbrush or toothette (i.e., foam swab on a stick), can be used (CIII), but physicians should be aware that using the latter products are less desirable than using soft regular or ultrasoft toothbrushes because the toothettes remove less dental debris (*270*). Using toothpaste is optional, depending on the recipient's tolerance (*270*) (CIII). HSCT recipients and candidates undergoing conditioning therapy who are skilled at dental flossing should floss daily if this can be done without trauma (BIII). Routine dental supervision is advised to monitor and guide the patient's maintenance of oral and dental hygiene (BIII). To decrease the risk for mechanical trauma and infection of oral mucosa, fixed orthodontic appliances and space maintainers should not be worn from the start of conditioning therapy until preengraftment mucositis resolves, and these devices should not be worn during any subsequent periods of mucositis (*270*) (DIII). Dental and transplant teams and

the patient's community dentist should coordinate removal of these appliances and long-term rehabilitation of any oral lesions (BIII). However, patients who normally wear removable dental prostheses might be able to wear them during conditioning therapy before HSCT and during mucositis after HSCT, depending on the degree of tissue integrity at the denture-bearing sites and the ability of the patient to maintain denture hygiene on a daily basis (CIII).

Preventing Bacterial Intravascular Catheter-Related Infections

HSCT center personnel are advised to implement published guidelines for preventing intravascular device-related infections (*33*) (AIII). Contact with tap water at the central venous catheter site should be avoided (BIII). For long-term central venous access among children, HSCT physicians can use a totally implantable device among children aged <4 years if the anticipated duration of vascular access is >30 days (CII). However, such a device among children aged <4 years is not generally used as the actual HSCT infusion site because a) problems with skin fragility contraindicate repeated punctures over the port site and b) the port device might have an insufficient number of lumens for optimal patient management immediately after HSCT.

To prevent bloodstream infections associated with needleless intravenous access devices, HSCT recipients should a) cover and protect the catheter tip or end cap during bathing or showering to protect it from tap water contamination, b) change the device in accordance with manufacturers' recommendations, if available, and c) have a caregiver perform intravenous infusions whenever possible (*272,273*) (BII). Also, HSCT recipients and their caregivers should be educated regarding proper care of needleless intravenous access devices (*272*) (BII). No recommendation regarding the use of antibiotic-impregnated central venous catheters among HSCT recipients can be made because of lack of data.

Control of Specific Nosocomial Infections

Recommendations Regarding Legionella *Species*

HSCT physicians should always include Legionnaires' disease (LD) in the differential diagnosis of pneumonia among HSCT recipients (*140*) (AIII). Appropriate tests to confirm LD include a) culturing sputum, BAL, and tissue specimens; b) testing BAL specimens for *Legionellae* by direct fluorescent antibody; and c) testing for *Legionella pneumophila* serogroup 1 antigen in urine. The incubation period for LD is usually 2–10 days; thus, laboratory-confirmed legionellosis that occurs in a patient who has been hospitalized continuously for ≥10 days before the onset of illness is regarded as a definite case of nosocomial LD, and a laboratory-confirmed infection that occurs 2–9 days after hospital admission is a possible case of nosocomial LD (*140*). When a case of laboratory-confirmed nosocomial LD (*274,275*) is identified in a person who was in the inpatient HSCT center during all or part of the 2–10 days before illness onset, or if two or more cases of laboratory-confirmed LD occur among patients who had visited an outpatient HSCT center, hospital personnel should

- report the case(s) to the local or state health department if the disease is reportable in that state or if assistance is needed (*140*) (AIII); and

- in consultation with the hospital infection control team, conduct a thorough epidemiologic and environmental investigation to determine the likely environmental source(s) of *Legionella* species (e.g., showers, tap water faucets, cooling towers, and hot water tanks) (*274,276*) (AI).

The source of *Legionella* infection should be identified and decontaminated or removed (AIII). Extensive hospital investigations of an isolated case of possible nosocomial LD might not be indicated if the patient has had limited contact with the inpatient center during most of the incubation period (CIII). Because HSCT recipients are at much higher risk for disease and death from legionellosis compared with other hospitalized persons (*274*), periodic routine culturing for *Legionellae* in water samples from the center's potable water supply could be regarded as part of an overall strategy for preventing LD in HSCT centers (CIII). However, the optimal methodology (i.e., frequency or number of sites) for environmental surveillance cultures in HSCT centers has not been determined, and the cost-effectiveness of this strategy has not been evaluated. Because HSCT recipients are at high risk for LD and no data were found to determine a safe concentration of *Legionellae* organisms in potable water, the goal, if environmental surveillance for *Legionellae* is undertaken, should be to maintain water systems with no detectable organisms (AIII). Physicians should suspect legionellosis among HSCT recipients with nosocomial pneumonia even when environmental surveillance cultures do not yield *Legionellae* (AIII). If *Legionella* species are detected in the water supplying an HSCT center, the following should be done until *Legionella* species are no longer detected by culture:

- The water supply should be decontaminated (*140*) (AII).
- HSCT recipients should be given sponge baths with water that is not contaminated with *Legionella* species (e.g., not with the HSCT center's *Legionella* species-contaminated potable water system) (BIII).
- Patients should not take showers in LD-contaminated water (DIII).
- Water from faucets containing LD-contaminated water should not be used in patient rooms or the HSCT center and outpatient clinic to avoid creating infectious aerosols (CIII).
- HSCT recipients should be given sterile water instead of tap water for drinking, brushing teeth, or flushing nasogastric tubes during Legionellosis outbreaks (BIII).

HSCT center personnel should use only sterile water (i.e., not distilled unsterile water) for rinsing nebulization devices and other semicritical respiratory-care equipment after cleaning or disinfecting and for filling reservoirs of nebulization devices (*140*) (BII). HSCT centers should not use large-volume room air humidifiers that create aerosols (e.g., by Venturi principle, ultrasound, or spinning disk) and, thus, are actually nebulizers (*140*) (DI) unless these humidifier or nebulizers are sterilized or subjected to daily high-level disinfection and filled with sterile water only (*140*) (CIII).

When a new hospital with an HSCT center is constructed, the cooling towers should be placed so that the tower drift is directed away from the hospital's air-intake system, and the cooling towers should be designed so that the volume of aerosol drift is minimized (*140*) (BII). For operational hospital cooling towers, hospitals should

- install drift eliminators,

- regularly use an effective biocide,
- maintain cooling towers according to the manufacturer's recommendations, and
- keep adequate maintenance records (*140*) (BII).

HSCT physicians are encouraged to consult published recommendations regarding preventing nosocomial Legionellosis (*140,277*) (BIII). No data were found to determine whether drinking tap water poses a risk for *Legionella* exposure among HSCT recipients in the absence of an outbreak.

Recommendations Regarding Methicillin-Resistant Sta. aureus

HSCT center HCWs should follow basic infection control practices (e.g., hand washing between patients and use of barrier precautions, including wearing gloves whenever entering the methicillin-resistant *Sta. aureus* [MRSA] infected or colonized patient's room); these practices are essential for MRSA control (*62*) (AII). If MRSA is a substantial problem in the HSCT center and evidence exists of ongoing MRSA transmission, MRSA infected or colonized patients should be treated as a cohort (e.g., cared for exclusively by a limited number of HCWs) (BIII). HSCT transplant recipients with recurrent *Sta. aureus* infections should undergo extensive evaluation for persistent colonization, including cultures of nares, groin, axilla, and ostomy sites (e.g., tracheostomy or gastrointestinal tube) (BIII). For patients with recurrent MRSA infection, elimination of the carrier state should be attempted by applying a 2% mupirocin calcium ointment to the nares (BIII), although this strategy has been only marginally effective in certain institutions (*278*) (Appendix). High-level mupirocin-resistant MRSA has been reported in Europe, the Middle East, and South America (*279–283*) but is uncommon in the United States. As with any antibiotic, incorrect or overuse of mupirocin can result in mupirocin-resistant *Staphylococci*; therefore, mupirocin use should be reserved for infection control strategies only (*279,280*). For patients who fail mupirocin, physicians have used bacitracin, TMP-SMZ, or rifampin administered with another antibiotic, but no standardized protocol using these drugs for this indication has been evaluated and no recommendations can be made because of lack of data. Selection of a systemic antibiotic should be guided by susceptibility patterns.

Intravascular cannulas or other implantable devices that are infected or colonized with MRSA should be removed (AIII). Patients with MRSA should be placed under contact precautions until all antibiotics are discontinued and until three consecutive cultures, taken ≥1 weeks apart, are negative (*62*) (BIII). Screening cultures for MRSA include the anterior nares, any body site previously positive for MRSA, and any wounds or surgical sites.

Recommendations Regarding Staphylococcus *Species with Reduced Susceptibility to Vancomycin*

All HSCT centers should have sufficient laboratory capability to identify all *Staphylococci* isolates and their susceptibility patterns to antibiotics, including vancomycin (*284,285*) (AIII). Additionally, all HSCT center personnel should conduct routine surveillance for the emergence of *Staphylococcus* species strains with reduced susceptibility to vancomycin (*285,286*) (AIII). Reduced susceptibility should be considered for all *Sta. aureus* strains that have a vancomycin MIC of ≥4 µg/mL and all coagulase-negative

Staphylococci that have a vancomycin MIC of ≥8 µg/mL. If repeat testing of the organism in pure culture confirms the genus, species, and elevated vancomycin MICs, the following steps should be taken (*287*):

- The laboratory should immediately contact hospital infection control personnel, the patient's clinical center, and the patient's attending physician, as well as the local or state health department, and CDC's Hospital Infections Program Help Desk ([404] 639-6106 or [800] 893-0485) (*284,285,287,288*) (AIII).
- The HSCT center's infection control personnel, in collaboration with appropriate authorities (i.e., state and local health departments and CDC) should promptly initiate an epidemiologic and laboratory investigation (*287,288*) (AIII) and follow published guidelines for the control of such species (*285,287,288*) (BIII).
- Medical and nursing staff should
  - — institute contact precautions (e.g., wearing of gown and gloves, using antibacterial soap for hand washing, and wearing masks when contamination of the HCW with secretions is likely) as recommended for multidrug-resistant organisms (*62,284,287*);
  - — minimize the number of persons with access to colonized or infected patients (*287*); and
  - — treat as a cohort colonized or infected patients (e.g., care for them exclusively with a limited number of HCWs) (*286,287*) (AIII).
- If a patient in an HSCT center is colonized or infected with *Staphylococci* that have reduced susceptibility to vancomycin, the infection control personnel should follow published guidelines for the control of such species (*285,287,288*) (BIII).

Avoiding overuse and misuse of antibiotics will decrease the emergence of *Staphylococcus* species with reduced susceptibility to vancomycin (*286,287*). Therefore, medical and ancillary staff members who are responsible for monitoring antimicrobial use patterns in the facility should routinely review vancomycin-use patterns (*284,285,287*) (AIII). Additionally, HSCT center personnel should institute prudent use of all antibiotics, particularly vancomycin, to prevent the emergence of *Staphylococcus* with reduced susceptibility to vancomycin (*284,285,287–289*) (AII). Intravascular cannulas or other implantable devices that are infected or colonized with *Staphylococcus* species strains with reduced susceptibility to vancomycin should be removed (AIII).

Recommendations Regarding VRE

Use of intravenous vancomycin is associated with VRE emergence. Vancomycin and all other antibiotics, particularly antianaerobic agents (e.g., metronidazole and third-generation cephalosporins) must be used judiciously (*284,290–292*) (AII). Oral vancomycin use can be limited by treating recurrences of *Cl. difficile* diarrhea with oral metronidazole instead of vancomycin (BIII). Physicians have placed patients with a history of VRE or VRE colonization into continuous isolation during clinic visits and hospitalizations; however, this practice is controversial because certain non-HSCT recipients might clear VRE from their stools. No recommendation regarding use of continuous

isolation among HSCT recipients can be made because of lack of data. To control VRE exposure, strict adherence to the following standard infection control measures is necessary (*292*) (AI):

- Wash hands with antibacterial soap before entering and after leaving HSCT recipients' rooms, particularly those who have VRE colonization or infection; alternatively, wash hands with a waterless antiseptic agent (e.g., an alcohol-based rinse or gel) (*250*).
- Whenever possible, treat as a cohort patients who are known to be colonized or infected with VRE (*290*).
- Disinfect patient rooms and equipment (*291,293*), including surfaces of the hospital ward environment (e.g., floors, walls, bed frames, doors, bathroom surfaces) with an FDA- or EPA-registered disinfectant (*246,247*). A nontoxic disinfectant should be used for pediatric areas (BIII).
- Place patients with VRE under contact precautions until all antibiotics are discontinued (CIII) and repeated cultures are negative (*62*) (BIII). HCWs should always wear gloves when in the VRE patient or carrier's room and discard gloves in the patient's room before exiting.

No evidence exists that treating VRE carriers is beneficial; therefore, chronic antibiotic treatment of carriers is not recommended (DIII). HSCT recipients and candidates should be screened for VRE colonization at the time of interfacility transfer to allow for immediate institution of appropriate infection control practices and to minimize transmission of VRE between and within facilities (*294*) (BII). However, the role of outpatient surveillance in VRE control is unknown; such surveillance is costly and should not be undertaken in nonoutbreak settings (DIII). A history of having resolved VRE bacteremia or being a VRE carrier are not contraindications to HSCT (BIII).

Recommendations Regarding Cl. difficile

HSCT physicians should follow published recommendations for preventing and controlling *Cl. difficile* disease, including minimizing the duration of antibiotic therapy and number of antibiotics used for any indication (*295,296*) (AIII). All patients with *Cl. difficile* disease should be placed under contact precautions for the duration of illness (*62*) (AII). All HCWs who anticipate contact with a *Cl. difficile*-infected patient or the patient's environment or possessions should put on gloves before entering the patient's room (*62,295–298*) and before handling the patient's secretions and excretions (AI). During *Cl. difficile* outbreaks, HSCT center personnel should restrict use of antibiotics (e.g., clindamycin) (*299*) (BII). To prevent transmission of *Cl. difficile* to patients during nosocomial *Cl. difficile* outbreaks, HSCT center HCWs should a) use disposable rectal thermometers or tympanic thermometers; b) disinfect gastrointestinal endoscopes with 2% glutaraldehyde immersion for 10 minutes or use an equivalent disinfectant strategy (*255,256*); and c) perform surface sterilization of the hospital ward environment (e.g., floors, walls, bed frames, doors, bathroom surfaces) with an FDA- or EPA-registered sterilant (e.g., phosphate-buffered sodium hypochlorite solution [1,660 ppm available chloride]; unbuffered hypochlorite solution [500 ppm available chloride]; 0.04% formaldehyde and 0.03% glutaraldehyde [*255,295,300*]; or ethylene oxide [*247,296*]) (BII). Additionally, physicians should treat patients with *Cl. difficile* disease with antibiotics as recommended in published reports (*62,295*) (BII).

Certain researchers also recommend antibiotic treatment of *Cl. difficile* carriers (*301*). However, other researchers have reported that treatment of asymptomatic *Cl. difficile* carriers with metronidazole is not effective and that treatment with vancomycin is only effective temporarily (i.e., <2 months after treatment) (*302*). Consequently, no recommendation regarding treatment of asymptomatic *Cl. difficile* carriers can be made. Similarly, although symptomatic *Cl. difficile* disease recurrence or relapse occurs among 7%–20% of patients (*295*), data are insufficient to make a recommendation for preventing multiple *Cl. difficile* relapses.

The following practices are not recommended for *Cl. difficile* control:

- routine stool surveillance cultures for *Cl. difficile* for asymptomatic patients or HCWs, even during outbreaks (DIII);
- culturing HCWs' hands for *Cl. difficile* (DIII); or
- treating patients presumptively for *Cl. difficile* disease pending toxin results (DIII), unless the patient is very sick with a compatible syndrome or the hospital has a high prevalence of *Cl. difficile* (CIII).

Prophylactic use of lyophilized *Saccharomyces boulardii* to reduce diarrhea among antibiotic recipients is not recommended because this therapy is not associated with a substantial reduction in diarrhea associated with *Cl. difficile* disease (*303*) and has been associated with *Saccharomyces boulardii* fungemia (*304*) (DII).

Recommendations Regarding CRV Infections

Physicians should institute appropriate precautions and infection control measures for preventing nosocomial pneumonia among hospitalized HSCT recipients and candidates undergoing conditioning therapy, particularly during community or nosocomial CRV outbreaks (*140*) (AIII). Patients with URI or LRI symptoms should be placed under a) contact precautions for most viral respiratory infections including varicella; b) droplet precautions for influenza or adenovirus; or c) airborne precautions for measles or varicella to avoid transmitting infection to other HSCT candidates and recipients as well as to HCWs and visitors (BIII). Identifying HSCT recipients with RSV infection and placing them under contact precautions immediately (AIII) to prevent nosocomial transmission is critical. When suctioning the respiratory tract of patients with URI or LRI symptoms, HCWs should wear gowns, surgical masks, and eye protection to avoid contamination from the patient's respiratory secretions. All protective clothing (e.g., gown, gloves, surgical mask, and eye protection) should be put on when entering a patient's room and discarded in the same room before exiting; protective clothing should always be changed between patient rooms (*140*) (AIII). When caring for an HSCT recipient or candidate undergoing conditioning therapy with URI or LRI, HCWs and visitors should change gloves and wash hands a) after contact with a patient; b) after handling respiratory secretions or objects contaminated with secretions from one patient and before contact with another patient, object, or environmental surface; and c) between contacts with a contaminated body site and the respiratory tract of or respiratory device used on the same patient (*140*) (AII). This practice is critical because most respiratory infections are usually transmitted by contact, particularly by hand to nose and eye. Therefore just wearing a mask, without appropriate hand washing, glove-wearing, or use of eye protection is insufficient to prevent transmission of CRV infections.

Researchers have proposed that HSCT recipients or candidates undergoing conditioning therapy be placed under contact precautions during nosocomial outbreaks (*131*) (CIII). Even when no nosocomial or community outbreak of CRV infections exists, all persons who enter the HSCT center should be screened daily for URI symptoms, including visitors and HCWs (BIII). Researchers also describe systems where HCWs provide daily verification (e.g., using sign-in sheets) that they are free of URI symptoms before being allowed to provide HSCT patient care. HCWs and visitors with URI symptoms should be restricted from contact with HSCT recipients and candidates undergoing conditioning therapy to minimize the risk for CRV transmission (*131*) (AIII). All HCWs with URI symptoms should be restricted from patient contact and reassigned to nonpatient care duties until the HCW's symptoms resolve (BIII). Visitors with URI symptoms should be asked to defer their visit to the HSCT center (*131*) until their URI symptoms resolve (BIII).

Respiratory secretions of any hospitalized HSCT candidate or recipient with signs or symptoms of CRV infection should be tested promptly by viral culture and rapid diagnostic tests for CRV (BIII). Appropriate samples include nasopharyngeal washes, swabs, aspirates, throat swabs, and BAL fluid. This practice is critical because preemptive treatment of certain CRVs (e.g., influenza and RSV) (*133*) might prevent severe disease and death among HSCT recipients. Viral shedding among HSCT recipients with CRV infection has been reported to last ≤4 months for influenza (*143*), ≤2 years for adenovirus (*305,306*), and ≤22 days for RSV (*136*); however, RSV viral shedding has been reported to last 112 days in a child with severe combined immunodeficiency (*307*). Therefore, to prevent nosocomial transmission of CRV (*136*), HSCT center HCWs should recognize that prolonged CRV shedding can occur when determining the duration of appropriate precautions for CRV-infected HSCT recipients or candidates undergoing conditioning therapy (CIII). HSCT centers should use serial testing by using cultures from nasopharyngeal swabs, throat swabs or aspirates, or rapid antigen tests to help determine whether patients have stopped shedding influenza virus (BIII). Researchers have proposed that HSCT physicians conduct routine CRV surveillance among HSCT recipients to detect outbreaks and implement infection control measures as early as possible (CIII). During RSV season, HSCT recipients and candidates with signs or symptoms should be tested for RSV infection (i.e., the presence of RSV antigen in respiratory secretions tested by enzyme-linked immunosorbent assay and viral culture) starting with admission to the HSCT center. All patients who are RSV-antigen positive should be treated as a cohort during nosocomial RSV outbreaks because this practice reduces nosocomial RSV transmission (*130,131*) (BII). Symptomatic HCWs should be excluded from patient contact until symptoms resolve. HCWs and visitors with infectious conjunctivitis should be restricted from direct patient contact until the drainage resolves (i.e., usually, 5–7 days for adenovirus) and the ophthalmology consultant concurs that the infection and inflammation have resolved (*268*) (AII) to avoid possible transmission of adenovirus to HSCT recipients.

Preventing CRV exposure among HSCT recipients after hospital discharge is more challenging because of high CRV prevalence. Preventive measures should be individualized in accordance with the immunologic status and tolerance of the patient. In outpatient waiting rooms, patients with CRV infections should be separated to the extent possible from other patients (BIII).

Recommendations Regarding TB

HSCT candidates should be screened for TB by careful medical history and chart review to ascertain any history of prior TB exposure (AIII) because immunocompromised persons have higher risk for progression from latent TB infection to active disease (*244*). Also, physicians can administer a tuberculin skin test (TST) using the Mantoux method with five tuberculin units of purified protein derivative (CIII); but because of a patient's immunocompromise, this test might not be reliable. If a TST is administered, either the Tubersol® or Aplisol® formulation of purified protein derivative can be used (*244,308*). Persons with a recently positive TST or a history of a positive TST and no prior preventive therapy should be administered a chest radiograph and evaluated for active TB (*309*) (AI). For immunocompromised persons, a positive TST is defined as ≥5 mm of induration (*309,310*) because of their decreased ability to mount a delayed hypersensitivity response (CIII). Because immunosuppressive therapy decreases the sensitivity of the TST, HSCT physicians should not rely solely on the TST to determine whether latent TB infection is present and whether preventive therapy should be administered to HSCT recipients or candidates (DIII). Instead, a full 9-month course of isonicotinic acid hydrazide preventive therapy should be administered to immunocompromised HSCT recipients or candidates who have been substantially exposed to someone with active, infectious (i.e., sputum-smear positive) pulmonary or laryngeal TB, regardless of the HSCT recipient's or candidate's TST status (*309*) (BIII). A full 9-month course of isonicotinic acid hydrazide preventive therapy should also be administered to HSCT recipients or candidates with a positive TST who were not previously treated and have no evidence of active TB disease (*309*) (AIII) (Appendix). Routine anergy screening might not be reliable among HSCT recipients and candidates undergoing conditioning therapy and, therefore, is not recommended (DIII). An HSCT should not be canceled or delayed because of a positive TST (DIII).

Use of a 2-month course of a daily pyrazinamide/rifampin (PZA/RIF) regimen has been recommended as an alternate preventive therapy for persons with TB (*309*). However, limited data were found regarding safety and efficacy of this regimen among non-HIV–infected persons. Furthermore, rifampin has substantial drug interactions with certain medications, including cyclosporine, tacrolimus (FK506), corticosteroids, fluconazole, and pain medications. Therefore, routine use of the 2-month PZA/RIF prophylactic regimen among HSCT recipients is not recommended (DIII). However, this regimen can be used for HSCT candidates who are not at risk for serious rifampin drug interactions and whose HSCT is not scheduled until ≥2 weeks after completion of the 2-month PZA/RIF course (CIII). This delay will diminish the possibility of adverse effects of rifampin on drugs used for routine HSCT OI prophylaxis (e.g., fluconazole) (*311*). An HSCT candidate or recipient who has been exposed to an active case of extrapulmonary, and therefore, noninfectious TB does not require preventive therapy (DIII).

HSCT center personnel should follow guidelines regarding the control of TB in healthcare facilities (*244,245*), including instituting airborne precautions and negative-pressure rooms for patients with suspected or confirmed pulmonary or laryngeal TB (*62,244*) (AII). HCWs should wear N95 respirators, even in isolation rooms, to protect themselves from possible TB transmission from patients with active pulmonary or laryngeal TB, particularly during cough-inducing procedures (*62,244,245,312*) (AIII). To be maximally effective, respirators (e.g., N95) must be fit-tested, and all respirator users

must be trained to use them correctly (*243*) (AIII). Unless they become soiled or damaged, changing N95 respirators between patient rooms is not necessary (DIII). Bacillus of Calmette and Guérin vaccination is contraindicated among HSCT candidates and recipients because it might cause disseminated or fatal disease among immunocompromised persons (*313,314*) (EII). No role has been identified for chronic suppressive therapy or follow-up surveillance cultures among HSCT recipients who have a history of successfully treated TB (DIII).

Infection Control Surveillance

HSCT center personnel are advised to follow standard guidelines for surveillance of antimicrobial use and nosocomial pathogens and their susceptibility patterns (*315*) (BIII). HSCT center personnel should not perform routine fungal or bacterial cultures of asymptomatic HSCT recipients (*166,167*) (DII). In the absence of epidemiologic clusters of infections, HSCT center personnel should not perform routine periodic bacterial surveillance cultures of the HSCT center environment or of equipment or devices used for respiratory therapy, pulmonary-function testing, or delivery of inhalation anesthesia (*140*) (DIII). Researchers recommend that hospitals perform routine sampling of air, ceiling tiles, ventilation ducts, and filters to test for molds, particularly when construction or renovation occurs near or around the rooms of immunocompromised patients (*167,174*) or when clinical surveillance demonstrates a possible increase in mold (i.e., aspergillosis) cases (CIII). Strategies that might decrease fungal spores in the ventilation system include eliminating access of birds (i.e., primarily pigeons) to air-intake systems, removing bird droppings from the air-intake ducts, and eliminating moss from the hospital roof (*174*). Furthermore, in the absence of a nosocomial fungal outbreak, HSCT centers need not perform routine fungal cultures of devices and dust in the rooms of HSCT recipients and candidates undergoing conditioning therapy (DIII). HSCT center personnel should routinely perform surveillance for the number of aspergillosis cases occurring among HSCT recipients, particularly during hospital construction or renovation (BIII). A two-fold or greater increase in the attack rate of aspergillosis during any 6-month period indicates that the HSCT center environment should be evaluated for breaks in infection control techniques and procedures and that the ventilation system should be investigated carefully (*174*) (BIII).

STRATEGIES FOR SAFE LIVING AFTER HSCT — PREVENTING EXPOSURE AND DISEASE

Avoiding Environmental Exposures

HSCT recipients and candidates undergoing conditioning therapy, particularly allogeneic recipients, and parents of pediatric HSCT recipients and candidates should be educated regarding strategies to avoid environmental exposures to opportunistic pathogens (AIII).

Preventing Infections Transmitted by Direct Contact

HSCT recipients and candidates should wash their hands thoroughly (i.e., with soap and water) and often. For example, hands should be washed

- before eating or preparing food;
- after changing diapers;
- after gardening or touching plants or dirt;
- after touching pets or animals;
- after touching secretions or excretions or items that might have had contact with human or animal stool (e.g., clothing, bedding, toilets, or bedpans);
- after going outdoors; and
- before and after touching wounds (*249*) (AIII).

Conscientious hand washing is critical during the first 6 months after HSCT and during other periods of substantial immunosuppression (e.g., GVHD, systemic steroid use, or relapse of the underlying disease for which the transplant was performed) (AIII). Pediatric HSCT recipients and candidates should be supervised by adults during hand washing to ensure thorough cleaning (*316*) (BIII). Hand washing should be performed with an antimicrobial soap and water (AIII); alternatively, use of hygienic hand rubs is an acceptable means of maintaining hand hygiene (*250,251*). HSCT recipients who visit or live on farms should follow published recommendations for preventing cryptosporidiosis (*5,316,317–319*) (BIII).

Preventing Respiratory Infections

To prevent respiratory infections after hospital discharge, HSCT recipients should observe the following precautions:

- Frequent and thorough hand washing is critical (BIII), but HSCT recipients should also avoid touching their mucus membranes, unless they have washed their hands first, to avoid inoculating themselves with CRV.
- HSCT recipients should avoid close contact with persons with respiratory illnesses (BIII). When close contact is unavoidable, those persons with respiratory illnesses should be encouraged to wash their hands frequently and to wear surgical masks or, at a minimum, smother their sneezes and coughs in disposable tissues. Alternatively, the HSCT recipient can wear a surgical mask (CIII).
- HSCT recipients should avoid crowded areas (e.g., shopping malls or public elevators) where close contact with persons with respiratory illnesses is likely (BIII).
- HSCT candidates or recipients should be advised that certain activities and occupations (e.g., work in health-care settings, prisons, jails, or homeless shelters) can increase their risk for TB exposure (BIII). In deciding whether a patient should continue activities in these settings, physicians should evaluate the patient's specific duties, the precautions used to prevent TB exposure in the workplace, and the prevalence of TB in the community. The decision to continue or terminate such activities should be made jointly between patient and physician (BIII). HSCT recipients should avoid exposure to persons with active tuberculosis, particularly during the first 6 months after HSCT and during other periods of substantial immunosuppression (e.g., GVHD, systemic steroid use, or relapse of the underlying disease for which the transplant was performed) (BIII).

Researchers report that allogeneic recipients should avoid construction or excavation sites or other dust-laden environments for the first 6 months after HSCT and during other periods of substantial immunosuppression (e.g., GVHD, systemic steroid use, or relapse of the underlying disease for which the transplant was performed) to avoid exposures to molds (CIII). Researchers also report that outpatient HSCT recipients should be advised of travel routes to the HSCT center that will avoid or minimize exposure to construction sites (CIII).

Coccidioidomycosis is uncommon after allogeneic HSCT; however, researchers report that HSCT recipients traveling to or residing in coccidioidomycosis-endemic areas (e.g., the American southwest, Mexico, and Central and South America) should avoid or minimize exposure to disturbed soil, including construction or excavation sites, areas with recent earthquakes, farms, or other rural areas (CIII). Histoplasmosis (*Histoplasma capsulatum*) after allogeneic HSCT is also rare; however, researchers report that HSCT recipients in histoplasmosis-endemic areas should avoid exposure to chicken coops and other bird-roosting sites and caves for the first 6 months after HSCT and during periods of substantial immunosuppression (e.g., GVHD, systemic steroid use, or relapse of the underlying disease for which the transplant was performed) (CIII).

Smoking tobacco and exposure to environmental tobacco smoke are risk factors for bacterial and CRV infections among healthy adults and children (*320–325*); consequently, logic dictates that physicians advise HSCT recipients not to smoke and to avoid exposure to environmental tobacco smoke (CIII). However, no data were found that specifically assess whether smoking or environmental smoke exposure are risk factors for OIs among HSCT recipients. Researchers have reported that marijuana smoking might be associated with generation of invasive pulmonary aspergillosis among immunocompromised persons, including HSCT recipients (*326–329*). Therefore, HSCT recipients should refrain from smoking marijuana to avoid *Aspergillus* species exposure (*326,330–334*) (BIII).

Preventing Infections Transmitted Through Direct Contact and Respiratory Transmission

Researchers have proposed that immunocompromised HSCT recipients and candidates who are undergoing conditioning therapy avoid gardening or direct contact with soil, plants, or their aerosols to reduce exposure to potential pathogens (e.g., *To. gondii*, *Hi. capsulatum*, *Cryptococcus neoformans*, *Nocardia* species, and *Aspergillus* species) (CIII). HSCT recipients, particularly allogeneic recipients, could wear gloves while gardening or touching plants or soil (*335*) (CIII), and they should avoid creating plant or soil aerosols (BIII). Additionally, they should always wash their hands afterwards (*335*) and care for skin abrasions or cuts sustained during soil or plant contact (AIII).

Persons whose occupations involve animal contact (e.g., veterinarians, pet store employees, farmers, or slaughterhouse workers) could be at increased risk for toxoplasmosis and other zoonotic diseases. Although data are insufficient to justify a general recommendation against HSCT recipients working in such settings, these exposures should be avoided during the first 6 months after HSCT and during other periods of substantial immunosuppression (e.g., GVHD, systemic steroid use, or relapse of the underlying disease for which the transplant was performed) (BIII).

Safe Sex

Sexually active HSCT recipients should avoid sexual practices that could result in oral exposure to feces (*5,316*) (AIII). Sexually active patients who are not in long-term

monogamous relationships should always use latex condoms during sexual contact to reduce their risk for exposure to CMV, HSV, HIV, hepatitis B and C, and other sexually transmitted pathogens (AII). However, even long-time monogamous partners can be discordant for these infections. Therefore, during periods of immunocompromise, sexually active HSCT recipients in such relationships should consider using latex condoms during sexual contact to reduce the risk for exposure to these sexually transmitted infections (CIII).

Pet Safety

Preventing Pet-Transmitted Zoonotic Infections

HSCT physicians should advise recipients and candidates undergoing conditioning therapy of the potential infection risks posed by pet ownership; however, they should not routinely advise HSCT recipients to part with their pets, with limited exceptions. Generally, immunocompromised HSCT recipients and candidates undergoing conditioning therapy should minimize direct contact with animals (*336,337*), particularly those animals that are ill (e.g., with diarrhea) (*335*) (BIII). Immunocompromised persons who choose to own pets should be more vigilant regarding maintenance of their pet's health than immunocompetent pet owners (BIII). This recommendation means seeking veterinary care for their pet early in the pet's illness to minimize the possible transmission of the pet's illness to the owner (*335*) (BIII). Feeding pets only high-quality commercial pet foods reduces the possibility of illness caused by spoiled or contaminated foods, thus reducing the possibility of transmitting illness from the pet to the HSCT recipient. If eggs, poultry, or meat products are given to the pet as supplements, they should be well-cooked. Any dairy products given to pets should be pasteurized (*335*) (BIII). Pets should be prevented from drinking toilet bowl water and from having access to garbage; pets should not scavenge, hunt, or eat other animals' feces (*335*) (BIII).

If HSCT recipients have contact with pets or animals, they should wash their hands after handling them (particularly before eating) and after cleaning cages; HSCT recipients should avoid contact with animal feces to reduce the risk for toxoplasmosis, cryptosporidiosis, salmonellosis, and campylobacteriosis (*335*) (BIII). Adults should supervise hand washing of pediatric HSCT recipients (BIII). Immunocompromised HSCT recipients and candidates should not clean pet litter boxes or cages or dispose of animal waste (DIII). If this cannot be avoided, patients should wear disposable gloves during such activities and wash their hands thoroughly afterwards (BIII). Immunocompromised HSCT recipients and candidates should avoid adopting ill or juvenile pets (e.g., aged <6 months for cats) (*335*) and any stray animals (*5,316*) (BIII). Any pet that experiences diarrhea should be checked by a veterinarian for infection with *Cryptosporidium* (*5,316*), *Giardia* species (*335*), *Salmonella*, and *Campylobacter* (*5,335,337*) (BIII).

Immunocompromised HSCT recipients and candidates should not have contact with reptiles (e.g., snakes, lizards, turtles, or iguanas) (DII) to reduce their risk for acquiring salmonellosis (*335,338–341*). Additionally, patients should be informed that salmonellosis can occur from fomite contact alone (*342*). Therefore, HSCT recipients and candidates should avoid contact with a reptile, its food, or anything that it has touched, and if such contact occurs, recipients and candidates should wash their hands thoroughly afterwards (AIII). Immunocompromised HSCT recipients and candidates should avoid contact with ducklings and chicks because of the risk for acquiring *Salmonella* or

Campylobacter species infections (*338,343*) (BIII). Immunocompromised HSCT recipients and candidates should avoid contact with exotic pets (e.g., nonhuman primates) (BIII). Bird cage linings should be cleaned regularly (e.g., daily) (*337*). All persons, but particularly immunocompromised HSCT candidates and recipients, should wear gloves whenever handling items contaminated with bird droppings (*337*) (BIII) because droppings can be a source of *Cryptococcus neoformans*, *Mycobacterium avium*, or *Hi. capsulatum*. However, routine screening of healthy birds for these diseases is not recommended (*335*) (DIII). To minimize potential exposure to *Mycobacterium marinum*, immunocompromised HSCT recipients and candidates should not clean fish tanks (DIII). If this task cannot be avoided, patients should wear disposable gloves during such activities and wash their hands thoroughly afterwards (*335,337*) (BIII).

Preventing Toxoplasmosis

The majority of toxoplasmosis cases in the United States is acquired through eating undercooked meat (*335,337*). However, all HSCT recipients and candidates, particularly those who are *To. gondii* seronegative, should be informed of the risks for contracting toxoplasmosis from cat feces (BIII), but need not be advised to give away their cats (DII). For households with cats, litter boxes should not be placed in kitchens, dining rooms, or other areas where food preparation and eating occur (*335*). Additionally, litter boxes should be cleaned daily by someone other than the HSCT recipient during the first 6 months after HSCT and during periods of substantial immunosuppression (e.g., GVHD, steroid use, or relapse of the underlying disease for which the transplant was performed) to reduce the risk for transmitting toxoplasmosis to the HSCT recipient (BIII). Daily litter box changes will minimize the risk for fecal transmission of *To. gondii* oocysts, because fecal oocysts require ≥2 days of incubation to become infectious. If HSCT recipients perform this task during the first 6 months after HSCT and during subsequent periods of substantial immunocompromise (e.g., during GVHD, systemic steroid use, or relapse of the underlying neoplastic disease for which the transplant was performed), they should wear disposable gloves (*335*). Gloves should be discarded after a single use (BIII). Soiled, dried litter should be disposed of carefully to prevent aerosolizing the *To. gondii* oocysts (BIII). Cat feces (but not litter) can be flushed down the toilet (BIII). Also, persons who clean cat litter, particularly HSCT recipients, should wash their hands thoroughly with soap and water afterwards to reduce their risk for acquiring toxoplasmosis (BIII).

HSCT recipients and candidates with cats should keep their cats inside (BIII) and should not adopt or handle stray cats (DIII). Cats should be fed only canned or dried commercial food or well-cooked table food, not raw or undercooked meats, to eliminate the possibility of causing an illness that could be transmitted from the cat to the HSCT recipient (BIII). Pet cats of HSCT recipients do not need to be tested for toxoplasmosis (EII). Playground sandboxes should be kept covered when not in use to prevent cats from soiling them (BIII). HSCT recipients and candidates undergoing conditioning therapy should avoid drinking raw goat's milk to decrease the risk for acquiring toxoplasmosis (BIII).

Water and Other Beverage Safety

Although limited data were found regarding the risks for and epidemiology of *Cryptosporidium* disease among HSCT recipients, HSCT recipients are prudent to avoid possible exposures to *Cryptosporidium* (BIII) because it has been reported to cause

severe, chronic diarrhea, malnutrition, and death among other immunocompromised persons (*5,318,319*). HSCT recipients should avoid walking, wading, swimming, or playing in recreational water (e.g., ponds or lakes) that is likely to be contaminated with *Cryptosporidium*, *Es. coli* O157:H7 (*344–346*), sewage, or animal or human waste (BII). HSCT recipients should also avoid swallowing such water (e.g., while swimming) (*5,344,346*) as well as any water taken directly from rivers and lakes (*5,316*) (AIII).

HSCT recipients should not use well water from private wells or from public wells in communities with limited populations (DIII) because tests for microbial contamination are performed too infrequently (e.g., in certain locations, tests are performed ≤1 times/month) to detect sporadic bacterial contamination. However, drinking well water from municipal wells serving highly populated areas is regarded as safe from bacterial contamination because the water is tested ≥2 times/day for bacterial contamination. If HSCT recipients consume tap water, they should routinely monitor mass media (e.g., radio, television, or newspapers) in their area to immediately implement any boil-water advisories that might be issued for immunocompromised persons by state or local governments (BIII). A boil-water advisory means that all tap water should be boiled for ≥1 minutes before it is consumed. Tap water might not be completely free of *Cryptosporidium*. To eliminate the risk for *Cryptosporidium* exposure from tap water, HSCT recipients can boil tap water for ≥1 minutes before consuming it (e.g., drinking or brushing teeth) (*5*) (CIII). Alternately, they can use certain types of water filters (*316*) or a home distiller (*317*) to reduce their risk for *Cryptosporidium* (*5*) and other waterborne pathogens (CIII). If a home water filter* is used, it should be capable of removing particles ≥1 µm in diameter, or filter by reverse osmosis. However, the majority of these filters are not capable of removing smaller microbes (e.g., bacteria or viruses), and therefore, should only be used on properly treated municipal water. Further, the majority of these devices would not be appropriate for use on an unchlorinated private well to control viral or bacterial pathogens. Bottled water can be consumed if it has been processed to remove *Cryptosporidium* by one of three processes — reverse osmosis, distillation, or 1-µm particulate absolute filtration. To confirm that a specific bottled water has undergone one of these processes, HSCT recipients should contact the bottler directly.†

Patients can take other precautions in the absence of boil-water advisories to further reduce their risk for cryptosporidiosis. These extra precautions include avoiding fountain beverages and ice made from tap water at restaurants, bars, and theaters (*5*), fruit drinks made from frozen concentrate mixed with tap water, and iced tea or coffee made with tap water (*317*). Drinks that are likely to be *Cryptosporidium* safe for HSCT recipients include nationally distributed brands of bottled or canned carbonated soft drinks and beers (*5*); commercially packaged noncarbonated drinks that contain fruit juice; fruit juices that do not require refrigeration until after opening (e.g., those that are stored unrefrigerated on grocery shelves) (*5*); canned or bottled soda, seltzer or fruit drinks; steaming hot (≥175 F) tea or coffee (*317*); juices labeled as pasteurized; and nationally distributed brands of frozen fruit juice concentrate that are reconstituted with water from

*For a list of filters certified under NSF Standard 053 for cyst (i.e., *Cryptosporidium*) removal, contact the NSF International consumer line at (800) 673-8010 or <http://www.nsf.org/notice/crypto.html>.

† The International Bottled Water Association can be contacted at (703) 683-5213 from 9 a.m. to 5 p.m. EST or anytime at their Internet site (<http://www.bottledwater.org>) to obtain contact information regarding water bottlers.

a safe source (*5*). HSCT recipients should not drink unpasteurized milk or fruit or vegetable juices (e.g., apple cider or orange juice) to avoid infection with *Brucella* species, *Es. coli* O157:H7, *Salmonella* species, *Cryptosporidium*, and others (*319,347–351*) (DII).

Food Safety

HSCT candidates and household or family members who prepare food for them after HSCT should review food safety practices that are appropriate for all persons (*352*) (AIII), and food preparers should be educated regarding additional food safety practices appropriate for HSCT recipients. This review and education should be done before the conditioning regimen (i.e., chemotherapy and radiation) begins (BIII). Adherence to these guidelines will decrease the risk for foodborne disease among HSCT recipients.

Food Safety Practices Appropriate for All Persons

Raw poultry, meats, fish, and seafood should be handled on separate surfaces (e.g., cutting board or counter top) from other food items. Food preparers should always use separate cutting boards (i.e., one for poultry and other meats and one for vegetables and remaining cutting or carving tasks) (AIII), or the board(s) should be washed with warm water and soap between cutting different food items (AIII). To prevent foodborne illnesses caused by *Campylobacter jejuni* and *Salmonella enteritidis*, which can cause severe and invasive infections among immunocompromised persons (*353,354*), uncooked meats should not come in contact with other foods (BIII).

After preparing raw poultry, meats, fish, and seafood and before preparing other foods, food handlers should wash their hands thoroughly in warm, soapy water. Any cutting boards, counters, knives, and other utensils used should be washed thoroughly in warm, soapy water also (AIII). Food preparers should keep shelves, counter tops, refrigerators, freezers, utensils, sponges, towels, and other kitchen items clean (AIII). All fresh produce should be washed thoroughly under running water before serving (*355*) (AIII). Persons preparing food should follow published U.S. Department of Agriculture recommendations regarding safe food thawing (*356*) (BIII).

Persons cooking food for HSCT recipients should follow established guidelines for monitoring internal cooking temperatures for meats (*357*) (AII). The only method for determining whether the meat has been adequately cooked is to measure its internal temperature with a thermometer because the color of the meat after cooking does not reliably reflect the internal temperature. Different kinds of meat should be cooked to varying internal temperatures, all ≥150 F (AII). Specifically, the U.S. Department of Agriculture recommends that poultry be cooked to an internal temperature of 180 F; other meats and egg-containing casseroles and souffles should be cooked to an internal temperature of ≥160 F. Cold foods should be stored at <40 F; hot foods should be kept at >140 F (BIII). Food preparers should

- wash their hands before and after handling leftovers (AIII);
- use clean utensils and food-preparation surfaces (AIII);
- divide leftovers into small units and store in shallow containers for quick cooling (AII);
- refrigerate leftovers within 2 hours of cooking (AII).
- discard leftovers that were kept at room temperature for >2 hours (AIII);

- reheat leftovers or heat partially cooked foods to ≥165 F throughout before serving (AII);
- bring leftover soups, sauces, and gravies to a rolling boil before serving (AIII); and
- follow published guidelines for cold storage of food (*352*) (AII).

Additional Food Safety Practices Appropriate for HSCT Recipients

HSCT recipients' diets should be restricted to decrease the risk for exposure to foodborne infections from bacteria, yeasts, molds, viruses, and parasites (BIII). Currently, a low microbial diet is recommended for HSCT recipients (*358,359*) (BIII). This diet should be continued for 3 months after HSCT for autologous recipients. Allogeneic recipients should remain on the diet until all immunosuppressive drugs (e.g., cyclosporine, steroids, and tacrolimus) are discontinued. However, the HSCT physician should have final responsibility for determining when the diet can be discontinued safely. Only one study has reported that dietary changes (e.g., consuming yogurt) have decreased the risk for mycotic infections (e.g., candidal vaginitis) (*360*) (Table 3). HSCT recipients should not eat any raw or undercooked meat, including beef, poultry, pork, lamb, venison or other wild game, or combination dishes containing raw or undercooked meats or sweetbreads from these animals (e.g., sausages or casseroles) (AII). Also, HSCT recipients should not consume raw or undercooked eggs or foods that might contain them (e.g., certain preparations of hollandaise sauce, Caesar and other salad dressings, homemade mayonnaise, and homemade eggnog) because of the risk for infection with *Salmonella enteritidis* (*354*) (AII). HSCT recipients should not consume raw or undercooked seafood (e.g., oysters or clams) to prevent exposure to *Vibrio* species, viral gastroenteritis, and *Cryptosporidium parvum* (*361–364*) (AII).

HSCT recipients and candidates should only consume meat that is well-done when they or their caretakers do not have direct control over food preparation (e.g., when eating in a restaurant) (AI). To date, no evidence exists in the United States that eating food at a fast food restaurant is riskier than eating at a conventional sit-down restaurant. Generally, HSCT candidates undergoing conditioning therapy and HSCT recipients with neutropenia (i.e., ANC < 1,000/ml^3), GVHD, or immunosuppression should avoid exposures to naturopathic medicines that might contain molds (*365*) (DIII). HSCT recipients wishing to take naturopathic medications are advised to use them only as prescribed by a licensed naturopathic physician working in consultation with the recipient's transplant and infectious disease physicians (CIII).

Travel Safety

Travel to developing countries can pose substantial risks for exposure to opportunistic pathogens for HSCT recipients, particularly allogeneic recipients chronically immunosuppressed. HSCT recipients should not plan travel to developing countries without consulting their physicians (AIII), and travel should not occur until the period of severe immunosuppression has resolved. Generally, allogeneic recipients should not plan travel to developing countries for 6–12 months after HSCT, particularly if GVHD has occurred. Autologous recipients can travel to developing countries 3–6 months after HSCT if their physicians agree.

HSCT recipients should be informed regarding strategies to minimize the risk for acquiring foodborne and waterborne infections while traveling. They should obtain updated, detailed health information for international travelers from health organizations (*366,367*) (AIII). Generally, while traveling in developing countries, HSCT recipients should avoid consuming the following (BIII):

- raw fruits and vegetables,
- tap water or any potentially untreated or contaminated water,
- ice made from tap water or any potentially contaminated water,
- unpasteurized milk or any unpasteurized dairy products,
- fresh fruit juices,
- food and drinks from street vendors, and
- raw or undercooked eggs.

Steaming hot foods, fruits peeled by oneself, bottled and canned processed drinks, and hot coffee or tea are probably safe (*367,368*). Travelers should plan for treating their drinking water while in developing countries. If bottled water is not available, boiling is the best method of making water safe. However, if boiling water is not feasible, the traveler should carry supplies for disinfecting water (e.g., commercially available iodine disinfection tablets or a portable water filter) (*366,368*).

Antimicrobial prophylaxis for traveler's diarrhea is not recommended routinely for HSCT recipients traveling to developing countries (DIII) because traveler's diarrhea is not known to be more frequent or more severe among immunocompromised hosts. However, HSCT physicians who wish to provide prophylaxis to HSCT recipients who are traveling can prescribe a fluoroquinolone (e.g., ciprofloxacin hydrochloride) or TMP-SMZ (CIII), although resistance to TMP-SMZ is now common and resistance to fluoroquinolones is increasing in tropical areas (Appendix). Researchers recommend using bismuth subsalicylate to prevent traveler's diarrhea among adults (*366*). However, no data were found regarding safety and efficacy among HSCT recipients, and salicylates are not recommended for use among persons aged <18 years because salicylates are associated with Reye's syndrome (*369*).

HSCT recipients' immunization status should be assessed and their vaccinations updated as needed before travel (*366*). Influenza chemoprophylaxis with rimantadine or amantadine can be used for immunocompromised HSCT recipients who are traveling outside the continental United States and who could be exposed to influenza A (CIII).

HSCT RECIPIENT VACCINATIONS

Antibody titers to vaccine-preventable diseases (e.g., tetanus, polio, measles, mumps, rubella, and encapsulated organisms) decline during the 1–4 years after allogeneic or autologous HSCT (*66,370–373*) if the recipient is not revaccinated. Clinical relevance of decreased antibodies to vaccine-preventable diseases among HSCT recipients is not immediately apparent because a limited number of cases of vaccine-preventable diseases are reported among U.S. recipients. However, vaccine-preventable diseases still pose risks to the U.S. population. Additionally, evidence exists that certain vaccine-preventable diseases (e.g., encapsulated organisms) can pose increased risk for HSCT

recipients (*66*); therefore, HSCT recipients should be routinely revaccinated after HSCT so that they can experience immunity to the same vaccine-preventable diseases as others (Table 4).

HSCT center personnel have developed vaccination schedules for HSCT recipients (*374*). One study determined that HSCT center personnel used 3–11 different vaccination schedules per vaccine (*374*); consequently, the study authors requested national guidelines for doses and timing of vaccines after HSCT to eliminate confusion among HSCT center personnel regarding how to vaccinate their patients. To address this need, an interim vaccination schedule for HSCT recipients was drafted in collaboration with partner organizations, including CDC's Advisory Committee on Immunization Practices. The purpose of the vaccination schedule in these guidelines is to provide guidance for HSCT centers (Table 4). Although limited data were found regarding safety and immunogenicity (e.g., serologic studies of antibody titers after vaccination) among HSCT recipients, no data were found regarding vaccine efficacy among HSCT recipients (e.g., which determine whether vaccinated HSCT recipients have decreased attack rates of disease compared with unvaccinated HSCT recipients). Because certain HSCT recipients have faster immune system recovery after HSCT than others, researchers have proposed that different vaccination schedules be recommended for recipients of different types of HSCT. However, to date, data are too limited to do so. Therefore, the same vaccination schedule is recommended for all HSCT recipients (e.g., allogeneic, autologous, and bone marrow, peripheral, or UCB grafts) until additional data are published. In the tables, vaccines have only been recommended for use among HSCT recipients if evidence exists of safety and immunogenicity for those recipients. Vaccination of family members, household contacts, and HCWs are also recommended to minimize exposure of vaccine-preventable diseases among HSCT recipients (Tables 5–8).

HEMATOPOIETIC STEM CELL SAFETY

With allogeneic HSCT, the life of the recipient might depend on the timely selection of an acceptable HLA-matched donor. Only a limited number of HLA-matched donors might be identified; hence, the transplant physician often has to accept a higher risk for transmission of an infectious agent through HSCT than would be permitted for routine blood transfusion. This section provides strategies for the HSCT physician to minimize transmission of infectious diseases, whenever possible, from donors to recipients.*† Whether to select a donor who is at risk for or who has an infectious disease transmissible by HSCT, should be determined on a case-by-case basis (AIII) and is the final responsibility of the HSCT physician (AIII). If the only possible donor is at risk for or known to be infected with a bloodborne pathogen and the patient is likely to succumb rapidly from his or her disease if an HSCT is not received, the physician must carefully weigh the risks and benefits of using potentially infected donor cells. No person should be denied a potentially life-saving HSCT procedure solely on the basis of the risk for an infectious disease. However, HSCT physicians should avoid transplanting any infected or infectious donor hematopoietic stem cell product unless no other stem cell product can be obtained and

*The U.S. Public Health Service is reexamining the current donor deferral recommendations regarding risk behaviors for donors of organs, cells, tissues, xenotransplantation, and reproductive cells and tissue, including semen, and revisions to these guidelines could become necessary as the research evolves.

† Guidelines for screening UCB donors and their mothers are evolving and will not be addressed in this document.

the risk for death from not undergoing transplantation is deemed to be greater than the risk for morbidity or death from the infection that could potentially be transmitted (DII). If such a product is selected for use, it should be done on a case-by-case basis (*375*) and the following should be noted in the recipient's chart:

- knowledge and authorization of the recipient's HSCT physician regarding the potential for transmission of an infectious agent during HSCT, and
- advance informed consent from the recipient or recipient's legal guardian acknowledging the possible transmission of an infectious agent during the transplantation (AIII).

Subsequently, the HSCT physician should include the infectious agent in the differential diagnosis of any illness that the HSCT recipient experiences so that the infection, if transmitted, can be diagnosed early and treated preemptively, if possible. Infectious products (except those in which CMV seropositivity is the only evidence of infectiousness) should be labeled as being a biohazard or as untested for biohazards, as applicable. Tissue intended for autologous use should be labeled "For Autologous Use Only — Use Only for (Patient's Name)."

Preventing Transmission of Infections from HSCT Donors to Recipients

All prospective HSCT donors should be evaluated through a physical history and examination to determine their general state of health and whether they pose a risk for transmitting infectious diseases to the recipient (*376*). To detect transmissible infections, all HSCT donor collection site personnel should follow up-to-date published guidelines and standards for donor screening (e.g., medical history), physical exam, and serologic testing (*377–383*) (AIII). Initial donor screening and physical exam should be performed ≤8 weeks before the planned donation (BIII). Donor serologic testing should be done ≤30 days before donation to detect potentially transmissible infections (BII); additionally, researchers recommend that donors be retested ≤7 days before collection. If testing is done >7 days before donation, donor screening should be repeated to ensure that no new risk behaviors have occurred during the interval between the original screening and the time of donation (BIII). This practice is critical because if new behavioral risk factors have occurred, the potential donor might need to be deferred. Screening and testing should be done on all allogeneic or syngeneic donors (AIII). Screening and testing of autologous donors is recommended to ensure the safety of laboratory personnel and to prevent cross contamination (BIII). If autologous donors are not tested, their autologous units should be specially labeled and handled as if potentially infected (BIII). For donors screened in the United States, FDA-licensed or -approved tests should be used in accordance with the manufacturers' instructions (AIII), and the donor samples should be tested in laboratories certified by the Clinical Laboratory Improvement Amendments of 1988 (AIII).

All HSCT donors should be in good general health (*376*) (BIII). Acute or chronic illness in the prospective donor should be investigated to determine the etiology. Generally, persons who are ill should not be HSCT donors (DIII). A flu-like illness in a prospective donor at the time of evaluation or between the time of evaluation and donation should prompt evaluation of and serologic testing for infections that might pose a risk to the

recipient (e.g., EBV, CMV, *To. gondii*) (BIII). Persons with a positive serum EBV-viral capsid antigen IgM but negative serum EBV-viral capsid antigen IgG should not serve as donors for allogeneic T-cell–depleted HSCT, particularly for unrelated or mismatched transplants, until their serum EBV-viral capsid antigen IgG becomes positive (DIII). Persons with acute toxoplasmosis should not donate until the acute illness has resolved (DII); however, physicians should be aware that persons who are asymptomatically seropositive for *To. gondii* might transmit this infection through HSCT (*218*).

Prospective donors with symptoms of active TB should be evaluated for that disease (*383*) (BIII). Prospective donors with active TB should not donate (EIII) until the TB is well-controlled (e.g., no longer contagious as determined by the donor's primary physician) after appropriate medical therapy. However, no known risk exists from transplanting marrow from an untreated, tuberculin-positive donor who has no evidence of active disease. Screening potential donors for TB with Mantoux skin tests (DIII) is not necessary. Prospective HSCT donors who reside in or have traveled to areas endemic for rickettsia or other tickborne pathogens and who are suspected of having an acute tickborne infection should be temporarily deferred as donors until infection with these pathogens is excluded (DIII). Relevant pathogens include *Rickettsia rickettsii*, *Babesia microti* and other *Babesia* species, *Coxiella burnetii*, and the Colorado tick fever virus, which are the etiologic agents of Rocky Mountain spotted fever, babesiosis, Q fever, and Colorado tick fever, respectively; these pathogens have been reported to be transmitted by blood transfusion (*384–388*). Researchers recommend deferral for a past history of Q fever or babesiosis because these infections can be chronic and the babesiosis parasite might persist despite appropriate therapy (*389*) (CIII). Additionally, researchers have recommended deferring persons with acute human ehrlichiosis (e.g., human active human granulocytic ehrlichiosis [*390*], human monocytic ehrlichiosis, as well as any infections from *Ehrlichia ewingii*) from HSCT donation (CIII).

The medical history of the prospective HSCT donor should include the following:

- History of vaccinations (*377*) during the 4 weeks before donation (AII). If the potential donor is unsure of vaccinations received, his or her records should be reviewed. HSCT donation should be deferred for 4 weeks after the donor receives any live-attenuated vaccine (e.g., rubeola [measles], mumps, rubella [German measles], oral polio, varicella, yellow fever, and oral typhoid vaccines) (EIII). This deferral will avoid the possibility of infusing a live infectious agent into an HSCT recipient. HSCT donation need not be deferred for persons who have recently received toxoid or killed (i.e., inactivated), recombinant viral, bacterial, or rickettsial vaccines as long as the donor is asymptomatic and afebrile (*389*) (BIII). Such vaccines include tetanus toxoid, diphtheria toxoid, hepatitis A and B, cholera, influenza (i.e., killed intramuscular vaccine), meningococcal, paratyphoid, pertussis, plague, polio (i.e., inactivated polio vaccine), rabies, typhoid (i.e., inactivated intramuscular vaccine), or typhus vaccines (*389*).

- Travel history (BIII) to determine whether the donor has ever resided in or traveled to countries with endemic diseases that might be transmitted through HSCT (e.g., malaria). Permanent residents of nonendemic countries who have traveled to an area that CDC regards as endemic for malaria can be accepted as HSCT donors if 1 year has elapsed since the donor's departure from the endemic area and if the donor has been free of malaria symptoms, regardless of whether he or she received antimalarial chemoprophylaxis. Because cases of

HSCT-transmitted malaria have been reported (*391,392*), persons who have had malaria and received appropriate treatment should be deferred from HSCT donation for 3 years after becoming asymptomatic. Immigrants, refugees, citizens, or residents for ≥5 years of endemic countries can be accepted as HSCT donors if 3 years have elapsed since they departed the malarious area and if they have been free of malaria symptoms.

- History of Chagas' disease and leishmaniasis. Persons with active Chagas' disease or leishmaniasis should not serve as HSCT donors (DIII) because these diseases can be transmitted by transfusion (*227,229,231,393–395*). Researchers also recommend deferral of HSCT donation if a past history exists of either of these diseases because the parasite can persist despite therapy (*227–229,231, 389,393–395*) (CIII).

- History of any deferral from plasma or blood donation. The reason for such a deferral (*376*) and whether it was based on a reported infectious disease or behavioral or other risk factor should be investigated (BIII).

- History of viral hepatitis. A person with a history of viral hepatitis after his or her eleventh birthday should be excluded from HSCT donation (BIII).

- History of blood product transfusion, solid organ transplantation, or transplantation of tissue within the last 12 months (BIII). Such persons should be excluded from HSCT donation (DIII). Xenotransplant product recipients and their close contacts should be indefinitely deferred from donating any blood products, including hematopoietic stem cells, whole blood, or other blood components including plasma, leukocytes, and tissues (*396*) (AIII). Close contacts to be deferred from donations include persons who have engaged repeatedly in activities that could result in an intimate exchange of body fluids with a xenotransplantation product recipient. Such close contacts could include sexual partners, household members who share razors or toothbrushes, and HCWs or laboratory personnel with repeated percutaneous, mucosal, or other direct exposures.

- History of risk factors for classic Creutzfeldt-Jakob disease (CJD), including any blood relative with Creutzfeldt-Jakob disease, receipt of a human pituitary-derived growth hormone or receipt of a corneal or dura mater graft (*383,397–399*) (BIII). Potential HSCT donors should also be screened for new variant Creutzfeldt-Jakob Disease (nvCJD) risk factors, including a history of cumulative travel or residence in the United Kingdom for ≥6 months during 1980–1996 or receipt of injectable bovine insulin since 1980, unless the product was not manufactured since 1980 from cattle in the United Kingdom (*398*) (BIII). The clinical latency period for iatrogenic, classic CJD can be >30 years (*398*), and transmission of classic CJD by blood products is highly unlikely (*398*). Although no classic or nvCJD has ever been reported among HSCT recipients, persons with a history of classic or nvCJD risk factors should be excluded from donation for unrelated HSCT (DIII) if a choice exists between two otherwise equally suitable donors. The risk for transmitting classic or nvCJD from an HSCT donor to a recipient is unknown, but researchers believe that persons with nvCJD risk

factors could be at higher risk for transmitting nvCJD to HSCT recipients than persons with classic CJD risk factors.

- Past medical history that indicates the donor has clinical evidence of or is at high risk for acquiring a bloodborne infection (e.g., HIV-1 or -2, human T-lymphotropic virus [HTLV]-I or -II, hepatitis C, or hepatitis B) (*381,383*), including
  - — men who have had sex with another man during the preceding 5 years (*381,383*) (BIII);
  - — persons who report nonmedical intravenous, intramuscular, or subcutaneous injection of drugs during the preceding 5 years (*381*) (BIII);
  - — persons with hemophilia or related clotting disorders who have received human-derived clotting factor concentrates (*381*) (BIII);
  - — persons who have engaged in sex in exchange for money or drugs during the preceding 5 years (*381*) (BIII);
  - — persons who have had sex during the preceding 12 months with any person described previously (*381*) or with a person known or suspected to have HIV (*381*) or hepatitis B infections (BIII);
  - — persons who have been exposed during the preceding 12 months to known or suspected HIV, hepatitis B- or C-infected blood through percutaneous inoculation or through contact with an open wound, nonintact skin, or mucous membrane (*381*) (BIII);
  - — inmates of correctional systems (*379–381*) and persons who have been incarcerated for >72 consecutive hours during the previous 12 months (BIII);
  - — persons who have had or have been treated for syphilis or gonorrhea during the preceding 12 months (*376,379,380*) (BIII); and
  - — persons who within 12 months have undergone tattooing, acupuncture, ear or body piercing (*380,400,401*) in which shared instruments are known to have been used (BIII) or other nonsterile conditions existed.

Persons reporting any of these past medical histories should be excluded from donation (DIII).

The following serologic tests should be performed for each prospective donor:

- HIV-1 antigen, anti-HIV-1 and -2, anti-HTLV-I and -II, hepatitis B surface antigen, total antihepatitis B core antigen, antihepatitis C, anti-CMV, and a serologic test for syphilis (*376,379,380,383*) (AIII). Potential donors who have repeatedly reactive screening tests for HIV-1 antigen, anti-HIV-1 or -2, anti-HTLV-I or -II, antihepatitis C, hepatitis B surface antigen, or antihepatitis B core antigen should be excluded as HSCT donors (*381*) (EII). Persons who refuse infectious disease testing should also be excluded as HSCT donors (*381*) (EIII).
- Investigational nucleic acid tests to detect hepatitis C virus RNA and HIV RNA are currently being used in the United States to screen blood donors and could be

used for screening HSCT donors. If nucleic acid tests are approved by FDA, these tests should be incorporated into routine screening regimens for HSCT donors. When nucleic acid testing is done for HIV and hepatitis C investigationally, a positive result should exclude the potential donor.

All infectious disease testing and results should be reported to the HSCT physician before the candidate's conditioning regimen begins (*381*) (AIII). Bone marrow should be collected using sterile technique in a medically acceptable setting and according to standard operating procedures (AIII).

HSCT transplant center personnel should keep accurate records of all HSCT received and the disposition of each sample obtained (*381*). These tracking records must be separate from patients' medical records (e.g., in a log book) so that this information is easily obtainable. Recorded information should include the donor identification number, name of procurement of distribution center supplying the HSCT, recipient-identifying information, name of recipient's physician, and dates of a) receipt by the HSCT center and b) either transplantation to the recipient or further distribution (*381*) (AIII). All centers for donation, transplantation, or collection of hematopoietic stem cells should keep records of donor screening and testing, and HSCT harvesting, processing, testing, cryopreservation, storage, and infusion or disposal of each aliquot of donated hematopoietic progenitor cells for ≥10 years after the date of implantation, transplantation, infusion, or transfer of the product (*378*) (AIII). However, if that date is not known, records should be retained ≥10 years after the product's distribution, disposition, or expiration, whichever is latest.

Pediatric Donors

Children aged >18 months who are born to mothers with or at risk for HIV infection, who have not been breast-fed during the past 12 months, and whose HIV antibody tests, physical examination, and medical records do not indicate evidence of HIV infection can be accepted as donors (*381*) (BIII). Children aged <18 months who are born to mothers with or at risk for HIV infection and who have not been breast-fed by an HIV-infected woman during the past 12 months can be accepted as donors only if HIV infection has been excluded according to established criteria (*402*) (BIII). Children who have been breast-fed by an HIV-infected woman during the past 12 months should be excluded as stem cell donors regardless of HIV infection status (AIII). The mother and, if possible, the father of all pediatric stem-cell donors who are at risk for perinatal transmission of HIV and other bloodborne infections, should be interviewed by a health-care professional competent to elicit information regarding risk factors for possible bloodborne infection in the potential pediatric donor (AIII). Children who meet any of the adult donor exclusion criteria should not become HSCT donors (*381*) (EIII).

Preventing Infection from Extraneous Contamination of Donated Units

Personnel of donation, collection, or transplantation centers, cell-processing laboratories, and courier services should follow current standards for detecting and preventing extrinsic bacterial and fungal contamination of collected stem cell units at the collection

site, during processing and transportation, and at the transplant center (*376*) (AIII). Quality improvement programs and procedure manuals of collection centers, cell-processing laboratories, and transplant programs should include strategies for preventing transplant-associated infections. For example, collection centers should use aseptic techniques when collecting marrow, peripheral blood, and UCB hematopoietic stem cells (*376,378*) (AIII). Whenever possible, closed systems should be used for pooling hematopoietic stem cells during a collection procedure (BIII) because higher rates of microbial contamination seen in marrow harvests versus blood stem cell collections can be caused by use of open collecting systems (*375,403,404*). The highest risk for extraneous microbial contamination of hematopoietic stem cells occurs during extensive manipulation and processing in the laboratory (*404,405*). Potential sources include unprotected hands and laboratory equipment and freezers (*406*), particularly the liquid phases of liquid nitrogen freezers (*407*). Therefore, stem cell processing should be performed according to current standards (*378*) using approved manufacturing practices (AIII). Hematopoietic stem cell units thawed in a water bath should be enclosed in a second bag (i.e., double-bagged technique) to prevent contamination of the ports or caps from unsterile bath water (*407*) (BIII). Additionally, water baths should be cleaned routinely (BIII) and certain researchers have proposed that the bath contain sterile water (*407*) (CIII). Researchers also report sterilizing liquid nitrogen freezers before initial use for hematopoietic stem cell storage (*407*) until fungal and bacterial cultures are negative (CIII).

Cell-processing laboratory personnel should implement programs to detect extrinsic bacterial or fungal contamination of collected stem cell units, ideally before transplantation (AIII). Although repeated cultures are costly (*408*), donated hematopoietic stem cells should be cultured for aerobic bacteria and fungi ≥1 times during initial processing and freezing (BIII). Researchers also have proposed adding anaerobic bacterial cultures and culturing twice, once at the end of processing, and once after thawing just before use (*407*) (CIII). If bacterial culture results are positive, antibiotic-susceptibility tests should be performed (BIII). Results of cultures and antibiotic-susceptibility tests should be provided to the transplant physician before release of a cryopreserved marrow or blood stem cell unit, and as soon as feasible for transplants infused before completion of culture incubation (BIII).

Collection center, cell-processing laboratory, and transplant program personnel should maintain active surveillance of infections among persons who have received hematopoietic stem cells from those facilities to collect data regarding the number of infections after HSCT that might have been caused by exogenous contamination of donor stem cells (BIII) because this type of infection has been reported (*405*).

In Utero or Fetal HSCT

No national standards exist for in utero or fetal HSCT, and the overall risks for transmitting infections to a fetus through HSCT (*409,410*) have not been determined. However, in addition to precautions appropriate for adult recipients, physicians performing in utero or fetal HSCT are advised to evaluate potential donors for evidence of active infectious diseases that could cause serious congenital infections (e.g., rubella, varicella, CMV, syphilis, or *To. gondii*) in the fetus (CIII).

TABLE 1. Evidence-based rating system used to determine strength of recommendations

Category	Definition	Recommendation
A	Strong evidence for efficacy and substantial clinical benefit	Strongly recommended
B	Strong or moderate evidence for efficacy, but only limited clinical benefit	Generally recommended
C	Insufficient evidence for efficacy; or efficacy does not outweigh possible adverse consequences (e.g., drug toxicity or interactions) or cost of chemoprophylaxis or alternative approaches	Optional
D	Moderate evidence against efficacy or for adverse outcome	Generally not recommended
E	Strong evidence against efficacy or of adverse outcome	Never recommended

Source: Adapted from CDC. 1999 USPHS/IDSA guidelines for the prevention of opportunistic infections in persons infected with human immunodeficiency virus. MMWR 1999;48(RR-10):1–66.

TABLE 2. Evidence-based rating system used to determine quality of evidence supporting recommendation

Category	Definition
I	Evidence from at least one well-executed randomized, controlled trial
II	Evidence from at least one well-designed clinical trial without randomization; cohort or case-controlled analytic studies (preferably from more than one center); multiple time-series studies; or dramatic results from uncontrolled experiments
III	Evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees

Source: Adapted from CDC. 1999 USPHS/IDSA guidelines for the prevention of opportunistic infections in persons infected with human immunodeficiency virus. MMWR 1999;48(RR-10):1–66.

TABLE 3. Foods that pose a high risk for hematopoietic stem cell transplant (HSCT) recipients and safer substitutions

Foods That Pose a High Risk	Safer Substitutions
Raw and undercooked eggs* and foods containing them (e.g., french toast, omelettes, salad dressings, egg nog, and puddings)	Pasteurized or hard boiled eggs
Unpasteurized dairy products (e.g., milk, cheese, cream, butter, and yogurt)	Pasteurized dairy products
Fresh-squeezed, unpasteurized fruit and vegetable juices	Pasteurized juices
Unpasteurized cheeses or cheeses containing molds	Pasteurized cheeses
Undercooked or raw poultry, meats, fish, and seafood cooked fish, and seafood	Cooked poultry, well-done meats,
Vegetable sprouts (e.g., alfalfa, bean, and other seed sprouts)†	Should be avoided
Raw fruits with a rough texture (e.g., raspberries)§	Should be avoided
Smooth raw fruits	Should be washed under running water, peeled, or cooked
Unwashed raw vegetables¶	Should be washed under running water, peeled, or cooked
Undercooked or raw tofu	Cooked tofu (i.e., cut into ≤1-inch cubes and boiled for ≥5 minutes in water or broth before eating or using in recipes)
Raw or unpasteurized honey	Should be avoided
Deli meats, hot dogs, and processed meats**	Should be avoided unless further cooked
Raw, uncooked grain products	Cooked grain products including bread, cooked, and ready-to-eat cold cereal, pretzels, popcorn, potato chips, corn chips, tortilla chips, cooked pasta, and rice
Maté tea††	Should be avoided
All moldy and outdated food products	Should be avoided
Unpasteurized beer (e.g., home-brewed and certain microbrewery beer)	Pasteurized beer (i.e., retail bottled or canned, or draft beer that has been pasteurized after fermentation)
Raw, uncooked brewers yeast	Should be avoided; HSCT recipients should avoid any contact with raw yeast (e.g., they should not make bread products themselves)
Unroasted raw nuts	Cooked nuts
Roasted nuts in the shell	Canned or bottled roasted nuts or nuts in baked products

* **Source:** CDC. Outbreaks of *Salmonella* serotype enteritidis infection associated with consumption of raw shell eggs—United States, 1994–1995. MMWR 1996; 45(34):737–42.

¶ **Source:** CDC. Foodborne outbreak of cryptosporidiosis—Spokane, Washington, 1997. MMWR 1998;47(27):565–7.

** **Source:** CDC. Update: multistate outbreak of listeriosis—United States, 1998–1999. MMWR 1999;47(51):1117–8.

†† **Source:** Kusminsky G, Dictar M, Arduino S, Zylberman M, Sanchez Avalos JC. Do not drink Maté: an additional source of infection in South American neutropenic patients. Bone Marrow Transplant 1996;17(1):127.

TABLE 4. Recommended vaccinations for hematopoietic stem cell transplant* (HSCT) recipients, including both allogeneic and autologous recipients

For these guidelines, HSCT recipients are presumed immunocompetent at ≥24 months after HSCT if they are not on immunosuppressive therapy and do not have graft-versus-host disease (GVHD).

Vaccine or toxoid	Time after HSCT			Rating
	12 months	14 months	24 months	
Inactivated vaccine or toxoid				
Diphtheria, tetanus, pertussis				
Children aged <7 years*	Diphtheria toxoid-tetanus toxoid-pertussis vaccine (DTP) or diphtheria toxoid-tetanus toxoid (DT)†	DTP or DT	DTP or DT	BIII
Children aged ≥7 years§	Tetanus-diphtheria toxoid (Td)	Td	Td	BII
Haemophilus influenzae type b (Hib) conjugate¶	Hib conjugate	Hib conjugate	Hib conjugate	BII
Hepatitis (HepB)**	HepB	HepB	HepB	BIII
23-valent pneumococcal polysaccharide (PPV23)††	PPV23	—	PPV23	BIII
Hepatitis A§§	Routine administration not indicated			Not rated because of limited data
Influenza¶¶	Lifelong, seasonal administration, beginning before HSCT and resuming at ≥6 months after HSCT			BII
Meningococcal***	Routine administration not indicated			Not rated because of limited data
Inactivated polio (IPV)†††	IPV	IPV	IPV	BII
Rabies§§§	Routine administration not indicated			Not rated because of limited data
Lyme disease	Routine administration not indicated; limited data regarding safety, efficacy, or immunogenicity among HSCT recipients			Not rated because of limited data
Live-attenuated vaccine				
Measles-mumps-rubella (MMR)¶¶¶ ***†	—	—	MMR	BIII
Varicella vaccine §§§§	Contraindicated for HSCT recipients			EIII
Rotavirus vaccine	Not recommended for any person in the United States¶¶¶¶			EII

TABLE 4. (*Continued*) Recommended vaccinations for hematopoietic stem cell transplant* (HSCT) recipients, including both allogeneic and autologous recipients

* Studies report that an HSCT recipient can be primed if the donor has had primary vaccination series. Studies also report that a recipient's antibody titer before HSCT might affect the titer 1 year after HSCT (**Source**: Lum LG. Kinetics of immune reconstitution after human marrow transplantation. Blood 1987;69[2]:369–80). No data were found regarding safety and immunogenicity of pertussis vaccination among HSCT recipients.

† DT should be used whenever a contraindication exists to pertussis vaccination.

§ HSCT recipients should be revaccinated with tetanus-diphtheria toxoids every 10 years, as routinely recommended for all adolescents and adults (**Sources**: CDC. Diphtheria, tetanus, and pertussis: recommendations of vaccine use and other prevention measures; recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1991;40[No. RR-10]:1–28; and CDC. Use of vaccines and immunoglobulin in persons with altered immunocompetence: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1993;42[No. RR-4]:1–18).

¶ Hib conjugate vaccine is recommended for HSCT recipients of any age (**Sources**: CDC. Recommendations for use of *Haemophilus* b conjugate vaccines and a combined diphtheria, tetanus, pertussis, and *Haemophilus* b vaccine: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1993;42[No. RR-13]:1–15; and CDC. Use of vaccines and immunoglobulin in persons with altered immunocompetence: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1993;42[No. RR-4]:1–18).

** Hepatitis B vaccination is recommended for all susceptible persons aged ≤18 years and for adults who have risk factors for hepatitis B virus infection (**Sources**: CDC. Hepatitis B virus: a comprehensive strategy for eliminating transmission in the United States through universal childhood vaccination; recommendations of the Immunization Practices Advisory Committee [ACIP]. MMWR 1991;40[No. RR-13]:1–25; and CDC. Notice to readers: update; recommendations to prevent hepatitis B virus transmission—United States. MMWR 1995;44[30]:574–5). ACIP hepatitis B vaccination recommendations indicate that high doses (40 µg/dose) are recommended for adult dialysis patients and other immunocompromised adults (**Source**: CDC. Notice to readers: update; recommendations to prevent hepatitis B virus transmission—United States. MMWR 1995;44[30]:574–5). No data were found regarding immunocompromised children and their response to higher doses of vaccine. Postvaccination testing for antibody to hepatitis B surface antigen is recommended 1–2 months after the third vaccine dose to ensure protection among immunocompromised persons (**Source**: CDC. Notice to readers: update; recommendations to prevent hepatitis B virus transmission—United States. MMWR 1995;44[30]:574–5). Persons who do not respond to the primary vaccine series should complete a second 3-dose series.

†† The 23-valent pneumococcal polysaccharide vaccine might not be protective against pneumococcal infection among HSCT recipients. The second dose of vaccine is not a booster dose, but provides a second chance for immunologic response among persons who failed to respond to the first dose (**Source**: Guinan EC, Molrine DC, Antin JH, et al. Polysaccharide conjugate vaccine responses in bone marrow transplant patients. Transplant 1994;57[5]:677–84). Adjunctive antibiotic prophylaxis against encapsulated organisms, including pneumococcal disease, is recommended for allogeneic recipients with chronic GVHD (**Source**: Bortin MM, Horowitz MM, Gale RP, et al. Changing trends in allogeneic bone marrow transplantation for leukemia in the 1980s. JAMA 1992; 268[5]:607–12). No data were found regarding safety and immunogenicity of the 7-valent conjugate pneumococcal vaccine among HSCT recipients; therefore, no recommendation regarding use of this vaccine can be made.

§§ No data were found regarding immunogenicity, safety, and efficacy of hepatitis A vaccine among HSCT recipients. Researchers report that hepatitis A vaccination can be used for investigational use among HSCT recipients aged ≥24 months at ≥12 months after HSCT and who are at increased risk for hepatitis A or its adverse consequences (e.g., persons with chronic liver disease, including chronic GVHD, and children living in areas with consistently elevated hepatitis A incidence) (**Source**: CDC. Prevention of hepatitis A through active or passive immunization: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1999;48[No. RR-12]:1–37).

¶¶ Children aged <9 years receiving influenza vaccination for the first time require two doses. Children aged ≤12 years should receive only split-virus influenza vaccine. Persons aged >12 years can receive whole- or split-virus vaccine. ACIP's and the American Academy of Pediatrics' dosing schedule should be used (**Sources**: American Academy of Pediatrics. Influenza. In: Pickering LK, ed. 2000 red book: report of the Committee on Infectious Diseases. 25th ed. Elk Grove Village, IL: American Academy of Pediatrics, 2000:351–9; and CDC. Prevention and control of influenza: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 2000;49[No. RR-3]:1–38). For optimal influenza prevention, both vaccination and influenza chemoprophylaxis should be used among HSCT recipients.

*** Administration of meningococcal vaccine should be evaluated for HSCT recipients who live in endemic areas or areas experiencing outbreaks (**Source**: CDC. Control and prevention of meningococcal disease and control and prevention of serogroup C meningococcal disease: evaluation and management of suspected outbreaks. MMWR 1997;46[No. RR-5]:1–21). However, meningococcal vaccine immunogenicity and efficacy among HSCT recipients have not been studied.

††† Inactivated polio virus vaccine is immunogenic among HSCT recipients, although no data were found regarding efficacy and more data are needed regarding optimal methods and timing of immunization (**Sources**: Henning KJ, White MH, Sepkowitz KA, Armstrong D. National survey of immunization practices following allogeneic bone marrow transplantation. JAMA 1997;277[14]:1148–51; and CDC. Poliomyelitis prevention in the United States: introduction of a sequential vaccination schedule of inactivated poliovirus vaccine followed by oral poliovirus vaccine; recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1997;46[No. RR-3]:1–25).

TABLE 4. (*Continued*) Recommended vaccinations for hematopoietic stem cell transplant* (HSCT) recipients, including both allogeneic and autologous recipients

§§§ Clinicians can administer preexposure rabies vaccine to HSCT recipients with potential occupational exposures to rabies (**Source**: CDC. Human rabies prevention—United States, 1999: recommendations of the Advisory Committee on Immunization Practices [ACIP] MMWR 1999;48[No. RR-1]:1–21; and published erratum, MMWR 1999;48[1]:16). However, the safety and immunogenicity of rabies vaccination among HSCT recipients has not been studied. Preexposure rabies vaccination should probably be delayed until 12–24 months after HSCT. Administration of rabies vaccine with human rabies immunoglobulin postexposure can be administered anytime after HSCT as indicated. Existing ACIP and American Academy of Pediatrics guidelines for postexposure human rabies immunoglobulin and vaccine administration should be followed, which include administering 5 doses of rabies vaccine administered on days 0, 3, 7, 14, and 28 postexposure (**Sources**: American Academy of Pediatrics. Rabies. In: Pickering LK, ed. 2000 red book: report of the Committee on Infectious Diseases. 25th ed. Elk Grove Village, IL: American Academy of Pediatrics;2000:475–82; and CDC. Human rabies prevention—United States, 1999: recommendations of the Advisory Committee on Immunization Practices [ACIP] MMWR 1999;48[No. RR-1]:1–21; published erratum, MMWR 1999;48[1]:16).

¶¶¶ The first dose of measles-mumps-rubella vaccine should be administered ≥24 months after HSCT if the HSCT recipient is presumed immunocompetent. The second measles-mumps-rubella dose is recommended 6–12 months later (BIII); however, the benefit of a second dose among HSCT recipients has not been evaluated. During outbreaks, the second dose can be administered 4 weeks after the first dose (**Source**: CDC. Use of vaccines and immunoglobulin in persons with altered immunocompetence: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1993;42[No. RR-4]:1–18).

**** The half-life of intravenous immunoglobulin is decreased among HSCT recipients, but its effect on vaccine immunogenicity has not been evaluated. ACIP's and the American Academy of Pediatrics' recommendations regarding intervals between administration of immunoglobulin preparations for various indications and vaccines containing live measles virus should be used (**Sources**: American Academy of Pediatrics. Measles. In: Pickering LK, ed. 2000 red book: report of the Committee on Infectious Diseases. 25th ed. Elk Grove Village, IL: American Academy of Pediatrics, 2000:385–96; CDC. Measles, mumps, and rubella—vaccine use and strategies for elimination of measles, rubella, and congenital rubella syndrome and control of mumps: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1998;47[No. RR-8]:1–48; and CDC. General recommendations on immunization: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1994;43[No. RR-1]:1–38).

†††† Use of live vaccines (e.g., measles-mumps-rubella) is indicated only among immunocompetent persons and is contraindicated for recipients after HSCT who are not presumed immunocompetent (**Sources**: CDC. Prevention of varicella: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1996;45[No. RR-11]:1–36; and CDC. General recommendations on immunization: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1994;43[No. RR-1]:1–38). Further research is needed to determine the safety, immunogenicity, and efficacy of varicella vaccine among HSCT recipients.

§§§§ To protect HSCT recipients from varicella exposure, all varicella-susceptible health-care workers, family members, and close contacts of the recipient should be vaccinated against varicella (**Source**: American Academy of Pediatrics. Varicella-zoster infections. In: Pickering LK, ed. 2000 red book: report of the committee on Infectious diseases. 25th ed. Elk Grove Village, IL: American Academy of Pediatrics;2000:624–38).

¶¶¶¶ **Source**: CDC. Withdrawal of rotavirus vaccine recommendation. MMWR 1999;48[43]:1007.

Additional Notes: All indicated nonlive vaccines should be administered to HSCT recipients regardless of HSCT type or presence of GVHD. Live-attenuated vaccines, (e.g., measles-mumps-rubella, varicella, Bacillus Calmette-Guérin, yellow fever, and oral typhoid vaccines) should not be administered to any HSCT recipient with active GVHD or immunosuppression (**Source**: CDC. Role of BCG [Bacillus of Calmette and Guérin] vaccine in the prevention and control of tuberculosis in the United States: a joint statement by the Advisory Council for the Elimination of Tuberculosis and the Advisory Committee on Immunization Practices. MMWR 1996;45[No. RR-4]:1–18). To date, no adverse events have been reported (e.g., exacerbation of GVHD) among vaccinated HSCT recipients. However, data regarding immunization among HSCT recipients are limited and further studies are needed to evaluate safety, efficacy, and immunogenicity of the proposed HSCT immunization schedule. Use of combination vaccines is encouraged (**Source**: CDC. Combination vaccines for childhood immunization: recommendations of the Advisory Committee on Immunization Practices [ACIP], the American Academy of Pediatrics [AAP], and the American Academy of Family Physicians [AAFP]. MMWR 1999;48[No. RR-5]:1–15). No contraindications to simultaneous administration of any vaccines exist, except cholera and yellow fever. Adverse events after vaccination should be reported promptly to the Vaccine Adverse Event Reporting System (VAERS), P.O. Box 1100, Rockville, MD 20849-1100. Forms and information can be obtained from VAERS ([800] 822-7967). If the HSCT recipient has lapsed immunizations after HSCT (i.e., has missed one or more vaccine doses), the immunization schedule does not have to be restarted. Instead, the missing vaccine dose should be administered as soon as possible or during the next scheduled clinic appointment.

Table 5. Vaccinations for family, close contacts, and health-care workers (HCWs) of hematopoietic stem cell transplantation (HSCT) recipients*

Vaccine	Recommendations for use	Rating
Hepatitis A†	Routine vaccination is recommended for persons at increased risk for hepatitis A or its adverse consequences (e.g., persons with chronic liver disease or persons traveling to hepatitis A-endemic countries) and for children aged ≥24 months living in areas with consistently elevated hepatitis A incidence.†	BII
Influenza§ ¶	Household contacts — Vaccination is strongly recommended during each influenza season (i.e., October–May) beginning in the season before the transplant and continuing to ≥24 months after HSCT. All household contacts of immunocompromised HSCT recipients should be vaccinated annually as long as these conditions persist.	AI
	HCWs and home caregivers — Annual vaccination is strongly recommended during each influenza season.	AI
Polio**	Vaccination is not routinely recommended for adults but should be administered when polio vaccination is indicated according to published Advisory Committee on Immunization Practices guidelines; when polio vaccine is administered, inactivated polio vaccine should be used.	AI
Measles-mumps-rubella††	Vaccination is recommended for all persons who are aged ≥12 months and who are not pregnant or immunocompromised.	AI
Rotavirus§§	Contraindicated because intussusception has been reported among infants during the first 1–2 weeks after rotavirus vaccination with substantially increased frequency.	EII
Varicella¶¶	Vaccination should be administered to all susceptible HCWs, household contacts, and family members who are aged ≥12 months and who are not pregnant or immunocompromised. When varicella vaccination is administered to persons aged ≥13 years, 2 doses are required, administered 4–8 weeks apart.	AIII

* This vaccination schedule refers only to vaccine-preventable diseases that are spread person-to-person.

† **Source**: CDC. Prevention of hepatitis A through active or passive immunization: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR 1999;48(No. RR-12):1–37.

§ Children aged <9 years receiving influenza vaccination for the first time require 2 doses. Children aged ≤12 years should receive only split-virus influenza vaccine. Persons aged >12 years can receive whole- or split-virus vaccine (**Sources**: CDC. Prevention and control of influenza: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 2000;49[No. RR-3]:1–38; and CDC. Immunization of health care workers: recommendations of the Advisory Committee on Immunization Practices [ACIP] and the Hospital Infection Control Practices Advisory Committee. MMWR 1997;46[No. RR-18]:1–42).

¶ If HCWs, family members, or other close contacts of HSCT recipients receive influenza vaccination during an influenza A outbreak, they should also receive amantadine or rimantadine chemoprophylaxis for 2 weeks after the influenza vaccination (BI) while the vaccinee develops an immunologic response to the vaccine. However, if a nosocomial outbreak occurs with an influenza A strain that is not contained in the available influenza vaccine, HCWs, family members, and other close contacts of HSCT recipients and candidates should be administered influenza A chemoprophylaxis with amantadine or rimantadine until the end of the outbreak (**Source**: CDC. Prevention and control of influenza: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 2000;49[No. RR-3]:1–38) (BIII). HCWs, family members, or other close contacts can be offered a neuroaminidase inhibitor (e.g., zanamivir or oseltamivir) using the same strategies outlined previously, if one or more of the following exists: a) rimantadine or amantadine cannot be tolerated; b) the outbreak strain of influenza A is amantadine- or rimantadine-resistant; or c) the outbreak strain is influenza B (**Sources**: Monto AS, Robinson DP, Herlocher ML, Hinson JM Jr, Elliott MJ, Crisp A. Zanamivir in the prevention of influenza among healthy adults: a randomized controlled trial. JAMA 1999;282[1]:31–5; Hayden FG, Atmar RL, Schilling M, et al. Use of the selective oral neuraminidase inhibitor oseltamivir to prevent influenza. New Engl J Med 1999;341[18]:1336–43; Hayden FG, Gubareva L, Klein T, et al. Inhaled zanamivir for preventing transmission of influenza in families [Abstract LB-2]. In: Final program, abstracts and exhibits addendum, 38th Interscience Conference on Antimicrobial Agents and Chemotherapy. Washington, DC: American Society for Microbiology, 1991:1; and CDC. Neuraminidase inhibitors for treatment of influenza A and B infections. MMWR 1999;48[No. RR-14]:1–10) (BI). Zanamivir can be administered to persons aged ≥12 years, and oseltamivir can be administered to persons aged ≥18 years.

** **Caution**: Vaccine-strain polio virus in oral polio vaccine can be transmitted person-to-person; therefore, oral polio vaccine administration is contraindicated among household contacts of immunocompromised persons. If oral polio vaccine is inadvertently administered to a household contact of an HSCT recipient, ACIP's and the American Academy of Pediatrics' recommendations should be followed to minimize close contact with the immunocompromised person for 4–6 weeks after vaccination (**Sources**: American Academy of Pediatrics. Poliovirus infections. In: Pickering LK, ed. 2000 red book: report of the Committee on Infectious Diseases. 25th ed. Elk Grove Village, IL: American Academy of Pediatrics, 2000:465–70; CDC. Immunization of health care workers: recommendations of the Advisory Committee on Immunization Practices (ACIP) and the Hospital Infection Control

Table 5. (*Continued*) Vaccinations for family, close contacts, and health-care workers (HCWs) of hematopoietic stem cell transplantation (HSCT) recipients*

Practices Advisory Committee. MMWR 1997;46[No. RR-18]:1–42; and CDC. Poliomyelitis prevention in the United States: introduction of a sequential vaccination schedule of inactivated poliovirus vaccine followed by oral poliovirus vaccine; recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1997;46[No. RR-3]:1–25). Although vaccine-associated paralytic poliomyelitis has not been reported among HSCT recipients after exposure to household contacts inadvertently vaccinated with oral polio vaccine, inactivated polio vaccine should be used among family members, close contacts, and HCWs to avoid person-to-person transmission of vaccine-strain polio virus (**Source**: CDC. Poliomyelitis prevention in the United States: introduction of a sequential vaccination schedule of inactivated poliovirus vaccine followed by oral poliovirus vaccine; recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1997;46[No. RR-3]:1–25).

†† No evidence exists that live-attenuated vaccine-strain viruses in measles-mumps-rubella vaccine have ever been transmitted from person-to-person, except rubella vaccine virus from a nursing mother to her infant (**Source**: CDC. Measles, mumps, and rubella—vaccine use and strategies for elimination of measles, rubella, and congenital rubella syndrome and control of mumps: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1998;47[No. RR-8]:1–48).

** HCWs, family members, close contacts and visitors who do not have a documented history of varicella-zoster infection or who are seronegative should receive this vaccination before being allowed to visit or have direct contact with an HSCT recipient (AIII). Ideally, varicella-zoster–susceptible HCWs, family members, household contacts, and potential visitors of immunocompromised HSCT recipients should be vaccinated as soon as the decision to perform an HSCT is made. The vaccination dose or doses should be completed ≥4 weeks before the conditioning regimen begins or ≥6 weeks (42 days) before contact with the HSCT recipient is planned (BIII). If a varicella vaccinee develops a postvaccination rash within 42 days of vaccination, the vaccinee should avoid contact with HSCT recipients until all rash lesions are crusted or the rash has resolved (**Sources**: CDC. Prevention of varicella: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1996;45[No. RR-11]:1–36; and CDC. Immunization of health care workers: recommendations of the Advisory Committee on Immunization Practices [ACIP] and the Hospital Infection Control Practices Advisory Committee. MMWR 1997;46[No. RR-18]:1–42).

TABLE 6. Vaccinations for hematopoietic stem cell transplant (HSCT) recipients traveling to areas endemic for selected vaccine-preventable diseases

Vaccine	Recommendations for use	Rating
Bacillus of Calmette and Guérin (live-attenuated vaccine)	Use of live-attenuated vaccine is contraindicated among HSCT recipients at <24 months after HSCT and among all persons who are immunocompromised.* No data were found regarding use among HSCT recipients.	EIII
Cholera	Vaccination is not indicated. No data were found regarding safety and immunogenicity among HSCT recipients.†	DIII
Hepatitis A	No data were found regarding immunogenicity, safety, or efficacy of hepatitis A vaccine among HSCT recipients; therefore, intramuscular immunoglobulin use is preferred for hepatitis A prophylaxis among HSCT recipients. However, administration of intramuscular immunoglobulin does not replace avoidance behaviors (e.g., careful selection of food and water).§ Researchers recommend that hepatitis A vaccination be evaluated for investigational use among HSCT recipients aged ≥24 months; however, no recommendation can be made because of limited data.	Not rated because of limited data
Japanese B encephalitis	No data were found regarding safety, immunogenicity, or efficacy among HSCT recipients.¶	Not rated because of limited data
Lyme disease	No data were found regarding safety, immunogenicity, or efficacy among HSCT recipients.	Not rated because of limited data
Meningococcal vaccine	Vaccine should be administered to HSCT recipients traveling to endemic areas or to areas experiencing outbreaks.** However, meningococcal vaccine immunogenicity and efficacy have not been studied among HSCT recipients.	Not rated because of limited data
Plague	No data were found regarding safety, immunogenicity, or efficacy among HSCT recipients.††	Not rated because of limited data
Polio (inactivated polio vaccine only)	Booster dose can be administered as indicated.§§	CIII
Rabies	Researchers recommend that administration of a preexposure series be evaluated for persons at ≥12 months after HSCT if they anticipate travel to endemic areas.¶¶ However, no data were found regarding safety, immunogenicity, or efficacy among HSCT recipients.	Not rated because of limited data
Typhoid, oral (live-attenuated vaccine)	Use of oral typhoid vaccine (live-attenuated strain) is contraindicated among HSCT recipients at <24 months after HSCT and among those who are immunocompromised.*** No data were found regarding safety, immunogenicity, or efficacy among HSCT recipients.	EIII
Typhoid (intramuscular)	No data were found regarding safety, immunogenicity, or efficacy among HSCT recipients.	Not rated because of limited data
Yellow fever (live-attenuated vaccine)	Use of live-attenuated vaccine is contraindicated among HSCT recipients at <24 months after HSCT and among all immunocompromised persons.††† No data were found regarding safety, immunogenicity, or efficacy among HSCT recipients.	EIII

Additional Note: Specific advice for international travelers, including information regarding endemic diseases by country, is available through CDC's automated travelers' hotline at (404) 332-4559; by facsimile at (404) 335-4565; on the Internet at <http://www.cdc.gov>; and by file transfer protocol at <ftp.cdc.gov>.

TABLE 7. Use of passive immunization for hematopoietic stem cell transplant (HSCT) recipients exposed to vaccine-preventable diseases

Preparation	Recommendations for Use	Rating
Cytomegalovirus immunoglobulin	Not recommended for prophylaxis among HSCT recipients because of its lack of efficacy.*	DI
Hepatitis B immunoglobulin	Immunocompromised persons who have percutaneous or permucosal exposure to hepatitis B virus should receive 2 doses administered 1 month apart. For immunocompetent persons, the need for postexposure prophylaxis depends on the vaccination history and antibody to hepatitis B surface antigen response status of the exposed person.†	CIII
Human rabies immunoglobulin	Should be administered with rabies vaccine at anytime after HSCT as indicated for postexposure rabies prophylaxis. Existing Advisory Committee on Immunization Practices guidelines for postexposure should be followed, with 5 doses of rabies vaccine administered on days 0, 3, 7, 14, and 28 postexposure.§	CIII
Respiratory syncytial virus immunoglobulin¶	Because of high rates of case fatality from respiratory syncytial virus pneumonia among HSCT recipients, HSCT physicians can administer HSCT recipients with upper or lower respiratory infection preemptive therapy with a high titer of neutralizing antibodies to prevent severe disease and death until controlled trials can be performed.**	CIII
Respiratory syncytial virus monoclonal antibody	Physicians can use respiratory syncytial virus monoclonal antibody†† investigationally as preemptive therapy (Appendix).	Not rated because of limited data
Tetanus immunoglobulin	Postexposure vaccination should be administered with or without tetanus immunoglobulin as indicated for tetanus exposure§§ that occurs anytime after HSCT.	CIII
Varicella-zoster immunoglobulin¶¶	Ideally, should be administered to HSCT recipients ≤96 hours after close contact with a person with varicella or shingles if the HSCT recipient is at a) <24 months after HSCT or b) ≥24 months after HSCT and still immunocompromised. Administration can extend the varicella incubation period from 10–21 days to 10–28 days. If the HSCT recipient experiences a varicella-zoster virus-like rash after contact with or exposure to a person with varicella or herpes zoster, antiviral drug therapy should be administered until ≥2 days after all lesions have crusted.***	AII
Intramuscular immunoglobulin	Should be administered to hepatitis A-susceptible HSCT recipients who anticipate hepatitis A exposure, (e.g., during travel to endemic areas) and for postexposure prophylaxis as indicated.††† Should also be administered after measles exposure among HSCT recipients who were not vaccinated against measles after HSCT.§§§	BIII
Intravenous immunoglobulin¶¶¶	Can be administered to HSCT recipients with severe hypogammaglobulinemia (immunoglobulin G < 400 mg/dl) ≤100 days after HSCT to prevent bacterial infections**** (Appendix).	CIII

Elk Grove Village, IL: American Academy of Pediatrics;2000:475–82; and CDC. Human rabies prevention—United States, 1999: recommendations of the Advisory Committee on Immunization Practices (ACIP) MMWR 1999;48(No. RR-1):1–21; published erratum, MMWR 1999;48(1):16.

TABLE 7. (*Continued*) Use of passive immunization for hematopoietic stem cell transplant (HSCT) recipients exposed to vaccine-preventable diseases

¶ Researchers recommend substituting respiratory syncytial virus immunoglobulin for intravenous immunoglobulin for HSCT recipients on replacement intravenous immunoglobulin therapy during respiratory syncytial virus season (i.e., November–April) (**Source**: American Academy of Pediatrics. Respiratory syncytial virus. In: Pickering LK, ed. 2000 red book: report of the Committee on Infectious Diseases. 25th ed. Elk Grove Village, IL: American Academy of Pediatrics;2000:483–7) (CIII). However, no data were found demonstrating safety and efficacy of respiratory syncytial virus immunoglobulin use among HSCT recipients.

§§ **Source**: CDC. Diphtheria, tetanus, and pertussis: recommendations of vaccine use and other prevention measures; recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR 1991;40(No. RR-10):1–28.

¶¶ If intravenous immunoglobulin replacement therapy (>250 mg/kg) has been administered <2 weeks before varicella or zoster rash exposure, varicella-zoster immunoglobulin administration is probably not required. Varicella-zoster immunoglobulin is distributed by the American Red Cross, except in Massachusetts, where it is distributed by the Massachusetts Public Health Biologic Laboratories (now a unit of the University of Massachusetts) (**Source**: CDC. Prevention of varicella: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1996;45[No. RR-11]:1–36).

*** **Source**: CDC. Prevention of varicella: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR 1996;45(No. RR-11):1–36.

††† **Source**: CDC. Prevention of hepatitis A through active or passive immunization: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR 1999;48(No. RR-12):1–37.

§§§ **Sources**: CDC. Measles, mumps, and rubella—vaccine use and strategies for elimination of measles, rubella, and congenital rubella syndrome and control of mumps: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR 1998;47(No. RR-8):1–48; and Eibl MM, Wedgwood RJ. Intravenous immunoglobulin: a review. Immunodeficiency Reviews 1989;1:1–42.

¶¶¶ When administered, serum immunoglobulin G levels should be monitored regularly (e.g., every 2 weeks).

**** **Sources**: Antman KH, Rowlings PA, Vaughn WP, et al. High-dose chemotherapy with autologous hematopoietic stem cell support for breast cancer in North America. J Clin Oncol 1997;15(5):1870–9; and Wolff SN, Fay JW, Herzig RH, et al. High-dose weekly intravenous immunoglobulin to prevent infections in patients undergoing autologous bone marrow transplantation or severe myelosuppressive therapy. Ann Intern Med 1993;118(12):937–42.

Additional Notes: Intravenous immunoglobulin can be obtained from the American Red Cross Blood Services, although shortages occasionally occur. Physicians who have difficulty obtaining urgently needed intravenous immunoglobulin and other immunoglobulin products are advised to contact any of the following:

- American Red Cross Customer Service Center, (800) 261-5772;
- Alpha Therapeutic Corporation, (800) 421-0008;
- Baxter Healthcare Corporation, (847) 940-5955;
- Bayer Pharmaceutical Division, (800) 288-8370;
- Aventis Behring Customer Support, (800) 683-1288;
- Novartis Pharmaceuticals Corporation, (973) 781-8300, or the Intravenous Immunoglobulin Emergency Hotline, (888) 234-2520; or
- Immune Deficiency Foundation, (800) 296-4433.

Physicians who are unable to obtain intravenous immunoglobulin for a licensed indication from one of these sources should contact the Product Shortage Officer at the Food and Drug Administration's Center for Biologics Evaluation and Research, Office of Compliance, (301) 827-6220, for assistance. Patients with immunoglobulin E anti-immunoglobulin A antibodies are at high risk for experiencing anaphylaxis from immunoglobulin administration (**Source**: Burks AW, Sampson HA, Buckley RH. Anaphylactic reactions after gamma globulin administration in patients with hypogammaglobulinemia. New Engl J Med 1986;314[9]:560–4). Therefore, persons with immunoglobulin A deficiency should not be administered standard immunoglobulin preparations (DIII; BIII). However, researchers report that use of immunoglobulin A-depleted immunoglobulin preparations can be used with caution in these persons (**Sources**: Burks AW, Sampson HA, Buckley RH. Anaphylactic reactions after gamma globulin administration in patients with hypogammaglobulinemia. New Engl J Med 1986;314[9]:560–4; Siberry GK, Iannone R, eds. Harriet Lane handbook: a manual for pediatric house officers. 15th ed.; St. Louis, MO: Mosby, Inc., 2000:339;739; and Stiehm ER. Human intravenous immunoglobulin in primary and secondary antibody deficiencies [Review]. Pediatr Infect Dis J 1997;16[7]:696–707).

TABLE 8. Vaccine information

Vaccine or toxoid	Trade name	Manufacturer/ telephone number	Storage recommendation
Diphtheria toxoid-tetanus toxoid-pertussis vaccine	Tripedia®	Aventis Pasteur, Inc. (800) Vaccine	Store at 2–8 C (36–46 F); do not freeze
	Infanrix®	SmithKline Beecham (800) 877-1158	
	Acel-Imune®	Wyeth-Lederle (800) 572-8221	
	Certiva®	North American Vaccine (888) 628-2829	
Diphtheria toxoid-tetanus toxoid-pertussis vaccine–*Haemophilus influenzae* type b	Tetramune®	Wyeth-Lederle (800) 572-8221	Store at 2–8 C (36–46 F); do not freeze
	DTP/ACTHib®	Aventis Pasteur, Inc. (800) Vaccine	
	TriHibit®		
Tetanus-diphtheria toxoid (adult) and Diphtheria-tetanus toxoid (pediatric)	Generic	Aventis Pasteur, Inc. (800) Vaccine Wyeth-Lederle (800) 572-8221	Store at 2–8 C (36–46 F); do not freeze
Haemophilus influenzae type b	ACTHib®	Aventis Pasteur, Inc. (800) Vaccine	Store at 2–8 C (36–46 F); do not freeze
	HibTiter®	Wyeth-Lederle (800) 572-8221	
	PedvaxHIB®	Merck Human Health Division (800) MerckRX (ordering) (800) NSCmerc (questions)	
	OmniHIB®	SmithKline Beecham (800) 877-1158	
Haemophilus influenzae type b-Hepatitis B	COMVAX®	Merck Human Health Division (800) MerckRX (ordering) (800) NSCmerc (questions)	Store at 2–8 C (36–46 F); do not freeze
Inactivated polio vaccine	IPOL®	Aventis Pasteur, Inc. (800) Vaccine	
Measles-mumps-rubella Measles-rubella Mumps-rubella Measles Mumps Rubella	M-M-R II® M-R-Vax II® Biavax II® Attenuvax® Mumpsvax® Meruvax II®	Merck Human Health Division (800) MerckRX (ordering) (800) NSCmerc (questions)	Store at 2–8 C (36–46 F); freezing is permissible
Varicella	Varivax®		Maintain in a frozen state of –15 C (5 F) or colder
Hepatitis A	Vaqta® Havix®	SmithKline Beecham (800) 877-1158	Store at 2–8 C (36–46 F); do not freeze
Hepatitis B	Engerix-B® Recombivax B®	Merck Human Health Division (800) MerckRX (ordering) (800) NSCmerc (questions)	Store at 2–8 C (36–46 F); do not freeze
Influenza	Fluzone®	Aventis Pasteur, Inc. (800) Vaccine	Store at 2–8 C (36–46 F); do not freeze
	Fluvirin®	Celltech Medeva Pharmaceutical (800) 234-5535	
	Flu-Shield®	Wyeth-Ayerst Laboratories (800) 358-7443	
	Fluogen®	Monarch Pharmaceuticals (888) 358-6436	
Japanese encephalitis	JE-VAX	Research Foundation for Microbial Diseases of Osaka University, Japan; Distributed by Aventis Pasteur, Inc. (800) Vaccine SmithKline Beecham	Store at 2–8 C (36–46 F); do not freeze

TABLE 8. (*Continued*) Vaccine information

Vaccine or toxoid	Trade name	Manufacturer/ telephone number	Storage recommendation
Lyme disease	LYMErix™	(800) 877-1158	Store at 2–8 C 36–46 F); do not freeze
Pneumococcal 23-valent	Pru-Immune-23®	Wyeth-Lederle (800) 572-8221	Store at 2–8 C (36–46 F); do not freeze
	Pneumovax 23®	Merck Human Health Division (800) MerckRX (ordering) (800) NSCmerc (questions)	
Meningococcal	Menomune-A/C/Y/W-135®	Aventis Pasteur, Inc. (800) Vaccine	Store at 2–8 C (36–46 F); do not freeze
Rabies	Generic	BioPort Corporation (517) 327-1500; distributed by SmithKline Beecham (800) 877-1158	Store at 2–8 C (36–46 F); do not freeze
	Imovax Rabies® and Imovax Rabies ID®	Aventis Pasteur, Inc. (800) Vaccine	
	RabAvert™	Chiron Corporation (800) 244-7668	
Typhoid	Typhoid Vaccine U.S. P.	Wyeth-Lederle (800) 572-8221	
Typhoid Vi polysaccharide	Typhim Vi™	Aventis Pasteur, Inc. (800) Vaccine	

Notes: Persons needing additional vaccine information or CDC's Advisory Committee on Immunization Practices guidelines can contact the CDC Immunization Hotline at (800) CDC-SHOT ([800] 232-7468) or at <http:// www.cdc.gov/nip>. Adverse events after vaccination should be reported promptly to the Vaccine Adverse Event Reporting System (VAERS), P.O. Box 1100, Rockville, MD 20849-1100. Forms and information can be obtained from VAERS at (800) 822-7967.

Appendix

Dosing Charts for Preventing Opportunistic Infections Among Hematopoietic Stem Cell Transplant Recipients

I. Preventive regimens for adult or adolescent hematopoietic stem cell transplant (HSCT) recipients

Pathogen: Cytomegalovirus

Indication	First choice	Alternatives
Universal prophylaxis for cytomegalovirus disease among all allogeneic adult or adolescent HSCT recipients at risk throughout phase II (i.e., from engraftment to day 100 after HSCT)	Ganciclovir, 5 mg/kg/dose intravenously every 12 hours for 5–7 days, followed by 5–6 mg/kg intravenously daily for 5 days/week from engraftment until day 100 after HSCT (AI)	Foscarnet, 60 mg/kg intravenously every 12 hours for 7 days, followed by 90–120 mg/kg intravenously daily until day 100 after HSCT (CIII)
Or preemptive cytomegalovirus treatment administered <100 days after HSCT to all allogeneic adult or adolescent HSCT recipients at risk: Start ganciclovir when the patient experiences any level of cytomegalovirus antigenemia or viremia or has ≥2 consecutively positive cytomegalovirus-DNA polymerase chain reaction tests	Ganciclovir, 5 mg/kg/dose intravenously every 12 hours for 7–14 days, followed by 5 mg/kg/day for 5 days/week until day 100 after HSCT or for a minimum of 3 weeks, whichever is longer (AI); or administer ganciclovir for a total of 3–6 weeks; antigen or polymerase chain reaction tests should be negative when ganciclovir is stopped; reinstitute ganciclovir if subsequent weekly cytomegalovirus antigenemia screening tests become positive (BI)	
Preemptive treatment for cytomegalovirus seropositive autologous adult or adolescent HSCT recipients at <100 days after HSCT: Start ganciclovir when antigenemia is ≥5 cells/slide, but CD34+-selected patients should be treated at any level of antigenemia*	Ganciclovir, 5 mg/kg/dose intravenously every 12 hours for 7 days, followed by 5 mg/kg/day intravenously for 5 days/week for 2 weeks (BII)	
Preemptive treatment of allogeneic adult or adolescent HSCT recipients >100 days after HSCT: Start ganciclovir when a) antigenemia is ≥5 cells/slide or b) the patient has had ≥2 consecutively positive viremia or polymerase chain reaction tests (e.g., in a person receiving steroids for graft-versus-host disease or who received ganciclovir or foscarnet at <100 days after HSCT)	Ganciclovir, 5 mg/kg/dose intravenously every 12 hours for 7 days, followed by 5 mg/kg/day intravenously for 5 days/week for 2 weeks (BIII)	

* **Source**: Holmberg LA, Boeckh M, Hooper H, et al. Increased incidence of cytomegalovirus disease after autologous CD34-selected peripheral blood stem cell transplantation [Clinical observations, interventions, and therapeutic trials]. Blood 1999;94(12):4029–35.

Notes: Patients who do not tolerate standard doses of ganciclovir should be administered foscarnet. Ganciclovir and foscarnet doses should be modified for renal impairment. Prehydration is required for foscarnet administration.

Pathogen: Herpes simplex virus

Indication	First choice	Alternatives
Prevention of herpes simplex virus reactivation among seropositive adult or adolescent HSCT recipients: Start acyclovir at the beginning of conditioning therapy and continue until engraftment or until mucositis resolves (i.e., approximately 30 days after HSCT for allogeneic HSCT recipients)	Acyclovir, 200 mg by mouth 3 times/day or 250 mg/m^2/dose infused over 1 hour intravenously every 12 hours (BIII)	Valacyclovir, 500 mg by mouth daily (CIII)

Note: For patients requiring prophylaxis for cytomegalovirus and herpes simplex virus after engraftment, ganciclovir alone provides effective prophylaxis for both pathogens.

Pathogen: Varicella-zoster virus

Indication	First choice	Alternatives
Prevention of varicella-zoster virus disease after exposure among adult or adolescent HSCT recipients who are at <24 months after HSCT or who are at ≥24 months after HSCT and on immunosuppressive therapy or have chronic graft-versus-host disease: Ideally, administer prophylaxis within 96 hours (preferably, within 48 hours) after close contact with a person who has chickenpox or shingles	Varicella-zoster immunoglobulin, 5 vials (1.25 ml each or 625 units total) intramuscularly (AII)	None

Pathogen: Influenza

Indication	First choice	Alternatives
Prevention of influenza A or B among adult or adolescent HSCT recipients	Lifelong annual seasonal (i.e., October–May) influenza vaccination starting before HSCT and restarting 6 months after HSCT (BIII); whole- or split-virus influenza vaccine, 0.5 ml/dose intramuscularly	None
Prophylaxis and preemptive treatment among all HSCT recipients during community and nosocomial outbreaks of influenza A	Rimantadine, 100 mg by mouth 2 times/day (CIII)	Amantadine, 100 mg by mouth 2 times/day (CIII)

Notes: Rimantadine dose should be reduced for patients with impaired renal function or for severely impaired hepatic function. Amantadine dose should be reduced for renal impairment.

Pathogen: Bacterial infections, general prophylaxis

Indication	First choice	Alternatives
Prevention of bacterial infections among allogeneic adult or adolescent HSCT recipients with severe hypogammaglobulinemia (i.e., serum immunoglobulin G level < 400 mg/dl) at <100 days after HSCT	Intravenous immunoglobulin, 500 mg/kg/week (CIII)	None

Notes: Patients with immunoglobulin E anti-immunoglobulin A antibodies are at high risk for experiencing anaphylaxis from immunoglobulin administration (**Source**: Burks AW, Sampson HA, Buckley RH. Anaphylactic reactions after gamma globulin administration in patients with hypogammaglobulinemia. New Engl J Med 1986;314[9]:560–4). Therefore, persons with immunoglobulin A deficiency should not receive standard immunoglobulin products (**Source**: Siberry GK, Iannone R, eds. Harriet Lane handbook: a manual for pediatric house officers. 15th ed.; St. Louis, MO: Mosby, Inc., 2000:339;739) (DIII). However, researchers have reported that use of immunoglobulin A-depleted immunoglobulin preparations can be used with caution among these persons (**Sources**: Burks AW, Sampson HA, Buckley RH. Anaphylactic reactions after gamma globulin administration in patients with hypogammaglobulinemia. New Engl J Med 1986;314[9]:560–4; Stiehm ER. Human intravenous immunoglobulin in primary and secondary antibody deficiencies [Review]. Pediatr Infect Dis J 1997;16[7]:696–707; and American Academy of Pediatrics. Passive immunization. In: Pickering LK, ed. 2000 red book: report of the Committee on Infectious Diseases. 25th ed. Elk Grove Village, IL: American Academy of Pediatrics;2000:41–53). Researchers also propose checking serum immunoglobulin G levels every 2 weeks among patients receiving intravenous immunoglobulin replacement therapy.

Pathogen: *Streptococcus pneumoniae*

Indication	First choice	Alternatives
Prevention of pneumococcal disease among adult or adolescent HSCT recipients	23-valent pneumococcal polysaccharide vaccine at 12 and 24 months after HSCT (BIII)	None

Note: Penicillin-resistant *Streptococcus pneumoniae* is increasing in the United States.

Pathogen: *Haemophilus influenzae* type b

Indication	First choice	Alternatives
Prevention of invasive *Haemophilus influenzae* type b (Hib) disease among adult or adolescent HSCT recipients	Hib conjugate vaccine administered at 12, 14, and 24 months after HSCT (BII)	None
Generally, HSCT recipients who are household contacts of a person with Hib disease should be administered rifampin prophylaxis* (BIII); however, prophylaxis is not needed for adult or adolescent HSCT recipients who are household contacts of a person with Hib disease if all household contacts aged <4 years are fully vaccinated	Rifampin 600 mg by mouth daily for 4 days (BIII)	

* **Source**: American Academy of Pediatrics. *Haemophilus influenzae* infections. In: Pickering LK, ed. 2000 red book: report of the Committee on Infectious Diseases. 25th ed. Elk Grove Village, IL: American Academy of Pediatrics;2000:262–72.

Pathogen: Methicillin-resistant *Staphylococcus aureus*

Indication	First choice	Alternatives
Elimination of methicillin-resistant *Staphylococcus aureus* carrier state among adults or adolescents to prevent this disease among chronic carriers	Mupirocin calcium ointment 2%; use a cotton-tipped applicator or equivalent to apply to nares 2 times/day for 5 days or to wounds daily for 2 weeks	None

Pathogen: *Candida* species

Indication	First choice	Alternatives
Prophylaxis for disease from fluconazole-susceptible *Candida* species among a) allogeneic adult or adolescent HSCT recipients or b) autologous adult or adolescent HSCT recipients with lymphoma or leukemia and who have or will have prolonged neutropenia and mucosal damage from intense conditioning regimens or graft manipulation or who have recently received fludarabine or 2-chlorodeoxyadenosine: Administer prophylaxis from the day of transplantation (i.e., day 0) until engraftment (i.e., approximately 30 days after HSCT) or until 7 days after the absolute neutrophil count > 1,000 cells/mm^3	Fluconazole, 400 mg by mouth or intravenously daily (AI)	None

Pathogen: *Pneumocystis carinii*

Indication	First choice	Alternatives
Prophylaxis for *Pneumocystis carinii* pneumonia among a) all allogeneic adult or adolescent HSCT recipients or b) autologous adult or adolescent HSCT recipients with underlying hematologic malignancies (e.g., lymphoma or leukemia) or for those receiving intense conditioning regimens or graft manipulation or for those who have recently received fludarabine or 2-chlorodeoxyadenosine:* Administer prophylaxis from time of engraftment for ≥6 months after HSCT; continue >6 months after HSCT for the duration of immunosuppression for all persons who a) are receiving immunosuppressive therapy (e.g., prednisone or cyclosporine) or who b) have chronic graft-versus-host disease	Trimethoprim-sulfamethoxazole, 1 double-strength tablet by mouth daily or 1 single-strength tablet by mouth daily or 1 double-strength tablet by mouth 3 times/week (AII); researchers also recommend administering prophylaxis for 1–2 weeks before HSCT (i.e., day –14 to –2) (CIII)	Dapsone, 50 mg by mouth 2 times/day or 100 mg by mouth daily (BIII) or pentamidine, 300 mg every 3–4 weeks by Respirgard II™ nebulizer (CIII)

* **Source**: Tuan IZ, Dennison D, Weisdorf DJ. *Pneumocystis carinii* pneumonitis after bone marrow transplantation. Bone Marrow Transplant 1992;10(3):267–72.

Note: Patients who are receiving sulfadiazine-pyrimethamine for toxoplasmosis therapy are protected against *Pneumocystis carinii* and do not need additional prophylaxis.

Pathogen: *Toxoplasma gondii*

Indication	First choice	Alternatives
Prophylaxis of *Toxoplasma gondii* disease among seropositive allogeneic adult or adolescent HSCT recipients: Start after engraftment and administer as long as patients remain on immunosuppressive therapy (i.e., generally, until 6 months after HSCT)	Trimethoprim-sulfamethoxazole, 1 double-strength tablet by mouth daily or 1 single-strength tablet by mouth daily or 1 double-strength table by mouth 3 times/week (AII)	For those persons who are intolerant of trimethoprim-sulfamethoxazole, the following drugs can be substituted: Clindamycin, 300–450 mg by mouth every 6–8 hours; plus pyrimethamine, 25–75 mg by mouth daily; plus leucovorin, 10–25 mg by mouth 4 times/day (CIII)

Note: Among allogeneic HSCT recipients, clinical toxoplasmosis has occurred despite the use of trimethoprim-sulfamethoxazole for *Pneumocystis carinii* prophylaxis (**Source**: Slavin MA, Meyers JD, Remington JS, Hackman RC. *Toxoplasma gondii* infection in marrow transplant recipients: a 20 year experience. Bone Marrow Transplant 1994;13[5]:549–57).

Pathogen: *Strongyloides* species

Indication	First choice	Alternatives
Prevention of strongyloidiasis hyperinfection among adult or adolescent HSCT candidates whose HSCT screening tests are positive for *Strongyloides* species or who have an unexplained eosinophilia and a travel or residence history suggestive of exposure to *Strongyloides stercoralis*: Administer prophylaxis before HSCT	Ivermectin, 200 µg/kg by mouth daily for 2 consecutive days* (BIII); 1 tablet = 6 mg; doses administered as follows: Body weight (kg) — Oral dose <15 — Not recommended ≥15–24 — ½ tablet 25–35 — 1 tablet 36–50 — 1½ tablets 51–65 — 2 tablets 66–79 — 2½ tablets ≥80 — 200 µg/kg	Albendazole, 400 mg by mouth daily for 3 days or thiabendazole, 25 mg/kg by mouth 2 times/day for 2 days (BIII); maximum dose, 3 g/24 hours

*__Sources__: Liu LX, Weller PF. Strongyloidiasis and other intestinal nematode infections [Review]. Infect Dis Clin North Am 1993;7(3):655–82; and Naquira C, Jimenez G, Guerra JG, et al. Ivermectin for human strongyloidiasis and other intestinal helminths. Am J Trop Med Hyg 1989;40:304–9.

Notes: Among immunocompromised patients, multiple courses at 2-week intervals might be required; however, cure might not be achievable. Safety and efficacy of ivermectin has not been established during pregnancy. Albendazole and thiabendazole are contraindicated during pregnancy.

Pathogen: Traveler's diarrhea

Indication	First choice	Alternatives
Prophylaxis among adult or adolescent HSCT recipients who are immunocompromised and who plan to travel in developing countries	Ciprofloxacin, 500 mg by mouth daily for the duration of stay in developing countries (BIII) or bismuth subsalicylate, 2 oz by mouth 4 times/day or 2 tablets by mouth 4 times/day; can be administered for ≤3 weeks to prevent travelers' diarrhea in adults aged >18 years only	Trimethoprim-sulfamethoxazole, 1 double-strength tablet by mouth daily for the duration of stay in developing country (CIII)

Notes: Use of aspirin-containing products including bismuth subsalicylate is contraindicated in persons aged <18 years unless prescribed by a physician because these products have been associated with Reye's syndrome (**Source**: Belay E, Bresee JS, Holman RC, Khan AS, Shahriari A, Schonberger LB. Reye's syndrome in the United States from 1981 through 1997. New Engl J Med 1999;340[18]:1377–82). Ciprofloxacin, norfloxacin, and ofloxacin are not approved for use among children aged <18 years.

Pathogen: *Mycobacteria tuberculosis*

Indication	First choice	Alternatives
Prevention of *Mycobacteria tuberculosis* among a) highly immunocompromised adult or adolescent HSCT recipients or candidates who have been substantially exposed to someone with active, infectious (e.g., sputum smear positive) pulmonary or laryngeal tuberculosis, regardless of the HSCT recipient's or candidate's tuberculin skin test status, or b) adult or adolescent HSCT recipients or candidates with a positive tuberculin skin test and who were not previously treated and have no evidence of active tuberculosis disease	Isoniazid, 5 mg/kg/day by mouth or intramuscularly for 9 months (i.e., for ≥270 doses);* maximum dose, 300 mg/day, and pyridoxine (vitamin B_6), 25–50 mg by mouth daily for 9 months; administer to nutritionally deficient HSCT recipients and candidates while on isoniazid preventive therapy to reduce the occurrence of isoniazid-induced neuropathy* (BIII)	None

*__Source__: CDC. Prevention and treatment of tuberculosis among patients infected with human immunodeficiency virus: principles of therapy and revised recommendations. MMWR 1998;47(No. RR-20):1–58.

Notes: A twice-weekly schedule of isoniazid and pyridoxine can be administered (CIII). The twice-weekly isoniazid dose is 15 mg/kg by mouth or intramuscularly (maximum dose, 900 mg). The twice-weekly pyridoxine dose is 50–100 mg by mouth. A 2-month pyrazinamide/rifampin preventive therapy regimen can be used for HSCT candidates who are not at risk for serious rifampin drug interactions and whose HSCT is not scheduled until ≥2 weeks after the 2-month course is completed (**Sources**: CDC. Notice to readers: use of short-course tuberculosis preventive therapy regimens in HIV-seronegative persons. MMWR 1998;47[42]:911–2; and CDC. Prevention and treatment of tuberculosis among patients infected with human immunodeficiency virus: principles of therapy and revised recommendations. MMWR 1998;47[No. RR-20]:1–58) (CIII). The usual pyrazinamide dose is 15–30 mg/kg/day by mouth or 50–70 mg/kg/dose by mouth 2 times/week (maximum daily pyrazinamide dose, 2.0 gm; maximum twice-weekly dose, 3.5 gm). Rifampin dose is 10 mg/kg/day by mouth or intravenously or 10 mg/kg/dose administered 2 times/week by mouth or intravenously (maximum rifampin dose, 600 mg). Routine use of a 2-month pyrazinamide/rifampin preventive therapy regimen is not recommended after HSCT because of the risk for serious rifampin drug interactions (DIII). Persons who have been exposed to rifampin- and isoniazid-resistant tuberculosis should be placed on preventive therapy regimens that involve ≥2 antituberculosis drugs to which the infecting strain is susceptible, and a tuberculosis specialist should be consulted (**Source**: CDC. Prevention and treatment of tuberculosis among patients infected with human immunodeficiency virus: principles of therapy and revised recommendations. MMWR 1998;47[No. RR-20]:1–58) (BIII). A tuberculosis specialist should also be consulted for patients who are intolerant to isoniazid (AIII). All intermittent dosing strategies should be administered as directly observed therapy (AIII).

II. Preventive regimens for pediatric hematopoietic stem cell transplant (HSCT) recipients

Pathogen: Cytomegalovirus

Indication	First choice	Alternatives
Universal prophylaxis for cytomegalovirus disease among all allogeneic pediatric HSCT recipients at risk throughout phase II (i.e., from engraftment to day 100 after HSCT)	Ganciclovir, 5 mg/kg/dose intravenously every 12 hours for 5–7 days, followed by 5 mg/kg/dose intravenously daily for 5 days/week from engraftment until day 100 after HSCT (AI)	Foscarnet, 60 mg/kg intravenously every 12 hours for 14 days, followed by 90–120 mg/kg/day until day 100 after HSCT (CIII)
Or preemptive cytomegalovirus treatment administered <100 days after HSCT to all allogeneic pediatric HSCT recipients at risk: Start ganciclovir when the patient experiences any level of cytomegalovirus antigenemia or viremia or has ≥2 consecutively positive cytomegalovirus-DNA polymerase chain reaction tests	Ganciclovir, 5 mg/kg/dose intravenously every 12 hours for 7–14 days, followed by 5 mg/kg/day for 5 days/week until day 100 after HSCT or for a minimum of 3 weeks, whichever is longer (AI); or administer ganciclovir for a total of 3–6 weeks; antigen or polymerase chain reaction tests should be negative when ganciclovir is stopped; reinstitute ganciclovir if subsequent weekly cytomegalovirus antigenemia screening tests become positive (BI)	
Preemptive treatment for cytomegalovirus seropositive autologous pediatric HSCT recipients at <100 days after HSCT: Start ganciclovir when antigenemia is ≥5 cells/slide, but CD34+-selected patients should be treated at any level of antigenemia*	Ganciclovir, 5 mg/kg/dose intravenously every 12 hours for 7 days, followed by 5 mg/kg/day intravenously for 5 days/week for 2 weeks (BII)	
Preemptive treatment of allogeneic pediatric HSCT recipients >100 days after HSCT: Start ganciclovir when a) antigenemia is ≥5 cells/slide or b) the patient has had ≥2 consecutively positive viremia or polymerase chain reaction tests (e.g., in a person receiving steroids for graft-versus-host disease or who received ganciclovir or foscarnet at <100 days after HSCT)	Ganciclovir, 5 mg/kg/dose intravenously every 12 hours for 7 days, followed by 5 mg/kg/day intravenously for 5 days/week for 2 weeks (BIII)	

* **Source**: Holmberg LA, Boeckh M, Hooper H, et al. Increased incidence of cytomegalovirus disease after autologous CD34-selected peripheral blood stem cell transplantation [Clinical observations, interventions, and therapeutic trials]. Blood 1999;94(12):4029–35.

Notes: Patients who do not tolerate standard doses of ganciclovir should be administered foscarnet. Ganciclovir and foscarnet doses should be modified for renal impairment. Prehydration is required for foscarnet administration.

Pathogen: Herpes simplex virus

Indication	First choice	Alternatives
Prevention of herpes simplex virus reactivation among seropositive pediatric HSCT recipients: Start acyclovir at the beginning of conditioning therapy and continue until engraftment or until mucositis resolves (i.e., approximately 30 days after HSCT for allogeneic HSCT recipients)	Acyclovir, 250 mg/m^2/dose intravenously every 8 hours (BIII) or 125 mg/m^2/dose intravenously every 6 hours (CIII)	Acyclovir 600–1,000 mg/24 hours by mouth, divided in 3–5 doses/day

Note: For patients requiring prophylaxis for cytomegalovirus and herpes simplex virus after engraftment, ganciclovir alone provides effective prophylaxis for both pathogens. Valacyclovir is not approved for use among children.

Pathogen: Varicella-zoster virus

Indication	First choice	Alternatives
Prevention of varicella-zoster virus disease after exposure among pediatric HSCT recipients who are at <24 months after HSCT or who are at ≥24 months after HSCT and on immunosuppressive therapy or have chronic graft-versus-host disease: Ideally, administer prophylaxis within 96 hours (preferably, within 48 hours) after close contact with a person who has chickenpox or shingles	Varicella-zoster immunoglobulin, 125 units (1.25 ml)/10 kg (22 lbs) of body weight administered intramuscularly; maximum dose, 625 units or 5 vials (All); doses administered as follows: Body weight (kg) — Dose — Number of vials 0–10 — 125 units — 1 10.1–20 — 250 units — 2 20.1–30 — 375 units — 3 30.1–40 — 500 units — 4 >40 kg — 625 units — 5	Limited data demonstrate that a 1-week course of high-dose acyclovir might prevent varicella

Pathogen: Influenza

Indication	First choice	Alternatives
Prevention of influenza A and B among pediatric HSCT recipients	Lifelong annual seasonal (i.e., October–May) influenza vaccination before HSCT and resuming ≥6 months after HSCT (BIII); doses administered as follows: Age: 6–35 mo — Number of doses: 0.25 ml — Type of influenza vaccine: Split-virus* 3–8 years — 0.5 ml — Split-virus* 9–12 years — 0.5 ml — Split-virus >12 years — 0.5 ml — Whole- or split-virus	None
Prophylaxis and preemptive treatment of influenza A among pediatric HSCT recipients during nosocomial or community influenza A outbreaks	Rimantadine, for children aged 1–9 years, 5 mg/kg/day once daily or divided in 2 doses (CIII); maximum daily dose, 150 mg; for children aged ≥10 years (weight, <40 kg), 5 mg/kg/day by mouth, divided in 2 doses; for children aged ≥10 years (weight, ≥40 kg), 100 mg by mouth 2 times/day	Amantadine, for children aged 1–9 years, 5 mg/kg/day; maximum daily dose, 150 mg; for children aged ≥10 years (weight, <40 kg), 5 mg/kg/day by mouth, divided in 2 doses; for children aged ≥10 years (weight, ≥40 kg), 100 mg by mouth 2 times/day; maximum daily dose, 200 mg

* Children aged <9 years receiving influenza vaccination for the first time require 2 doses of vaccine spaced ≥1 months apart.

Notes: Neither rimantadine nor amantadine are Federal Drug Administration-approved for children aged <1 year. Rimantadine and amantadine doses should be reduced for patients with impaired renal function.

Pathogen: Respiratory syncytial virus

Indication	First choice	Alternatives
Prophylaxis for respiratory syncytial virus (RSV) lower respiratory infection among hypogammaglobulinemic pediatric HSCT recipients	RSV intravenous immunoglobulin can be administered in place of intravenous immunoglobulin during RSV season (i.e., November–April in the United States) for pediatric HSCT recipients who are on routine intravenous immunoglobulin therapy* (e.g., those with hypogammaglobulinemia) (CIII); usual RSV intravenous immunoglobulin dose is 750 mg/kg/month or a 1-mg/1-mg dosing substitution of RSV intravenous immunoglobulin for intravenous immunoglobulin can be used for patients who normally require high intravenous immunoglobulin doses to maintain serum immunoglobulin G > 400 mg/dl; can administer more frequently than monthly as needed to keep serum immunoglobulin G > 400 mg/dl	None
Preemptive treatment of RSV upper respiratory infection or early lower respiratory infection among pediatric HSCT recipients	Aerosolized ribavirin,* 6 g/300 ml sterile water to make a concentration of 20 mg/ml; administer 18 hours/day for 10 days in a tent (CIII); for HSCT recipients with lower respiratory infections who cannot tolerate a tent or who have RSV upper respiratory infection, administer ribavirin as 2 g for 2 hours every 8 hours by face mask for 10 days; use small particle aerosol generator model SPAG-2	

*__Source__: American Academy of Pediatrics. Respiratory syncytial virus. In: Pickering LK, ed. 2000 red book: report of the Committee on Infectious Disease. 25th ed. Elk Grove Village, IL: American Academy of Pediatrics;2000: 483–7.

__Notes__: RSV intravenous immunoglobulin is contraindicated among patients with immunoglobulin A deficiency or who might have allergic reactions or anaphylaxis when receiving blood products containing immunoglobulin A (DIII). RSV monoclonal antibody is under investigational use among HSCT recipients for treatment with ribavirin but not for prophylaxis.

Pathogen: Bacterial infections, general prophylaxis

Indication	First choice	Alternatives
Prevention of bacterial infections among allogeneic pediatric HSCT recipients with severe hypogammaglobulinemia (i.e., serum immunoglobulin G level < 400 mg/dl) at <100 days after HSCT	Intravenous immunoglobulin 400 mg/kg/month; increase dose or frequency as needed to keep serum immunoglobulin G levels > 400 mg/dl (CIII)	None

Notes: Patients with immunoglobulin E anti-immunoglobulin A antibodies are at high risk for experiencing anaphylaxis from immunoglobulin administration (**Source**: Burks AW, Sampson HA, Buckley RH. Anaphylactic reactions after gamma globulin administration in patients with hypogammaglobulinemia. New Engl J Med 1986;314[9]:560–4). Therefore, persons with immunoglobulin A deficiency should not receive standard immunoglobulin products (**Source**: Siberry GK, Iannone R, eds. Harriet Lane handbook: a manual for pediatric house officers. 15th ed.; St. Louis, MO: Mosby, Inc., 2000:339;739) (DIII). However, researchers report that use of immunoglobulin A-depleted immunoglobulin preparations can be used with caution in these persons (**Sources**: Burks AW, Sampson HA, Buckley RH. Anaphylactic reactions after gamma globulin administration in patients with hypogammaglobulinemia. New Engl J Med 1986;314[9]:560–4; Siberry GK, Iannone R, eds. Harriet Lane handbook: a manual for pediatric house officers. 15th ed.; St. Louis, MO: Mosby, Inc., 2000:339;739; Stiehm ER. Human intravenous immunoglobulin in primary and secondary antibody deficiencies [Review]. Pediatr Infect Dis J 1997;16[7]:696–707; American Academy of Pediatrics. Passive immunization. In: Pickering LK, ed. 2000 red book: report of the Committee on Infectious Diseases. 25th ed. Elk Grove Village, IL: American Academy of Pediatrics;2000:41–53). Researchers also propose checking serum immunoglobulin G levels every 2 weeks for patients receiving intravenous immunoglobulin replacement therapy.

Pathogen: *Streptococcus pneumoniae*

Indication	First choice	Alternatives
Prevention of pneumococcal disease among pediatric HSCT recipients	23-valent pneumococcal polysaccharide vaccine at 12 and 24 months after HSCT (BIII)	None

Notes: The 23-valent pneumococcal polysaccharide vaccine should not be administered to children aged <2 years because of lack of efficacy (DI). Penicillin-resistant *Streptococcus pneumoniae* is increasing in the United States.

Pathogen: *Haemophilus influenzae* type b

Indication	First choice	Alternatives
Prevention of invasive *Haemophilus influenzae* type b (Hib) disease among pediatric HSCT recipients	Hib conjugate vaccine administered at 12, 14, and 24 months after HSCT (BII)	None
Generally, pediatric HSCT recipients who are household contacts of a person with Hib disease should be administered rifampin prophylaxis* (BIII); however, prophylaxis is not needed for pediatric HSCT recipients who are household contacts of a person with Hib disease if all household contacts aged <4 years are fully vaccinated	Rifampin, administered as follows: Age — Dose 0–1 mo — 10 mg/kg by mouth daily for 4 days >1 mo — 20mg/kg by mouth daily for 4 days Maximum dose, 600 mg/day (BIII)	None

* **Source**: American Academy of Pediatrics. *Haemophilus influenzae* infections. In: Pickering LK, ed. 2000 red book: report of the Committee on Infectious Diseases. 25th ed. Elk Grove Village, IL: American Academy of Pediatrics;2000:262–72.

Pathogen: Methicillin-resistant *Staphylococcus aureus*

Indication	First choice	Alternatives
Elimination of methicillin-resistant *Staphylococcus aureus* carrier state among pediatric patients to prevent this disease among chronic carriers	Mupirocin calcium ointment 2%; use a cotton-tipped applicator or equivalent to apply to nares 2 times/day for 5 days or to wounds daily for 2 weeks*	Bacitracin is regarded safe for use among children, and the dose is the same as for mupirocin; however, no standardized protocol has been evaluated

* Safety of mupirocin calcium ointment 2% use among children aged <12 years has not be established.

Pathogen: *Candida* species

Indication	First choice	Alternatives
Prophylaxis for disease from fluconazole-susceptible *Candida* species among a) allogeneic pediatric HSCT recipients or b) autologous pediatric HSCT recipients with lymphoma or leukemia and who have or will have prolonged neutropenia and mucosal damage from intense conditioning regimens or graft manipulation or who have recently received fludarabine or 2-chlorodeoxyadenosine: Administer prophylaxis from the day of transplantation (i.e., day 0) until engraftment (i.e., approximately 30 days after HSCT) or until 7 days after the absolute neutrophil count > 1,000 cells/mm^3	Fluconazole, for children aged 6 months–13 years, administer 3–6 mg/kg/day by mouth or intravenously (AI); maximum dose, 600 mg/day; for children aged >13 years, administer 400 mg by mouth or intravenously daily (AI)	None

Pathogen: *Pneumocystis carinii*

Indication	First choice	Alternatives
Prophylaxis for *Pneumocystis carinii* pneumonia among a) all allogeneic pediatric HSCT recipients or b) autologous pediatric HSCT recipients with underlying hematologic malignancies (e.g., lymphoma or leukemia) or for those receiving intense conditioning regimens or graft manipulation or for those who have recently received fludarabine or 2-chlorodeoxyadenosine:* Administer prophylaxis from time of engraftment for ≥6 months after HSCT; continue >6 months after HSCT for the duration of immunosuppression for all persons who a) are receiving immunosuppressive therapy (e.g., prednisone or cyclosporine) or who b) have chronic graft-versus-host disease	Trimethoprim-sulfamethoxazole, 150 mg trimethoprim/750 mg sulfamethoxazole/m^2/day by mouth in 2 divided doses 3 times/week on consecutive days (AII); or a single dose by mouth 3 times/week on consecutive days; or by mouth in 2 divided doses daily for 7 days; or by mouth in 2 divided doses 3 times/week on alternate days; researchers also report administering prophylaxis for 1–2 weeks before HSCT (i.e., day –14 to –2) (CIII)	Dapsone, for HSCT recipients aged ≥1 months, 2 mg/kg (maximum dose, 100 mg) by mouth daily (BIII); or intravenous pentamidine, 4 mg/kg every 2–4 weeks; or aerosolized pentamidine, for HSCT recipients aged ≤5 years, 9 mg/kg/dose; or for HSCT recipients aged >5 years, 300 mg; should be administered every month by Respirgard II™ nebulizer (CIII)

* **Source**: Tuan IZ, Dennison D, Weisdorf DJ. *Pneumocystis carinii* pneumonitis after bone marrow transplantation. Bone Marrow Transplant 1992;10(3):267–72.

Notes: Trimethoprim-sulfamethoxazole is not recommended for patients aged <2 months because of risk for kernicterus. Patients who are receiving sulfadiazine-pyrimethamine for toxoplasmosis therapy are protected against *Pneumocystis carinii* and do not need additional prophylaxis.

Pathogen: *Toxoplasma gondii*

Indication	First choice	Alternatives
Prophylaxis of *Toxoplasma gondii* disease among seropositive allogeneic pediatric HSCT recipients: Start after engraftment and administer as long as patients remain on immunosuppressive therapy (i.e., generally, until 6 months after HSCT)	Trimethoprim-sulfamethoxazole, 150 mg trimethoprim/750 mg sulfamethoxazole/m^2/day by mouth in 2 divided doses 3 times/week on consecutive days (AII); or a single dose by mouth 3 times/week on consecutive days; or by mouth in 2 divided doses daily for 7 days; or by mouth in 2 divided doses 3 times/weekly on alternate days	For those persons who are intolerant of trimethoprim-sulfamethoxazole, the following drugs can be substituted: Clindamycin, 20–30 mg/kg/day by mouth, divided in 4 divided doses daily; plus pyrimethamine, 1 mg/kg by mouth daily; plus leucovorin, 5 mg by mouth every 3 days (CIII)

Note: Trimethoprim-sulfamethoxazole is not recommended for patients aged <2 months because of risk for kernicterus. Among allogeneic HSCT recipients, clinical toxoplasmosis has occurred despite the use of trimethoprim-sulfamethoxazole for *Pneumocystis carinii* prophylaxis (**Source**: Slavin MA, Meyers JD, Remington JS, Hackman RC. *Toxoplasma gondii* infection in marrow transplant recipients: a 20 year experience. Bone Marrow Transplant 1994;13[5]:549–57).

Pathogen: *Strongyloides* species

Indication	First choice	Alternatives
Prevention of strongyloidiasis hyperinfection among pediatric HSCT candidates whose HSCT screening tests are positive for *Strongyloides* species or who have an unexplained eosinophilia and a travel or residence history suggestive of exposure to *Strongyloides stercoralis*: Administer prophylaxis before HSCT	Ivermectin, 200 µg/kg by mouth daily for 2 consecutive days* (BIII); 1 tablet = 6 mg; doses administered as follows: Body weight (kg) — Oral dose <15 — Not recommended ≥15–24 — ½ tablet 25–35 — 1 tablet 36–50 — 1½ tablets 51–65 — 2 tablets 66–79 — 2½ tablets ≥80 — 200 µg/kg	Thiabendazole, 25 mg/kg 2 times daily for 2 days; maximum dose, 3 g/24 hours

* **Sources**: Liu LX, Weller PF. Strongyloidiasis and other intestinal nematode infections [Review]. Infect Dis Clin North Am 1993;7(3):655–82; and Naquira C, Jimenez G, Guerra JG, et al. Ivermectin for human strongyloidiasis and other intestinal helminths. Am J Trop Med Hyg 1989;40:304–9.

Notes: Ivermectin safety among children weighing <15 kg has not been established. Among immunocompromised patients, multiple courses of ivermectin at 2-week intervals might be required; however, cure might not be achievable. Safety and efficacy of ivermectin has not been established during pregnancy. Thiabendazole is contraindicated during pregnancy.

Pathogen: Traveler's diarrhea

Indication	First choice	Alternatives
Prophylaxis among pediatric HSCT recipients who are immunocompromised and who plan to travel in developing countries	Trimethoprim-sulfamethoxazole, 150 mg trimethoprim/750 mg sulfamethoxazole/m^2/day by mouth, divided in 2 doses 3 times/ week on consecutive days (CIII); can be administered for duration of stay in developing country	Trimethoprim-sulfamethoxazole, single dose by mouth 3 times/ week on consecutive days

Notes: Use of aspirin-containing products including bismuth subsalicylate is contraindicated in persons aged <18 years unless prescribed by a physician because these products have been associated with Reye's syndrome (**Source**: Belay E, Bresee JS, Holman RC, Khan AS, Shahriari A, Schonberger LB. Reye's syndrome in the United States from 1981 through 1997. New Engl J Med 1999;340[18]:1377–82). Trimethoprim-sulfamethoxazole is not recommended for patients aged <2 months because of risk for kernicterus. Resistance to trimethoprim-sulfamethoxazole is common in tropical areas. Usual doses of trimethoprim-sulfamethoxazole for *Pneumocystis carinii* pneumonia prophylaxis should provide limited protection against traveler's diarrhea.

Pathogen: ***Mycobacteria tuberculosis***

Indication	First choice	Alternatives
Prevention of *Mycobacteria tuberculosis* among a) highly immunocompromised pediatric HSCT recipients or candidates who have been exposed to someone with active, infectious (e.g., sputum smear positive) pulmonary or laryngeal tuberculosis, regardless of the HSCT recipient's or candidate's tuberculin skin test status, or b) pediatric HSCT recipients or candidates with a positive tuberculin skin test and who were not previously treated and have no evidence of active tuberculosis disease	Isoniazid, 10–20 mg/kg/day by mouth or intramuscularly for 9 months (i.e., for ≥270 doses);* maximum dose, 300 mg/day, and pyridoxine (vitamin B_6), 1–2 mg/kg/day by mouth daily for 9 months; dose required might vary by age and condition;† administer to nutritionally deficient HSCT recipients and candidates while on isoniazid preventive therapy to reduce the occurrence of isoniazid-induced neuropathy* (BIII)	None

* **Sources**: American Academy of Pediatrics. Tuberculosis. In: Pickering LK, ed. 2000 red book: report of the Committee on Infectious Diseases. 25th ed. Elk Grove Village, IL: American Academy of Pediatrics;2000:593–613; CDC. Prevention and treatment of tuberculosis among patients infected with human immunodeficiency virus: principles of therapy and revised recommendations. MMWR 1998;47(No. RR-20):1–58; and CDC. Notice to readers: use of short-course tuberculosis preventive therapy regimens in HIV-seronegative persons. MMWR 1998;47(42):911–2.

† **Source**: Siberry GK, Iannone R, eds. Harriet Lane handbook: a manual for pediatric house officers. 15th ed.; St. Louis, MO: Mosby, Inc., 2000:834–5.

Notes: A twice-weekly schedule of isoniazid and pyridoxine can be administered (CIII). The twice-weekly isoniazid dose is 20–40 mg/kg by mouth or intramuscularly (maximum dose, 900 mg). A 2-month pyrazinamide/rifampin preventive therapy regimen can be used for HSCT candidates who are not at risk for serious rifampin drug interactions and whose HSCT is not scheduled until ≥2 weeks after the 2-month course is completed. Rifampin dose is 10–20 mg/kg/day by mouth or intravenously or 10–20 mk/kg/dose by mouth or intravenously, administered 2 times/week (maximum pyrazinamide dose, 3.5 g; maximum rifampin dose, 600 mg) (**Sources**: CDC. Notice to readers: use of short-course tuberculosis preventive therapy regimens in HIV-seronegative persons. MMWR 1998;47[42]:911–2; and CDC. Prevention and treatment of tuberculosis among patients infected with human immunodeficiency virus: principles of therapy and revised recommendations. MMWR 1998;47[No. RR-20]:1–58.) (CIII). The usual pyrazinamide dose is 15–30 mg/kg/day by mouth or 50–70 mg/kg/dose by mouth 2 times/week (maximum) (maximum daily pyrazinamide dose, 2 g). Routine use of a 2-month pyrazinamide/rifampin preventive therapy regimen is not recommended after HSCT because of the risk for serious rifampin drug interactions (DIII). Persons who have been exposed to rifampin- and isoniazid-resistant tuberculosis should be placed on preventive therapy regimens that involve ≥2 antituberculosis drugs to which the infecting strain is susceptible (**Source**: CDC. Prevention and treatment of tuberculosis among patients infected with human immunodeficiency virus: principles of therapy and revised recommendations. MMWR 1998;47[No. RR-20]:1–58), and a tuberculosis specialist should be consulted (BIII). A tuberculosis specialist should also be consulted for patients who are intolerant to isoniazid (AIII). All intermittent dosing strategies should be administered as directly observed therapy (AIII).

WEEKLY REPORT

October 20, 2000 / Vol. 49 / No. RR-10

Recommendations and Reports

Continuing Education Activity Sponsored by CDC

Guidelines for Preventing Opportunistic Infections Among Hematopoietic Stem Cell Transplant Recipients: Recommendations of CDC, the Infectious Disease Society of America, and the American Society of Blood and Marrow Transplantation

EXPIRATION — OCTOBER 20, 2001

You must complete and return the response form electronically or by mail by **October 20, 2001**, to receive continuing education credit. If you answer all of the questions, you will receive an award letter for 4.5 hours Continuing Medical Education (CME) credit, 0.45 hour Continuing Education Units (CEUs), or 5.3 hours Continuing Nursing Education (CNE) credit. If you return the form electronically, you will receive educational credit immediately. If you mail the form, you will receive educational credit in approximately 30 days. No fees are charged for participating in this continuing education activity.

INSTRUCTIONS

By Internet

1. Read this *MMWR* (Vol. 49, RR-10), which contains the correct answers to the questions beginning on the next page.
2. Go to the *MMWR* Continuing Education Internet site at <http://www.cdc.gov/mmwr/cme/conted.html>.
3. Select which exam you want to take and select whether you want to register for CME, CEU, or CNE credit.
4. Fill out and submit the registration form.
5. Select exam questions. To receive continuing education credit, you must answer all of the questions. Questions with more than one correct answer will instruct you to "Indicate all that apply."
6. Submit your answers no later than **October 20, 2001**.
7. Immediately print your Certificate of Completion for your records.

By Mail

1. Read this *MMWR* (Vol. 49, RR-10), which contains the correct answers to the questions beginning on the next page.
2. Complete all registration information on the response form, including your name, mailing address, phone number, and e-mail address, if available.
3. Indicate whether you are registering for CME, CEU, or CNE credit.
4. Select your answers to the questions, and mark the corresponding letters on the response form. To receive continuing education credit, you must answer all of the questions. Questions with more than one correct answer will instruct you to "Indicate all that apply."
5. Sign and date the response form or a photocopy of the form and send no later than **October 20, 2001**, to
   Fax: 404-639-4198
   Mail: MMWR CE Credit
   Office of Scientific and Health Communications
   Epidemiology Program Office, MS C-08
   Centers for Disease Control and Prevention
   1600 Clifton Rd, N.E.
   Atlanta, GA 30333
6. Your Certificate of Completion will be mailed to you within 30 days.

ACCREDITATION

Continuing Medical Education (CME). This activity has been planned and implemented in accordance with the Essential Areas and Policies of the Accreditation Council for Continuing Medical Education through the joint sponsorship of CDC, the Infectious Disease Society of America, and the American Society of Blood and Marrow Transplantation. CDC is accredited by the Accreditation Council for Continuing Medical Education (ACCME) to provide continuing medical education for physicians. CDC designates this educational activity for a maximum of 4.5 hours in category 1 credit towards the AMA Physician's Recognition Award. Each physician should claim only those hours of credit that he/she actually spent in the educational activity.

Continuing Education Unit (CEU). CDC has been approved as an authorized provider of continuing education and training programs by the International Association for Continuing Education and Training and awards 0.45 hour Continuing Education Units (CEUs).

Continuing Nursing Education (CNE). This activity for 5.3 contact hours is provided by CDC, which is accredited as a provider of continuing education in nursing by the American Nurses Credentialing Center's Commission on Accreditation.

Goals and Objectives

This *MMWR* provides guidelines for preventing opportunistic infections (OIs) among hematopoietic stem cell transplant (HSCT) recipients. The goals of these guidelines are to summarize current data regarding preventing opportunistic infections among HSCT recipients and provide evidence-based recommended strategies for preventing these OIs. Upon completion of this educational activity, the reader should be able to identify strategies for a) preventing exposure and disease from bacterial, viral, fungal, protozoa, and helminth infections and b) hospital infection control, safe living, vaccinations, and hematopoietic stem cell safety.

To receive continuing education credit, please answer all of the following questions.

1. What are the three phases of immune system recovery after HSCT?

A. Phase I, –45–21 days; phase II, 30–100 days; and phase III, >100 days.
B. Phase I, 0–21 days; phase II, 30–90 days; and phase III, >90 days.
C. Phase I, 0–30 days; phase II, 30–120 days; and phase III, >120–365 days.
D. Phase I, <30 days; phase II, 30–100 days; and phase III, >100 days.
E. None of the above.

2. Which opportunistic infections commonly occur during phase I?

A. Cytomegalovirus, *Pneumocystis carinii* pneumonia, and aspergillosis.
B. Cytomegalovirus, *Pneumocystis carinii* pneumonia, and varicella-zoster virus.
C. Herpes simplex virus, cytomegalovirus, and *Candida* species.
D. Herpes simplex virus, *Candida* species, and aspergillosis.
E. Herpes simplex virus, aspergillosis, and varicella-zoster virus.

3. HSCT recipients should avoid eating which of the following foods?

A. Raw or undercooked meat.
B. Unpasteurized dairy products.
C. Vegetable sprouts.
D. Soft cheese.
E. All of the above.

4. Which of the following statements is true regarding vaccinations that HSCT recipients should receive?

A. Diphtheria and tetanus toxoids at 12, 14, and 24 months after HSCT.
B. Measles, mumps, rubella vaccinations at 12 and 24 months after HSCT.
C. Pneumococcal vaccinations at 12, 14, and 24 months after HSCT.
D. Varicella-zoster immunoglobulin at 24 months after HSCT.
E. Oral polio vaccine at 12, 14, and 24 months after HSCT.

5. Recommended aspergillosis prophylaxis is . . .

A. Fluconazole, 400 mg by mouth or intravenously daily.
B. Fluconazole, 200 mg by mouth or intravenously daily.
C. Amphotericin B, 1 mg/kg/day intravenously.
D. Itraconazole capsules, 200 mg by mouth daily.
E. None of the above.

6. Which of the following statements is not true regarding use of laminar air flow rooms in HSCT centers?

A. Substantial survival benefit has been reported for all HSCT recipients.
B. Substantial survival benefit has been reported for allogeneic HSCT recipients with aplastic anemia and human lymphocyte antigen-identical sibling donors.
C. Patients are protected from infection during aspergillosis outbreaks related to hospital construction.
D. Use of laminar air flow rooms for HSCT recipients is optional.

7. The number of recommended air exchanges per hour in an HSCT recipient's hospital room is . . .

A. <6.
B. <8.
C. <10.
D. >12.
E. ≥15.

8. Patient rooms in HSCT centers should have negative air pressure when compared with hallways and anterooms.

A. True.
B. False.

9. HSCT recipients should be cared for routinely by using . . .

A. standard precautions.
B. airborne precautions.
C. droplet precautions.
D. contact precautions.
E. all of the above.

10. The single-most critical and effective procedure for preventing nosocomial infection is . . .

A. following isolation precautions.
B. following ventilation precautions.
C. hand washing.
D. environmental disinfection.
E. excluding visitors experiencing illness from the HSCT center.

11. An HSCT recipient can be exposed safely to visitors with . . .

A. an upper respiratory infection.
B. a covered shingles rash.
C. a varicella-zoster virus-like rash occurring ≤4 weeks after the person has received a varicella-zoster virus vaccination.
D. a history of oral polio vaccination within the previous 3–6 weeks.
E. a history of vaccination with inactivated polio vaccine within the previous 3–6 weeks.

12. When constructing cooling towers for a new hospital with an HSCT center, all of the following should be done to prevent legionellosis except . . .

A. installing drift eliminators.
B. regularly using an effective biocide.
C. maintaining the cooling towers according to the manufacturer's directions.
D. locating the cooling towers so that drift is directed towards the hospital's air-intake system.
E. keeping adequate maintenance records.

13. Which of the following animals is a safe pet for HSCT recipients?

A. Reptile.
B. Duckling.
C. Nonhuman primate.
D. Cat aged ≥6 months.
E. Stray dog.

In questions 14–17, match the recommended prophylaxis drug with the pathogen it protects against.

14. Acyclovir.
15. Foscarnet.
16. Dapsone.
17. Fluconazole.

A. *Candida* species.
B. *Aspergillus* species.
C. Herpes simplex virus.
D. Cytomegalovirus.
E. *Pneumocystis carinii*.

Correct answers for questions 1–17.

1. D; 2. D; 3. E; 4. A; 5. E; 6. A; 7. D; 8. B; 9. A; 10. C; 11. E; 12. D; 13. D; 14. C; 15. D; 16. E; 17. A.

18. Indicate your work setting.

A. State/local health department.
B. Other public health setting.
C. Hospital clinic/private practice.
D. Managed care organization.
E. Academic institution.
F. Other.

19. Which best describes your professional activities?

A. Patient care — emergency/urgent care department.
B. Patient care — inpatient.
C. Patient care — primary-care clinic or office.
D. Laboratory/pharmacy.
E. Public health.
F. Other.

20. I plan to use these recommendations as the basis for . . . (*Indicate all that apply.*)

A. health education materials.
B. insurance reimbursement policies.
C. local practice guidelines.
D. public policy.
E. other.

21. Each month, approximately how many patients do you see?

A. None.
B. 1–5.
C. 6–20.
D. 21–50.
E. 51–100.
F. >100.

22. How much time did you spend reading this report and completing the exam?

A. 2–2.5 hours.
B. More than 2.5 hours but fewer than 3 hours.
C. 3–3.5 hours.
D. More than 3.5 hours but fewer than 4 hours.
E. More than 4.5 hours.

23. After reading this report, I am confident I can identify strategies for preventing exposure and disease from bacterial infections among HSCT recipients.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

24. After reading this report, I am confident I can identify strategies for preventing exposure and disease from viral infections among HSCT recipients.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

25. After reading this report, I am confident I can identify strategies for preventing exposure and disease from fungal infections among HSCT recipients.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

26. After reading this report, I am confident I can identify strategies for preventing exposure and disease from protozoa infections among HSCT recipients.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

27. After reading this report, I am confident I can identify strategies for preventing exposure and disease from helminth infections among HSCT recipients.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

28. After reading this report, I am confident I can identify strategies for hospital infection control for HSCT recipients.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

29. After reading this report, I am confident I can identify strategies for safe living for HSCT recipients.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

30. After reading this report, I am confident I can identify strategies for vaccinations for HSCT recipients.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

31. After reading this report, I am confident I can identify strategies for hematopoietic stem cell safety for HSCT recipients.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

32. The objectives are relevant to the goal of this report.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

33. The figure, tables, and appendix are useful.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

34. Overall, the presentation of the report enhanced my ability to understand the material.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

35. These recommendations will affect my practice.

A. Strongly agree.
B. Agree.
C. Neither agree nor disagree.
D. Disagree.
E. Strongly disagree.

MMWR Response Form for Continuing Education Credit
October 20, 2000/Vol. 49/No. RR-10

Guidelines for Preventing Opportunistic Infections Among Hematopoietic Stem Cell Transplant Recipients: Recommendations of CDC, the Infectious Disease Society of America, and the American Society of Blood and Marrow Transplantation

To receive continuing education credit, you must
1. ***provide your contact information;***
2. ***indicate your choice of CME, CEU, or CNE credit;***
3. ***answer <u>all</u> of the test questions;***
4. ***sign and date this form or a photocopy;***
5. ***submit your answer form by October 20, 2001.***

Failure to complete these items can result in a delay or rejection of your application for continuing education credit.

Guidelines for the Prevention of Intravascular Catheter-Related Infections

Naomi P. O'Grady, MD*; Mary Alexander, BS‡; E. Patchen Dellinger, MD§; Julie L. Gerberding, MD, MPH‖; Stephen O. Heard, MD¶; Dennis G. Maki, MD#; Henry Masur, MD*; Rita D. McCormick, RN**; Leonard A. Mermel, DO‡‡; Michele L. Pearson, MD§§; Issam I. Raad, MD‖‖; Adrienne Randolph, MD, MSc¶¶; and Robert A. Weinstein, MD##

ABSTRACT. These guidelines have been developed for practitioners who insert catheters and for persons responsible for surveillance and control of infections in hospital, outpatient, and home health-care settings. This report was prepared by a working group comprising members from professional organizations representing the disciplines of critical care medicine, infectious diseases, health-care infection control, surgery, anesthesiology, interventional radiology, pulmonary medicine, pediatric medicine, and nursing. The working group was led by the Society of Critical Care Medicine (SCCM), in collaboration with the Infectious Disease Society of America (IDSA), Society for Healthcare Epidemiology of America (SHEA), Surgical Infection Society (SIS), American College of Chest Physicians (ACCP), American Thoracic Society (ATS), American Society of Critical Care Anesthesiologists (ASCCA), Association for Professionals in Infection Control and Epidemiology (APIC), Infusion Nurses Society (INS), Oncology Nursing Society (ONS), Society of Cardiovascular and Interventional Radiology (SCVIR), American Academy of Pediatrics (AAP), and the Healthcare Infection Control Practices Advisory Committee (HICPAC) of the Centers for Disease Control and Prevention (CDC) and is intended to replace the *Guideline for Prevention of Intravascular Device-Related Infections* published in 1996. These guidelines are intended to provide evidence-based recommendations for preventing catheter-related infections. Major areas of emphasis include 1) educating and training health-care providers who insert and maintain catheters; 2) using maximal sterile barrier precautions during central venous catheter insertion; 3) using a 2% chlorhexidine preparation for skin antisepsis; 4) avoiding routine replacement of central venous catheters as a strategy to prevent infection; and 5) using antiseptic/antibiotic impregnated short-term central venous catheters if the rate of infection is high despite adherence to other strategies (ie, education and training, maximal sterile barrier precautions, and 2% chlorhexidine for skin antisepsis). These guidelines also identify performance indicators that can be used locally by health-care institutions or organizations to monitor their success in implementing these evidence-based recommendations. *Pediatrics* 2002; 110(5). INTRODUCTION

This report provides health-care practitioners with background information and specific recommendations to reduce the incidence of intravascular catheter-related bloodstream infections (CRBSI). These guidelines replace the *Guideline for Prevention of Intravascular Device-Related Infections*, which was published in 1996.[1]

The *Guidelines for the Prevention of Intravascular Catheter-Related Infections* have been developed for practitioners who insert catheters and for persons who are responsible for surveillance and control of infections in hospital, outpatient, and home health-care settings. This report was prepared by a working group composed of professionals representing the disciplines of critical care medicine, infectious diseases, health-care infection control, surgery, anesthesiology, interventional radiology, pulmonary medicine, pediatrics, and nursing. The working group was led by the Society of Critical Care Medicine (SCCM), in collaboration with Infectious Disease Society of America (IDSA), Society for Healthcare Epidemiology of America (SHEA), Surgical Infection Society (SIS), American College of Chest Physicians (ACCP), American Thoracic Society (ATS), American Society of Critical Care Anesthesiologists (ASCCA), Association for Professionals in Infection Control and Epidemiology (APIC), Infusion Nurses Society (INS), Oncology Nursing Society (ONS), Society of Cardiovascular and Interventional Radiology

APPENDIX A

Examples of Clinical Definitions for Catheter-Related Infections Localized Catheter Colonization

Significant growth of a microorganism (>15 CFU) from the catheter tip, subcutaneous segment of the catheter, or catheter hub

Exit Site Infection

Erythema or induration within 2 cm of the catheter exit site, in the absence of concomitant BSI and without concomitant purulence

Clinical Exit Site Infection (or Tunnel Infection)

Tenderness, erythema, or site induration >2 cm from the catheter site along the subcutaneous tract of a tunneled (eg, Hickman, Broviac) catheter, in the absence of concomitant BSI

Pocket Infection

Purulent fluid in the subcutaneous pocket of a totally implanted intravascular catheter that might or might not be associated with spontaneous rupture and drainage or necrosis of the overlaying skin, in the absence of concomitant BSI

Infusate-Related BSI

Concordant growth of the same organism from the infusate and blood cultures (preferably percutaneously drawn) with no other identifiable source of infection

CRBSI

Bacteremia/fungemia in a patient with an intravascular catheter with at least 1 positive blood culture obtained from a peripheral vein, clinical manifestations of infections (ie, fever, chills, and/or hypotension), and no apparent source for the BSI except the catheter. One of the following should be present: a positive semiquantitative (>15 CFU/catheter segment) or quantitative (>103 CFU/catheter segment catheter) culture whereby the same organism (species and antibiogram) is isolated from the catheter segment and peripheral blood; simultaneous quantitative blood cultures with a >5:1 ratio CVC versus peripheral; differential period of CVC culture versus peripheral blood culture positivity of >2 hours.

Surveillance Definitions for Primary BSIs, NNIS System

Laboratory-Confirmed BSI

Should meet at least 1 of the following criteria:

Criterion 1: Patient has a recognized pathogen cultured from 1 or more blood cultures, and the pathogen cultured from the blood is not related to an infection at another site.

Criterion 2: Patient has at least 1 of the following signs or symptoms: fever (>100.4°F [>38°C]), chills, or hypotension, and at least 1 of the following:

1. Common skin contaminant (eg, diphtheroids, *Bacillus* species, *Propionibacterium* species, coagulase-negative staphylococci, micrococci) cultured from 2 or more blood cultures drawn on separate occasions
2. Common skin contaminant (eg, diphtheroids, *Bacillus* species, *Propionibacterium* species, coagulase-negative staphylococci, micrococci) cultured from at least 1 blood culture from a patient with an intravenous line, and the physician institutes appropriate antimicrobial therapy
3. Positive antigen test on blood (eg, *Hemophilus influenzae*, *Streptococcus pneumoniae*, *Neisseria meningitides*, group B streptococcus)
   and signs and symptoms with positive laboratory results are not related to an infection at another site.

Criterion 3: Patient aged <1 year has at least 1 of the following signs or symptoms: fever (>100.4°F [>38°C]), hypothermia (<98.6°F [<37°C]), apnea, or bradycardia, and at least 1 of the following:

1. Common skin contaminant (eg, diphtheroids, *Bacillus* species, *Propionibacterium* species, coagulase-negative staphylococci, micrococci) cultured from 2 or more blood cultures drawn on separate occasions
2. Common skin contaminant (eg, diphtheroids, *Bacillus* species, *Propionibacterium* species, coagulase-negative staphylococci, micrococci) cultured from at least 1 blood culture from a patient with an intravenous line, and the physician institutes appropriate antimicrobial therapy
3. Positive antigen test on blood (eg, *H influenzae*, *S pneumoniae*, *N meningitides*, group B streptococcus)
   and signs and symptoms with positive laboratory results are not related to an infection at another site.

Clinical Sepsis

Should meet at least 1 of the following criteria:

Criterion 1: Patient has at least 1 of the following clinical signs with no other recognized cause: fever (>100.4°F [>38°C]), hypotension (systolic pressure <90 mmHg), or oliguria (<20 mL/h), and blood culture not done or no organisms or antigen detected in blood and no apparent infection at another site, and physician institutes treatment for sepsis.

Criterion 2: Patient aged <1 year has at least 1 of the following clinical signs or symptoms with no other recognized cause: fever (>100.4°F [>38°C]), hypothermia (<98.6°F [<37°C]), apnea, or bradycardia, and blood culture not done or no organisms or antigen detected in blood and no apparent infection at another site, and physician institutes treatment for sepsis.

Catheter-Associated BSI

Defined by the following:

- Vascular access device that terminates at or close to the heart or 1 of the great vessels. An umbilical artery or vein catheter is considered a central line.
- BSI is considered to be associated with a central line if the line was in use during the 48-hour period before development of the BSI. If the time interval between onset of infection and device use is >48 hours, then there should be compelling evidence that the infection is related to the central line.

Arterial or Venous Infection

Included are arteriovenous graft, shunt, fistula, or intravenous cannulation. Should meet at least 1 of the following criteria:

Criterion 1: Patient has organisms cultured from arteries or veins removed during a surgical operation and blood culture not done or no organisms cultured from blood.

Criterion 2: Patient has evidence of arterial or venous infection seen during a surgical operation or histopathologic examination.

Criterion 3: Patient has at least 1 of the following signs or symptoms with no other recognized cause: fever (>100.4°F [>38°C]), pain, erythema, or heat at involved vascular site and >15 CFUs cultured from an intravascular cannula tip using a semiquantitative culture method and blood culture not done or no organisms cultured from blood.

Criterion 4: Patient has purulent drainage at the involved vascular site and blood culture not done or no organisms cultured from blood.

Criterion 5: Patient aged <1 year has at least 1 of the following signs or symptoms with no other recognized cause: fever (>100.4°F [>38°C]), hypothermia (<98.6°F [<37°C]), apnea, bradycardia, lethargy, or pain, erythema or heat at involved vascular site and >15 colonies cultured from intravascular cannula tip using semiquantitative method and blood culture not done or no organisms cultured from blood.

(SCVIR), American Academy of Pediatrics (AAP), and the Healthcare Infection Control Practices Advisory Committee (HICPAC) of the Centers for Disease Control and Prevention (CDC). The recommendations presented in this report reflect consensus of HICPAC and other professional organizations.

INTRAVASCULAR CATHETER-RELATED INFECTIONS IN ADULT AND PEDIATRIC PATIENTS: AN OVERVIEW

Background

Intravascular catheters are indispensable in modern-day medical practice, particularly in intensive care units (ICUs). Although such catheters provide necessary vascular access, their use puts patients at risk for local and systemic infectious complications, including local site infection, CRBSI, septic thrombophlebitis, endocarditis, and other metastatic infections (eg, lung abscess, brain abscess, osteomyelitis, and endophthalmitis).

Health-care institutions purchase millions of intravascular catheters each year. The incidence of CRBSI varies considerably by type of catheter, frequency of catheter manipulation, and patient-related factors (eg, underlying disease and acuity of illness). Peripheral venous catheters are the devices most frequently used for vascular access. Although the incidence of local or bloodstream infections (BSIs) associated with peripheral venous catheters is usually low, serious infectious complications produce considerable annual morbidity because of the frequency with which such catheters are used. However, the majority of serious catheter-related infections are associated with central venous catheters (CVCs), especially those that are placed in patients in ICUs. In the ICU setting, the incidence of infection is often higher than in the less acute in-patient or ambulatory setting. In the ICU, central venous access might be needed for extended periods of time; patients can be colonized with hospital-acquired organisms; and the catheter can be manipulated multiple times per day for the administration of fluids, drugs, and blood products. Moreover, some catheters can be inserted in urgent situations, during which optimal attention to aseptic technique might not be feasible. Certain catheters (eg, pulmonary artery catheters and peripheral arterial catheters) can be accessed multiple times per day for hemodynamic measurements or to obtain samples for laboratory analysis, augmenting the potential for contamination and subsequent clinical infection.

The magnitude of the potential for CVCs to cause morbidity and mortality resulting from infectious complications has been estimated in several studies.[2] In the United States, 15 million CVC days (ie, the total number of days of exposure to CVCs by all patients in the selected population during the selected time period) occur in ICUs each year.[2] If the average rate of CVC-associated BSIs is 5.3 per 1,000 catheter days in the ICU,[3] approximately 80,000 CVC-associated BSIs occur in ICUs each year in the United States. The attributable mortality for these BSIs has ranged from no increase in mortality in studies that controlled for severity of illness,[4–6] to 35% increase in mortality in prospective studies that did not use this control.[7,8] Thus, the attributable mortality remains unclear. The attributable cost per infection is an estimated $34,508–$56,000,[5,9] and the annual cost of caring for patients with CVC-associated BSIs ranges from $296 million to $2.3 billion.[10]

A total of 250,000 cases of CVC-associated BSIs have been estimated to occur annually if entire hospitals are assessed rather than ICUs exclusively.[11] In this case, attributable mortality is an estimated 12%–25% for each infection, and the marginal cost to the health-care system is $25,000 per episode.[11]

Therefore, by several analyses, the cost of CVC-associated BSI is substantial, both in terms of morbidity and in terms of financial resources expended. To improve patient outcome and reduce health-care costs, strategies should be implemented to reduce the incidence of these infections. This effort should be multidisciplinary, involving health-care professionals who insert and maintain intravascular catheters, health-care managers who allocate resources, and patients who are capable of assisting in the care of their catheters. Although several individual strategies have been studied and shown to be effective in reducing CRBSI, studies using multiple strategies have not been conducted. Thus, it is not known whether implementing multiple strategies will have an additive effect in reducing CRBSI, but it is logical to use multiple strategies concomitantly.

Terminology and Estimates of Risk

The terminology used to identify different types of catheters is confusing, because many clinicians and researchers use different aspects of the catheter for informal reference. A catheter can be designated by the type of vessel it occupies (eg, peripheral venous, central venous, or arterial); its intended life span (eg, temporary or short-term versus permanent or long-term); its site of insertion (eg, subclavian, femoral, internal jugular, peripheral, and peripherally inserted central catheter [PICC]); its pathway from skin to vessel (eg, tunneled versus nontunneled); its physical length (eg, long versus short); or some special characteristic of the catheter (eg, presence or absence of a cuff, impregnation with heparin, antibiotics or antiseptics, and the number of lumens). To accurately define a specific type of catheter, all of these aspects should be described (Table 1).

The rate of all catheter-related infections (including local infections and systemic infections) is difficult to determine. Although CRBSI is an ideal parameter because it represents the most serious form of catheter-related infection, the rate of such infection depends on how CRBSI is defined.

Health-care professionals should recognize the difference between surveillance definitions and clinical definitions. The surveillance definitions for catheter-associated BSI includes all BSIs that occur in patients with CVCs, when other sites of infection have been excluded (Appendix A). That is, the surveillance definition overestimates the true incidence of CRBSI because not all BSIs originate from a catheter. Some bacteremias are secondary BSIs from undocumented

TABLE 1. Catheters Used for Venous and Arterial Access

Catheter Type	Entry Site	Length	Comments
Peripheral venous catheters (short)	Usually inserted in veins of forearm or hand	<3 in	Phlebitis with prolonged use; rarely associated with bloodstream infection
Peripheral arterial catheters	Usually inserted in radial artery; can be placed in femoral, axillary, brachial, posterior tibial arteries	<3 in	Low infection risk; rarely associated with bloodstream infection
Midline catheters	Inserted via the antecubital fossa into the proximal basilic or cephalic veins; does not enter central veins	3–8 in	Anaphylactoid reactions have been reported with catheters made of elastomeric hydrogel; lower rates of phlebitis than short peripheral catheters
Nontunneled CVCs	Percutaneously inserted into central veins (subclavian, internal jugular, or femoral)	8 cm or longer, depending on patient size	Account for majority of CRBSI
Pulmonary artery catheters	Inserted through a Teflon introducer in a central vein (subclavian, internal jugular, or femoral)	30 cm or longer, depending on patient size	Usually heparin bonded; similar rates of bloodstream infection as CVC; subclavian site preferred to reduce infection risk
PICCs	Inserted into basilic, cephalic, or brachial veins and enter the superior vena cava	20 cm or longer, depending on patient size	Lower rate of infection than nontunneled CVCs
Tunneled CVCs	Implanted into subclavian, internal jugular, or femoral veins	8 cm or longer, depending on patient size	Cuff inhibits migration of organisms into catheter tract, lower rate of infection than nontunneled CVC
Totally implantable	Tunneled beneath skin and have devices subcutaneous port accessed with a needle; implanted in subclavian or internal jugular vein	8 cm or longer, depending on patient size	Lowest risk for CRBSI; improved patient self-image; no need for local catheter site care; surgery required for catheter removal
Umbilical catheters	Inserted into either umbilical vein or umbilical artery	6 cm or less, depending on patient size	Risk for CRBSI similar to catheters placed in umbilical vein versus artery

sources (eg, postoperative surgical sites, intra-abdominal infections, and hospital-associated pneumonia or urinary tract infections). Thus, surveillance definitions are really definitions for catheter-associated BSIs. A more rigorous definition might include only those BSIs for which other sources were excluded by careful examination of the patient record, and where a culture of the catheter tip demonstrated substantial colonies of an organism identical to those found in the bloodstream. Such a clinical definition would focus on catheter-related BSIs. Therefore, to accurately compare a health-care facility's infection rate to published data, comparable definitions also should be used.

CDC and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) recommend that the rate of catheter-associated BSIs be expressed as the number of catheter associated BSIs per 1,000 CVC days.[12,13] This parameter is more useful than the rate expressed as the number of catheter-associated infections per 100 catheters (or percentage of catheters studied), because it accounts for BSIs over time and therefore adjusts risk for the number of days the catheter is in use.

Epidemiology and Microbiology

Since 1970, CDC's National Nosocomial Infection Surveillance System (NNIS) has been collecting data on the incidence and etiologies of hospital-acquired infections, including CVC-associated BSIs in a group of nearly 300 US hospitals. The majority of hospital-acquired BSIs are associated with the use of a CVC, with BSI rates being substantially higher among patients with CVCs than among those without CVCs. Rates of CVC-associated BSI vary considerably by hospital size, hospital service/unit, and type of CVC. During 1992–2001, NNIS hospitals reported ICU rates of CVC-associated BSI ranging from 2.9 (in a cardiothoracic ICU) to 11.3 (in a neonatal nursery for infants weighing <1,000 g) BSIs per 1,000 CVC days (Table 2).[14]

The relative risk (RR) of catheter-associated BSI also has been assessed in a meta-analysis of 223 prospective studies of adult patients.[11] RR of infection was best determined by analyzing rates of infection both by BSIs per 100 catheters and BSIs per 1,000 catheter days. These rates, and the NNIS-derived data, can be used as benchmarks by individual hos-

TABLE 2. Pooled Means of the Distribution of CVC-Associated Bloodstream Infection Rates in Hospitals That Report to the NNIS System, January 1992 to June 2001

Type of ICU	Number of ICUs	Catheter Days	Pooled Mean/ 1000 Catheter Days
Coronary	102	252 325	4.5
Cardiothoracic	64	419 674	2.9
Medical	135	671 632	5.9
Medical/surgical			
Major teaching	123	579 704	5.3

Trauma	25	116 709	7.9
Respiratory	7	21 265	3.4

Issued August 2001.[290,291]

pitals to estimate how their rates compare with other institutions. Rates are influenced by patient-related parameters, such as severity of illness and type of illness (eg, third-degree burns versus postcardiac surgery), and by catheter-related parameters, such as the condition under which the catheter was placed (eg, elective versus urgent) and catheter type (eg, tunneled versus nontunneled or subclavian versus jugular).

Types of organisms that most commonly cause hospital-acquired BSIs change over time. During 1986–1989, coagulase-negative staphylococci, followed by *Staphylococcus aureus*, were the most frequently reported causes of BSIs, accounting for 27% and 16% of BSIs, respectively (Table 3).[15] Pooled data from 1992 through 1999 indicate that coagulase-negative staphylococci, followed by enterococci, are now the most frequently isolated causes of hospital-acquired BSIs.[12] Coagulase-negative staphylococci account for 37%[12] and *S aureus* account for 12.6% of reported hospital-acquired BSIs.[12] Also notable was the susceptibility pattern of *S aureus* isolates. In 1999, for the first time since NNIS has been reporting susceptibilities, >50% of all *S aureus* isolates from ICUs were resistant to oxacillin.[12]

In 1999, enterococci accounted for 13.5% of BSIs, an increase from 8% reported to NNIS during 1986–1989. The percentage of enterococcal ICU isolates resistant to vancomycin also is increasing, escalating from 0.5% in 1989 to 25.9% in 1999.[12]

Candida spp caused 8% of hospital-acquired BSIs reported to NNIS during 1986–1989,[15,16] and during 1992–1999.[12,17,18] Resistance of *Candida* spp to commonly used antifungal agents is increasing. Although NNIS has not reported the percentage of BSIs caused by non-*albicans* species or fluconazole susceptibility data, other epidemiologic and clinical data document that fluconazole resistance is an increasingly relevant consideration when designing empiric therapeutic regimens for CRBSIs caused by yeast. Data from the Surveillance and Control of Pathogens of Epidemiologic Importance (SCOPE) Program documented that 10% of *C albicans* bloodstream isolates from hospitalized patients were resistant to fluconazole.[17] Additionally, 48% of *Candida* BSIs were caused by non-*albicans* species, including *C glabrata* and *C krusei*, which are more likely than *C albicans* to demonstrate resistance to fluconazole and itraconazole.[18,19]

Gram-negative bacilli accounted for 19% of catheter-associated BSIs during 1986–1989[15] compared with 14% of catheter-associated BSIs during 1992–1999.[12] An increasing percentage of ICU-related isolates are caused by *Enterobacteriaceae* that produce extended-spectrum β-lactamases (ESBLs), particularly *Klebsiella pneumoniae*.[20] Such organisms not only are resistant to extended-spectrum cephalosporins, but also to frequently used, broad spectrum antimicrobial agents.

TABLE 3. Most Common Pathogens Isolated From Bloodstream Infections [12,15]

Pathogen	1986–1989 (%)	1992–1999 (%)
Coagulase-negative staphylococci	27	37
S aureus	16	13
Enterococcus	8	13
Gram-negative rods	19	14
E coli	6	2
Enterobacter	5	5
P aeruginosa	4	4
K pneumoniae	4	3
Candida species	8	8

Pathogenesis

Migration of skin organisms at the insertion site into the cutaneous catheter tract with colonization of the catheter tip is the most common route of infection for peripherally inserted, short-term catheters.[21,22] Contamination of the catheter hub contributes substantially to intraluminal colonization of long-term catheters.[23–25] Occasionally, catheters might become hematogenously seeded from another focus of infection. Rarely, infusate contamination leads to CRBSI.[26]

Important pathogenic determinants of catheter-related infection are 1) the material of which the device is made and 2) the intrinsic virulence factors of the infecting organism. In vitro studies demonstrate that catheters made of polyvinyl chloride or polyethylene are likely less resistant to the adherence of microorganisms than are catheters made of Teflon, silicone elastomer, or polyurethane.[27,28] Therefore, the majority of catheters sold in the United States are no longer made of polyvinyl chloride or polyethylene. Some catheter materials also have surface irregularities that enhance the microbial adherence of certain species (eg, coagulase-negative staphylococci, *Acinetobacter calcoaceticus*, and *Pseudomonas aeruginosa*[29–31]); catheters made of these materials are especially vulnerable to microbial colonization and subsequent infection. Additionally, certain catheter materials are more thrombogenic than others, a characteristic that also might predispose to catheter colonization and catheter-related infection.[31,32] This association has led to emphasis on preventing catheter-related thrombus as an additional mechanism for reducing CRBSI.

The adherence properties of a given microorganism also are important in the pathogenesis of catheter-related infection. For example, *S aureus* can adhere to host proteins (eg, fibronectin) commonly present on catheters.[33,34] Also, coagulase-negative staphylococci adhere to polymer surfaces more readily than do other pathogens (eg, *Escherichia coli* or *S aureus*). Additionally, certain strains of coagulase-negative staphylococci produce an extracellular polysaccharide often referred to as "slime."[35,36] In the presence of catheters, this slime potentiates the pathogenicity of coagulase-negative staphylococci by allowing them to withstand host defense mechanisms (eg, acting as a barrier to engulfment and killing by polymorphonuclear leukocytes) or by making them less susceptible to antimicrobial agents (eg, forming a matrix that binds antimicrobials before their contact with the organism cell wall).[37] Certain *Candida* spp, in the presence of glucose-containing fluids, might produce slime similar to that of their bacterial counterparts, potentially explaining

the increased proportion of BSIs caused by fungal pathogens among patients receiving parenteral nutrition fluids.[38]

STRATEGIES FOR PREVENTION OF CATHETER-RELATED INFECTIONS IN ADULT AND PEDIATRIC PATIENTS

Quality Assurance and Continuing Education

Measures to minimize the risk for infection associated with intravascular therapy should strike a balance between patient safety and cost effectiveness. As knowledge, technology, and health-care settings change, infection control and prevention measures also should change. Well-organized programs that enable health-care providers to provide, monitor, and evaluate care and to become educated are critical to the success of this effort. Reports spanning the past two decades have consistently demonstrated that risk for infection declines following standardization of aseptic care,[39–43] and that insertion and maintenance of intravascular catheters by inexperienced staff might increase the risk for catheter colonization and CRBSI.[43,44] Specialized "IV teams" have shown unequivocal effectiveness in reducing the incidence of catheter-related infections and associated complications and costs.[45–45] Additionally, infection risk increases with nursing staff reductions below a critical level.[48]

Site of Catheter Insertion

The site at which a catheter is placed influences the subsequent risk for catheter-related infection and phlebitis. The influence of site on the risk for catheter infections is related in part to the risk for thrombophlebitis and density of local skin flora.

Phlebitis has long been recognized as a risk for infection. For adults, lower extremity insertion sites are associated with a higher risk for infection than are upper extremity sites.[49–51] In addition, hand veins have a lower risk for phlebitis than do veins on the wrist or upper arm.[52]

The density of skin flora at the catheter insertion site is a major risk factor for CRBSI. Authorities recommend that CVCs be placed in a subclavian site instead of a jugular or femoral site to reduce the risk for infection. No randomized trial satisfactorily has compared infection rates for catheters placed in jugular, subclavian, and femoral sites. Catheters inserted into an internal jugular vein have been associated with higher risk for infection than those inserted into a subclavian or femoral vein.[22,53,54]

Femoral catheters have been demonstrated to have relatively high colonization rates when used in adults.[55] Femoral catheters should be avoided, when possible, because they are associated with a higher risk for deep venous thrombosis than are internal jugular or subclavian catheters.[56–60] and because of a presumption that such catheters are more likely to become infected. However, studies in pediatric patients have demonstrated that femoral catheters have a low incidence of mechanical complications and might have an equivalent infection rate to that of nonfemoral catheters.[61–63] Thus, in adult patients, a subclavian site is preferred for infection control purposes, although other factors (eg, the potential for mechanical complications, risk for subclavian vein stenosis, and catheter-operator skill) should be considered when deciding where to place the catheter. In a meta-analysis of eight studies, the use of bedside ultrasound for the placement of CVCs substantially reduced mechanical complications compared with the standard landmark placement technique (RR = 0.22; 95% confidence interval [CI] = 0.10–0.45).[64] Consideration of comfort, security, and maintenance of asepsis as well as patient-specific factors (eg, preexisting catheters, anatomic deformity, and bleeding diathesis), RR of mechanical complications (eg, bleeding and pneumothorax), the availability of bedside ultrasound, and the risk for infection should guide site selection.

Type of Catheter Material

Teflon or polyurethane catheters have been associated with fewer infectious complications than catheters made of polyvinyl chloride or polyethylene.[27,65,66] Steel needles used as an alternative to catheters for peripheral venous access have the same rate of infectious complications as do Teflon catheters.[67,68] However, the use of steel needles frequently is complicated by infiltration of intravenous (IV) fluids into the subcutaneous tissues, a potentially serious complication if the infused fluid is a vesicant.[68]

Hand Hygiene and Aseptic Technique

For short peripheral catheters, good hand hygiene before catheter insertion or maintenance, combined with proper aseptic technique during catheter manipulation, provides protection against infection. Good hand hygiene can be achieved through the use of either a waterless, alcohol-based product[69] or an antibacterial soap and water with adequate rinsing.[70] Appropriate aseptic technique does not necessarily require sterile gloves; a new pair of disposable nonsterile gloves can be used in conjunction with a "no-touch" technique for the insertion of peripheral venous catheters. However, gloves are required by the Occupational Safety and Health Administration as standard precautions for the prevention of bloodborne pathogen exposure.

Compared with peripheral venous catheters, CVCs carry a substantially greater risk for infection; therefore, the level of barrier precautions needed to prevent infection during insertion of CVCs should be more stringent. Maximal sterile barrier precautions (eg, cap, mask, sterile gown, sterile gloves, and large sterile drape) during the insertion of CVCs substantially reduces the incidence of CRBSI compared with standard precautions (eg, sterile gloves and small drapes).[22,71] Although the efficacy of such precautions for insertion of PICCs and midline catheters has not been studied, the use of maximal barrier precautions also is probably applicable to PICCs.

Skin Antisepsis

In the United States, povidone iodine has been the most widely used antiseptic for cleansing arterial catheter and CVC-insertion sites.[72] However, in one

study, preparation of central venous and arterial sites with a 2% aqueous chlorhexidine gluconate lowered BSI rates compared with site preparation with 10% povidone-iodine or 70% alcohol.[73] Commercially available products containing chlorhexidine have not been available until recently; in July 2000, the US Food and Drug Administration (FDA) approved a 2% tincture of chlorhexidine preparation for skin antisepsis. Other preparations of chlorhexidine might not be as effective. Tincture of chlorhexidine gluconate 0.5% is no more effective in preventing CRBSI or CVC colonization than 10% povidone iodine, as demonstrated by a prospective, randomized study of adults.[74] However, in a study involving neonates, 0.5% chlorhexidine reduced peripheral IV colonization compared with povidone iodine (20/418 versus 38/408 catheters; $p = 0.01$).[75] This study, which did not include CVCs, had an insufficient number of participants to assess differences in BSI rates. A 1% tincture of chlorhexidine preparation is available in Canada and Australia, but not yet in the United States. No published trials have compared a 1% chlorhexidine preparation to povidone-iodine.

Catheter Site Dressing Regimens

Transparent, semipermeable polyurethane dressings have become a popular means of dressing catheter insertion sites. Transparent dressings reliably secure the device, permit continuous visual inspection of the catheter site, permit patients to bathe and shower without saturating the dressing, and require less frequent changes than do standard gauze and tape dressings; the use of these dressings saves personnel time.

In the largest controlled trial of dressing regimens on peripheral catheters, the infectious morbidity associated with the use of transparent dressings on approximately 2,000 peripheral catheters was examined.[65] Data from this study suggest that the rate of colonization among catheters dressed with transparent dressings (5.7%) is comparable to that of those dressed with gauze (4.6%) and that no clinically substantial differences exist in either the incidences of catheter-site colonization or phlebitis. Furthermore, these data suggest that transparent dressings can be safely left on peripheral venous catheters for the duration of catheter insertion without increasing the risk for thrombophlebitis.[65]

A meta-analysis has assessed studies that compared the risk for catheter-related BSIs for groups using transparent dressings versus groups using gauze dressing.[76] The risk for CRBSIs did not differ between the groups. The choice of dressing can be a matter of preference. If blood is oozing from the catheter insertion site, gauze dressing might be preferred.

In a multi-center study, a chlorhexidine-impregnated sponge (Biopatch) placed over the site of short-term arterial and CVCs reduced the risk for catheter colonization and CRBSI.[77] No adverse systemic effects resulted from use of this device.

Catheter Securement Devices

Sutureless securement devices can be advantageous over suture in preventing catheter-related BSIs. One study, which involved only a limited number of patients and was underpowered, compared a sutureless device with suture for the securement of PICCS; in this study, CRBSI was reduced in the group of patients that received the sutureless device.[78]

In-Line Filters

In-line filters reduce the incidence of infusion-related phlebitis.[79,80] No data support their efficacy in preventing infections associated with intravascular catheters and infusion systems. Proponents of filters cite several potential benefits to using these filters, including 1) reducing the risk for infection from contaminated infusate or proximal contamination (ie, introduced proximal to the filter); 2) reducing the risk for phlebitis in patients who require high doses of medication or in those in whom infusion-related phlebitis already has occurred; 3) removing particulate matter that might contaminate IV fluids[81]; and 4) filtering endotoxin produced by gram-negative organisms in contaminated infusate[82] These theoretical advantages should be tempered by the knowledge that infusate-related BSI is rare and that filtration of medications or infusates in the pharmacy is a more practical and less costly way to remove the majority of particulates. Furthermore, in-line filters might become blocked, especially with certain solutions (eg, dextran, lipids, and mannitol), thereby increasing the number of line manipulations and decreasing the availability of administered drugs.[83] Thus, for reducing the risk for CRBSI, no strong recommendation can be made in favor of using in-line filters.

Antimicrobial/Antiseptic Impregnated Catheters and Cuffs

Certain catheters and cuffs that are coated or impregnated with antimicrobial or antiseptic agents can decrease the risk for CRBSI and potentially decrease hospital costs associated with treating CRBSIs, despite the additional acquisition cost of an antimicrobial/antiseptic impregnated catheter.[84] All of the studies involving antimicrobial/antiseptic impregnated catheters have been conducted using triple-lumen, noncuffed catheters in adult patients whose catheters remained in place <30 days. Although all of the studies have been conducted in adults, these catheters have been approved by FDA for use in patients weighing >3 kg. No antiseptic or antimicrobial impregnated catheters currently are available for use in weighing <3 kg.

Chlorhexidine/Silver Sulfadiazine

Catheters coated with chlorhexidine/silver sulfadiazine only on the external luminal surface have been studied as a means to reduce CRBSI. Two meta-analyses[2,85] demonstrated that such catheters reduced the risk for CRBSI compared with standard noncoated catheters. The mean duration of catheter placement in one meta-analysis ranged from 5.1 to

11.2 days.[86] The half-life of antimicrobial activity against *S epidermidis* is 3 days in vitro for catheters coated with chlorhexidine/silver sulfadiazine; this antimicrobial activity decreases over time.[87] The benefit for the patients who receive these catheters will be realized within the first 14 days.[86] A second-generation catheter is now available with chlorhexidine coating both the internal and external luminal surfaces. The external surface has three times the amount of chlorhexidine and extended release of the surface bound antiseptics than that in the first generation catheters. The external surface coating of chlorhexidine is combined with silver-sulfadiazine, and the internal surface is coated with chlorhexidine alone. Preliminary studies indicate that prolonged anti-infective activity provides improved efficacy in preventing infections.[88] Although rare, anaphylaxis has been reported with the use of these chlorhexidine/silver sulfadiazine catheters in Japan.[89] Whether patients will become colonized or infected with organisms resistant to chlorhexidine/silver sulfadiazine has not been determined.[86]

Chlorhexidine/silver sulfadiazine catheters are more expensive than standard catheters. However, one analysis has suggested that the use of chlorhexidine/silver sulfadiazine catheters should lead to a cost savings of $68 to $391 per catheter[90] in settings in which the risk for CRBSI is high despite adherence to other preventive strategies (eg, maximal barrier precautions and aseptic techniques). Use of these catheters might be cost effective in ICU patients, burn patients, neutropenic patients, and other patient populations in which the rate of infection exceeds 3.3 per 1,000 catheter days.[86]

Minocycline/Rifampin

In a multicenter randomized trial, CVCs impregnated on both the external and internal surfaces with minocycline/rifampin were associated with lower rates of CRBSI when compared with the first-generation chlorhexidine-silver sulfadiazine impregnated catheters.[91] The beneficial effect began after day 6 of catheterization. None of the catheters were evaluated beyond 30 days. No minocycline/rifampin-resistant organisms were reported. However, in vitro data indicate that these impregnated catheters could increase the incidence of minocycline and rifampin resistance among pathogens, especially staphylococci. The half-life of antimicrobial activity against *S epidermidis* is 25 days with catheters coated with minocycline/rifampin, compared with 3 days for the first-generation catheters coated with chlorhexidine/silver sulfadiazine in vitro.[87] In vivo, the duration of antimicrobial activity of the minocycline/rifampin catheter is longer than that of the first-generation chlorhexidine/silver sulfadiazine catheter.[91] No comparative studies have been published using the second-generation chlorhexidine/silver sulfadiazine catheter. Studies are needed to evaluated whether the improved performance of the minocycline/rifampin catheters results from the antimicrobial agents used or from the coating of both the internal and external surfaces. As with chlorhexidine/silver sulfadiazine catheters, some clinicians have recommended that the minocycline/rifampin catheters be considered in patient populations when the rate of CRBSI exceeds 3.3 per 1,000 catheter days.[86] Others suggest that reducing all rates of CRBSI should be the goal.[92] The decision to use chlorhexidine/silver sulfadiazine or minocycline/rifampin impregnated catheters should be based on the need to enhance prevention of CRBSI after standard procedures have been implemented (eg, educating personnel, using maximal sterile barrier precautions, and using 2% chlorhexidine skin antisepsis) and then balanced against the concern for emergence of resistant pathogens and the cost of implementing this strategy.

Platinum/Silver

Ionic metals have broad antimicrobial activity and are being used in catheters and cuffs to prevent CRBSI. A combination platinum/silver impregnated catheter is available in Europe and has recently been approved by FDA for use in the United States. Although these catheters are being marketed for their antimicrobial properties, no published studies have been presented to support an antimicrobial effect.

Silver Cuffs

Ionic silver has been used in subcutaneous collagen cuffs attached to CVCs.[93] The ionic silver provides antimicrobial activity and the cuff provides a mechanical barrier to the migration of microorganisms along the external surface of the catheter. In studies of catheters left in place ≥20 days, the cuff failed to reduce the incidence of CRBSI.[94,95] Two other studies of short-term catheters could not demonstrate efficacy because of the minimal number of CRBSIs observed.[93,96]

Systemic Antibiotic Prophylaxis

No studies have demonstrated that oral or parenteral antibacterial or antifungal drugs might reduce the incidence of CRBSI among adults.[97–99] However, among low birth weight infants, two studies have assessed vancomycin prophylaxis; both demonstrated a reduction in CRBSI but no reduction in mortality.[100,101] Because the prophylactic use of vancomycin is an independent risk factor for the acquisition of vancomycin-resistant enterococcus (VRE),[102] the risk for acquiring VRE likely outweighs the benefit of using prophylactic vancomycin.

Antibiotic/Antiseptic Ointments

Povidone-iodine ointment applied at the insertion site of hemodialysis catheters has been studied as a prophylactic intervention to reduce the incidence of catheter-related infections. One randomized study of 129 hemodialysis catheters demonstrated a reduction in the incidence of exit-site infections, catheter-tip colonization, and BSIs with the routine use of povidone-iodine ointment at the catheter insertion site compared with no ointment at the insertion site.[103]

Several studies have evaluated the effectiveness of mupirocin ointment applied at the insertion sites of CVCs as a means to prevent CRBSI.[104–106] Although mupirocin reduced the risk for CRBSI,[106] mupirocin ointment also has been associated with mupirocin

resistance,[107,108] and might adversely affect the integrity of polyurethane catheters.[109,110]

Nasal carriers of *S aureus* have a higher risk for acquiring CRBSI than do noncarriers.[103,111] Mupirocin ointment has been used intranasally to decrease nasal carriage of *S aureus* and lessen the risk for CRBSI. However, resistance to mupirocin develops in both *S aureus* and coagulase-negative staphylococci soon after routine use of mupirocin is instituted.[107,108]

Other antibiotic ointments applied to the catheter insertion site also have been studied and have yielded conflicting results.[112–114] In addition, rates of catheter colonization with *Candida* spp might be increased with the use of antibiotic ointments that have no fungicidal activity.[112,114] To avoid compromising the integrity of the catheter, any ointment that is applied to the catheter insertion site should be checked against the catheter and ointment manufacturers' recommendations regarding compatibility.

Antibiotic Lock Prophylaxis

To prevent CRBSI, antibiotic lock prophylaxis has been attempted by flushing and filling the lumen of the catheter with an antibiotic solution and leaving the solution to dwell in the lumen of the catheter. Three studies have demonstrated the usefulness of such prophylaxis in neutropenic patients with long-term catheters.[115–117] In two of the studies, patients received either heparin alone (10 U/ml) or heparin plus 25 micrograms/ml of vancomycin. The third study compared vancomycin/ciprofloxacin/heparin (VCH) to vancomycin/heparin (VH) and then to heparin alone. The rate of CRBSI with vancomycin-susceptible organisms was significantly lower (VCH, $p = 0.022$; VH, $p = 0.028$) and the time to the first episode of bacteremia with vancomycin-susceptible organisms was substantially longer (VCH, $p = 0.036$; VH, $p = 0.011$) in patients receiving either vancomycin/ciprofloxacin/heparin or vancomycin/heparin compared with heparin alone.[115–117] One study involving a limited number of children revealed no difference in rates of CRBSI between children receiving a heparin flush compared with those receiving heparin and vancomycin.[118] However, because the use of vancomycin is an independent risk factor for the acquisition of VRE,[102] this practice is not recommended routinely.

An anticoagulant/antimicrobial combination comprising minocycline and ethylenediaminetetraacetic acid (EDTA) has been proposed as a lock solution because it has antibiofilm and antimicrobial activity against gram-positive, gram-negative, and *Candida* organisms,[119] as well as anticoagulant properties. However, no controlled or randomized trials have demonstrated its efficacy.

Anticoagulants

Anticoagulant flush solutions are used widely to prevent catheter thrombosis. Because thrombi and fibrin deposits on catheters might serve as a nidus for microbial colonization of intravascular catheters,[120,121] the use of anticoagulants might have a role in the prevention of CRBSI.

In a meta-analysis evaluating the benefit of heparin prophylaxis (3 U/ml in TPN, 5,000 U every 6 or 12 hours flush, or 2,500 U low molecular weight heparin subcutaneously) in patients with short-term CVCs, the risk for catheter-related central venous thrombosis was reduced with the use of prophylactic heparin.[122] However, no substantial difference in the rate for CRBSI was observed. Because the majority of heparin solutions contain preservatives with antimicrobial activity, whether any decrease in the rate of CRBSI is a result of the reduced thrombus formation, the preservative, or both is unclear.

The majority of pulmonary artery, umbilical, and central venous catheters are available with a heparin-bonded coating. The majority are heparin-bonded with benzalkonium chloride, which provides the catheters with antimicrobial activity[123] and provides an anti-thrombotic effect.[124]

Warfarin also has been evaluated as a means for reducing CRBSI by reducing thrombus formation on catheters.[125,126] In patients with long-term CVCs, low-dose warfarin (ie, 1 mg/day) reduced the incidence of catheter thrombus. No data demonstrate that warfarin reduces the incidence of CRBSI.

Replacement of Catheters

Peripheral Venous Catheters

Scheduled replacement of intravascular catheters has been proposed as a method to prevent phlebitis and catheter-related infections. Studies of short peripheral venous catheters indicate that the incidence of thrombophlebitis and bacterial colonization of catheters increases when catheters are left in place >72 hours.[66,67,127] However, rates of phlebitis are not substantially different in peripheral catheters left in place 72 hours compared with 96 hours.[128] Because phlebitis and catheter colonization have been associated with an increased risk for catheter-related infection, short peripheral catheter sites commonly are rotated at 72–96-hour intervals to reduce both the risk for infection and patient discomfort associated with phlebitis.

Midline Catheters

Midline catheters have been associated with lower rates of phlebitis than short peripheral catheters and with lower rates of infection than CVCs.[129–131] In one prospective study of 140 midline catheters, their use was associated with a BSI rate of 0.8 per 1,000 catheter-days.[131] No specific risk factors, including duration of catheterization, were associated with infection. Midline catheters were in place a median of 7 days, but for as long as 49 days. Although the findings of this study suggested that midline catheters can be changed only when there is a specific indication, no prospective, randomized studies have assessed the benefit of routine replacement as a strategy to prevent CRBSI associated with midline catheters.

CVCs, Including PICCs and Hemodialysis Catheters

Catheter replacement at scheduled time intervals as a method to reduce CRBSI has not lowered rates.

Two trials have assessed a strategy of changing the catheter every 7 days compared with a strategy of changing catheters as needed.[132,133] One of these studies involved 112 surgical ICU patients needing CVCs, pulmonary artery catheters, or peripheral arterial catheters,[132] whereas the other study involved only subclavian hemodialysis catheters.[133] In both studies, no difference in CRBSI was observed in patients undergoing scheduled catheter replacement every 7 days compared with patients whose catheters were replaced as needed.

Scheduled guidewire exchanges of CVCs is another proposed strategy for preventing CRBSI. The results of a meta-analysis of 12 randomized controlled trials assessing CVC management failed to prove any reduction of CRBSI rates through routine replacement of CVCs by guidewire exchange compared with catheter replacement on an as-needed basis.[134] Thus, routine replacement of CVCs is not necessary for catheters that are functioning and have no evidence of causing local or systemic complications.

Catheter replacement over a guidewire has become an accepted technique for replacing a malfunctioning catheter or exchanging a pulmonary artery catheter for a CVC when invasive monitoring no longer is needed. Catheter insertion over a guidewire is associated with less discomfort and a significantly lower rate of mechanical complications than are those percutaneously inserted at a new site[135]; in addition, this technique provides a means of preserving limited venous access in some patients. Replacement of temporary catheters over a guidewire in the presence of bacteremia is not an acceptable replacement strategy, because the source of infection is usually colonization of the skin tract from the insertion site to the vein.[22,135] However, in selected patients with tunneled hemodialysis catheters and bacteremia, catheter exchange over a guidewire, in combination with antibiotic therapy, might be an alternative as a salvage strategy in patients with limited venous access.[136–139]

Hemodialysis Catheters

The use of catheters for hemodialysis is the most common factor contributing to bacteremia in dialysis patients.[140,141] The RR for bacteremia in patients with dialysis catheters is sevenfold the risk for patients with primary arteriovenous fistulas.[142] Despite the National Kidney Foundation's effort to reduce the number of hemodialysis patients maintained with catheter access, catheter use increased from 12.7% in 1995 to 22.2% in 1999.[143] Rates for bacteremia per 100 patient months were 0.2 for arteriovenous fistulas, 0.5 for grafts, 5.0 for cuffed catheters, and 8.5 for noncuffed catheters (CDC, unpublished data, 1999).

To reduce the rate of infection, hemodialysis catheters should be avoided in favor of arteriovenous fistulas and grafts. If temporary access is needed for dialysis, a cuffed catheter is preferable to a noncuffed catheter, even in the ICU setting, if the catheter is expected to stay in place for >3 weeks.[11,144]

Pulmonary Artery Catheters

Pulmonary artery catheters are inserted through a Teflon introducer and typically remain in place an average of 3 days. The majority of pulmonary artery catheters are heparin bonded, which reduces not only catheter thrombosis but also microbial adherence to the catheter.[145] Meta-analysis indicates that standard nonheparin-bonded pulmonary artery catheter rates of CRBSI are 5.5 per 1,000 catheter days; for heparin-bonded pulmonary artery catheters, this rate is 2.6 per 1,000 catheter days.[11] Because the majority of pulmonary artery catheters are heparin-bonded, the RR of infection with these catheters is similar to that of CVC (2.6 versus 2.3 per 1,000 catheter days).[11]

A prospective study of 442 pulmonary artery catheters demonstrated an increased risk for CRBSI after 5 days (0/442 CRBSI before 5 days versus 5/442 CSBSI after 5 days; $P < 0.001$).[146] A prospective observational study of 71 pulmonary artery catheters demonstrated higher infection rates in catheters left in place longer than 7 days (2% before 7 days versus 16% after 7 days; $P = 0.056$).[147] However, no studies indicate that catheter replacement at scheduled time intervals is an effective method to reduce CRBSI.[132,135] In patients who continue to require hemodynamic monitoring, pulmonary artery catheters do not need to be changed more frequently than every 7 days. No specific recommendation can be made regarding routine replacement of catheters that need to be in place for >7 days.

Pulmonary artery catheters are usually packaged with a thin plastic sleeve that prevents touch contamination when placed over the catheter. In a study of 166 catheters, patients who were randomly assigned to have their catheters self-contained within this sleeve had a reduced risk for CRBSI compared with those who had a pulmonary artery catheter placed without the sleeve ($P = 0.002$).[148]

Peripheral Arterial Catheters

Peripheral arterial catheters are usually inserted into the radial or femoral artery and permit continuous blood pressure monitoring and blood gas measurements. The rate of CRBSI is comparable to that of temporary CVCs (2.9 versus 2.3 per 1,000 catheter days).[11] One study of peripheral arterial catheters demonstrated no difference in infection rates between changing catheters at scheduled times and changing arterial catheters on an as-needed basis.[132] One observational study of 71 arterial catheters revealed that 10 local infections and four CRBSIs occurred in patients who had peripheral arterial catheters in place for >4 days compared with one local infection and no CRBSIs in patients whose catheters were in place <4 days ($P < 0.05$).[147] Because the risk for CRBSI is likely similar to that of short-term CVCs, arterial catheters can be approached in a similar way. No specific recommendation can be made regarding replacement of catheters that need to be in place for >5 days.

APPENDIX B. Summary of Recommended Frequency of Replacements for Catheters, Dressings, Administration Sets, and Fluids

Catheter	Replacement and Relocation of Device	Replacement of Catheter Site Dressing	Replacement of Administration Sets	Hang Time for Parenteral Fluids
Peripheral venous catheters	In adults, replace catheter and rotate site no more frequently than every 72–96 h. Replace catheters inserted under emergency basis and insert a new catheter at a different site within 48 h. In pediatric patients, do not replace peripheral catheters unless clinically indicated.	Replace dressing when the catheter is removed or replaced or when the dressing becomes damp, loosened, or soiled. Replace dressings more frequently in diaphoretic patients. In patients who have large bulky dressings that prevent palpation or direct visualization of the catheter insertion site, remove the dressing and visually inspect the catheter at least daily and apply a new dressing.	Replace IV tubing, including add-on devices, no more frequently than at 72-h intervals unless clinically indicated. Replace tubing used to administer blood, blood products, or lipid emulsions within 24 h of initiating the infusion. No recommendation for replacement of tubing used for intermittent infusions. Consider short extension tubing connected to the catheter to be a portion of the device. Replace such extension tubing when the catheter is changed.	No recommendation for the hang time of IV fluids, including non–lipid-containing parenteral nutrition fluids. Complete infusion of lipid-containing parenteral nutrition fluids (eg, 3-in-1 solutions) within 24 h of hanging the fluid. Complete infusion of lipid emulsions alone within 12 h of hanging the fluid. Complete infusions of blood products within 4 h of hanging the product.
Midline catheters	No recommendation for the frequency of the catheter replacement	As above.	As above.	As above.
Peripheral arterial catheters	In adults, do not replace catheters routinely to prevent catheter-related infection. In pediatric patients, no recommendation for the frequency of catheter replacement. Replace disposable or reusable transducers at 96-hour intervals. Replace continuous flush device at the time the transducer is replaced.	Replace dressing when the catheter is replaced; when the dressing becomes damp, loosened, or soiled; or when inspection of the site is necessary.	Replace the IV tubing at the time the transducer is replaced (ie, 96-h intervals).	Replace the flush solution at the time the transducer is replaced (ie, 96-h intervals).
CVCs including peripherally inserted central catheters and hemodialysis catheters*	Do not routinely replace catheters.	Replace gauze dressings every 2 d and transparent dressings every 7 d on short-term catheters. Replace the dressing when the catheter is replaced; when the dressing becomes damp, loosened, or soiled; or when inspection of the site is necessary.	Replace IV tubing and add-on devices no more frequently than at 72-h intervals. Replace tubing used to administer blood products or lipid emulsions within 24 h of initiating the infusion.	No recommendation for the hang time of IV fluids, including non–lipid-containing parenteral nutrition fluids. Complete infusions of lipid-containing fluids within 24 h of hanging the fluid.
Pulmonary artery catheters	Do not replace catheter to prevent catheter-related infection.	As above.	As above.	As above.
Umbilical catheters	Do not routinely replace catheters.	Not applicable.	Replace IV tubing and add-on devices no more frequently than at 72-h intervals. Replace tubing used to administer blood products or lipid emulsions within 24 h of initiating the infusion.	No recommendations for the hang time of IV fluids, including non–lipid-containing parenteral nutrition fluids. Complete infusion of lipid-containing fluids within 24 h of hanging the fluid.

* Includes nontunneled catheters, tunneled catheters, and totally implanted devices.

Replacement of Administration Sets

The optimal interval for routine replacement of IV administration sets has been examined in three well-controlled studies. Data from each of these studies reveal that replacing administration sets no more frequently than 72 hours after initiation of use is safe and cost-effective.[149–151] Data from a more recent study demonstrated that rates of phlebitis were not substantially different if administration sets were left in place 96 hours compared with 72 hours.[128] When a fluid that enhances microbial growth is infused (eg, lipid emulsions and blood products), more frequent changes of administration sets are indicated, because these products have been identified as independent risk factors for CRBSI.[152–158]

Stopcocks (used for injection of medications, administration of IV infusions, and collection of blood samples) represent a potential portal of entry for microorganisms into vascular access catheters and IV fluids. Stopcock contamination is common, occurring in 45% and 50% in the majority of series. Whether such contamination is a substantial entry point of CRBSI has been difficult to prove.

"Piggyback" systems are used as an alternative to stopcocks. However, they also pose a risk for contamination of the intravascular fluid if the device entering the rubber membrane of an injection port is exposed to air or comes into direct contact with nonsterile tape used to fix the needle to the port. Modified piggyback systems have the potential to prevent contamination at these sites.[159]

Needleless Intravascular Catheter Systems

Attempts to reduce the incidence of sharp injuries and the resultant risk for transmission of bloodborne infections to health-care workers have led to the design and introduction of needleless infusion systems. When the devices are used according to manufacturers' recommendations, they do not substantially affect the incidence of CRBSI.[160–167]

Multidose Parenteral Medication Vials

Parenteral medications commonly are dispensed in multidose, parenteral medication vials that might be used for prolonged periods for one or more patients. Although the overall risk for extrinsic contamination of multidose vials is likely minimal,[168] the consequences of contamination might result in life-threatening infection.[169,170] Single-use vials are frequently preservative-free and might pose a risk for contamination if they are punctured several times.

SPECIAL CONSIDERATIONS FOR INTRAVASCULAR CATHETER-RELATED INFECTIONS IN PEDIATRIC PATIENTS

Prevention of CRBSI in children requires additional considerations, although only certain studies have been performed specifically in children. Pediatric data have been derived largely from studies in neonatal or pediatric ICUs and pediatric oncology patients.

Epidemiology

As in adults, the majority of BSIs in children are associated with the use of an intravascular catheter. From 1995 through 2000, the pooled mean catheter-associated BSI rate for all pediatric ICUs reporting data to NNIS was 7.7 per 1,000 catheter days.[171,172] Umbilical catheter and CVC-associated BSI rates for neonatal ICUs ranged from 11.3 per 1,000 catheter days in children with birth weight <1,000 g to 4.0 per 1,000 catheter days in children whose birth weight was >2,500 g.[171] Catheter utilization rates were comparable in adult and pediatric ICUs.[172,173]

Microbiology

As in adults, the majority of CRBSIs in children are caused by coagulase-negative staphylococci. During 1992–1999, these bacteria accounted for 37.7% of BSIs in pediatric ICUs reporting to NNIS.[12] Exposure to lipids has been identified as an independent risk factor for development of coagulase-negative staphylococcal bacteremia in very low birth weight infants (ie, those weighing <1,000 g) (odds ratio [OR] = 9.4; 95% CI = 1.2–74.2),[155] as well as candidemia in the neonatal ICU (OR = 5.33; 95% CI = 1.23–48.4).[154] Gram-negative bacteria accounted for 25% of BSIs reported in pediatric ICUs,[172] whereas enterococci and *Candida* spp accounted for 10% and 9%, respectively.[172]

Peripheral Venous Catheters

As in adults, the use of peripheral venous catheters in pediatric patients might be complicated by phlebitis, infusion extravasation, and catheter infection.[174] Catheter location, infusion of parenteral nutritional fluids with continuous IV lipid emulsions, and length of ICU stay before catheter insertion have all increased pediatric patients' risk for phlebitis. However, contrary to the risk in adults, the risk for phlebitis in children has not increased with the duration of catheterization.[174,175]

Peripheral Arterial Catheters

In a prospective study of 340 peripheral arterial catheters in children, the following two risk factors for catheter-related infection were identified: 1) use of an arterial system that permitted backflow of blood into the pressure tubing and 2) duration of catheterization.[176] Although a correlation was found between duration of arterial catheterization and risk for catheter colonization, the risk remained constant for 2–20 days at 6.2%.[176]

Umbilical Catheters

Although the umbilical stump becomes heavily colonized soon after birth, umbilical-vessel catheterization often is used for vascular access in newborn infants. Umbilical vessels can be cannulated easily and permit both collection of blood samples and measurement of hemodynamic status. The incidences of catheter colonization and BSI are similar for umbilical vein catheters and umbilical artery catheters. In several studies, an estimated 40%–55% of umbilical artery catheters were colonized and 5%

resulted in CRBSI; umbilical vein catheters were associated with colonization in 22%–59% of cases[177–179] and with CRBSI in 3%–8% of cases.[178] Although CRBSI rates are similar for umbilical catheters in the high position (ie, above the diaphragm) compared with the low position (ie, below the diaphragm and above the aortic bifurcation), catheters placed in the high position result in a lower incidence of vascular complications without an increase in adverse sequelae.[178]

Risk factors for infection differ for umbilical artery and umbilical vein catheters. In one study, neonates with very low birth weight who also received antibiotics for >10 days were at increased risk for umbilical artery CRBSIs.[178] In comparison, those with higher birth weight and receipt of parenteral nutrition fluids were at increased risk for umbilical vein CRBSI. Duration of catheterization was not an independent risk factor for infection of either type of umbilical catheter.

CVCs

Because of the limited vascular sites in children, attention should be given to the frequency with which catheters are replaced in these patients. In a study in which survival analysis techniques were used to examine the relation between the duration of central venous catheterization and complications in pediatric ICU patients, all of the patients studied (n = 397) remained uninfected for a median of 23.7 days.[180] In addition, no relation was found between duration of catheterization and the daily probability of infection ($r = 0.21$; $P > 0.1$), suggesting that routine replacement of CVCs likely does not reduce the incidence of catheter-related infection.[180]

Catheter Site Care

Although data regarding the use of the chlorhexidine-impregnated sponge (Biopatch in children are limited, one randomized, controlled study involving 705 neonates reported a substantial decrease in colonized catheter tips in infants in the Biopatch group compared with the group that had standard dressings (15% versus 24%; RR = 0.6; 95% CI = 0.5–0.9), but no difference in the rates of CRBSI or BSI without a source. Biopatch was associated with localized contact dermatitis in infants of very low birth weight. Of 98 neonates with very low birth weight, 15 (15%) developed localized contact dermatitis; four (1.5%) of 237 neonates weighing >1,000 g developed this reaction ($P < 0.0001$). Infants with gestational age <26 weeks who had CVCs placed at age <8 days were at increased risk for having localized contact dermatitis, whereas no infants in the control group developed this local reaction.[181]

Performance Indicators

Performance indicators for reducing CRBSI are 1) implementation of educational programs that include didactic and interactive components for those who insert and maintain catheters; 2) use of maximal sterile barrier precautions during catheter placement; 3) use of chlorhexidine for skin antisepsis; and 4) rates of catheter discontinuation when the catheter is no longer essential for medical management. The impact these recommendations will have on individual institutions should be evaluated using specific performance indicators.

RECOMMENDATIONS FOR PLACEMENT OF INTRAVASCULAR CATHETERS IN ADULTS AND CHILDREN

These recommendations are designed to reduce the infectious complications associated with intravascular catheter use. Recommendations should be considered in the context of the institution's experience with catheter-related infections, experience with other adverse catheter-related complications (eg, thrombosis, hemorrhage, and pneumothorax), and availability of personnel skilled in the placement of intravascular devices. Recommendations are provided for 1) intravascular-catheter use in general; 2) specific devices; and 3) special circumstances (ie, intravascular-device use in pediatric patients and CVC use for parenteral nutrition and hemodialysis access). Recommendations regarding the frequency of replacing catheters, dressings, administration sets, and fluids also are provided (Appendix B).

As in previous guidelines issued by CDC and HICPAC, each recommendation is categorized on the basis of existing scientific data, theoretical rationale, applicability, and economic impact. The CDC/HICPAC system for categorizing recommendations is as follows:

Category IA. Strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies.

Category IB. Strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies, and a strong theoretical rationale.

Category IC. Required by state or federal regulations, rules, or standards.

Category II. Suggested for implementation and supported by suggestive clinical or epidemiologic studies or a theoretical rationale.

Unresolved issue. Represents an unresolved issue for which evidence is insufficient or no consensus regarding efficacy exists.

I. Health-care worker education and training
   A. Educate health-care workers regarding the indications for intravascular catheter use, proper procedures for the insertion and maintenance of intravascular catheters, and appropriate infection-control measures to prevent intravascular catheter-related infections.[39,43,45–47,182–187] **Category IA**
   B. Assess knowledge of and adherence to guidelines periodically for all persons who insert and manage intravascular catheters.[39,43,46,182,188] **Category IA**
   C. Ensure appropriate nursing staff levels in ICUs to minimize the incidence of CRBSIs.[48,189,190] **Category IB**

II. Surveillance
   A. Monitor the catheter sites visually or by palpation through the intact dressing on a reg-

ular basis, depending on the clinical situation of individual patients. If patients have tenderness at the insertion site, fever without obvious source, or other manifestations suggesting local or BSI, the dressing should be removed to allow thorough examination of the site[1,191–193] **Category IB**

B. Encourage patients to report to their healthcare provider any changes in their catheter site or any new discomfort. **Category II**

C. Record the operator, date, and time of catheter insertion and removal, and dressing changes on a standardized form. **Category II**

D. Do not routinely culture catheter tips.[8,194,195] **Category IA**

III. Hand hygiene

A. Observe proper hand-hygiene procedures either by washing hands with conventional antiseptic-containing soap and water or with waterless alcohol-based gels or foams. Observe hand hygiene before and after palpating catheter insertion sites, as well as before and after inserting, replacing, accessing, repairing, or dressing an intravascular catheter. Palpation of the insertion site should not be performed after the application of antiseptic, unless aseptic technique is maintained[43,70,196–200] **Category IA**

B. Use of gloves does not obviate the need for hand hygiene.[43,198,199] **Category IA**

IV. Aseptic technique during catheter insertion and care

A. Maintain aseptic technique for the insertion and care of intravascular catheters.[22,71,201,202] **Category IA**

B. Wear clean or sterile gloves when inserting an intravascular catheter as required by the Occupational Safety and Health Administration Bloodborne Pathogens Standard. **Category IC.** Wearing clean gloves rather than sterile gloves is acceptable for the insertion of peripheral intravascular catheters if the access site is not touched after the application of skin antiseptics. Sterile gloves should be worn for the insertion of arterial and central catheters.[201,203] **Category IA**

C. Wear clean or sterile gloves when changing the dressing on intravascular catheters. **Category IC**

V. Catheter insertion

Do not routinely use arterial or venous cutdown procedures as a method to insert catheters.[204–206] **Category IA**

VI. Catheter site care

A. Cutaneous antisepsis

1. Disinfect clean skin with an appropriate antiseptic before catheter insertion and during dressing changes. Although a 2% chlorhexidine-based preparation is preferred, tincture of iodine, an iodophor, or 70% alcohol can be used.[73,75,207,208] **Category IA**
2. No recommendation can be made for the use of chlorhexidine in infants aged <2 months. **Unresolved issue**
3. Allow the antiseptic to remain on the insertion site and to air dry before catheter insertion. Allow povidone iodine to remain on the skin for at least 2 minutes, or longer if it is not yet dry before insertion.[73,75,207,208] **Category IB**
4. Do not apply organic solvents (eg, acetone and ether) to the skin before insertion of catheters or during dressing changes.[209] **Category IA**

VII. Catheter-site dressing regimens

A. Use either sterile gauze or sterile, transparent, semipermeable dressing to cover the catheter site.[146,210–212] **Category IA**

B. Tunneled CVC sites that are well healed might not require dressings. **Category II**

C. If the patient is diaphoretic, or if the site is bleeding or oozing, a gauze dressing is preferable to a transparent, semi-permeable dressing.[146,210–212] **Category II**

D. Replace catheter-site dressing if the dressing becomes damp, loosened, or visibly soiled.[146,210] **Category IB**

E. Change dressings at least weekly for adult and adolescent patients depending on the circumstances of the individual patient.[211] **Category II**

F. Do not use topical antibiotic ointment or creams on insertion sites (except when using dialysis catheters) because of their potential to promote fungal infections and antimicrobial resistance.[107,213] **Category IA** (See Central Venous Catheters, Including PICCs, Hemodialysis, and Pulmonary Artery Catheters, in Adult and Pediatric Patients, Section II.I.)

G. Do not submerge the catheter under water. Showering should be permitted if precautions can be taken to reduce the likelihood of introducing organisms into the catheter (eg, if the catheter and connecting device are protected with an impermeable cover during the shower.[214,215] **Category II**

VIII. Selection and replacement of intravascular catheters

A. Select the catheter, insertion technique, and insertion site with the lowest risk for complications (infectious and noninfectious) for the anticipated type and duration of IV therapy.[22,55,59,216–218] **Category IA**

B. Promptly remove any intravascular catheter that is no longer essential.[219,220] **Category IA**

C. Do not routinely replace central venous or arterial catheters solely for the purposes of reducing the incidence of infection.[134,135,221] **Category IB**

D. Replace peripheral venous catheters at least every 72–96 hours in adults to prevent phlebitis.[128] Leave peripheral venous catheters in place in children until IV therapy is com-

pleted, unless complications (eg, phlebitis and infiltration) occur.[174,175,222,223] **Category IB**

E. When adherence to aseptic technique cannot be ensured (ie, when catheters are inserted during a medical emergency), replace all catheters as soon as possible and after no longer than 48 hours.[22,71,201,202] **Category II**

F. Use clinical judgment to determine when to replace a catheter that could be a source of infection (eg, do not routinely replace catheters in patients whose only indication of infection is fever). Do not routinely replace venous catheters in patients who are bacteremic or fungemic if the source of infection is unlikely to be the catheter.[224] **Category II**

G. Replace any short-term CVC if purulence is observed at the insertion site, which indicates infection.[224,225] **Category IB**

H. Replace all CVCs if the patient is hemodynamically unstable and CRBSI is suspected.[224,225] **Category II**

I. Do not use guidewire techniques to replace catheters in patients suspected of having catheter-related infection.[134,135] **Category IB**

IX. Replacement of administration sets[a], needleless systems, and parenteral fluids

A. Administration sets

1. Replace administration sets, including secondary sets and add-on devices, no more frequently than at 72-hour intervals, unless catheter-related infection is suspected or documented.[23,149–151] **Category IA**
2. Replace tubing used to administer blood, blood products, or lipid emulsions (those combined with amino acids and glucose in a 3-in-1 admixture or infused separately) within 24 hours of initiating the infusion.[158,226–229] **Category IB**. If the solution contains only dextrose and amino acids, the administration set does not need to be replaced more frequently than every 72 hours.[226] **Category II**
3. Replace tubing used to administer propofol infusions every 6 or 12 hours, depending on its use, per the manufacturer's recommendation.[230] **Category IA**

B. Needleless intravascular devices

1. Change the needleless components at least as frequently as the administration set.[160–162,164–167] **Category II**
2. Change caps no more frequently than every 72 hours or according to manufacturers' recommendations.[160,162,165,166] **Category II**
3. Ensure that all components of the system are compatible to minimize leaks and breaks in the system.[163] **Category II**
4. Minimize contamination risk by wiping the access port with an appropriate antiseptic and accessing the port only with sterile devices.[162,163,165] **Category IB**

C. Parenteral fluids

1. Complete the infusion of lipid-containing solutions (eg, 3-in-1 solutions) within 24 hours of hanging the solution.[156–158,226,229] **Category IB**
2. Complete the infusion of lipid emulsions alone within 12 hours of hanging the emulsion. If volume considerations require more time, the infusion should be completed within 24 hours.[156–158] **Category IB**
3. Complete infusions of blood or other blood products within 4 hours of hanging the blood.[231–234] **Category II**
4. No recommendation can be made for the hang time of other parenteral fluids. **Unresolved issue**

X. IV-injection ports

A. Clean injection ports with 70% alcohol or an iodophor before accessing the system[164,235,236] **Category IA**

B. Cap all stopcocks when not in use.[235] **Category IB**

XI. Preparation and quality control of IV admixtures

A. Admix all routine parenteral fluids in the pharmacy in a laminar-flow hood using aseptic technique.[237,238] **Category IB**

B. Do not use any container of parenteral fluid that has visible turbidity, leaks, cracks, or particulate matter or if the manufacturer's expiration date has passed.[237] **Category IB**

C. Use single-dose vials for parenteral additives or medications when possible.[237,239] **Category II**

D. Do not combine the leftover content of single-use vials for later use.[237,239] **Category IA**

E. If multidose vials are used

1. Refrigerate multidose vials after they are opened if recommended by the manufacturer. **Category II**
2. Cleanse the access diaphragm of multidose vials with 70% alcohol before inserting a device into the vial.[236] **Category IA**
3. Use a sterile device to access a multidose vial and avoid touch contamination of the device before penetrating the access diaphragm.[235,240] **Category IA**
4. Discard multidose vial if sterility is compromised.[235,240] **Category IA**

XII. In-line filters

Do not use filters routinely for infection-control purposes.[80,241] **Category IA**

XIII. IV-therapy personnel

Designate trained personnel for the insertion

[a]Administration sets include the area from the spike of tubing entering the fluid container to the hub of the vascular access device. However, a short extension tube might be connected to the catheter and might be considered a portion of the catheter to facilitate aseptic technique when changing administration sets.

and maintenance of intravascular catheters.[46,47,210,242] **Category IA**

XIV. Prophylactic antimicrobials
Do not administer intranasal or systemic antimicrobial prophylaxis routinely before insertion or during use of an intravascular catheter to prevent catheter colonization or BSI.[97,98,108,243] **Category IA**

PERIPHERAL VENOUS CATHETERS, INCLUDING MIDLINE CATHETERS, IN ADULT AND PEDIATRIC PATIENTS

I. Selection of peripheral catheter
   A. Select catheters on the basis of the intended purpose and duration of use, known complications (eg, phlebitis and infiltration), and experience of individual catheter operators.[67,68,244] **Category IB**
   B. Avoid the use of steel needles for the administration of fluids and medication that might cause tissue necrosis if extravasation occurs.[67,68] **Category IA**
   C. Use a midline catheter or PICC when the duration of IV therapy will likely exceed 6 days.[244] **Category IB**

II. Selection of peripheral-catheter insertion site
   A. In adults, use an upper- instead of a lower-extremity site for catheter insertion. Replace a catheter inserted in a lower-extremity site to an upper-extremity site as soon as possible.[67,245] **Category IA**
   B. In pediatric patients, the hand, the dorsum of the foot, or the scalp can be used as the catheter insertion site. **Category II**
   C. Replacement of catheter
      1. Evaluate the catheter insertion site daily, by palpation through the dressing to discern tenderness and by inspection if a transparent dressing is in use. Gauze and opaque dressings should not be removed if the patient has no clinical signs of infection. If the patient has local tenderness or other signs of possible CRBSI, an opaque dressing should be removed and the site inspected visually. **Category II**
      2. Remove peripheral venous catheters if the patient develops signs of phlebitis (eg, warmth, tenderness, erythema, and palpable venous cord), infection, or a malfunctioning catheter.[66] **Category IB**
      3. In adults, replace short, peripheral venous catheters at least 72–96 hours to reduce the risk for phlebitis. If sites for venous access are limited and no evidence of phlebitis or infection is present, peripheral venous catheters can be left in place for longer periods, although the patient and the insertion sites should be closely monitored.[66,128,247] **Category IB**
      4. Do not routinely replace midline catheters to reduce the risk for infection.[131] **Category IB**
      5. In pediatric patients, leave peripheral venous catheters in place until IV therapy is completed, unless a complication (eg, phlebitis and infiltration) occurs.[174,175,222,223] **Category IB**

III. Catheter and catheter-site care
Do not routinely apply prophylactic topical antimicrobial or antiseptic ointment or cream to the insertion site of peripheral venous catheters.[107,213] **Category IA**

CVCs, INCLUDING PICCs, HEMODIALYSIS, AND PULMONARY ARTERY CATHETERS, IN ADULT AND PEDIATRIC PATIENTS

I. Surveillance
   A. Conduct surveillance in ICUs and other patient populations to determine CRBSI rates, monitor trends in those rates, and assist in identifying lapses in infection-control practices.[3,12,16,247–250] **Category IA**
   B. Express ICU data as the number of catheter-associated BSIs per 1,000 catheter-days for both adults and children and stratify by birth weight categories for neonatal ICUs to facilitate comparisons with national data in comparable patient populations and healthcare settings.[3,12,16,247–250] **Category IB**
   C. Investigate events leading to unexpected life-threatening or fatal outcomes. This includes any process variation for which a recurrence would likely present an adverse outcome.[13] **Category IC**

II. General principles
   A. Use a CVC with the minimum number of ports or lumens essential for the management of the patient.[251–254] **Category IB**
   B. Use an antimicrobial or antiseptic-impregnated CVC in adults whose catheter is expected to remain in place >5 days if, after implementing a comprehensive strategy to reduce rates of CRBSI, the CRBSI rate remains above the goal set by the individual institution based on benchmark rates (Table 2) and local factors. The comprehensive strategy should include the following three components: educating persons who insert and maintain catheters, use of maximal sterile barrier precautions, and a 2% chlorhexidine preparation for skin antisepsis during CVC insertion.[84–86,90,91,255] **Category IB**
   C. No recommendation can be made for the use of impregnated catheters in children. **Unresolved issue**
   D. Designate personnel who have been trained and exhibit competency in the insertion of catheters to supervise trainees who perform catheter insertion.[39,43,46,182,187,188] **Category IA**
   E. Use totally implantable access devices for patients who require long-term, intermittent vascular access. For patients requiring frequent or continuous access, a PICC or

tunneled CVC is preferable.[256,257] **Category II**

F. Use a cuffed CVC for dialysis if the period of temporary access is anticipated to be prolonged (eg, >3 weeks).[144,258] **Category IB**

G. Use a fistula or graft instead of a CVC for permanent access for dialysis.[142] **Category IB**

H. Do not use hemodialysis catheters for blood drawing or applications other than hemodialysis except during dialysis or under emergency circumstances. **Category II**

I. Use povidone-iodine antiseptic ointment at the hemodialysis catheter exit site after catheter insertion and at the end of each dialysis session only if this ointment does not interact with the material of the hemodialysis catheter per manufacturer's recommendation.[103,114,144] **Category II**

III. Selection of catheter insertion site

A. Weigh the risk and benefits of placing a device at a recommended site to reduce infectious complications against the risk for mechanical complications (eg, pneumothorax, subclavian artery puncture, subclavian vein laceration, subclavian vein stenosis, hemothorax, thrombosis, air embolism, and catheter misplacement).[22,55,59,218] **Category IA**

B. Use a subclavian site (rather than a jugular or a femoral site) in adult patients to minimize infection risk for nontunneled CVC placement.[22,55,59,60] **Category IA**

C. No recommendation can be made for a preferred site of insertion to minimize infection risk for a tunneled CVC.[61–63] **Unresolved issue**

D. Place catheters used for hemodialysis and pheresis in a jugular or femoral vein rather than a subclavian vein to avoid venous stenosis if catheter access is needed.[259–263] **Category IA**

IV. Maximal sterile barrier precautions during catheter insertion

A. Use aseptic technique including the use of a cap, mask, sterile gown, sterile gloves, and a large sterile sheet, for the insertion of CVCs (including PICCS) or guidewire exchange.[22,71] **Category IA**

B. Use a sterile sleeve to protect pulmonary artery catheters during insertion.[148] **Category IB**

V. Replacement of catheter

A. Do not routinely replace CVCs, PICCs, hemodialysis catheters, or pulmonary artery catheters to prevent catheter-related infections.[132,134,135] **Category IB**

B. Do not remove CVCs or PICCs on the basis of fever alone. Use clinical judgment regarding the appropriateness of removing the catheter if infection is evidenced elsewhere or if a noninfectious cause of fever is suspected.[224,264] **Category II**

C. Guidewire exchange

1. Do not use guidewire exchanges routinely for nontunneled catheters to prevent infection.[135,265] **Category IB**
2. Use a guidewire exchange to replace a malfunctioning nontunneled catheter if no evidence of infection is present.[135,265] **Category IB**
3. Use a new set of sterile gloves before handling the new catheter when guidewire exchanges are performed.[22,71] **Category II**

VI. Catheter and catheter-site care

A. General measures

Designate one port exclusively for hyperalimentation if a multilumen catheter is used to administer parenteral nutrition.[266] **Category II**

B. Antibiotic lock solutions

Do not routinely use antibiotic lock solutions to prevent CRBSI. Use prophylactic antibiotic lock solution only in special circumstances (eg, in treating a patient with a long-term cuffed or tunneled catheter or port who has a history of multiple CRBSIs despite optimal maximal adherence to aseptic technique).[115,116,267,268] **Category II**

C. Catheter-site dressing regimens

1. Replace the catheter-site dressing when it becomes damp, loosened, or soiled or when inspection of the site is necessary.[65,146,211] **Category IA**
2. Replace dressings used on short-term CVC sites every 2 days for gauze dressings and at least every 7 days for transparent dressings, except in those pediatric patients in which the risk for dislodging the catheter outweighs the benefit of changing the dressing.[211] **Category IB**
3. Replace dressings used on tunneled or implanted CVC sites no more than once per week, until the insertion site has healed.[211] **Category IB**
4. No recommendation can be made regarding the necessity for any dressing on well-healed exit sites of long-term cuffed and tunneled CVCs. **Unresolved issue**

D. No recommendation can be made for the use of chlorhexidine sponge dressings to reduce the incidence of infection. **Unresolved issue**

E. Do not use chlorhexidine sponge dressings in neonates aged <7 days or of gestational age <26 weeks.[181] **Category II**

F. No recommendation can be made for the use of sutureless securement devices. **Unresolved issue**

G. Ensure that catheter-site care is compatible with the catheter material.[109,110] **Category IB**

H. Use a sterile sleeve for all pulmonary artery catheters.[148] **Category IB**

ADDITIONAL RECOMMENDATIONS FOR PERIPHERAL ARTERIAL CATHETERS AND PRESSURE MONITORING DEVICES FOR ADULT AND PEDIATRIC PATIENTS

I. Selection of pressure monitoring system
Use disposable, rather than reusable, transducer assemblies when possible.[269–273] **Category IB**

II. Replacement of catheter and pressure monitoring system
   A. Do not routinely replace peripheral arterial catheters to prevent catheter-related infections.[132,147,221,274] **Category II**
   B. Replace disposable or reusable transducers at 96-hour intervals. Replace other components of the system (including the tubing, continuous-flush device, and flush solution) at the time the transducer is replaced.[22,270] **Category IB**

III. Care of pressure monitoring systems
   A. General measures
      1. Keep all components of the pressure monitoring system (including calibration devices and flush solution) sterile.[269,275–277] **Category IA**
      2. Minimize the number of manipulations of and entries into the pressure monitoring system. Use a closed-flush system (ie, continuous flush), rather than an open system (ie, one that requires a syringe and stopcock), to maintain the patency of the pressure monitoring catheters.[272,278] **Category II**
      3. When the pressure monitoring system is accessed through a diaphragm rather than a stopcock, wipe the diaphragm with an appropriate antiseptic before accessing the system.[272] **Category IA**
      4. Do not administer dextrose-containing solutions or parenteral nutrition fluids through the pressure monitoring circuit.[272,279,280] **Category IA**
   B. Sterilization or disinfection of pressure monitoring systems
      1. Use disposable transducers.[272,279–282] **Category IB**
      2. Sterilize reusable transducers according to the manufacturers' instructions if the use of disposable transducers is not feasible.[272,279–282] **Category IA**

RECOMMENDATIONS FOR UMBILICAL CATHETERS

I. Replacement of catheters
   A. Remove and do not replace umbilical artery catheters if any signs of CRBSI, vascular insufficiency, or thrombosis are present.[283] **Category II**
   B. Remove and do not replace umbilical venous catheters if any signs of CRBSI or thrombosis are present.[283] **Category II**
   C. No recommendation can be made for treating through an umbilical venous catheter suspected of being infected. **Unresolved issue**
   D. Replace umbilical venous catheters only if the catheter malfunctions. **Category II**

II. Catheter-site care
   A. Cleanse the umbilical insertion site with an antiseptic before catheter insertion. Avoid tincture of iodine because of the potential effect on the neonatal thyroid. Other iodine-containing products (eg, povidone-iodine) can be used.[75,177,178,284,285] **Category IB**
   B. Do not use topical antibiotic ointment or creams on umbilical catheter insertion sites because of the potential to promote fungal infections and antimicrobial resistance.[107,213] **Category IA**
   C. Add low doses of heparin (0.25–1.0 F/ml) to the fluid infused through umbilical arterial catheters.[286–288] **Category IB**
   D. Remove umbilical catheters as soon as possible when no longer needed or when any sign of vascular insufficiency to the lower extremities is observed. Optimally, umbilical artery catheters should not be left in place >5 days.[283,289] **Category II**
   E. Umbilical venous catheters should be removed as soon as possible when no longer needed but can be used up to 14 days if managed aseptically.[290,291] **Category II**

AMERICAN COLLEGE OF RHEUMATOLOGY
POSITION STATEMENT

SUBJECT: Guidelines for Referral of Children and Adolescents to Pediatric Rheumatologists

PRESENTED BY: Pediatric Section of the American College of Rheumatology

BACKGROUND:

This document was developed to provide a general understanding of the reasons for involving a pediatric rheumatologist in patient care and to identify circumstances when referral to a pediatric rheumatologist is appropriate. The ultimate objective in providing medical care for children with rheumatic diseases is to achieve the best possible health outcome in the most cost-effective setting.

Rheumatic diseases are an important cause of disability in childhood. Proper diagnosis and early aggressive intervention can minimize both short and long term morbidity of these conditions. Without proper therapy, acute rheumatic fever, systemic lupus erythematosus, dermatomyo-sitis, progressive systemic sclerosis, and many forms of vasculitis can be fatal. Other conditions such as juvenile rheumatoid arthritis and spondyloarthropathies which do not acutely threaten life, can be associated with lifetime disability. Rheumatic diseases in childhood differ from those in adults. There are important age related impacts of the diseases on the developing immune, neurologic and musculoskeletal systems. These chronic diseases have profound psychosocial effects on patients and their families.

The goals of treatment of childhood rheumatologic diseases are to control disease activity, preserve normal physical, social and emotional growth and development, minimize chronic disability and deformity, and achieve remission of disease. In pediatric rheumatic diseases, findings on physical examination often take precedence over laboratory findings in the establishment of a diagnosis and a treatment plan. Children and adolescents are often difficult to evaluate due to their development and behavioral stages; therefore the importance of a skilled examiner cannot be over emphasized.

Pediatric rheumatologists are physicians who specialize in providing comprehensive care to children with rheumatologic diseases and their families. They are pediatricians who have completed an additional 2-3 years of specialized training in pediatric rheumatology and are usually Board Certified in Pediatric Rheumatology. (In some cases these physicians may have been trained initially as internists rather than pediatricians). Pediatric rheumatologists are specifically trained to be highly skilled in: 1) differential diagnosis in children and adolescents; 2) efficient use of diagnostic interventions in children and adolescents; 3) selecting the most appropriate therapy (including other consultative services) for children and adolescents with rheumatic diseases; 4) monitoring long term therapy for effectiveness and side effects unique to children and adolescents; 5) achieving favorable outcomes in terms of control of rheumatologic diseases and prevention of disability; 6) coordination of care for children and adolescents with multisystem diseases; and 7) dealing with chronically ill children, adolescents and their families.

Most pediatric rheumatologists are located at University centers and work with a multi-disciplinary team that includes one or more pediatric rheumatologists and other health care professionals who specialize in the treatment of rheumatologic diseases, such as registered nursed, physical therapists, occupational therapists and social workers. A pediatric rheumatology center will also have available the services frequently needed by these patients such as nutrition, pediatric orthopedics, pediatric nephrology, pediatric ophthalmology, pediatric cardiology, child psychology/psychiatry, maxillo-facial surgery, pediatric dermatology, and physiatry.

The major strength of the multidisciplinary team is facilitating the achievement of the goals of treatment of childhood rheumatic diseases in the least costly setting In those geographic areas of the country where visits to a pediatric rheumatologist or center can only be accomplished one to two times per year, a local adult rheumatologist may be part of this treatment team as well. Due to the limited availability of pediatric rheumatology services in many areas of the country, adult rheumatologists who have training and experience in pediatric rheumatology should also be utilized as part of the multidisciplinary team to facilitate the achievement of the goals of treatment of childhood rheumatic diseases.

POSITION

Children and adolescents with the following diseases or in the following situations may benefit from referral to a pediatric rheumatologist:

- 1. Patients with unclear diagnoses
    - Prolonged fever
    - Loss of function
        - inability to attend school
        - regression in physical skills
    - Normal laboratory findings but local or generalized pain and/or swelling
    - Abnormal laboratory findings but symptoms and/or examination do not fit clinical criteria for a specific rheumatic disease
    - Complaints not consistent with laboratory findings or physical examination
    - Unexplained physical findings such as rash, fever, arthritis, anemia, weakness, weight loss, fatigue or anorexia
    - Unexplained musculoskeletal pain
    - Undefined autoimmune disease
- 2. Diagnostic evaluation and long-term management of:
    - Juvenile rheumatoid arthritis
    - Mixed connective tissue disease
    - Scleroderma ï systemic and localized
    - Spondyloarthropathies
        - ankylosing spondylitis
        - Reiterôs syndrome
        - psoriatic arthritis
        - arthritis associated with inflammatory bowel
    - Chronic vasculitis
        - Polyarteritis nodosa
        - Wegnerôs granulomatosis
        - Behcetôs syndrome
        - Takayasuôs arteritis
        - hypocomplementemic vasculitis
        - hypersensitivity vasculitis

- Systemic lupus erythematosus
- Anti-phospholipid syndrome
- Cerebral vasculitis
- Sarcoidosis
- Juvenile Dermatomyositis
- Lyme disease with arthritis
- Sjº grenÕs Syndrome
- Chronic recurrent multifocal osteomyelitis
- Neonatal onset multisystem inflammatory disease
- Post-infectious arthritis
- Post-infectious vasculitis
- Relapsing polychondritis

- 3. Confirm diagnosis and help formulate and/or participate in a treatment plan for the following conditions:

    - Henoch-Schonlein Purpura
    - Apophysitis
    - Reactive (post infectious) arthritis
    - Osteochondroses
    - Serum sickness
    - Growing pains
    - Kawasaki disease
    - Iritis
    - Acute rheumatic fever
    - Erythromelalgia
    - Fibromyalgia
    - RaynaudÕs disease
    - Reflex sympathetic dystrophy
    - Cold induced injury
    - Pain syndromes
    - Osteoporosis
    - Over use syndromes; hypermobility
    - Osteoarthritis
    - Complex autoimmune hemolytic anemia
    - Periodic fever syndromes
    - Complex autoimmune thrombocytopenia

4. Diagnostic or treatment plan evaluation for autoimmune disorders associated with other primary diseases such as: immunodeficiency, neoplasm, infectious disease, endocrine disorders, genetic and metabolic diseases, post-transplantation, cystic fibrosis and arthritis associated with birth defects.

5. Provide second opinion or confirmatory evaluation when requested in certain cases where primary care physicians request expert opinion for families requiring subspecialty input to cope with disease process, accept treatment plan, allay anxiety and provide education.

APPROVAL DATE: 11/11/97

AMERICAN ACADEMY OF PEDIATRICS

Surgical Advisory Panel

Guidelines for Referral to Pediatric Surgical Specialists

ABBREVIATION. AAP, American Academy of Pediatrics.

The Surgical Advisory Panel of the American Academy of Pediatrics (AAP), in response to a recommendation from the AAP Subspecialty Work Group and with the collaboration of the Surgical Sections of the AAP, has created referral guidelines intended to serve as voluntary practice parameters to assist general pediatricians in determining when and where to refer their patients to pediatric surgical specialists. It is recognized that the guidelines here may be difficult to achieve. Communities vary. Specialties overlap, and more than 1 type of pediatric or other surgical specialist may be qualified to manage a particular problem. Many complex pediatric problems are optimally managed by a medical-surgical team rather than an individual surgical specialist. This does not negate the value of the guidelines, however, because the child who needs specialized surgical care is best served by the skills of the appropriate pediatric surgical specialist.

Major congenital anomalies, malignancies, major trauma, and chronic illnesses in infants and children should be managed by pediatric medical and surgical specialists at pediatric referral centers. Such centers dedicated to children can provide expertise in many areas, including the pediatric medical and surgical specialties, pediatric radiology, pediatric anesthesiology, pediatric pathology, and pediatric intensive care. The optimal management of the child with complex problems, chronic illness, or disabilities requires coordination, communication, and cooperation of the pediatric surgical specialist with the child's primary care pediatrician or physician.

When a surgical condition has been identified, ideally, a pediatric surgical specialist should be called to address the issues related to this condition with the family and the respective pediatrician. In rural areas where it would be a hardship to the family and the child to travel long distances, the family in conjunction with the primary care pediatrician/physician should weigh the advantages of traveling to a center with a pediatric surgical specialist for surgical care. The primary care pediatrician or physician should consider calling the pediatric surgical specialist to discuss whether a consultation is advised in cases where, geographically, the specialist is not near.

Finally, however, it should be noted that the guidelines are voluntary standards for practice management. Each pediatrician must make an independent judgment in each case on the basis of facts and circumstances presented to him or her.

PEDIATRIC GENERAL SURGERY REFERRAL GUIDELINES

A pediatric surgeon has completed a 5-year residency training in general surgery, plus a 2-year fellowship in pediatric surgery. He or she is certified by the American Board of Surgery in both General Surgery and in Pediatric Surgery. For purposes of developing these guidelines, the following age group definitions are used: infant (0–1 year), child (2–12 years), and adolescent (13–18 years).

- Patients 5 years or younger who may need surgical care should be cared for by a pediatric surgeon.
- Infants and children with perforated appendicitis should be cared for by a pediatric surgeon. If a nonpediatric surgeon makes the diagnosis or suspects the diagnosis of perforated appendicitis in a child, the child should be transferred to the care of a pediatric surgeon.
- Seriously injured infants and children may be stabilized at a local hospital and then should be transferred to a pediatric trauma center.
- Infants, children, and adolescents with solid malignancies should be cared for from the outset by a pediatric surgeon or pediatric surgical specialist and a pediatric medical cancer specialist.
- Minimally invasive procedures (eg, laparoscopy, thoracoscopy) in infants and children should be performed by a pediatric surgeon trained in these techniques.
- Infants and children with medical conditions that increase operative risk (eg, congenital heart disease) who must undergo a common surgical procedure (eg, hernia repair) should be cared for by a pediatric surgeon.

In the interest of good patient care, it is suggested that a general surgeon who cares for pediatric surgical problems not listed in the above categories should have had a minimum 6-month rotation as a junior or senior resident during his or her general surgical residency on a pediatric surgical service run by a pediatric surgeon. Emphasis in the training rotation should be on surgery of children older than 5 years.

A general surgeon performing surgery on children not listed in the above categories should care for a sufficient number of children annually to maintain a high level of competence and should annually attend pediatric surgery postgraduate courses and meetings.

PEDIATRIC OTOLARYNGOLOGY REFERRAL GUIDELINES

A pediatric otolaryngologist has completed a 4- to 5-year residency in otolaryngology/head and neck surgery and is certified by the American Board of Otolaryngologic Surgery. In addition, he or she has completed 1 or 2 years of fellowship training in pediatric otolaryngology. For purposes of developing these guidelines, the following age group definitions are used: infant (0–1 year), child (2–12 years), and adolescent (13–18 years).

The following patients should be referred to a pediatric otolaryngologist:

- Infants, children, and adolescents with congenital malformations of head and neck structures, including the ear, nasal passages, oral cavity, and laryngotracheal airway.
- Infants and children with sensory impairments, including conductive or sensorineural hearing loss, vertiginous disorders, unilateral and bilateral true vocal fold paralysis, facial nerve paralysis, and oromotor dysfunction as evidenced by speech, swallowing, or drooling problems.
- Infants and children with acquired otolaryngologic disorders involving the ear (eg, cholesteatoma), the pharynx (eg, obstructive adenotonsillar hypertrophy), the laryngotracheal airway (eg, postintubation laryngotracheal stenosis), the aerodigestive tract (eg, foreign body aspirations), and the facial skeleton (eg, maxillofacial trauma).
- Infants, children, and adolescents with neoplasms or vascular malformations of the head and neck structures, including the laryngotracheal airway.
- Infants and children with medical conditions that increase operative risk (eg, congenital heart disease) who must undergo a common otolaryngologic procedure (eg, adenotonsillectomy).
- Infants and children requiring operative airway endoscopy for the evaluation of stridor.

The following patients are preferably managed by a pediatric otolaryngologist:

- Infants and children with complicated infections that may require surgery involving the ear (eg, otitis media with effusion and hearing change), the nose and paranasal sinuses (eg, chronic rhinosinusitis), the pharynx (eg, recurrent adenotonsillitis), the airway (eg, epiglottitis), and the neck (eg, retropharyngeal abscess).

ENDOSCOPY REFERRAL GUIDELINES

Specialists in several pediatric surgical and pediatric medical fields are trained to perform endoscopic procedures in infants and children. For purposes of developing these guidelines, the following age group definitions are used: infant (0–1 year) and child (2–12 years).

- Endoscopy of the airways (eg, bronchoscopy, laryngoscopy) in infants and children should be performed by a pediatric surgeon or a pediatric otolaryngologist or an appropriately trained pediatric medical specialist, which may include a pediatric pulmonologist or a pediatric intensivist.
- Esophagoscopy in infants and children should be performed by a pediatric surgeon, a pediatric otolaryngologist, or a pediatric gastroenterologist.
- Endoscopy of the gastrointestinal tract distal to the esophagus (eg, esophagogastroduodenoscopy, colonoscopy) in infants and children should be performed by a pediatric surgeon or a pediatric gastroenterologist.

PEDIATRIC OPHTHALMOLOGY REFERRAL GUIDELINES

A pediatric ophthalmologist has completed a residency in ophthalmology, is certified by the American Board of Ophthalmological Surgery, and has completed additional training in pediatric ophthalmology. For purposes of developing these guidelines, the following age group definitions are used: infant (0–1 year), child (2–12 years), and adolescent (13–18 years).

Pediatric patients with the following conditions should be referred to a pediatric ophthalmologist:

- Children 7 years or younger who are nonverbal or unable to read letters and in whom there is reason to suspect eye disease.
- Infants or children with retinoblastoma or other tumors of the eye and orbital area.
- Infants or children with known or suspected cataracts, glaucoma, or blindness.
- Infants or children diagnosed with, or at risk of, retinopathy of prematurity.
- Infants or children with congenital or genetic ocular anomalies or infections (eg, aniridia, toxoplasmosis).
- Infants or children with systemic syndromes, metabolic disorders, or chromosomal abnormalities with possible ocular involvement (eg, juvenile rheumatoid arthritis, galactosemia, diabetes mellitus, Marfan syndrome, Down syndrome).
- Infants or children suspected of being abused and in whom there is a possibility of eye injury.

Pediatric patients with the following conditions are preferably managed by a pediatric ophthalmologist:

- Infants with congenital nystagmus and children with early onset nystagmus.
- Children with strabismus or amblyopia (ie, dimness of vision without detectable organic lesion of the eye) or risk factors for strabismus or amblyopia (eg, family history of amblyopia, orbital or eyelid hemangioma).

- Children with a family history of congenital or genetic ocular anomalies (eg, aniridia), infections (eg, toxoplasmosis), tumors (eg, retinoblastoma), or a family history of systemic or metabolic syndromes (eg, juvenile rheumatoid arthritis, galactosemia, diabetes mellitus), chromosomal abnormalities (eg, Down syndrome), or other disorders with possible ocular involvement.
- Infants or children with exposure during gestation to drugs or other substances (including alcohol) that may cause congenital anomalies of the eyes.
- Infants or children with poor vision or delayed attainment of vision-related developmental milestones and infants and children with severe refractive errors or a strong family history of severe refractive errors.
- Infants or children with ocular or periocular inflammation not responding to initial topical and/or systemic antibiotic therapy or not clearing within 3 weeks of treatment and children with suspected herpes simplex or zoster infections involving the eye or a history of these infections involving the eye.

PEDIATRIC UROLOGY REFERRAL GUIDELINES

A pediatric urologist has completed a residency in urology and is certified by the American Board of Urologic Surgery and has completed additional training in a pediatric urology fellowship. In select situations, a urologist may have gained a lifetime of pediatric experience but started practice before such fellowships were available. For purposes of developing these guidelines, the following group definitions are used: infant (0–1 year), child (2–12 years), and adolescent (13–18 years).

- Undescended testicles and elective congenital hydrocele/hernia are optimally corrected in infancy or early childhood; the operation should be performed by a pediatric urologist or surgical specialist.
- Hypospadias is usually repaired in infancy or early childhood; the operation should be performed by a pediatric urologist.
- Complex congenital urologic problems (eg, duplex systems, ureterocele, bladder exstrophy, moderate or severe vesicoureteral reflux, posterior urethral valves) should preferably be managed by a pediatric urologist.
- Solid malignancies of the kidney, bladder, and testicle should be treated from the outset by a pediatric urologist or surgical specialist in conjunction with a pediatric medical cancer specialist.
- Intersex (ambiguous genitalia) conditions should be comanaged from the outset by the primary care pediatrician and a pediatric urologist or surgical specialist. The management team should include a pediatric endocrinologist and a psychologist in consultation with the primary care pediatrician and pediatric urologist or surgical specialist.
- Cystoscopic procedures in infants and children preferably should be performed by a pediatric urologist.
- A pediatric urology consultation should be considered when a child has prolonged, severe daytime voiding difficulty.
- A pediatric urologist should be involved in the care of children with spinal cord disorders (eg, myelomeningocele, spinal cord injuries).
- Infants or children with major urologic injuries should be stabilized at the nearest medical center and then transported to a pediatric trauma center.
- Infants or children with testicular torsion should be evaluated at the nearest medical center and operated on promptly.

When a urinary tract abnormality has been identified prenatally, a pediatric urologist or surgeon should be consulted as a member of the fetal treatment team.

PEDIATRIC ORTHOPEDIC SURGERY REFERRAL GUIDELINES

A pediatric orthopedic surgeon has completed a residency in orthopedics and completed an additional fellowship in pediatric orthopedics. An orthopedic tumor surgeon has completed a residency in orthopedics, plus additional training in orthopedic oncology and devotes his or her practice to patients with cancer of the bones and joints. For purposes of developing these guidelines, the following age group definitions are used: infant (0–1 year), child (2–12 years), and adolescent (13–18 years).

- Malignant bone tumors should be managed by an orthopedic tumor surgeon, in conjunction with a pediatric medical cancer specialist.
- Benign bone tumors should be managed by a pediatric orthopedic surgeon or an orthopedic tumor surgeon.
- Congenital deformities of the upper extremity should be managed by a pediatric orthopedic surgeon or a pediatric hand surgeon.

The following patients may be best cared for by a pediatric orthopedic surgeon:

- Infants with serious malformations of the limbs (eg, idiopathic clubfoot, congenital limb deficiency).
- Children and adolescents with significant limb deformity secondary to metabolic bone disease or other types of growth arrest.
- Infants, children, and adolescents with developmental dysplasia of the hip. (Screening for developmental dysplasia of the hip is performed by the primary care pediatrician.)
- Infants, children, and adolescents with bone or joint infection (eg, osteomyelitis, septic arthritis), in conjunction with the primary care pediatrician and pediatric infectious disease specialist.
- Children with Perthes disease (ie, osteochondritis of the femoral head).
- Children and adolescents with slipped capital femoral epiphysis.
- Infants, children, and adolescents with severe scoliosis or limb length discrepancy.

- Infants, children, and adolescents with deformity or gait abnormality secondary to neuromuscular conditions (eg, cerebral palsy).
- Infants, children, and adolescents with complex fractures and dislocations.

PEDIATRIC NEUROLOGICAL SURGERY REFERRAL GUIDELINES

A pediatric neurosurgeon is a board-certified neurosurgeon who has completed a fellowship in pediatric neurosurgery after completing a residency in general neurosurgery and is certified by the American Board of Pediatric Neurologic Surgery. For purposes of developing these guidelines, the following age group definitions are used: infant (0–1 year), child (2–12 years), and adolescent (13–18 years).

In the interest of good patient care, it is suggested that any general neurosurgeon who will manage pediatric neurosurgical problems not listed in the categories below should have had a minimum 6-month rotation as a junior or senior resident during his or her general neurosurgical residency on a pediatric neurosurgical service run by a trained pediatric neurosurgeon. Attendance at pediatric neurosurgical conferences and meetings at least every 12 months is also necessary for the general neurosurgeon caring for pediatric neurosurgical patients.

- Patients 5 years or younger who may need neurosurgical care for congenital anomalies or neoplasms of the brain or spinal cord should be cared for by a pediatric neurosurgeon.
- Infants and children with injuries to the head, spinal cord, or peripheral nerves may be stabilized at a local hospital and should then be transferred to a pediatric trauma center with pediatric neurosurgical coverage.
- Infants, children, and adolescents with brain tumors should be cared for from the outset by pediatric neurosurgical and pediatric medical cancer specialists.
- Infants, children, and adolescents with tumors of the spinal cord or peripheral nerves should be cared for from the outset by pediatric neurosurgical and pediatric medical cancer specialists.
- Infants and children with deformities of the cranium (eg, craniosynostosis) or spine (eg, spina bifida) should be cared for by a pediatric neurosurgeon.
- Infants and children with hematomas/hygromas of the brain should be cared for by a pediatric neurosurgeon.
- Infants and children with abscesses of the brain or spinal cord should be cared for by a pediatric neurosurgeon, in conjunction with the primary pediatrician and a pediatric infectious disease specialist.
- Infants with myelomeningocele are preferably cared for by a pediatric neurosurgeon (as part of a medical-surgical team).
- Infants with hydrocephalus are preferably cared for by a pediatric neurosurgeon.
- Infants and children with medical conditions that increase operative risk (eg, congenital heart disease) who must undergo a common neurosurgical procedure (eg, shunt for hydrocephalus) should be cared for by a pediatric neurosurgeon.
- Neuroendoscopy procedures in infants and children should be performed by a pediatric neurosurgical endoscopist.

PEDIATRIC PLASTIC SURGERY REFERRAL GUIDELINES

A pediatric plastic surgeon is certified by the American Board of Plastic Surgery. He or she has completed the requirements of residency training for board certification in plastic surgery (usually a total of 6 or more years of surgical and surgical specialty training), plus additional training in pediatric plastic surgery. For purposes of developing these guidelines, the following age group definitions are used: infant (0–1 year), child (2–12 years), and adolescent (13–18 years).

- Infants and children with congenital malformations of head and neck structures including the face and skull (eg, cleft lip and palate, craniosynostosis) should be referred to a pediatric plastic surgeon.
- Infants and children with congenital malformations of the limbs (eg, syndactyly) should be referred to a pediatric plastic surgeon.
- Infants, children, and adolescents who are seriously burned or injured should be stabilized at a local hospital and then transferred to a pediatric burn/trauma center with a pediatric plastic surgeon as part of the treatment team.
- Infants, children, and adolescents with large cutaneous pigmented or vascular lesions (eg, nevi, port wine stains, arteriovenous malformations) should be referred to a pediatric plastic surgeon.
- Infants, children, and adolescents with large soft-tissue tumors that, when excised, leave defects requiring tissue transfer or reconstruction are preferably cared for by a pediatric plastic surgeon.
- The pediatric plastic surgeon is optimally part of a multispecialty team (with pediatricians and other pediatric surgical specialists) in management of conditions such as myelomeningocele or complex problems requiring tissue expansion or microsurgical procedures.

Because the care of infants, children, and adolescents changes and advances rapidly, these guidelines should be updated at regular intervals.

The American Academy of Pediatrics promotes the inclusion of the gynecologic examination in the primary care setting within the medical home. Gynecologic issues are commonly seen by clinicians who provide primary care to adolescents. Some of the most common concerns include questions related to pubertal development; menstrual disorders such as dysmenorrhea, amenorrhea, oligomenorrhea, and abnormal uterine bleeding; contraception; and sexually transmitted and non–sexually transmitted infections. The gynecologic examination is a key element in assessing pubertal status and documenting physical findings. Most adolescents do not need an internal examination involving a speculum or bimanual examination. However, for cases in which more extensive examination is needed, the primary care office with the primary care clinician who has established rapport and trust with the patient is often the best setting for pelvic examination. This report reviews the gynecologic examination, including indications for the pelvic examination in adolescents and the approach to this examination in the office setting. Indications for referral to a gynecologist are included. The pelvic examination may be successfully completed when conducted without pressure and approached as a normal part of routine young women's health care. *Pediatrics* 2010;126: 583–590

INTRODUCTION

Gynecologic issues are commonly seen by clinicians who provide primary care to adolescents. Some of the most common problems include questions related to pubertal development; menstrual disorders such as dysmenorrhea, amenorrhea, oligomenorrhea, and abnormal uterine bleeding; contraception; and sexually transmitted infections (STIs) and non–STIs. Approximately one-half of adolescents attending high school have been sexually active, which places them at risk for STIs and pregnancy.[1] Younger adolescents often have questions about pubertal development, and the gynecologic examination is a key element in assessing pubertal status and documenting physical findings.

The American Academy of Pediatrics (AAP) promotes the inclusion of the pelvic examination in the primary care setting within the medical home. The examination can be a positive experience when conducted without pressure and approached as a normal part of routine young women's health care. At a minimum, examination of the external genitalia should be included as part of the annual comprehensive physical examination of children and adolescents of all ages. Routinely explaining and including this examination normalizes the experience rather

than setting it apart as something that is only performed as an exception. Most adolescents do not need an internal examination involving a speculum or bimanual examination. However, for cases in which more extensive examination is needed, the primary care office is often the best setting for pelvic examination. The primary care clinician, who has established rapport, trust, and a comfort level with the patient, is allowed to prepare the patient in advance and to more successfully address preconceived negative attitudes and fears.

Although pediatric residency training includes instruction in performing the pelvic examination, many pediatricians may not use these skills in their current practice setting. The purpose of this report is to provide pediatricians with background information regarding indications for the pelvic examination, along with information about the equipment and supplies needed and techniques used in performing the examination in the primary care office setting.

INDICATIONS FOR THE PELVIC EXAMINATION

Fewer adolescents require a complete screening pelvic examination because of recent changes in recommendations for the initiation and follow-up of abnormal Papanicolaou (Pap) test results, as well as newer tests available to screen for STIs, which can be performed on urine specimens, vaginal swabs, or cervical samples. However, there are instances in which the pelvic examination is a crucial part of the medical evaluation. The goals of a pelvic examination are primarily to screen for and diagnose diseases and abnormalities but also to provide education about gynecologic issues and reassure the patient about normal, healthy anatomy. Because of previous negative experiences or inaccurate information relayed by peers or family members, the adolescent may be fearful or anxious about the examination. It is important to proactively allay any fears before performing the examination. Issues that need to be addressed up front with the patient include fear of discovering a disease or abnormality, possible pain or discomfort, embarrassment in undressing or exposing the genital area, and uneasiness with the examiner, particularly when the clinician is male or a trainee. Clinicians should always be sensitive to the possibility of past or current sexual abuse, which can affect the patient's comfort with the examination and her preference regarding the gender of the examiner. When performed in a thoughtful and sensitive manner, the pelvic examination can be a positive experience. In some cases, it may be helpful to have the patient make an appointment specifically for the pelvic examination to ensure that the provider does not feel rushed in the midst of a busy day of clinical practice.

Indications for the pelvic examination are listed in Table 1. In the past, a history of sexual activity was an automatic indication for a full pelvic examination to perform Pap tests and STI testing and to act as a prerequisite to prescribing hormonal contraception. Certainly, the external genitalia of all patients should be examined to confirm normal anatomy, assess pubertal development, and look for evidence of abnormal lesions, infection, or trauma. However, with the availability of urine-based and vaginal-swab STI testing, examination with a speculum in an asymptomatic patient is not necessary for diagnosing asymptomatic STIs.[2,3] Other non–sexually transmitted vaginal infections, such as bacterial vaginosis and yeast infections, can also be diagnosed with a vaginal swab obtained by either the provider or the patient.[4,5]

TABLE 1 Indications for a Pelvic Examination

Persistent vaginal discharge
Dysuria or urinary tract symptoms in a sexually active female
Dysmenorrhea unresponsive to nonsteroidal anti-inflammatory drugs
Amenorrhea
Abnormal vaginal bleeding
Lower abdominal pain
Contraceptive counseling for an intrauterine device or diaphragm
Perform Pap test
Suspected/reported rape or sexual abuse
Pregnancy

Previous recommendations to perform Pap tests at the onset of sexual activity have changed. Current guidelines state that the first Pap test should be performed at 21 years of age, except if a patient has immune suppression or infection with HIV, in which case annual Pap tests are started with the onset of sexual activity. Adolescents who had been screened previously and had documented cervical intraepithelial neoplasia (CIN) 2 or 3 or carcinoma would require continued screening as outlined in the new recommendations.[6]

Cervical cancer generally develops several decades after initial exposure to human papillomavirus (HPV) and is rare in women younger than 21 years. Although many sexually active adolescents are exposed to HPV, and some develop abnormal cervical cells, these changes resolve without intervention in the vast majority of adolescents. Furthermore, there are indications that interventions for abnormal cervical cytology in this age group cause unnecessary anxiety and have the potential to contribute to pregnancy complications in the future.

A speculum or bimanual examination is now considered unnecessary before prescribing most forms of contraception. The package insert for oral contraceptive pills specifically states that a gynecologic examination is not necessary. The rationale is that there is

nothing that would be found on the pelvic examination that would be a contraindication to prescribing oral contraceptive pills. The same reasoning can be applied to the contraceptive patch, ring, progestin-releasing implant, and medroxyprogesterone injections. A urine-based pregnancy test and STI screen can be performed, if indicated, before a clinician prescribes hormonal contraception. The 2 exceptions would be an intrauterine device (IUD) or diaphragm, for which anatomic variation could affect insertion or appropriate sizing of the device.

A complete pelvic examination is always indicated in cases of suspected or reported rape or sexual abuse and/or as part of the evaluation of lower abdominal pain. In the case of lower abdominal pain, the examination is performed to identify the source of pain, which may be caused by pelvic inflammatory disease, ovarian mass or torsion, and/or normal or ectopic pregnancy. When rape or sexual abuse has occurred in the previous 72 hours, a pelvic examination should be performed in a clinical setting along with the physical examination to identify and document evidence of trauma and to collect and safeguard forensic specimens obtained in a standardized manner. The necessary supplies, equipment, and staff knowledge and skills may not be available in the primary care office setting; therefore, some patients may need referral to a specialized medical center.

Persistent symptomatic vaginal discharge is another indication for a speculum examination. Although nucleic acid amplification tests (NAATs) can be used on non–clean-catch urine samples to detect *Chlamydia trachomatis* and *Neisseria gonorrhoeae* infections, cervical or vaginal specimens may be more sensitive, depending on the test that is used.[2] Although vaginal swab specimens obtained during the speculum examination can be used to diagnose trichomoniasis, bacterial vaginosis, and yeast infection, a blind vaginal swab is sufficient for obtaining an adequate sample for diagnosing these infections. Visualizing the cervix also allows for assessment for the presence of mucopurulent discharge and friability, which have been associated with the diagnosis of chlamydia and gonorrhea. The speculum examination is also important for ruling out other causes of discharge, such as a foreign body or a cervical abnormality such as a large ectropion.

Another indication for a complete pelvic examination is menstrual disorders, including dysmenorrhea that is unresponsive to first-line therapy with nonsteroidal anti-inflammatory drugs (NSAIDs) and/or hormonal therapy, amenorrhea, and abnormal vaginal bleeding. In these instances, the pelvic examination is important for confirming normal anatomy, isolating the source of pain, ruling out lesions or masses, and identifying sources of vaginal/uterine bleeding. A complete pelvic examination with a speculum may not be necessary for all adolescents with abnormal vaginal bleeding if it is determined that the clinical scenario is that of an individual with heavy and/or prolonged menses within the first few years after menarche who promptly responds to medical management and does not have any indication of trauma or history of sexual activity or abuse.

PREPARATION FOR THE PELVIC EXAMINATION

Before performing a pelvic examination, it is important to explain the components of the examination to the patient and to show the patient the equipment that will be used. Allowing the patient to touch the speculum to demonstrate that it is smooth and will not injure her can be reassuring. Use of anatomic models, pictures in handouts, and pamphlets that describe the examination are valuable adjuncts. The amount of detail included depends on the age and maturity level of the patient. Depending on the patient's preference, having the patient's mother or another trusted female, such as a relative, present for both the preexamination preparation and the examination itself can sometimes be helpful and reassuring to the patient.

It is important to reassure the patient that nothing will be done without telling her first and that, although the examination may be uncomfortable, it should not be painful in the absence of pelvic abnormality. Patients should be encouraged to give feedback to the clinician during the examination if they are not comfortable, either physically or emotionally. The patient should be reminded that she is in control of her body and that it is fine to say, "Wait a minute," "Stop," or "That's not comfortable." For a cooperative patient, the examination can be completed in 10 to 15 minutes. However, the examination should be performed only when there is adequate time allotted, particularly if it is the patient's first examination or if the patient has had a previous negative experience. If the patient does not appear to be tolerating the examination, it should be stopped and tried again at a later time to minimize negative experiences. In addition to explaining some relaxation techniques to the patient, pressing on the perineal muscle without inserting a finger in the vagina and having the patient practice contracting and relaxing that area can be helpful in later successfully inserting the speculum or a finger during the bimanual examination.

Before performing the examination, the patient should be asked to empty her bladder. This will minimize any pain or discomfort, particularly dur-

ing the bimanual examination. The pelvic examination should be performed in the lithotomy position on an examination table with stirrups. Although frog-leg or knee-chest position is used to examine younger girls, the use of stirrups is preferred when performing a speculum examination to allow for proper insertion and positioning of the speculum. The room should be set up to ensure privacy with a curtain or locked door, and gowns and draping should be provided. Chaperones are strongly recommended, with the permission of the patient, even when the patient and clinician are the same gender, to help avoid any false accusations of impropriety. The chaperone can also serve as the assistant to the clinician, which improves efficiency in collecting specimens.

The equipment needed to perform a pelvic examination is listed in Table 2 and includes materials used to perform Pap tests and STI/non-STI cervicitis/vaginitis evaluation. Warm running water is helpful to provide lubrication for the speculum before insertion. Jelly lubricants should not be used on the speculum, because they interfere with the results of Pap tests and STI tests. The jelly lubricant is reserved for the bimanual examination, which is always performed after the speculum examination is completed. Nonlatex gloves are needed, particularly for those who have latex sensitivity or allergy. A variety of specula of varying widths should be available. The pediatric/infant speculum should never be used on a pubertal female, because it does not have the required 4-in length to reach the cervix. The speculum commonly used in a sexually active female is the Pederson speculum, which is 7/8 in wide. In cases of virginal adolescents or those who cannot relax their vaginal muscles, the Huffman speculum can be useful, because it is narrower, with a width of 0.5 in, but has the required length. Use of the Graves speculum should be avoided, because its width can cause unnecessary discomfort. Plastic disposable specula are available in the appropriate sizes. Specula with self-contained lighting can be useful, because they make visualization easier.

TABLE 2 Materials and Equipment Needed for the Pelvic Examination

Room with warm running water
Room with a curtain or locked door
Examination table with stirrups
Adequate adjustable light source
Nonlatex gloves
Water-soluble lubricant
Gowns, drapes
Speculum: Pederson, Huffman
Pap test materials: liquid-based or slide, cytobrush, paddle, fixative
Culture/antigen tests for STIs: chlamydia, gonorrhea, trichomoniasis
Urine pregnancy tests
Swabs: cotton, calcium alginate, Dacron
Microscopy materials: glass slides and cover slips, saline solution, 10% potassium hydroxide
pH paper
Tampons/pads
Tissues

In light of existing barriers to reproductive health services for adolescents with disabilities, the need for access to appropriate screening and sexual education cannot be overstated. Young women with physical disabilities may require modification of the physical approach to the examination because of limb, pelvic, or spine deformity or immobility. The teenager with physical, behavioral, or developmental disability may require a referral to a gynecologist and possibly an examination under anesthesia. The same may apply to patients who are unable or unwilling to cooperate. All efforts should be made to perform the examination in the office setting, but forcing a patient to undergo pelvic examination is always contraindicated (refer to the AAP clinical report on sexuality of disabled children and adolescents[7]).

PERFORMING THE PELVIC EXAMINATION AND COMMON FINDINGS

External Genitalia

The first part of the pelvic examination is inspection of the pubic hair, noting Tanner stage (sexual maturity rating) and the presence of any lesions, including pubic lice, nits, folliculitis, and other inflammatory lesions such as hidradenitis suppurativa. Folliculitis presents as papules and pustules primarily in the pubic hair region. They can be mildly tender and are usually smaller than hidradenitis suppurativa, which causes larger, tender, draining lesions that represent recurrent infection of apocrine glands. Folliculitis is particularly common with the increased popularity of shaving pubic hair. Teenagers need to be counseled that shaving should be performed carefully with adequate lubrication to minimize trauma. In addition, although not as common as in other body locations, some teenagers will have genital piercings. Teenagers should be counseled on proper hygiene and potential medical complications of piercing in the genital area, particularly those that involve the clitoris.

The external genitalia are examined next to assess for signs of inflammation, including redness or swelling, as well as any pigmentary changes, including hypopigmentation, which can be seen in lichen sclerosis or vitiligo. Clitoral size should be evaluated after retracting the clitoral hood, and the width should be $<$10 mm. An enlarged clitoris can indicate elevated androgens associated with a problem at the level of the ovary or adrenal gland. The hymen should be assessed for patency and configuration, including the presence of an imperforate, microperforate, or cribriform hymen or hymenal band, which may impair uterine blood flow or preclude use of tampons. A

pubertal female with an imperforate hymen should be referred promptly to a gynecologist to prevent accumulation of blood in the vagina and upper genital tract. Other abnormalities, such as a vertical or transverse vaginal septum, would be an indication for further evaluation to rule out other genital tract anomalies. If there are any questions about patency of the vagina, a saline-soaked cotton swab can be gently inserted to demonstrate patency. The Bartholin glands are located in the posterior vestibule at the 4 and 8 o'clock positions. When infected, they present with swelling, erythema, and tenderness that can extend into the entire labia minora. Although any vaginal organism can infect the glands, they are commonly infected by STI pathogens, including gonorrhea and chlamydia. The Skene glands are located on each side of the urethra, and infection can present as erythematous areas lateral to the urethra. Insertion of a finger into the vagina and anterior pressure may produce discharge from the ducts.

Any lesions, including papules, vesicles, pustules, ulcers, fissures, and warts, should be noted. These could be signs of an STI or other dermatologic conditions. In addition, any signs of trauma, including laceration, should be noted. Ulcers found on the external genitalia as well as in the vagina are commonly caused by herpes simplex virus (HSV), syphilis, or chancroid, which are sexually transmitted. Although lymphogranuloma venereum can present with an ulcer, it is an uncommon STI in the United States.[8] Because HSV and syphilis are the most common cause of genital ulcers in the United States, a viral culture for HSV and serologic tests for syphilis should be performed for suspicious lesions. Some ulcers are not acquired sexually, including aphthous spectrum ulcers and those caused by Epstein-Barr virus infection.[9] Genital warts (condylomata acuminata) can present as flat or exophytic and are attributable to human papillomavirus. Condylomata lata are flesh-colored papules on mucous membranes, which can be confused with warts but are filled with spirochetes and are a manifestation of secondary syphilis.[8]

The presence of any blood coming from the vagina should be noted; vaginal discharge should be assessed, including amount, color, and odor. The perianal area should be included in the external examination with specific reference to evidence of trauma, discharge, or warts. Inguinal nodes should be palpated for size, tenderness, and consistency. Enlarged painful nodes could be an indication of an STI, including syphilis or herpes simplex virus.

Speculum Examination

The speculum examination is performed after completion of the external examination. Although not always necessary, a single finger can be inserted along the posterior vaginal wall before insertion of the speculum to locate the cervix. Lubricating the speculum with warm water can facilitate insertion of the speculum, and anterior pressure should be avoided during the insertion process to prevent pain along the urethra. If the speculum is completely inserted before opening the blades, the cervix frequently is easily viewed without much further manipulation. Opening the speculum before inserting it the complete length of the vagina can be painful. Once inserted, the vaginal walls should be inspected for discharge and lesions.

The cervix should be completely visualized to note the presence of any lesions as well as the presence or absence of an ectropion (transition between the columnar and squamous epithelium) on the exocervix. The ectropion is a normal developmental finding of the adolescent cervix in which the squamocolumnar junction is on the exocervix. This usually regresses into the cervical canal with advancing gynecologic age. When prominent, the ectropion can cause significant vaginal discharge. Friability and hyperemia of the cervix can indicate infection with an STI. White plaques on the cervix that cannot be removed with a swab could indicate condyloma acuminata, and red punctate lesions (strawberry cervix) may be seen with trichomoniasis. The cervix has a bluish hue, known as cervical cyanosis or Chadwick sign, in pregnancy.

During the speculum examination, samples are obtained for laboratory and office-based analysis. If the office has a microscope, vaginal pool samples can be examined immediately to diagnosis yeast infection, bacterial vaginosis, or trichomoniasis. Samples are obtained from the pooled vaginal secretions for wet prep, potassium hydroxide examination, and vaginal pH testing. A cotton swab is used to collect vaginal secretions, which can be placed in a tube with 1 mL of normal saline solution and then used to prepare a glass slide for microscopic examination. Alternatively, the slide can be directly smeared with the swab, after which a drop of saline or potassium hydroxide is added. With the wet saline solution preparation, the clinician looks for an increased number of white blood cells as an indication of infection; clue cells (bacterial-covered epithelial cells), which are a sign of bacterial vaginosis; moving flagellated trichomonads; and hyphae or budding yeast. Potassium hydroxide preparation is helpful for identifying yeast not seen on the saline-solution preparation. Ideally, the wet mount should be read as soon as the pelvic examination is completed to increase the likelihood of detecting trichomonads. In the case

of bacterial vaginosis, when the vaginal secretions are mixed with potassium hydroxide, there is a characteristic fishy odor, known as a positive whiff test, because of the amines that are present in the discharge. The normal vaginal pH should be <4.5; pH is elevated with bacterial vaginosis and trichomoniasis. An easy method for measuring pH is to dip the pH paper in the secretions left on the tip of the speculum after it is removed and then to read the color change within 10 seconds. Other tests that are commercially available include cards that measure pH and for the presence of amines, which may be helpful in the diagnosis of bacterial vaginosis. The wet mount can miss trichomoniasis 30% to 50% of the time; culture, nucleic acid probe, or antigen-based rapid testing may be more sensitive in detecting this infection.[3] Clinicians can consult with their referral laboratory about performing the wet-mount or potassium-hydroxide examination if a microscope is not available in the office or if Clinical Laboratory Improvement Act compliance is an issue.

When indicated, Papanicolaou tests are obtained by using a Papanicolaou paddle, which is rotated 360° to sample the entire exocervix, and a cytobrush is used to collect an endocervical specimen. The cytobrush can cause bleeding, which may be more prominent in patients with an STI. The patient should be warned about the possibility of some light bleeding or spotting after the Pap test. Liquid-based Pap tests are preferred, because they produce fewer inadequate readings and false-negative results. An additional benefit of liquid-based Pap tests is that, in some cases, STI testing can be performed on the same specimen. Alternatively, direct smearing of a slide, which is immediately fixed before air drying, is still used in many laboratories. It is important to verify with the cytology laboratory whether they use 1- or 2-slide Pap tests in which the endocervical or ectocervical specimens are either placed on 1 slide or separated. Any nonulcerative lesions of the cervix should be evaluated with a Pap test, and any patient with unknown suspicious lesions should be referred to a gynecologist for further evaluation regardless of the Pap test result. The Pap test is performed before obtaining the endocervical swab for STI testing.

Cervical specimens should be obtained for gonorrhea and chlamydia testing by using an NAAT, culture, or DNA probe (nonamplified DNA testing). Some of the NAATs for gonorrhea and chlamydia have also been approved for vaginal swab specimens. In cases of sexual abuse or rape, cultures may be legally required for gonorrhea and chlamydia instead of the NAAT. For non-NAATs including culture, an endocervical specimen must be obtained for chlamydia, because this organism, unlike gonorrhea, is an intracellular organism that infects columnar cells. The NAATs are the most sensitive tests for chlamydia, but depending on transport issues, culture for gonorrhea may be equivalent to an NAAT. Testing using NAATs should not be performed sooner than 3 weeks after treatment for chlamydia or gonorrhea because of the possibility of false-positive results. Blind vaginal swab for *Trichomonas* testing is equivalent to a specimen obtained during speculum examination.[2,3,5]

Once the speculum examination is completed, the speculum is closed and then carefully removed with posterior pressure while avoiding pinching the sides of the vaginal wall. The speculum should never be removed in the open position.

Bimanual Examination

The bimanual examination is performed by inserting 1 or 2 fingers into the vagina with a water-based lubricant on the gloved hand. The cervix is assessed for consistency. The normal nonpregnant cervix is firm, while the cervix of a gravid uterus is softer. The cervix should be gently moved to assess for cervical motion tenderness, which indicates pelvic infection or inflammation. It is important to remember that adolescents, particularly those not experienced with the examination, commonly mistake movement or pressure for pain. Distinguishing between discomfort and true pain can be challenging. The uterus is then palpated for size and tenderness. The nonpregnant uterus is small and firm, whereas at 10 to 12 weeks' gestation, it is the size of a grapefruit and is softer, globular, and starting to protrude from the pelvis. The uterus starts becoming larger and softer between 8 and 10 weeks' gestation. The adnexa (ovaries) are then assessed for pain or masses. Normal ovaries are usually barely palpable.

When the examination is completed, the patient should be given time to remove any excess lubricant and offered tampons or pads for bleeding. The findings and recommendations are then discussed once the patient is dressed.

The common gynecologic abnormalities that are identified during pelvic examination are listed in Table 3.

REASONS TO REFER TO A GYNECOLOGIST

The role of the pediatrician is to recognize abnormalities that warrant referral to a gynecologist and to identify common infections that can be treated without referral. The types of conditions that should be referred to a gynecologist are listed in Table 4 and include masses, chronic pelvic pain, pregnancy, menstrual disorders unresponsive to medical management,

TABLE 3 Common Gynecologic Findings Seen on Gynecologic Examination

External genitalia
Bartholin gland abscess
Skene gland infection
Genital ulcers/fissures
Warts: condyloma acuminata
Papular lesions (condylomata lata from syphilis)
Molluscum contagiosum
Urethral prolapse
Folliculitis
Hidradenitis suppurativa
Vulvitis
Pigmentary changes
Papillomatosis
Cervix
Ectropion
Strawberry cervix
Human papillomavirus/condyloma
Cervical polyp
Cervical ulcers
Vagina
Ulcers
White adherent plaques: *Candida* species
Condyloma acuminata

TABLE 4 Reasons to Refer to a Gynecologist

Adnexal mass
Vulvar or cervical lesion of undetermined etiology
Possible genital tract anomaly (imperforate hymen, duplicated upper tracts, absence of vagina, uterus)
Abnormal Pap test result requiring colposcopy
Acute pelvic pain with possible ovarian torsion, ectopic pregnancy, tubo-ovarian abscess, adnexal mass
Pelvic inflammatory disease (if the clinician is not comfortable with management)
Chronic pelvic pain
Dysmenorrhea unresponsive to medical therapy
Abnormal vaginal bleeding unresponsive to medical therapy or with severe anemia
Intrauterine device insertion
Pregnancy

unknown vulvar or cervical lesions, abnormal Pap test results requiring colposcopy, and genital anomalies. Recently, changes were made in the recommendations for follow-up of abnormal Pap test results. As opposed to high-grade lesions, low-grade lesions and atypical squamous cells of undetermined significance should now be followed up by repeat Pap tests at 1-year intervals. Colposcopy is recommended only if the abnormality persists or becomes a high-grade lesion over a 2-year period.[6]

CONCLUSIONS

Many gynecologic issues can be managed by the primary care clinician without performing a speculum or bimanual examination. For conditions that require a complete pelvic examination, the patient may prefer to have it performed in a familiar setting rather than being referred to another provider. There are instances in which the pelvic examination must be performed during a problem visit and cannot be deferred to a separate, dedicated appointment time slot. These urgent situations may affect office costs in terms of physician and assistant time. However, providing urgent examinations will provide more comprehensive continuity of care for the patient. Specific details concerning billing and coding, including billing for confidential services, can be found in other AAP publications and policy statements.[10–13] With appropriate backup from a gynecologist, most medical gynecologic issues can be managed by the clinician in the primary care office setting.

Clinical Report—Head Lice

abstract

FREE

Head lice infestation is associated with limited morbidity but causes a high level of anxiety among parents of school-aged children. Since the 2002 clinical report on head lice was published by the American Academy of Pediatrics, patterns of resistance to products available over-the-counter and by prescription have changed, and additional mechanical means of removing head lice have been explored. This revised clinical report clarifies current diagnosis and treatment protocols and provides guidance for the management of children with head lice in the school setting. *Pediatrics* 2010;126:392–403

INTRODUCTION

Head lice (pediculosis capitis) have been companions of the human species since antiquity. In the United States, head lice infestation is common among children 3 to 12 years of age. Before the development of modern insecticides, various botanical treatments, inorganic poisons, and petroleum products were used to treat head lice infestation.[1] Shaving heads was also quite effective. The development of dichlorodiphenyltrichloroethane (DDT) after World War II offered a significant advancement in treatment and continues to be used in some developing countries.[2] Because of environmental concerns regarding DDT, other pharmaceutical agents, including lindane, pyrethrin, permethrin, and malathion, were developed to replace DDT.[3] Resistance to each of these pediculicides has developed. Inadequate treatment can sometimes be mistaken for drug resistance, and careful scrutiny is needed in making that determination.

A 1997 report estimated that approximately 6 to 12 million infestations occur each year in the United States,[4] but this number was based on sales of pediculicides and is most likely an overestimation. Anecdotal reports from the 1990s estimated annual direct and indirect costs totaling $367 million, including remedies and other consumer costs, lost wages, and school system expenses. More recently, treatment costs have been estimated at $1 billion.[5] Head lice are not a health hazard or a sign of poor hygiene and, in contrast to body lice, are not responsible for the spread of any disease.

Historically, diagnosis of head lice infestations by parents and other non–health care personnel and the easy availability of safe and effective over-the-counter (OTC) pediculicides for self-treatment essentially removed the physician from the treatment process. However, the potential for misdiagnosis and the resulting improper use of pediculicides raise concerns about unsafe use of these products, specifically when no lice are present or when products are used excessively.[6,7] In addition, the emergence of resistance to available products and the

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

development of new products, many without proof of efficacy or safety, call for increased physician involvement in the diagnosis and treatment of head lice. Optimal treatments are safe and effective, rapidly pediculicidal, ovicidal, easy to use, and affordable and incorporate a resistance-prevention strategy.[8] Because lice infestation is so benign, treatments must prove safe to ensure that the adverse effects of therapy are not worse than the infestation.

ETIOLOGIC AGENT

The adult head louse is 2 to 3 mm long (the size of a sesame seed), has 6 legs, and is usually tan to grayish-white in color. The female lives up to 3 to 4 weeks and, once mature, can lay up to 10 eggs per day. These tiny eggs are firmly attached to the base of the hair shaft within approximately 4 mm of the scalp with a glue-like substance produced by the louse. Viable eggs camouflaged with pigment to match the hair color of the infested person often are seen more easily at the posterior hairline. Empty egg casings (nits) are easier to see because they appear white against darker hair. (Note that some experts refer to "eggs" as containing the developing nymph and use "nits" to refer to empty egg casings; others use the term "nits" to refer to both eggs and the empty casings.) The eggs are incubated by body heat and typically hatch in 8 to 9 days, but hatching can vary from 7 to 12 days depending on whether the ambient climate is hot or cold. Once it hatches, a nymph leaves the shell casing and passes through a total of 3 nymph stages (instars) during the next 9 to 12 days and then reaches the adult stage. The female louse can mate and begin to lay viable eggs approximately 1.5 days after becoming an adult. If not treated, this cycle may repeat itself approximately every 3 weeks.[9] The louse feeds by injecting small amounts of saliva with vasodilatory and anticoagulation properties and sucking tiny amounts of blood from the scalp every few hours. Itching results from sensitization to components of the saliva. With a first case of head lice, itching may not develop for 4 to 6 weeks, because it takes that amount of time for sensitivity to result. Head lice usually survive for less than 1 day away from the scalp at room temperature, and their eggs cannot hatch at an ambient temperature lower than that near the scalp.[2]

CLINICAL DISEASE

Head lice, unlike body lice, do not transmit any disease agent.[4,10] Itching can develop in a sensitized individual. Rarely, scratching may cause impetigo or other skin infection, which can lead to local adenopathy.

EPIDEMIOLOGY

In the United States, head lice infestation is most common among preschool- and elementary school-aged children. Caregivers and household members of people infested with head lice can also be at increased risk. All socioeconomic groups are affected, and head lice infestations are common in many parts of the world. In some remote communities in Central and South America, nearly all inhabitants have at least a few head lice.[11] In Australia, the prevalence in schoolchildren is 13%, with a range between schools of 0% to 28%[12]; in Brazil, the prevalence is 43% in a slum and 28% in a fishing village[13]; in China, the prevalence is 14%, with a range of 0% to 52%[14]; and in the United Kingdom, the prevalence is 2%, with an annual incidence of 37%.[15] Head lice infestation is not significantly influenced by hair length or by frequent brushing or shampooing. However, in the United States, where daily brushing is routine for many, infested individuals rarely have more than a dozen live lice, whereas individuals in cultures with different grooming practices often have a hundred or more live lice.

TRANSMISSION

Lice cannot hop or fly; they crawl. However, there are reports that combing dry hair can build up enough static electricity to physically eject an adult louse from an infested scalp more than 1 m.[3] Transmission in most cases occurs by direct contact with the head of an infested individual.[16] Indirect spread through contact with personal belongings of an infested individual (combs, brushes, hats) is much less likely but may occur rarely.[17] Lice found on combs are likely to be injured or dead,[18] and a healthy louse is not likely to leave a healthy head unless there is a heavy infestation.[19] This is further illustrated by 2 studies from Australia. In 1 study, examination of carpets on 118 classroom floors found no lice despite more than 14 000 live lice found on the heads of 466 children using these classrooms.[20] In a second study, live lice were found on only 4% of pillowcases used by infested volunteers.[21] Thus, the major focus of control activities should be to reduce the number of lice on the head and to lessen the risks of head-to-head contact.

DIAGNOSIS

The gold standard for diagnosing head lice is finding a live louse on the head, which can be difficult because lice avoid light and can crawl quickly. Studies have revealed that diagnosis of infestation by using a louse comb is quicker and more efficient.[22] Some experts have suggested using a lubricant (water, oil, or conditioner) to "slow down" the movement of lice and eliminate the possibility of static electricity.[23] The tiny eggs may be easier to spot, especially at the nape of the neck or behind the ears, within 1 cm of the scalp. It is important not to confuse eggs or nits with dandruff, hair casts,

or other hair debris, all of which have been misdiagnosed as nits. Nits are more difficult to remove, because they are firmly attached to the hair shaft. It is also important not to confuse live eggs with dead or empty egg cases (nits). Many presumed "lice" and "nits" submitted by physicians, nurses, teachers, and parents to a laboratory for identification were found to be artifacts such as dandruff, hairspray droplets, scabs, dirt, or other insects (eg, aphids blown by the wind and caught in the hair).[7] In general, eggs found more than 1 cm from the scalp are unlikely to be viable, although some researchers in warmer climates have found viable eggs farther from the scalp.[2] A viable egg will develop an "eye spot" that is evident on microscopic examination several days after being laid.[2]

PREVENTION

It is probably impossible to prevent all head lice infestations. Young children come into head-to-head contact with each other frequently. It is prudent for children to be taught not to share personal items such as combs, brushes, and hats. However, no one should refuse to wear protective headgear because of fear of head lice. In environments where children are together, adults should be aware of the signs and symptoms of head lice infestation, and infested children should be treated promptly to minimize spread to others.

TREATMENT

Never initiate treatment unless there is a clear diagnosis of head lice. The ideal treatment for lice would be completely safe, free of harmful chemicals, readily available without a prescription, easy to use, and inexpensive. When recommending a treatment, pediatricians should take into account effectiveness and safety, local patterns of resistance (if known), ease of use, and cost. Published reviews of available efficacy studies and comparative trials of pediculicides have used different inclusion criteria and reached different conclusions.[1,24] A Cochrane review concerning pediculicides was published in 1999 and updated in 2001[25] but was withdrawn in 2007,[26] and a substantial update is underway. Many of the cited studies were completed before the development of resistance to available pediculicides or were conducted in areas where the lice were naive to pediculicides.

Therapy could be initiated with OTC permethrin 1% or pyrethrins when resistance to these products is not suspected. Malathion 0.5% can be used in people who are 24 months of age or older when resistance to permethrin or pyrethrins is documented or when treatment with these products fails despite their correct use. Other treatments can be considered for people who cannot afford or who wish to avoid pediculicides. The pediatrician (or someone in the community, such as the school nurse) should be skilled in the identification of an active infestation with head lice to avoid treating patients unnecessarily or falsely identifying "resistance" in the community to a certain product. Improper application of the pediculicide should be considered first as a cause of treatment failure.

Finally, it should be noted that these recommendations are intended for use by pediatricians and other practitioners in the United States. Malathion is not available in Canada, and the Canadian Paediatric Society recently updated its position statement on head lice infestation.[27] Pediatricians who work in other countries, especially developing countries in which head lice are naive to pediculicides, should use products or methods that are most economical, effective, and safe. The following products and methods can be effective for treating head lice.

Pediculicides

Permethrin (1%)

Permethrin has been the most studied pediculicide in the United States and is the least toxic to humans.[1] Introduced in 1986 as a prescription-only treatment, 1% permethrin lotion was approved for OTC use in 1990 and is marketed as a "crème rinse" (Nix [Pfizer Consumer Health Care Group, New York, NY]). One percent permethrin lotion is currently recommended as one of the drugs of choice for head lice.[28] Permethrin is a synthetic pyrethroid with extremely low mammalian toxicity. Reported adverse effects include pruritus, erythema, and edema. Permethrin is less allergenic than pyrethrins and does not cause allergic reactions in individuals with plant allergies. The product is applied to damp hair that is first shampooed with a nonconditioning shampoo and then towel dried. It is left on for 10 minutes and then rinsed off. Permethrin leaves a residue on the hair that is designed to kill nymphs emerging from the 20% to 30% of eggs not killed with the first application.[29] However, conditioners and silicone-based additives present in almost all currently available shampoos impair permethrin adherence to the hair shaft and reduce its residual effect.[8] Therefore, it is suggested that the application be repeated in 7 to 10 days if live lice are seen. Many experts now recommend routine re-treatment, preferably on day 9.[8,30] An alternate treatment schedule on days 0, 7, and 13 to 15 has been proposed for nonovicidal products.[31] Resistance to 1% permethrin has been reported,[8,32–35] but the prevalence of this resistance is not known.

Pyrethrins Plus Piperonyl Butoxide

Manufactured from natural extracts from the chrysanthemum, pyrethrins are formulated with piperonyl butoxide (RID [Bayer, Morristown, NJ], A-200

[Hogil Pharmaceutical Corp, Purchase, NY], R & C [GlaxoSmithKline, Middlesex, United Kingdom], Pronto [Del Laboratories, Uniondale, NY], Clear Lice System [Care Technologies, Darien, CT]). Pyrethrins are neurotoxic to lice but have extremely low mammalian toxicity. Pyrethrins should be avoided in people who are allergic to chrysanthemums. The labels warn against possible allergic reaction in patients who are sensitive to ragweed, but modern extraction techniques minimize the chance of product contamination, and reports of true allergic reactions have been rare.[36] These products are available in shampoo or mousse formulations that are applied to dry hair and left on for 10 minutes before rinsing out. No residual pediculicidal activity remains after rinsing. In addition, none of these natural pyrethrins are totally ovicidal (newly laid eggs do not have a nervous system for several days); 20% to 30% of the eggs remain viable after treatment,[29] which necessitates a second treatment to kill newly emerged nymphs hatched from eggs that survived the first treatment. Previous recommendations have been to re-treat in 7 to 10 days; however, new evidence based on the life cycle of lice suggests that re-treatment at day 9 is optimal. An alternate schedule of 3 treatments with nonovicidal products on days 0, 7, and 13 to 15 has been proposed.[31] Although pyrethrins were extremely effective when introduced in the mid-1980s, recent study results have indicated that efficacy has decreased substantially because of development of resistance.[6] The prevalence of resistance has not been systematically studied but seems to be highly variable from community to community and country to country.

Malathion (0.5%)

The organophosphate (cholinesterase inhibitor) 0.5% malathion (Ovide [Taro Pharma, Hawthorne, NY]) was reintroduced for the treatment of head lice in the United States in 1999 after being taken off the market twice, most recently in 1986, because of problems related to prolonged application time, flammability, and odor. It is available only by prescription as a lotion that is applied to dry hair, left to air dry, then washed off after 8 to 12 hours, although some study results have suggested effectiveness when left on for as short a time as 20 minutes.[37] Head lice in the United Kingdom and elsewhere have shown resistance to malathion preparations, which have been available for decades in those countries.[38,39] The current US formulation of malathion (Ovide lotion, 0.5%) differs from the malathion products available in Europe in that it contains terpineol, dipentene, and pine needle oil, which themselves have pediculicidal properties[25] and may delay development of resistance. Malathion has high ovicidal activity,[29] and a single application is adequate for most patients. However, the product should be reapplied in 7 to 9 days if live lice are still seen. A concern is the high alcohol content of the product (78% isopropyl alcohol), which makes it highly flammable. Patients and their parents, therefore, should be instructed to allow the hair to dry naturally; not to use a hair dryer, curling iron, or flat iron while the hair is wet; and not to smoke near a child receiving treatment. Safety and effectiveness of malathion lotion have not been established in children younger than 6 years, and the product is contraindicated in children younger than 24 months. Because malathion is a cholinesterase inhibitor, there is a theoretical risk of respiratory depression if accidentally ingested, although no such cases have been reported.

Benzyl Alcohol 5%

Benzyl alcohol 5% (Ulesfia [Sciele Pharma, Atlanta, GA]) was approved by the US Food and Drug Administration (FDA) in April 2009 for treatment of head lice in children older than 6 months. The product is not neurotoxic and kills head lice by asphyxiation. Two studies demonstrated that more than 75% of the subjects treated were free of lice 14 days after initial treatment. The most common adverse reactions after treatment included pruritus, erythema, pyoderma, and ocular irritation. Benzyl alcohol is available by prescription and is not ovicidal: package instructions state that it is to be applied topically for 10 minutes and repeated in 7 days,[40] although as with other nonovicidal products, consideration should be given to retreating in 9 days or using 3 treatment cycles (days 0, 7, and 13–15), as mentioned previously.

Lindane (1%)

On the market since 1951 for the medical treatment of lice and scabies, lindane (Kwell [Reed & Carnick, Jersey City, NJ]) is an organochloride that has central nervous system toxicity in humans; several cases of severe seizures in children using lindane have been reported.[9,41–44] For the treatment of head lice, it is available only by prescription as a 1% lindane shampoo that should be left on for no more than 4 minutes, and a repeat application should be performed in 9 to 10 days. It has low ovicidal activity (30%–50% of eggs are not killed[29]), and resistance has been reported worldwide for many years.[3,45] For these reasons, it should be used cautiously.[30] The FDA has warned that lindane shampoo should only be used for patients who cannot tolerate or whose infestation has failed to respond to first-line treatment with safer medications for the treatment of head lice. The FDA has issued a public health advisory concerning the use of lindane, which emphasized that it is a second-line treatment, is contraindicated for use in neonates, and should be used with extreme caution in chil-

dren and in individuals who weigh less than 50 kg (110 lb) and in those who have HIV infection or take certain medications that can lower the seizure threshold.[46] Lindane is no longer recommended by the American Academy of Pediatrics (*Red Book* 2009[47]) or the *Medical Letter* for use as a pediculicide. The use of lindane has been banned in California.

Removal of Topical Pediculicides

All topical pediculicides should be rinsed from the hair over a sink rather than in the shower or bath to limit skin exposure and with warm rather than hot water to minimize absorption attributable to vasodilation.[48]

Topical Reactions

Itching or mild burning of the scalp caused by inflammation of the skin in response to topical pharmaceutical agents can persist for many days after lice are killed and is not a reason for re-treatment. Topical corticosteroids and oral antihistamines may be beneficial for relieving these signs and symptoms.

Scabicides Used Off-label for Lice

Permethrin (5%)

Five percent permethrin (Elimite [Allergan, Irvine, CA]) is available by prescription only as a cream, usually applied overnight for scabies for infants as young as 2 months. It has anecdotally been recommended for the treatment of head lice that seem to be recalcitrant to other treatments.[49] No randomized case-control studies have reported efficacy to date. The results of 1 study suggested that lice resistant to 1% permethrin will not succumb to higher concentrations.[34] Permethrin 5% is not currently approved by the FDA for use as a pediculicide.

Crotamiton (10%)

This product is available by prescription only as a lotion (Eurax [Westwood-Squibb Pharmaceuticals, Buffalo, NY]), usually used to treat scabies. One study showed it to be effective against head lice when applied to the scalp and left on for 24 hours before rinsing out.[50] Other reports have suggested that 2 consecutive nighttime applications safely eradicate lice from adults.[51] Safety and absorption in children, adults, and pregnant women have not been evaluated. Crotamiton is not currently approved by the FDA for use as a pediculicide.

Oral Agents Used Off-Label for Lice

Ivermectin

This product (Stromectol [Merck & Co, West Point, PA]) is an anthelmintic agent structurally similar to macrolide antibiotic agents but without antibacterial activity. A single oral dose of 200 μg/kg, repeated in 10 days, has been shown to be effective against head lice.[52,53] Most recently, a single oral dose of 400 μg/kg repeated in 7 days has been shown to be more effective than 0.5% malathion lotion.[54] Ivermectin may cross the blood/brain barrier and block essential neural transmission; young children may be at higher risk of this adverse drug reaction. Therefore, ivermectin should not be used for children who weigh less than 15 kg.[55,56] Ivermectin is also available as a 1% topical preparation that is applied for 10 minutes and has shown promising results that warrant further testing.[6] However, neither form of ivermectin is currently approved by the FDA as a pediculicide.

Sulfamethoxazole-Trimethoprim

The oral antibiotic agent sulfamethoxazole-trimethoprim (Septra [GlaxoSmith-Kline], Bactrim [Roche Laboratories, Nutley, NJ], and generic cotrimoxazole) has been cited as effective against head lice.[57] It is postulated that this antibiotic agent kills the symbiotic bacteria in the gut of the louse or perhaps has a direct toxic effect on the louse. The results of 1 study indicated increased effectiveness when sulfamethoxazole-trimethoprim was given in combination with permethrin 1% when compared with permethrin 1% or sulfamethoxazole-trimethoprim alone; however, the treatment groups were small.[58] Rare severe allergic reactions (Stevens-Johnson syndrome) to this medication make it a potentially undesirable therapy if alternative treatments exist.[9] It is not currently approved by the FDA for use as a pediculicide.

"Natural" Products

Essential oils have been widely used in traditional medicine for the eradication of head lice, but because of the variability of their constitution, the effects may not be reproducible.[59] Several products are marketed for treatment of head lice and are in wide use. As natural products, they are not required to meet FDA efficacy and safety standards for pharmaceuticals. Hair-Clean 1-2-3 (Quantum Health, Eugene, OR) [anise, ylang-ylang, coconut oils, and isopropyl alcohol] was found to be at least as effective as the permethrin product Nix by 1 investigator.[2] Although many plants naturally produce insecticides for their own protection that may be synthesized for use by humans, such as pyrethroids, some of these insecticidal chemicals produce toxic effects as well. The safety and efficacy of herbal products are currently not regulated by the FDA the same as medications.

Occlusive Agents

Occlusive agents applied to suffocate the lice are widely used but have not been evaluated for effectiveness in randomized, controlled trials. A "petrolatum shampoo" consisting of 30 to 40 g of standard petroleum jelly massaged on the entire surface of the hair and scalp and left on overnight with a

shower cap has been suggested. Diligent shampooing is usually necessary for at least the next 7 to 10 days to remove the residue. It is thought that the viscous substance obstructs the respiratory spiracles of the adult louse as well as the holes in the operculum of the eggs and blocks efficient air exchange.[60] Another interpretation is that the intense, daily attention to hair grooming results in removal of all the lice and nits. Hair pomades are easier to remove but may not kill eggs, and treatment should be repeated weekly for 4 weeks.[61] Other occlusive substances have been suggested (mayonnaise, tub margarine, herbal oils, olive oil), but to date, only anecdotal information is available concerning effectiveness. One study that examined several "home remedies" (vinegar, isopropyl alcohol, olive oil, mayonnaise, melted butter, and petroleum jelly) revealed that the use of petroleum jelly caused the greatest egg mortality, allowing only 6% to hatch.[62]

A 2004 study reported a 96% "cure" rate with a suffocation-based pediculicide lotion applied to the hair, dried on with a hand-held hair dryer, left on overnight, and washed out the next morning. The process must be repeated once per week for 3 weeks. The product contained no neurotoxins and did not require nit removal or extensive house cleaning.[63] The study was criticized for being uncontrolled, with no blinding, randomization, or comparison group.[64] The lotion used in the study was later identified as Cetaphil cleanser [Galderma Laboratories, Fort Worth, TX],[65] and instructions for its use are available on the Internet.[66] It has not been approved by the FDA for use as a pediculicide.

Dimethicone lotion (4% long-chain linear silicone in a volatile silicone base) in two 8-hour treatments 1 week apart eradicated head lice in 69% of participants in the United Kingdom.[67] In the United States, the OTC product LiceMD (Combe Inc, White Plains, NY) contains dimethicone. Isopropyl myristate 50% (Resultz [Nycomed Canada Inc, Oakville, Ontario, Canada]), a hair rinse that dissolves the waxy exoskeleton of the louse, which leads to dehydration and death of the louse, has recently become available in Canada.[68,69]

Desiccation

The LouseBuster is a custom-built machine (available commercially in late 2009) that uses one 30-minute application of hot air in an attempt to desiccate the lice. One study showed that subjects had nearly 100% mortality of eggs and 80% mortality of hatched lice.[70] The machine is expensive, and the operator requires special training in its use. A regular blow-dryer should not be used in an attempt to accomplish this result, because investigators have shown that wind and blow-dryers can cause live lice to become airborne and, thus, potentially spread to others in the vicinity.

Other Agents

Flammable or toxic substances such as gasoline or kerosene should never be used. Products intended for animal use should not be used to treat head lice in humans.

Manual Removal

Removal of nits immediately after treatment with a pediculicide is not necessary to prevent spread, because only live lice cause an infestation. Individuals may want to remove nits for aesthetic reasons or to decrease diagnostic confusion. Because none of the pediculicides are 100% ovicidal, manual removal of nits (especially the ones within 1 cm of the scalp) after treatment with any product is recommended by some. Nit removal can be difficult and tedious.[71] Fine-toothed "nit combs" are available to make the process easier.[72,73] Studies have suggested that lice removed by combing and brushing are damaged and rarely survive.[16] In the United Kingdom, community campaigns have been launched using "bug-buster" combs and ordinary shampoo,[74,75] with everyone being instructed to shampoo hair twice per week for 2 weeks and to vigorously comb out wet hair each time. The wet hair seems to slow down the lice. Combing dry hair does not seem to have the same effect; a study conducted in Australia in which children combed their hair daily at school with an ordinary comb determined that it was not effective.[76] Some have postulated that vigorous dry combing or brushing in close quarters may even spread lice by making them airborne via static electricity. One study showed that manual removal is not as effective as pediculicides and does not improve results, even when used as an adjunct to pediculicide treatment.[77]

There are battery-powered "electronic" louse combs with oscillating teeth (Quantum MagiComb) that claim to remove live lice and nits as well as combs that resemble small "bug zappers" (LiceGuard Robi-Comb [ARR Health Technologies, Needham, MA]) that claim to kill live lice.[78] No randomized, case-controlled studies have been performed with either type of comb. Their instructions warn not to use on people with a seizure disorder or a pacemaker.

Some products are available that claim to loosen the "glue" that attaches nits to the hair shaft, thus making the process of "nit-picking" easier. Vinegar or vinegar-based products (Clear Lice Egg Remover Gel [Care Technologies]) are intended to be applied to the hair for 3 minutes before combing out the nits. No clinical benefit has been demonstrated.[9,61] This product has not been tested with and is not recommended for use with permethrin, because it may interfere with

permethrin's residual activity. A variety of other products, from acetone and bleach to vodka and WD-40 (WD-40 Company, San Diego, CA), have proved to be ineffective in loosening nits from the hair shaft[61] and present an unacceptable risk to the patient. It seems that nature has protected the louse by making the nit sheath similar in composition to the hair, so that agents designed to unravel the nit sheath can also damage human hair.[79]

Although effective for removing lice and eggs, shaving the head generally is not recommended, because it can be distressing to a child or parent.

New Products

As new products are introduced, it is important to consider effectiveness, safety, expense, availability, patient preference, and ease of application. Assessment of the severity of the infestation, the number of recurrences, the local levels of resistance to available pediculicides, and the potential for transmission are also critical when recommending newer products.[35]

Pediculicide Resistance

No currently available pediculicide is 100% ovicidal, and resistance to lindane, pyrethrins, permethrin, and the UK formulation of malathion has been reported.[38,39,41,80–83] This resistance is not unanticipated, because insects develop resistance to products over time. The actual prevalence of resistance to particular products is not known and can be regional. It is important that health care professionals recommend safe and effective products. When faced with a persistent case of head lice after using a pharmaceutical pediculicide, health care professionals must consider several possible explanations, including:

- misdiagnosis (no active infestation or misidentification);
- lack of adherence (patient unable or unwilling to follow treatment protocol);
- inadequate treatment (not using sufficient product to saturate hair);
- reinfestation (lice reacquired after treatment);
- lack of ovicidal or residual killing properties of the product (eggs not killed can hatch and cause self-reinfestation); and/or
- resistance of lice to the pediculicide.

If resistance is proven, and an active infestation is documented, benzyl alcohol 5% can be prescribed if the patient is older than 6 months, or malathion 0.5% can be prescribed if the patient is older than 24 months if safe use can be reasonably ensured. For younger patients, or if the parent cannot afford or does not wish to use a pediculicide, manual removal via wet combing or an occlusive method may be recommended, with emphasis on careful technique and the use of 2 to 4 properly timed treatment cycles.

ENVIRONMENTAL INTERVENTIONS

If a person is identified with head lice, all household members should be checked for head lice, and those with live lice or nits within 1 cm of the scalp should be treated. In addition, it is prudent to treat family members who share a bed with the person with infestation, even if no live lice are found. Fomite transmission is less likely than transmission by head-to-head contact[9]; however, it is prudent to clean hair care items and bedding used by the individual with infestation. One study revealed that head lice can transfer to pillowcases at night, but the incidence is low (4%). Changing just the pillowcase could minimize this risk of head lice transmission.[21] Only items that have been in contact with the head of the person with infestation in the 24 to 48 hours before treatment should be considered for cleaning, given the fact that louse survival off the scalp beyond 48 hours is extremely unlikely. Such items may include clothing, headgear, furniture, carpeting, and rugs. Washing, soaking, or drying items at temperatures greater than 130°F will kill stray lice or nits. Furniture, carpeting, car seats, and other fabrics or fabric-covered items can be vacuumed. Although head lice are able to survive for prolonged periods in chlorinated water, it is unlikely that there is a significant risk of transmission in swimming pools. One study revealed that submerged head lice became immobile and remained in place on 4 people infested with head lice after 30 minutes of swimming.[84] Pediculicide spray is not necessary and should not be used. Viable nits are unlikely to incubate and hatch at room temperatures; if they did, the nymphs would need to find a source of blood for feeding within hours of hatching. Although it is rarely necessary, items that cannot be washed can be bagged in plastic for 2 weeks, a time when any nits that may have survived would have hatched and nymphs would die without a source for feeding. Herculean cleaning measures are not beneficial.

CONTROL MEASURES IN SCHOOLS

Screening

Screening for nits alone is not an accurate way of predicting which children are or will become infested, and screening for live lice has not been proven to have a significant effect on the incidence of head lice in a school community over time.[2,12,24] In addition, such screening has not been shown to be cost-effective. In a prospective study of 1729 schoolchildren screened for head lice, only 31% of the 91 children with nits had concomitant live lice. Only 18% of those with nits alone converted to having an active infestation during 14 days of observation.[85]

Although children with at least 5 nits within 1 cm of the scalp were significantly more likely to develop an infestation than were those with fewer nits (32% vs 7%), only one-third of the children at higher risk converted to having an active infestation. School exclusion of children with nits alone would have resulted in many of these children missing school unnecessarily. In addition, head lice infestations have been shown to have low contagion in classrooms.[86] Using anecdotal information that described the implementation of a "zero-tolerance" program at an elementary school, 1 source reported an average of 20 missed days per student dismissed for infestation.[5] Another study evaluated how often schoolchildren were inappropriately diagnosed and treated. Children without infestation received applications of pyrethroid-based OTC products almost as often as children with active infestations (62% vs 70%). Noninfested children were excluded from school because of presumed lice infestation more frequently than were children who were infested.[7] The results of several descriptive studies have suggested that education of parents in diagnosing and managing head lice may be helpful.[86–89] Because of the lack of evidence of efficacy, routine classroom or school-wide screening should be discouraged.

It may be useful to provide information periodically about the diagnosis, treatment, and prevention of head lice to the families of all children. Parents should be encouraged to check their children's heads for lice regularly and if the child is symptomatic. School screenings do not take the place of these more careful parental checks.[18,89–91] It may be helpful for the school nurse or other trained person to check a student's head if he or she is demonstrating symptoms.

Management on the Day of Diagnosis

Because a child with an active head lice infestation likely has had the infestation for 1 month or more by the time it is discovered and poses little risk to others from the infestation, he or she should remain in class but be discouraged from close direct head contact with others. If a child is diagnosed with head lice, confidentiality must be maintained. The child's parent or guardian should be notified that day by telephone or by having a note sent home with the child at the end of the school day stating that prompt, proper treatment of this condition is in the best interest of the child and his or her classmates. Common sense should prevail when deciding how "contagious" an individual child may be (a child with hundreds versus a child with 2 live lice). It may be prudent to check other children who were most likely to have had direct head-to-head contact with the infested child. In an elementary school, 1 way to deal with the problem is to notify the parents or guardians of children in an infested child's classroom, encouraging all children to be checked at home and treated, if appropriate, before returning to school the next day. Some experts argue that because of the relatively high prevalence of head lice in young school-aged children, it may make more sense to alert parents only if a high percentage of children in a classroom are infested. Other experts feel strongly that these "alert letters" cause unnecessary public alarm and reinforce the notion that a head lice infestation indicates a failure on the school's part rather than a community problem.[92] However, studies examining the efficacy of alert letters are not available; consequently, some schools choose to design guidelines that they believe best meet the needs of their student population, understanding that although a head lice infestation may not pose a public health risk, it may create a public relations dilemma for a school.

Criteria for Return to School

A child should not be restricted from school attendance because of lice, because head lice have low contagion within classrooms.[86] Some schools have had "no-nit" policies under which a child was not allowed to return to school until all nits were removed. However, most researchers agree that no-nit policies should be abandoned.[93] International guidelines established in 2007 for the effective control of head lice infestations stated that no-nit policies are unjust and should be discontinued, because they are based on misinformation rather than objective science.[94] The American Academy of Pediatrics and the National Association of School Nurses[95] discourage no-nit policies. However, nit removal may be considered for the following reasons:

- nit removal can decrease diagnostic confusion;
- nit removal can decrease the possibility of unnecessary re-treatment; and
- some experts recommend removal of nits within 1 cm of the scalp to decrease the small risk of self-reinfestation.

A knowledgeable school nurse, if present, can perform a valuable service by rechecking a child's head if requested to do so by a parent. In addition, the school nurse can offer extra help to families of children who are repeatedly or chronically infested. In rare instances, it may be helpful to make home visits or involve public health nurses to ensure that treatment is being conducted effectively. No child should be allowed to miss valuable school time because of head lice. Numerous anecdotal reports exist of children missing weeks of school and even being forced to repeat a grade because of head lice.[2,7,9,91]

Reassurance of Parents, Teachers, and Classmates

The school can be most helpful by making available accurate information about the diagnosis, treatment, and prevention of head lice in an understandable form to the entire school community. Information sheets in different languages and visual aids for families with limited literacy skills should be made available by schools and/or local health departments. If pediatricians and schools take the lead and react calmly, parents will be able to focus on appropriate treatment without becoming unduly upset.

Child Care and "Sleepover" Camps

Little information is available on the incidence and control of head lice outside of the school-aged population and outside of school. Because head lice are most readily transmitted by direct head-to-head contact, child care centers and camps where children share sleeping quarters may allow for easier spread. Reminding parents of the importance of carefully checking a child's head before and after a sleepover experience may be helpful.

SUMMARY OF KEY POINTS

1. No healthy child should be excluded from or allowed to miss school time because of head lice. No-nit policies for return to school should be abandoned.
2. Pediatricians should be knowledgeable about head lice infestations and treatments; they should take an active role as information resources for families, schools, and other community agencies.
3. Unless resistance to these products has been proven in the community, 1% permethrin or pyrethrins can be used for treatment of active infestations.
4. Instructions on the proper use of products should be carefully communicated. Because current products are not completely ovicidal, applying the product at least twice, at proper intervals, is recommended if permethrin or pyrethrin products are used or if live lice are seen after malathion therapy. Manual removal of nits immediately after treatment with a pediculicide is not necessary to prevent spread. In the school setting, nit removal may be considered to decrease diagnostic confusion.
5. If resistance to available OTC products has been proven in the community, if the patient is too young, or if parents do not wish to use a pediculicide, consider recommending "wet-combing" or an occlusive method (such as petroleum jelly or Cetaphil), with emphasis on careful technique, and repeating for at least 2 weekly cycles.
6. Benzyl alcohol 5% can be used for children older than 6 months, or malathion 0.5% can be used for children 2 years old or older, in areas where resistance to permethrin or pyrethrins has been demonstrated or for a patient with a documented infestation that has failed to respond to appropriately administered therapy with permethrin or pyrethrins.
7. New products should be evaluated for safety and effectiveness.
8. School personnel involved in detection of head lice infestation should be appropriately trained. The importance and difficulty of correctly diagnosing an active head lice infestation should be emphasized. Schools should examine any lice-related policies they have with this in mind.
9. Head lice screening programs have not been proven to have a significant effect over time on the incidence of head lice in the school setting and are not cost-effective. Parent education programs may be helpful in the management of head lice in the school setting.

AMERICAN ACADEMY OF PEDIATRICS

Committee on Genetics

Health Care Supervision for Children With Williams Syndrome

ABSTRACT. This set of guidelines is designed to assist the pediatrician to care for children with Williams syndrome diagnosed by clinical features and with regional chromosomal microdeletion confirmed by fluorescence in situ hybridization.

ABBREVIATIONS. WS, Williams syndrome; FISH, fluorescence in situ hybridization.

INTRODUCTION

Williams syndrome (WS, also Williams-Beuren syndrome), now recognized to be caused by a microdeletion of chromosome 7, is a multisystem disorder first identified as a distinct clinical entity in 1961.[1] It is present at birth and affects boys and girls equally. As routine genetic amniocentesis does not typically detect chromosome microdeletions, children with WS usually come to the attention of pediatricians during infancy or childhood. Initially thought to be a rare genetic disorder, increased awareness of the clinical features and establishment of a reliable diagnostic test have revealed WS to be one of the more commonly recognized genetic disorders in childhood. Williams syndrome is characterized by dysmorphic facies (100%), cardiovascular disease (most commonly supravalvar aortic stenosis [80%]), mental retardation (75%), a characteristic cognitive profile (90%), and idiopathic hypercalcemia (15%)[2–5] (Table 1).

The diagnosis historically has been made on the basis of clinical criteria (Fig 1), but recently it has been shown that 99% of patients with WS have a hemizygous submicroscopic deletion of 7q11.23 detectable by fluorescence in situ hybridization (FISH).[6–8] Chromosome analysis and the Williams Syndrome Chromosomal Region FISH test are recommended for confirmation of the diagnosis. (A child with the clinical features of WS and a negative FISH result should be referred to a clinical geneticist for further evaluation.) The deleted portion of the chromosome includes the *ELN* gene that codes for the structural protein elastin, an important component of the elastic fibers found in the connective tissue of many organs. The *elastin* deletion explains some of the characteristics of WS, such as some of the facial features, hoarse voice, bladder and bowel diverticula, cardiovascular disease, and orthopedic problems. The pathogenesis of other characteristics, such as hypercalcemia, mental retardation, and unique personality traits, remains unexplained. One possibility is that the loss of 1 or more genes contiguous to the *ELN* gene contributes to the phenotype.

The pediatrician can use knowledge of the clinical manifestations (Table 1) and natural history of WS to anticipate medical problems and to educate the family. Most children with WS are described as having similar facial features.[4,9] Although these features are often subtle, they tend to become more distinctive with advancing age. Facial features often include periorbital fullness, short nose with bulbous nasal tip, long philtrum, wide mouth, full lips, and mild micrognathia. Infants have full cheeks and a flat facial profile, whereas older children and adults often have a long narrow face and a long neck.[10,11] Blue- and green-eyed children with WS have a prominent "starburst" pattern to their irides (stellate iris).[12] Mild prenatal growth deficiency and a postnatal growth rate about 75% of normal are consistently observed features of the condition.[8,13]

The majority of children with WS have cardiovascular anomalies.[1,2,4] The most common cardiovascular defect is supravalvar aortic stenosis, an often progressive condition that may require surgical repair.[10,11] Peripheral pulmonary artery stenosis is often present in infancy and usually improves over time. Coarctation of the aorta, renal artery stenosis, and systemic hypertension are complications that when present may worsen over time.[4,11,14,15] Because the elastin protein is an important component of elastic fibers in the arterial wall, any artery may become narrowed.

Idiopathic infantile hypercalcemia is an intriguing feature of WS that can contribute to the presence of extreme irritability, vomiting, constipation, and muscle cramps associated with this condition.[4,9] Symptomatic hypercalcemia usually resolves during childhood, but lifelong abnormalities of calcium and vitamin D metabolism may persist. Hypercalciuria is common and predisposes to nephrocalcinosis. The cause of the abnormality in calcium metabolism is unknown.

An infant with WS often has difficulty feeding and may be brought for medical care because of gastroesophageal reflux, colic, or failure to thrive.[4,9,16] Other medical problems include Chiari I malformation, strabismus,[12] hyperopia,[12] chronic otitis media, hypodontia, malocclusion, bowel or bladder diverticula, hernias, joint laxity, joint contractures,[17] kyphosis, lordosis, renal or urinary tract malformations,[14,15] hypothyroidism, and rectal prolapse.

Children with WS have a unique cognitive and

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

PEDIATRICS (ISSN 0031 4005).

TABLE 1. Medical Problems in Williams Syndrome* by Organ System and Age

Organ System	Incidence (%)	Age		
		Infancy	Childhood	Adult
Ocular and visual				
Esotropia	50	x		
Hyperopia	50		x	x
Auditory				
Chronic otitis media	50	x	x

Chiari I malformation	10	x	x	x
Hypotonia (central)	80	x	x	
Hypertonia (peripheral)	50		x	x
Cognitive				
Developmental delay	95	x	x	
Mental retardation	75		x	x
Borderline intellectual functioning	20		x	x
Normal intelligence	5		x	x
Impaired visuospatial constructive cognition	95		x	x
Behavioral				
Attention-deficit hyperactivity disorder	70		x	
Generalized anxiety disorder	80		x	x

* Percentages based on the following: 1) review of rates of complications in several reports of series of patients with Williams syndrome, and 2) database of 315 children and adults with Williams syndrome evaluated by Colleen A. Morris, MD. SVAS indicates supravalvar aortic stenosis; SVPS, supravalvular pulmonic stenosis, PPS, peripheral pulmonary artery stenosis; and VSD, ventricular septal defect.

behavioral profile.[3,5,18] Cognitive, motor, and language delay are universal, and in 75% of the children, mental retardation is ultimately diagnosed.[19,20] Older children demonstrate a relative strength in language and auditory memory, with a significant weakness in visuospatial cognition.[5,18] Behavioral problems may include hypersensitivity to sound, sleep problems, attention-deficit/hyperactivity disorder,[20] and anxiety. Overfriendliness and an empathetic nature are commonly observed.[17]

Scored Points*

Growth (Past or Present Evidence of) ***If 3 of 5 items are checked, score 1 point*** _____

[ ] Post-term birth > 41 wk gestation
[ ] Prolonged colic > 4 m irritability
[ ] Failure to thrive/height and weight < 5th percentile
[ ] Chronic constipation
[ ] Vomiting or gastroesophageal reflux

Behavior and Development ***If 3 of 6 items are checked, score 1 point*** _____

[ ] Overly friendly personality
[ ] Visuospatial problems
[ ] Hypersensitivity to sound
[ ] Delayed speech acquisition, followed by excessive talking
[ ] Anxiety
[ ] Developmental delay or mental retardation

Facial Features ***If 8 of 17 items are checked, score 3 points*** _____

[ ] Bitemporal narrowing
[ ] Broad brow
[ ] Epicanthal folds or flat nasal bridge
[ ] Periorbital fullness
[ ] Strabismus (present or past)
[ ] Stellate lacy iris pattern
[ ] Short nose or anteversion of nares
[ ] Bulbous or full nasal tip
[ ] Full cheeks
[ ] Malar hypoplasia (flat cheek bones)
[ ] Long philtrum
[ ] Full prominent lips
[ ] Small, widely spaced teeth
[ ] Malocclusion
[ ] Wide mouth
[ ] Small jaw
[ ] Prominent ear lobes

Cardiovascular Problems (by Echocardiography) (a) ***If 1 of 2 items are checked, score 5 points*** _____

[ ] SVAS†
[ ] Peripheral pulmonary artery stenosis

Cardiovascular Problems (b) ***If 1 of 3 items are checked, score 1 point*** _____

[ ] Other congenital heart disease
[ ] Hypertension
[ ] Cardiac murmur

Connective Tissue Abnormality ***If 2 of 6 items are checked, score 2 points*** _____

[ ] Hoarse voice
[ ] Long neck or sloped shoulders
[ ] Inguinal hernia
[ ] Joint limitation or laxity
[ ] Bowel or bladder diverticula
[ ] Rectal prolapse

Calcium Studies ***If 1 of 2 items are checked, score 2 points*** _____

[ ] Hypercalcemia
[ ] Hypercalciuria

Total Points: _____

* If the score is < 3, a diagnosis of Williams syndrome is unlikely. If the score is ≥ 3, FISH studies should be considered. (Mean score for Williams syndrome was 9 [standard deviation = 2.86]. The scoring system is based on a study of 107 persons with Williams syndrome [confirmed by FISH] evaluated by Colleen A. Morris, MD; Frank Greenberg, MD; Paige Kaplan, MD; Martin Levinson, MD; and Barbara Pober, MD; with data analysis by Carolyn B. Mervis, PhD and Byron F. Robinson, MA; presented at the 1994 Williams Syndrome Association Convention; July 31, 1994; San Diego, CA.)

† If supravalvar aortic stenosis (SVAS) is present, referral to a geneticist and FISH studies are recommended.

Fig 1. Williams syndrome diagnostic scoring table: clinical diagnosis.

The medical care of children with WS requires an understanding of the natural history of the disorder, awareness of potential clinical complications, and ongoing assessment and periodic review at appropriate ages (Fig 2). Because the clinical manifestations during the neonatal period are variable, the diagnosis may not be suspected during early infancy. Accordingly, this statement includes a series of evaluations that should be considered at the time the diagnosis is suspected clinically; the diagnosis

Fig 2. Health supervision for children with Williams syndrome*.

should be confirmed by FISH analysis. The evaluations include the following:

- Complete physical and neurologic examination
- Growth parameters plotted on WS growth charts (Fig 3A–F)
- Cardiology evaluation
  –Full clinical evaluation by a cardiologist with expertise and experience in pediatric patients that includes 4-limb blood pressure measurements and echocardiography
- Genitourinary system evaluation
  –Ultrasonography of bladder and kidneys
  –Renal function studies (serum urea nitrogen and creatinine levels)
  –Urinalysis
- Calcium determinations (serum calcium, spot urine calcium, and creatinine levels) (Table 2)
- Thyroid function tests
- Ophthalmologic evaluation
- Multidisciplinary developmental evaluation (older than 2 years)
- FISH to determine ELN deletion

Referral to a clinical geneticist should be considered for individualized assessment and recommendations; a more extensive discussion of the clinical manifestations, natural history, recurrence risks, and future reproductive options; and evaluation of genetic risks for other family members.

SPECIAL CONSIDERATIONS FOR THE CHILD DIAGNOSED WITH WS

1. Do *not* give multivitamin preparations to children with WS because of the potential deleterious effects of vitamin D. Recommend diligent use of sunscreen to minimize autologous production of vitamin D.
2. Perform periodic cardiovascular evaluations, even after a baseline examination with normal findings.
3. Baseline cardiology evaluation should be performed by a cardiologist with pediatric expertise and experience.
4. Screen for the development of hypertension periodically according to guidelines of the American Academy of Pediatrics.
5. Establish a medical home with clear emphasis on continuity of care and the role of the family members as partners in the ongoing management and care of the child.

HEALTH SUPERVISION FROM BIRTH TO 1 YEAR (INFANCY)

Examination

1. Review and note clinical features and confirm diagnosis with FISH analysis
2. Routine health maintenance examinations and baseline evaluation
3. Growth and developmental evaluations using WS growth charts (Fig 3A–F)
4. Baseline cardiology evaluation by a cardiologist with pediatric expertise and experience
5. Review feeding issues (reflux, refusal, disordered suck or swallow, vomiting or symptoms of colic).
6. Consider pediatric ophthalmologic evaluation for strabismus, amblyopia, and refractive errors
7. Check for inguinal hernia
8. Objective hearing assessment at 6 to 12 months (recurrent otitis media is common)
9. Blood pressure measurement (both arms) annually and careful evaluation of femoral pulses
10. Early recognition and management of constipation
11. Pediatric anesthesia consultation for any child requiring surgery (several reports of unexpected deaths have been associated with the administration of anesthesia)[22]

Laboratory

1. Williams Syndrome Chromosomal Region FISH to confirm clinical diagnosis
2. Serum creatinine level
3. Urinalysis
4. Calcium levels
   a. Serum*
   b. Spot urine test to determine calcium-creatinine ratio†
5. Thyroid screen for newborns (according to state mandate)
6. Baseline ultrasonographic examination of the bladder and kidneys

Anticipatory Guidance

1. Individual support for the family (by family, friends, clergy), support groups, or both (see list)
2. Review increased risk for otitis media
3. Feeding (difficulty in transition to textured foods)
4. Do *not* prescribe multivitamin preparations containing vitamin D
5. Refer to early childhood intervention program

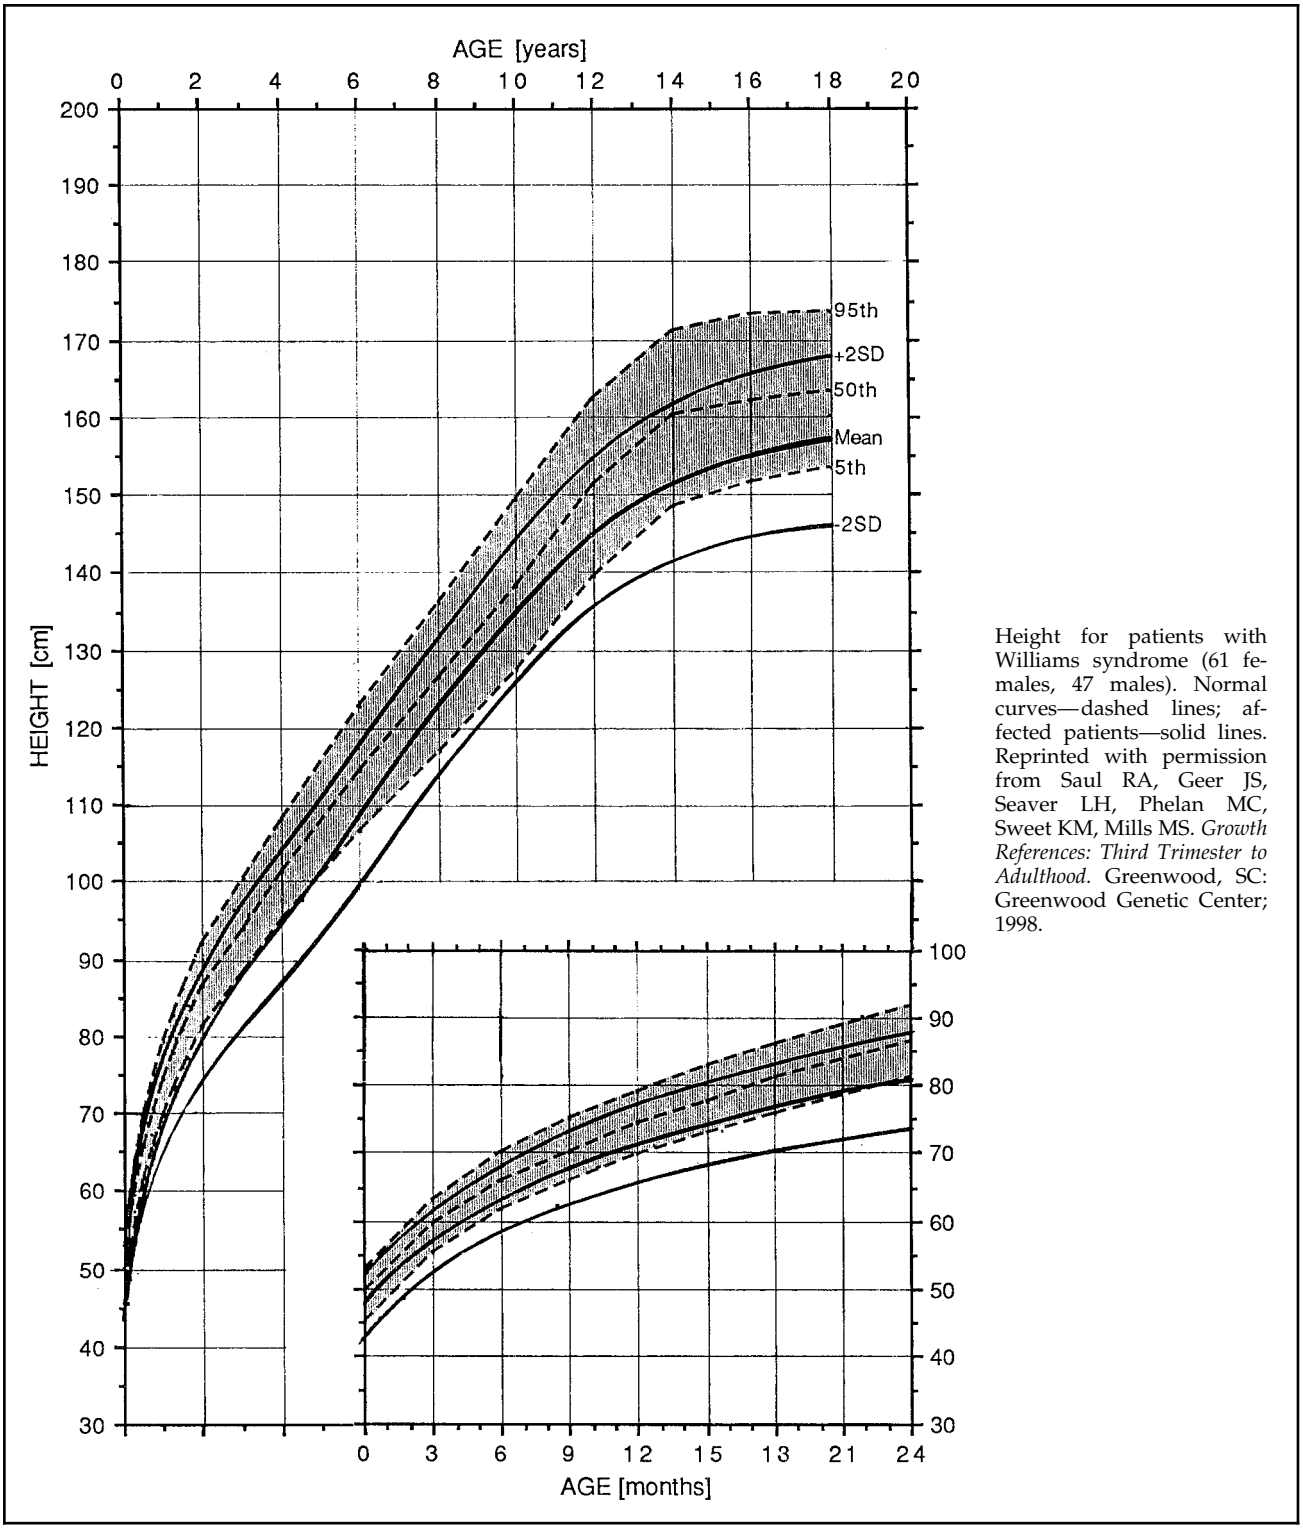
HEALTH SUPERVISION FROM 1 TO 5 YEARS (EARLY CHILDHOOD)

Examination

1. Annual health maintenance examinations and baseline evaluation (including careful auscultation of chest and abdomen for murmurs or bruits)
2. Developmental evaluation and growth evaluation using WS growth charts (Fig 3A–F)
3. Annual cardiology evaluation from 1 to 5 years
4. Feeding issues: watch for rectal prolapse and avoid constipation with stool softeners if necessary
5. Annual hearing and vision screening; objective audiologic evaluation and an ophthalmologic evaluation before age 3 years
6. Orthopedic issues: musculoskeletal and neurologic assessments to evaluate joints, muscle tone, spasticity, and hyperactive reflexes[17]

*If hypercalcemia is found, dietary calcium restriction should be implemented and diet should be monitored in conjunction with a pediatric dietician/nutritionist. Referral to a pediatric renal specialist should be considered.

†If hypercalciuria is found, 2 repeated urine studies of the calcium-creatinine ratio (morning and afternoon) should be performed. If the level is still elevated, repeat measurement of the serum calcium level and perform renal ultrasonography for nephrocalcinosis. Assess dietary calcium intake.[21]



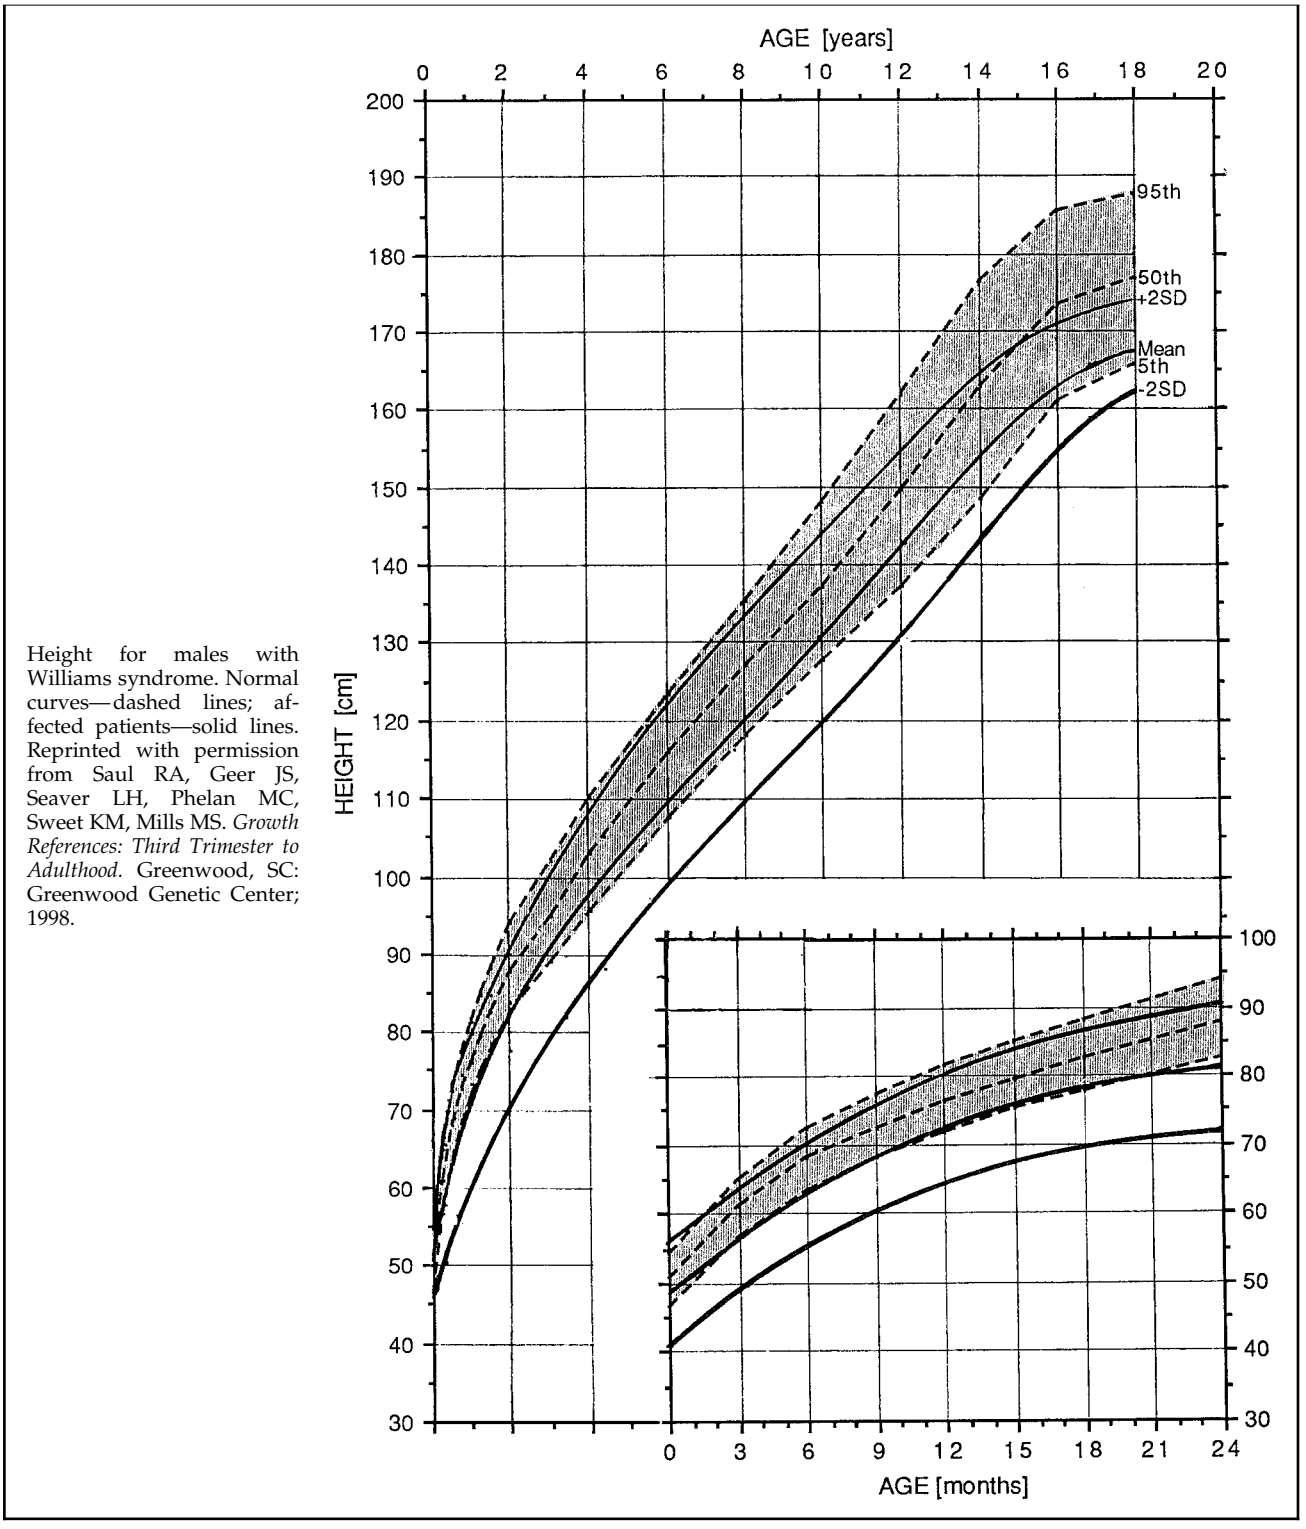
Height for patients with Williams syndrome (61 females, 47 males). Normal curves—dashed lines; affected patients—solid lines. Reprinted with permission from Saul RA, Geer JS, Seaver LH, Phelan MC, Sweet KM, Mills MS. *Growth References: Third Trimester to Adulthood*. Greenwood, SC: Greenwood Genetic Center; 1998.

Fig 3A. Williams syndrome—stature, females.

7. Pediatric anesthesia consultation for any child requiring surgery (several reports of unexpected deaths have been associated with the administration of anesthesia)[22]
8. Annual blood pressure measurement (both arms) and careful examination of femoral pulses
9. Multidisciplinary developmental assessment and treatment in early intervention programs (0–3 years) or school based programs (3 years and older)[1,5,19]
10. Dental referral

Laboratory

1. Yearly urinalysis
2. Annual total calcium measurement if the level was elevated at baseline or as needed if the child becomes symptomatic; if level was normal, measure every 2 to 3 years
3. Urinary calcium-creatinine ratio every 2 years
4. Thyroid function test every 4 years



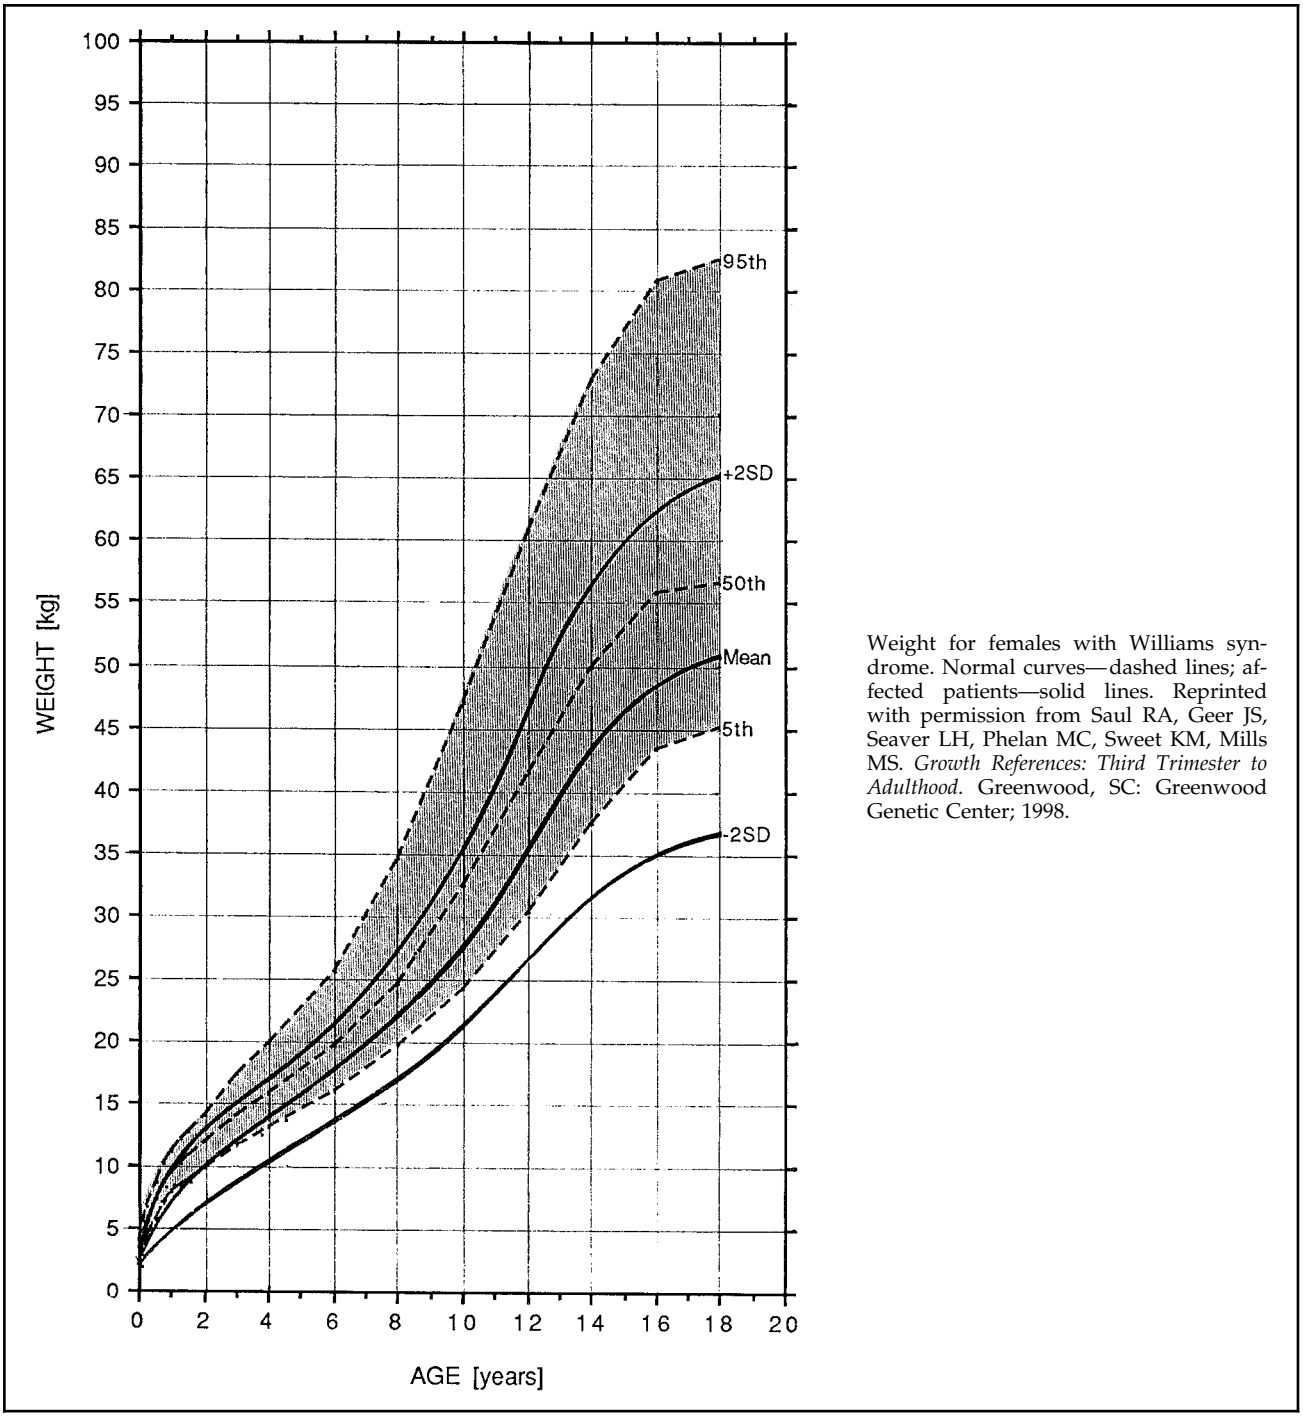
Height for males with Williams syndrome. Normal curves—dashed lines; affected patients—solid lines. Reprinted with permission from Saul RA, Geer JS, Seaver LH, Phelan MC, Sweet KM, Mills MS. *Growth References: Third Trimester to Adulthood.* Greenwood, SC: Greenwood Genetic Center; 1998.

Fig 3B. Williams syndrome—stature, males.

5. Serum creatinine level every 4 years

Anticipatory Guidance

1. Individual support for the family (by family, friends, clergy), support groups, or both
2. Review increased risk for otitis media
3. Ongoing feeding and dietary assessments
4. Therapy as needed (physical, speech and language, and occupational, including sensory integration)
5. Review constipation as a possible problem
6. Children with unexplained fever should be evaluated for urinary tract infection
7. Discuss developmental status, early intervention programs, and preschool programs



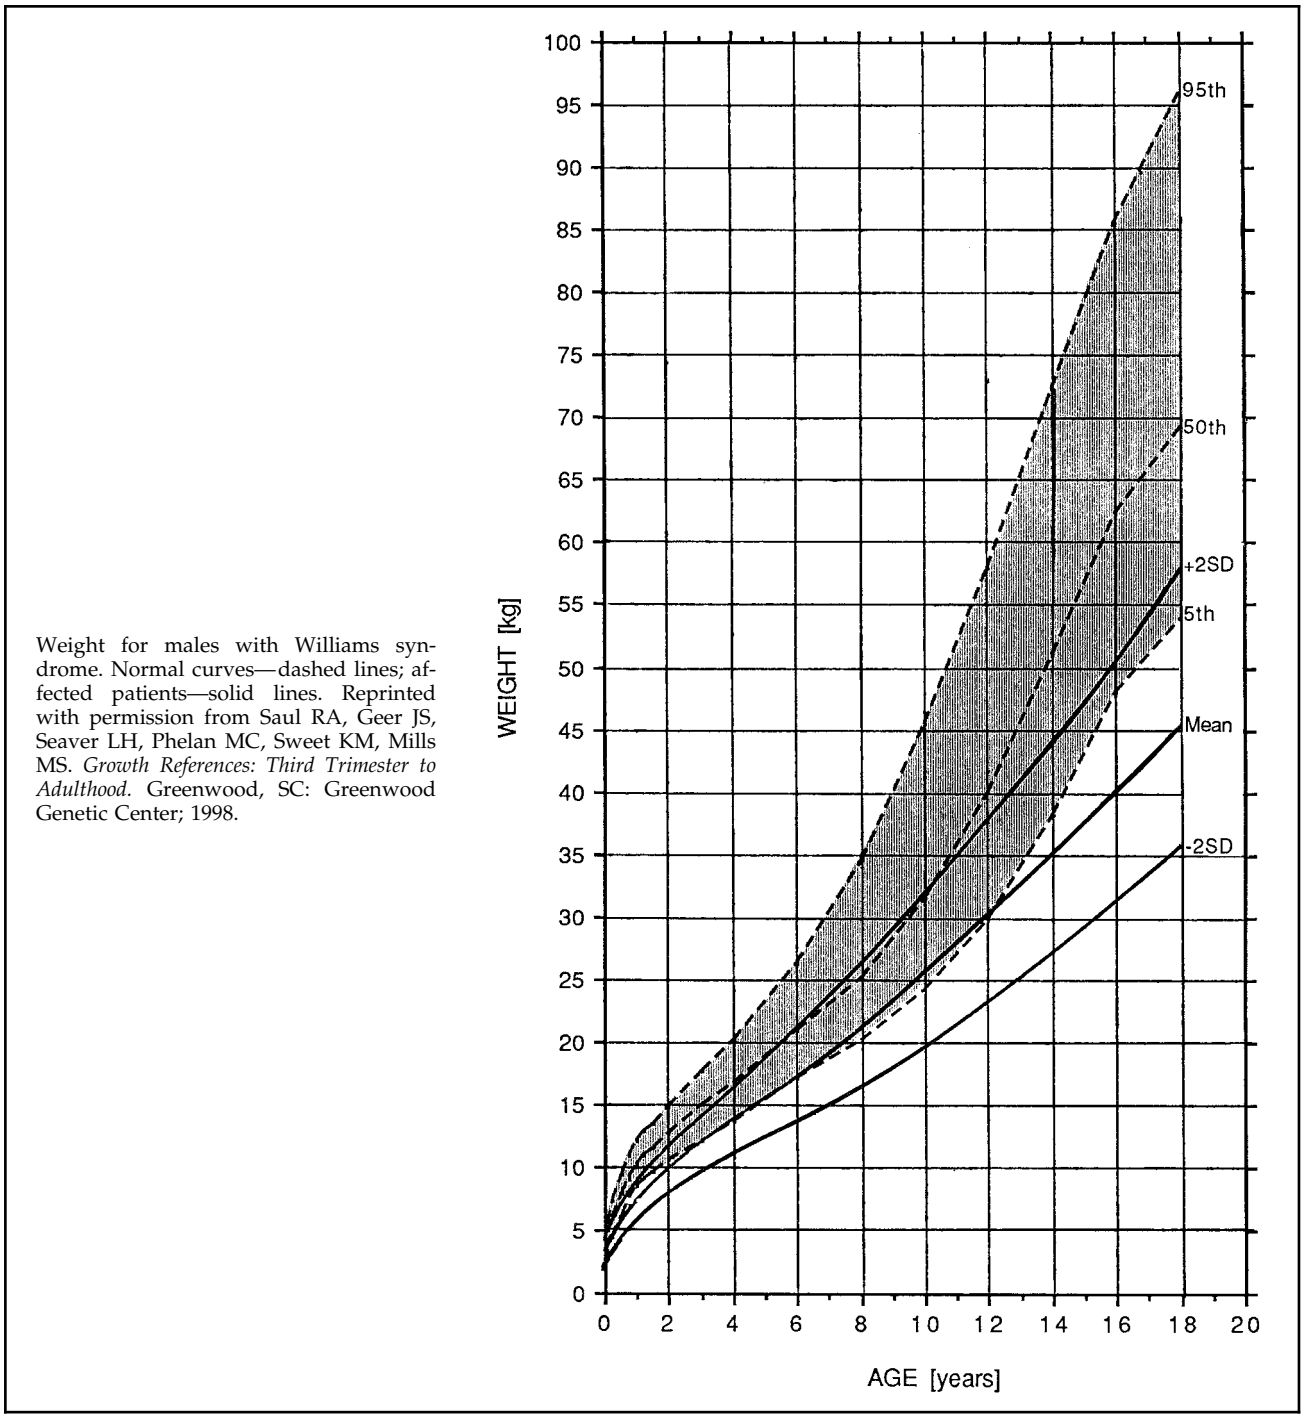
Weight for females with Williams syndrome. Normal curves—dashed lines; affected patients—solid lines. Reprinted with permission from Saul RA, Geer JS, Seaver LH, Phelan MC, Sweet KM, Mills MS. *Growth References: Third Trimester to Adulthood*. Greenwood, SC: Greenwood Genetic Center; 1998.

Fig 3C. Williams syndrome—weight, females.

HEALTH SUPERVISION FROM 5 YEARS TO 12 YEARS (LATE CHILDHOOD)

Examination

1. Annual health maintenance examinations and baseline evaluation
2. Developmental evaluation and growth evaluation using WS growth charts (Fig 3A–F)
3. Annual blood pressure measurements (both arms) and careful evaluation of femoral pulses
4. Cardiology evaluation as indicated by previous clinical findings. If results of previous evaluations are negative, repeated cardiology evaluation (for arterial stenoses, hypertension) should be performed at puberty
5. Ophthalmologic evaluation for strabismus and hyperopia
6. Orthopedic problems (eg, joint limitation, kyphosis, lordosis, scoliosis, and spasticity)



Weight for males with Williams syndrome. Normal curves—dashed lines; affected patients—solid lines. Reprinted with permission from Saul RA, Geer JS, Seaver LH, Phelan MC, Sweet KM, Mills MS. *Growth References: Third Trimester to Adulthood.* Greenwood, SC: Greenwood Genetic Center; 1998.

Fig 3D. Williams syndrome—weight, males.

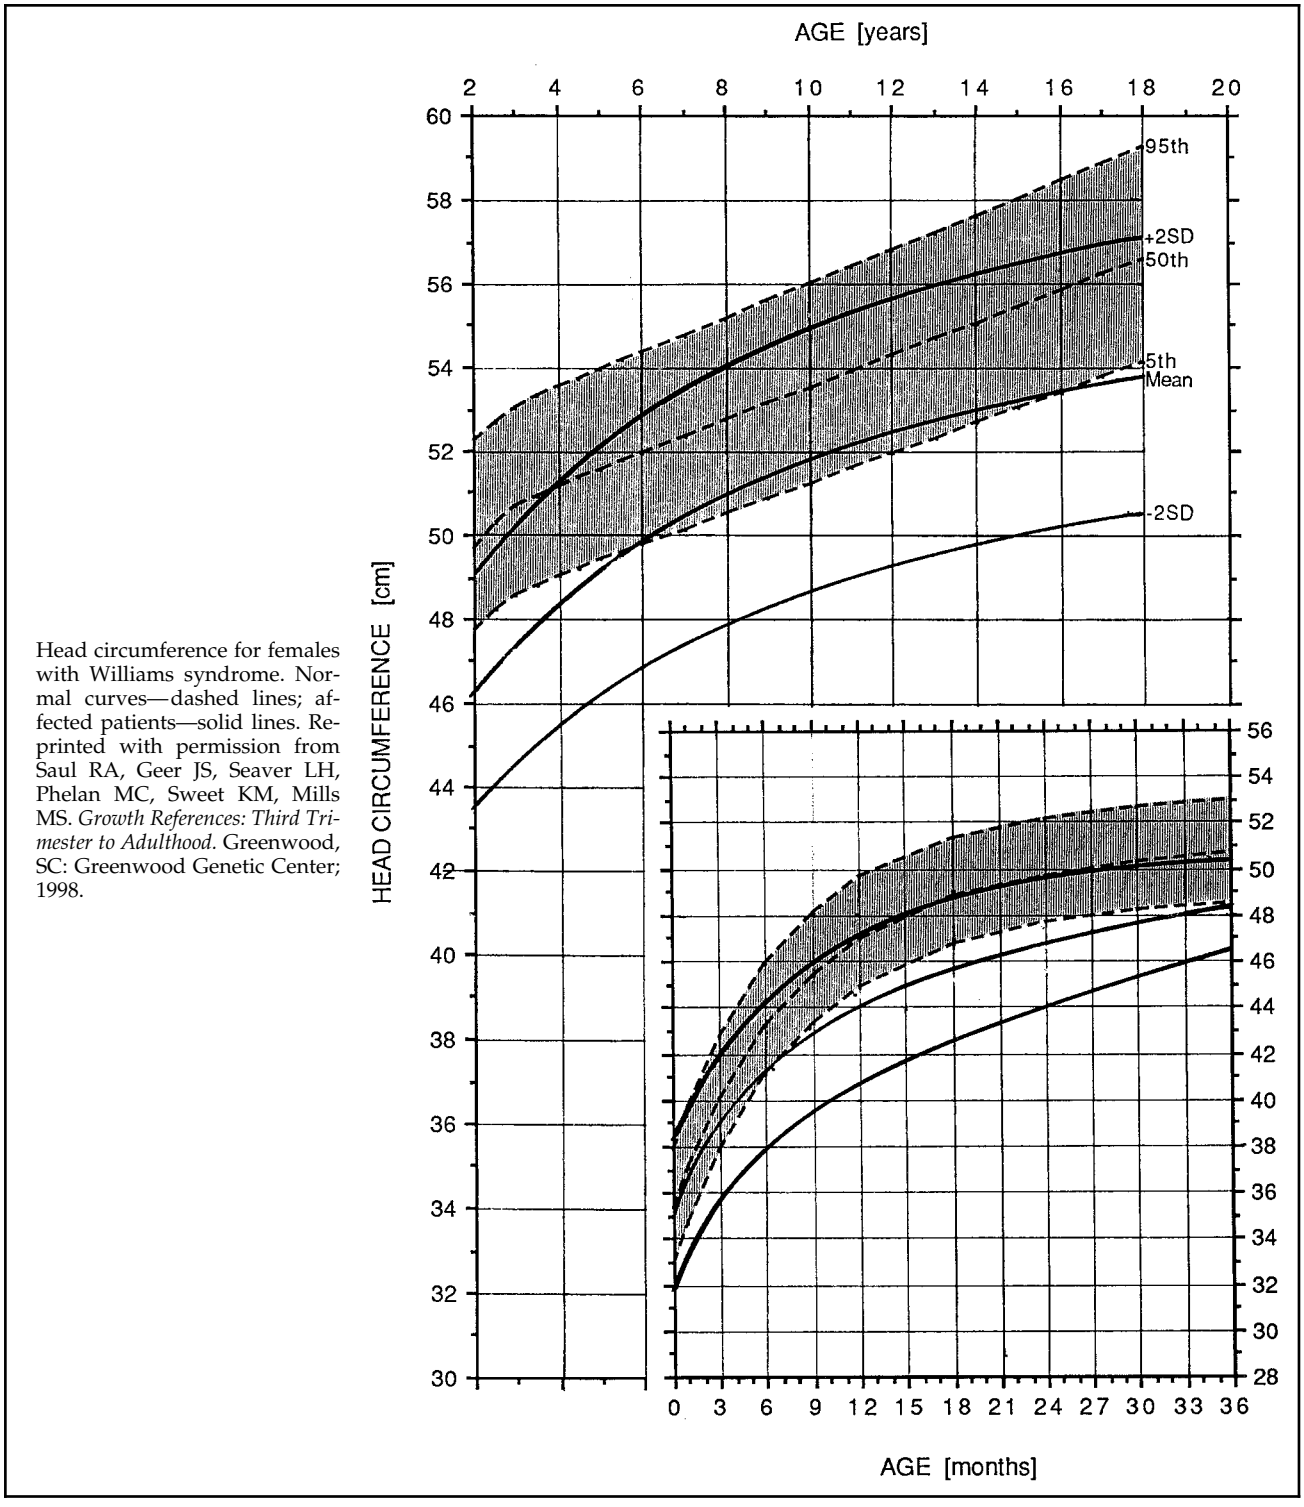
7. Hearing and vision screening annually
8. Pediatric anesthesia consultation for any child requiring surgery (several reports of unexpected deaths have been associated with the administration of anesthesia[22])
9. School readiness and placement and Individual Educational Plan at 5 years
10. Developmental and psychoeducational assessment; formal evaluation for attention-deficit hyperactivity disorder, anxiety, or both and discussion of treatment options[23]

Laboratory

1. Yearly urinalysis
2. Thyroid function tests every 4 years
3. Annual total calcium level if baseline result was elevated or child becomes symptomatic; otherwise measure level every 4 years
4. Urinary calcium-creatinine ratio every 2 years
5. Serum creatinine level every 2 to 4 years

Anticipatory Guidance

1. School readiness and placement



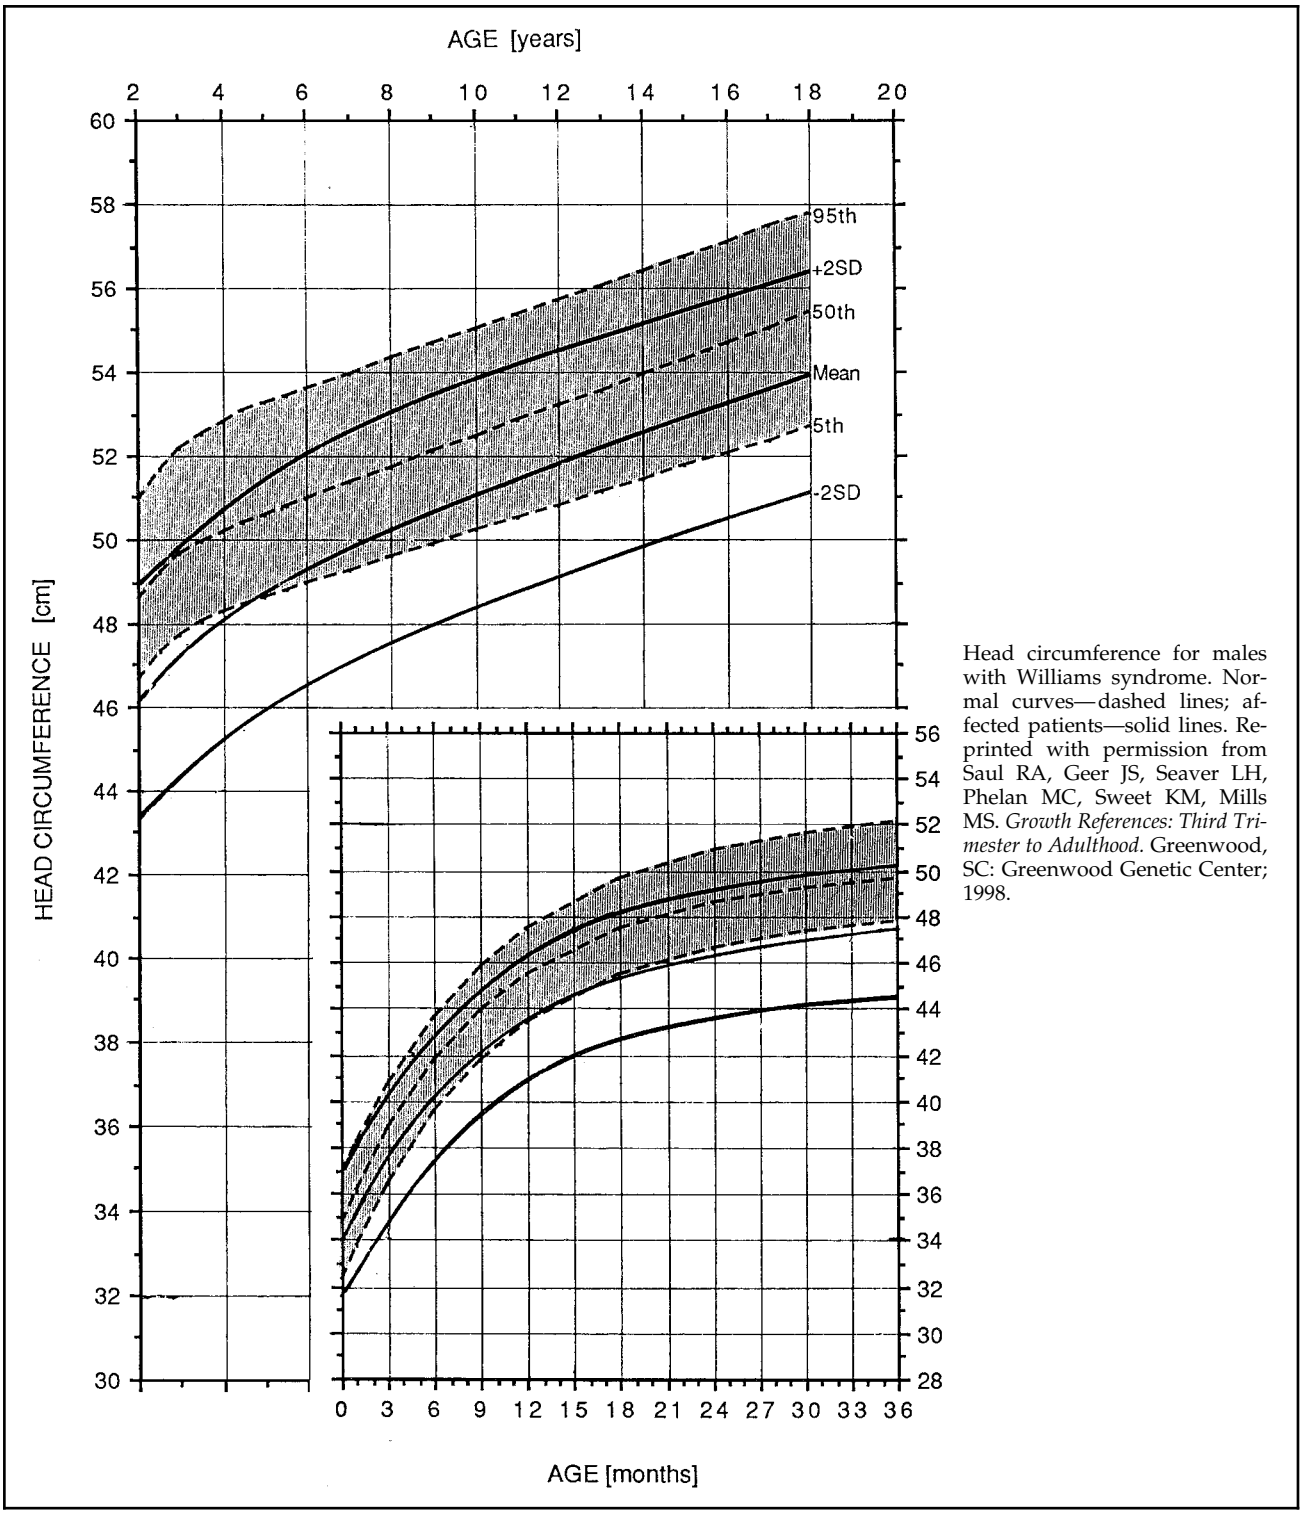
Head circumference for females with Williams syndrome. Normal curves—dashed lines; affected patients—solid lines. Reprinted with permission from Saul RA, Geer JS, Seaver LH, Phelan MC, Sweet KM, Mills MS. *Growth References: Third Trimester to Adulthood.* Greenwood, SC: Greenwood Genetic Center; 1998.

Fig 3E. Williams syndrome—head circumference, females.

2. Therapy as needed (physical, speech and language, and occupational, including sensory integration)
3. Long-term vocational planning
4. Discuss sexuality and adolescence; puberty is often early in WS, but true precocious puberty is rare
5. Discuss diet and exercise as obesity may become apparent in late childhood
6. Discuss treatment options for anxiety (counseling, relaxation techniques, and medications)
7. Estate planning for parents of a child with special needs

HEALTH SUPERVISION FROM 13 YEARS TO 18 YEARS (ADOLESCENCE)

Progressive medical problems including hypertension, progressive joint limitations, recurrent urinary



Head circumference for males with Williams syndrome. Normal curves—dashed lines; affected patients—solid lines. Fig 3F. Williams syndrome—head circumference, males.

tract infections, and gastrointestinal problems are common beginning in this age group and continuing throughout adult life.

Examination

1. Annual health maintenance examinations and baseline evaluation; blood pressure measurement (both arms)
2. Developmental evaluation and growth evaluation using WS growth charts (Fig 3A–F)
3. Cardiology evaluation if indicated by previous clinical findings
4. Pediatric anesthesia consultation for any child requiring surgery (several reports of unexpected deaths have been associated with the administration of anesthesia[22])
5. Consider ophthalmologic evaluation for hyperopia
6. Orthopedic problems (eg, joint limitation, kyphosis, lordosis, scoliosis, and spasticity)

TABLE 2. Normal Values for Random Urinary Calcium-Creatinine Ratios[21]

Age	Calcium-Creatinine Ratio (mg/mg ratio) (95th Percentile for Age)
<7 mo	0.86
7–18 mo	0.6
19 mo–6 y	0.42
Adults	0.22

7. Hearing and vision screening annually
8. Developmental and psychoeducational assessment; school placement and resource enhancement; vocational training; social skills training for peer interaction[10,11]
9. Gastrointestinal issues: consider diverticulitis and diverticulosis, cholelithiasis, and chronic constipation in adolescents with abdominal pain
10. Screen for generalized anxiety disorder[19]

Laboratory

1. Yearly urinalysis
2. Thyroid function test every 4 years
3. Total calcium level only if adolescent becomes symptomatic, otherwise, every 4 years
4. Urinary calcium-creatinine ratio every 2 years
5. Bladder and renal ultrasonography at puberty and every 5 years thereafter
6. Serum creatinine level every 2 to 4 years

Anticipatory Guidance

1. School placement
2. Therapy as needed (physical, occupational, speech, and language)
3. Discuss diagnosis with the adolescent; support groups for the adolescent (see American Academy of Pediatrics statement on "Transition of Care Provided for Adolescents With Special Needs")[24]
4. Discuss sexuality and reproductive issues
5. Encourage career counseling
6. Foster independence
7. Assist in transition to adult care (especially for cardiology care). Many pediatricians feel comfortable continuing to provide primary care well into young adulthood
8. Encourage daily exercise to include range of motion
9. Encourage prompt medical attention for urinary tract or gastrointestinal symptoms
10. Mental health issues

abstract

FREE

Youth in the juvenile correctional system are a high-risk population who, in many cases, have unmet physical, developmental, and mental health needs. Multiple studies have found that some of these health issues occur at higher rates than in the general adolescent population. Although some youth in the juvenile justice system have interfaced with health care providers in their community on a regular basis, others have had inconsistent or nonexistent care. The health needs of these youth are commonly identified when they are admitted to a juvenile custodial facility. Pediatricians and other health care providers play an important role in the care of these youth, and continuity between the community and the correctional facility is crucial. This policy statement provides an overview of the health needs of youth in the juvenile correctional system, including existing resources and standards for care, financing of health care within correctional facilities, and evidence-based interventions. Recommendations are provided for the provision of health care services to youth in the juvenile correctional system as well as specific areas for advocacy efforts. *Pediatrics* 2011; 128:1219–1235

INTRODUCTION

Youth in the juvenile correctional system are a high-risk population[1–3] who, in many cases, have unmet physical, developmental, and mental health needs. Multiple studies have found that some of these health issues occur at higher rates than in the general adolescent population.[3,4–6] Although some youth in the juvenile justice system have interfaced with health care providers in their community on a regular basis, others have had inconsistent or nonexistent care. The health needs of these youth are commonly identified when they are admitted to a juvenile custodial facility. On-site correctional health care providers must not only try to identify these health issues but also determine if there has been active medical management in the community. Pediatricians and other health care providers play an important role in the care of these youth, and continuity between the community and the correctional facility is crucial.

EPIDEMIOLOGY OF JUVENILE ARRESTS

In 2008, 11 million juveniles younger than 18 years were arrested.[7] Two-thirds of those arrested were referred to juvenile court, and 10% were referred to the adult criminal court system. One-third of all juveniles arrested were female. Gender differences exist in patterns of arrest-related charges such that adolescent girls are more likely to have runaway and prostitution/vice offenses, whereas boys have a

higher proportion of arrests in all other categories (eg, violent and property crimes). Girls are also more likely than adolescent boys to fight with family members and become involved in domestic disturbances.[8] Racial differences were seen in juvenile arrest patterns. Although black youth only represent 16% of the 10- to 17-year-old population in the United States, they represented 52% of the Violent Crime Index arrests and 33% of the Property Crime Index arrests (see Table 1). The greatest racial disparities were seen with some of the most serious crimes—murder, robbery, and assault.[9]

Reasons for these racial disparities are complex and involve social context as well as individual characteristics and are not well understood. When comparing minority youth to white youth, differing opinions exist about the relative contributions of several factors including possible differential involvement in various offenses and inequalities in the treatment of minority youth compared with white youth once within the juvenile justice system.[10] Youth arrests and delinquent behavior have been related to lower socioeconomic status (SES), family disruption (marital separation, divorce), living in households with only 1 biological parent, less residential stability (length of time living in 1 location), poorer neighborhood collective efficacy (capacity of residents to achieve social control over the environment), and educational failure.[11–13] Overall, poverty is likely to be the underlying factor that most influences trends in juvenile crime.[13]

SES plays a significant role for black and Hispanic youth, because they are more likely to live in poverty than their white counterparts.[13] Educational failure is correlated with unemployment/underemployment. Studies have found that employment can prevent or reduce delinquent behavior. Lower educational attainment is most likely to affect black and Hispanic youth, who have higher dropout rates than their white counterparts.[13] Family structure influences youth socialization and the capability to control the youth's behavior.[12] Family structure, itself, is not the cause of a youth's behavior. Rather it is linked to other factors, as illustrated by the correlation between single-parent households and increased probability of living in poverty.[13] Black youth are most likely to be living in a single-parent household, and Hispanic youth are less likely than white youth to be living with both parents.[13]

Not all juvenile arrests result in a custodial placement in either a short-term detention facility (usually ≤3 months) awaiting adjudication or a longer-term postadjudication residential facility. Custody rates are higher for male adolescents than female adolescents. Girls are more likely to be held for technical violations, such as violating the terms of probation, or status offenses, such as running away, rather than more serious illegal activities[9] (see Table 1). Data on custody rates are similar to data on arrest rates, which demonstrate disproportionate contact of minority youth with law enforcement. Although minority youth represent only 39% of the US juvenile population, they represented 65% of the national juvenile custody population in 2006.[9] These data become particularly relevant when considering unmet mental and physical health needs, because poorer health status is related to lower SES, and lower SES is more likely to be found among minority youth (see "Sociodemographic Factors and Health Status").

In 2006, the median time in custodial placement was 65 days, including both short-term and long-term facilities. Eighty percent of postadjudicated youth were in the facility for at least 30 days, and 57% were in the facility for at least 90 days. Twelve percent were still in placement at 1 year.[9] A significant number of youth are incarcerated for a period of time that would permit health care providers to diagnose, assess, and treat them for identified health problems.

TABLE 1 Definitions of Crimes, Offenses, and Violations

Violent Crime Index
Murder and nonnegligent manslaughter
Forcible rape
Robbery
Aggravated assault
Property Crime Index
Burglary
Larceny-theft
Motor vehicle theft
Arson
Status offense: an offense that is illegal for a minor but would not be criminal if committed by an adult
Runaway
Truancy
Curfew violation
Underage drinking
Technical violation: violation of a court order
Probation violation
Curfew violation

SOCIODEMOGRAPHIC FACTORS AND HEALTH STATUS

The categories of health needs of youth in the correctional system are similar to those of their peers in the community. They include dermatologic, respiratory, dental, gastrointestinal, genitourinary, and metabolic problems as well as developmental and mental health issues. Other categories are influenced, in part, by the youth's engagement in high-risk behaviors such as violence, substance abuse, and sexual activity, which may be more prevalent than those of their peers in the general population.[5,14] Some health issues result from living in impoverished and abusive environments (eg, traumatic brain injury [TBI], lead exposure, positive tuberculosis [TB] test results, and poor dental care). Others are acquired health problems (eg, hy-

pertension, diabetes) that are neglected or remain undiagnosed.[15] In some instances, youth have had inadequate health care, because they have been runaways or living in inconsistent living situations that do not allow for continuity of care.

Underlying the poorer health status of youth in the juvenile justice system is SES. Just as lower SES is correlated with juvenile delinquency, lower SES—specifically, income inequality—has been shown to correlate with teen births, overweight, and mental health problems.[16] Minority youth, including black and Hispanic youth, who are overrepresented in the juvenile justice system in the United States, are more likely to live in lower-SES environments and have been found to have overall poorer health care than their white counterparts. Studies have shown significant disparities between white and minority youth aged 0 through 17 years in insurance coverage, lack of a usual source of care, use of the emergency department, and not receiving adequate mental health care, dental care, or prescription medications.[17] Factors other than SES may also be important. A recent review of the literature confirmed racial/ethnic disparities in adolescent health care. However, the results also suggested that some disparities are not totally understood and seem to be independent of SES.[18]

EXTENT OF MEDICAL PROBLEMS

Few studies have provided a broad national perspective on the health needs of youth in the juvenile correctional system in the United States. The most recently published information is from the Survey of Youth in Residential Placement (SYRP).[3] The findings in this report are based on interviews with a nationally representative sample of 7073 youth in custody during the spring of 2003. The information was obtained by using audio computer-assisted self-interview methodology and included youth at both short-term detention and longer-term residential treatment facilities. The survey revealed high rates of mental health and substance abuse problems as well as traumatic experiences with documented rates that exceeded those of the general adolescent population. More than two-thirds of youth in this survey reported a health care need, including injury, problems with vision or hearing, dental needs, or "other illness."

Although more than 20 years old, another study with a national scope was conducted in 1991 by the National Commission on Correctional Health Care (NCCHC).[5] The study included 1801 youth from 39 short-term or long-term correctional facilities in the United States. These youth had higher rates of substance abuse, trauma, unprotected sexual activity, history of sexually transmitted infections (STIs), suicidal ideation, and reported violence than those in a general high school population.

In the following sections, the data regarding general physical health issues are reviewed, and mental health and substance use/abuse diagnoses are addressed.

GENERAL PHYSICAL HEALTH ISSUES

In addition to the SYRP and NCCHC studies, 3 other studies that involved either a single facility or a region have provided important information. Two studies similarly found that approximately half of youth in these facilities had an identified medical problem. The first study, the results of which were published in 1980, included youth admitted during an 11-year period to a secure detention facility in New York[15]; the second study, the results of which were published in 2000, included youth from 15 detention and longer-term facilities in the Maryland Juvenile Justice System.[19] The third study involved youth admitted to a detention center in Alabama in the mid-1990s and found that although most youth (76.9%) denied preexisting conditions or complaints at the time of admission, 10.6% had a medical condition that required medical follow-up after release.[20]

There are a few specific health concerns that require particular attention in this population.

Dental

The preponderance of dental needs was documented in a 30-year-old study in a detention center in New York, in which almost all of the youth (90%) required dental care.[15] A more recent study of youth in a juvenile detention center in Dallas County, Texas, conducted between 1999 and 2003,[21] found that among a random sampling of 419 dental screenings of 12- to 17-year-olds, half of them had untreated decay and fewer than one-fifth had preventive sealants. High-urgency dental problems defined as infection, tooth or jaw fracture, pulpitis, or severe periodontal disease with bleeding were found in 6.2% of the subjects. Moderate-urgency conditions, including cavitated asymptomatic decay or moderate gingivitis were found in 13.1%. One of the challenges noted by the authors was the inability to provide comprehensive treatment plans except in the case of long-term detainees.

Injury

Traumatic injuries are commonly identified in this population.[3,5,15,19,20,22] These injuries are caused by multiple etiologies that range from accidental to deliberate. The Maryland study[19] found that almost one-fifth of the youth experienced an injury including burns, head trauma, and musculoskeletal

injury, and that 12% of these youth had not had previous treatment. As demonstrated in the NCCHC study, interpersonal violence is an important cause of injury in this population.[5] Approximately 70% of the surveyed youth had been involved in at least 1 fight during the previous year, and one-quarter of them had experienced an injury that required medical attention. Three-quarters of youth in the NCCHC study reported fights that involved a weapon. There was a relationship between substance use and physical fights, use of weapons, and gang membership.

More details are described in the report of a study from a secure residential facility in North Carolina that examined the types of traumatic injuries experienced by 10- to 17-year-old youth.[22] More than half of the youth had an injury that required medical attention. One-third of the injuries were related to sports, 20% related to fights, 13% self-inflicted, 9% related to suicide attempts, 8% vocational, 3% related to horseplay, and 11% attributed to "other." The most common traumatic injury was musculoskeletal (one-third). One-quarter of the injuries were significant enough to necessitate referral for further evaluation to an outside facility.

A previous history of TBI is particularly significant in this population, because it can affect mental health and behavioral issues. Studies of detained adolescents have found high rates of TBI. Compared with youth without TBI, those with a positive history were more likely to have a psychiatric diagnosis, report earlier onset of criminal behavior and substance use, have more lifetime substance use problems, have more previous-year criminal acts, report lifetime suicidality, and demonstrate impulsivity or fearlessness in the year preceding incarceration.[23,24]

Tuberculosis

Residents of correctional facilities have among the highest rates of TB infection and are housed in an environment with an increased risk of exposure. For those reasons, it is recommended that adolescents in correctional facilities be screened annually for TB. A positive Mantoux skin test result is considered to be 10 mm or greater, which is a lower threshold than that for an adolescent without additional risk factors.[25]

Reproductive Health

Sexual Activity/Contraception

The 1991 NCCHC study[5] remains one of the best nationally representative samples evaluating sexual activity and contraceptive use among incarcerated youth. The study used a survey method based on the Centers for Disease Control and Prevention (CDC)'s Youth Risk Behavior Surveillance System, which allowed for comparison with a general high school population. Incarcerated youth reported higher rates of sexual activity and were more likely to report 4 or more lifetime sexual partners. Incarcerated youth also had much lower self-reported use of contraception or condoms at their most recent sexual intercourse.

STIs/HIV

Data from the CDC's 2009 Sexually Transmitted Disease Surveillance Report[26] demonstrated that youth in the juvenile detention system have among the highest rates of STIs (Table 2). Similar data were collected in another study that represented 12 juvenile correction facilities in 5 jurisdictions between 1996 and 1999.[27] Because of unprotected sex with multiple partners, prostitution, or injection drug use, youth in correctional facilities are also at increased risk of HIV and hepatitis C virus infection. In addition, they are at risk of hepatitis B virus infection when the vaccination series is incomplete. High rates of STIs, alcohol and drug use, and lack of consistent condom use also contribute to increased risk of HIV infection.[28–34]

TABLE 2 STI Rates Among Incarcerated Adolescents Aged 12 to 18 Years, 2009[26]

Disease	Overall Positivity, %	
	Female	Male
Chlamydia	14.8	6.6
Gonorrhea	3.9	1.0

Chlamydia data are from 83 juvenile detention facilities for women and 123 facilities for men. Gonorrhea data are from 71 juvenile detention facilities for women and 118 facilities for men.

Although the risk of STIs/HIV infection is high in incarcerated youth, many facilities fail to screen for either STIs or HIV. A study that used 2004 data from the Juvenile Residential Facility Census[35] found that only 18.5% of the facilities offered STI testing for all adolescents on admission and that 8.3% of the facilities did not even have STI testing available. Some facilities only provided STI testing services when requested by the youth or deemed medically necessary, which is especially problematic, because STIs are commonly asymptomatic. Even fewer facilities tested all youth for HIV or hepatitis C virus infection, and these tests were much less likely to be available.[35] One of the challenges associated with HIV testing by traditional methods is that it involves a blood draw and use of an outside laboratory. Youth may refuse phlebotomy and can be released from a short-term detention setting before obtaining the results. Currently available rapid HIV tests provide the option of a less invasive oral test and can provide results within 20 minutes while the youth waits. Providing opt-out HIV testing is recommended by the CDC as a part of routine health care, even in correctional facilities.[36]

Pregnancy/Fatherhood

The SYRP found that 14% of incarcerated youth have children; males (15%) were more likely to have fathered a child compared with 9% of females who reported having a child.[37] This rate is much higher than that of the general population of 12- to 20-year-olds, in which 2% of males and 6% of females have children. In addition, 12% of incarcerated youth were expecting a child. Overall, one-fifth of youth were currently a parent or expecting a child.[37]

These recent national data confirm previous reports in which incarcerated teenagers report higher pregnancy rates than those in the general adolescent population; more than one-third of the females report ever having been pregnant.[38,39] An analysis of data from the 2004 Juvenile Facilities Census[40] revealed that at least 2.1% of girls are pregnant while in juvenile justice residential facilities at any particular point in time. One study found that one-quarter of males had fathered a pregnancy, and 40% of those fathers reported responsibility for more than 1 pregnancy.[41] The 2004 Juvenile Facilities Census[40] found that only 15% to 17% of facilities test all girls for pregnancy on admission. Although a small proportion (4.5%–6.6%) fail to even provide pregnancy tests, the remainder of the facilities test only when it is medically necessary or requested by the adolescent.

For youth who are pregnant while incarcerated, there are additional challenges. As found in the 2004 Juvenile Facilities Census, almost one-quarter of the facilities do not offer access to obstetric services.[40] Similarly, another study that involved 430 short-term and long-term facilities from 41 states[42] found that prenatal services were lacking in one-third of them, and 60% reported at least 1 obstetric complication. Pregnancy among incarcerated teenagers is complicated by other existing problems including substance abuse, posttraumatic stress disorder, previous sexual abuse, and additional considerations regarding postdelivery options.[43] In addition to altered activity schedules and changes in menu options related to the higher caloric requirements of pregnancy, postpartum depression and other psychological problems require particular attention. Because most juvenile justice facilities do not have arrangements for infant residency or visitation, the adolescent and her family may be expected to make a plan for foster care placement.

MENTAL HEALTH

Overview

The available literature indicates that the prevalence of psychiatric and substance abuse disorders among youth in correctional facilities exceeds that of the general adolescent population.[3,44,45] In a review of the worldwide literature from the 1960s through the 1990s, Roberts et al[46] determined that the mean prevalence of psychiatric disorders in the general adolescent population was 16.5% (range: 6.2%–41.3%). In comparison, prevalence rates in the juvenile justice population range from 50% to 100% when disruptive behavior disorders are included.[47]

Inclusion of disruptive behavior disorders, such as conduct disorder, in the psychiatric disorder prevalence estimates is controversial, because most teenagers would not be incarcerated unless they came to the attention of authorities because of significant disruptive behaviors. To some extent, engaging in disruptive behavior is part of normal adolescent development. Multiple studies have found that most adolescents in the general population participate in behaviors that would be considered delinquent.[48] These behaviors, which include imitation of antisocial models/styles and social reinforcement, are usually transient. Most of the adolescent offenders (85%) known to the criminal justice system stop offending by the age of 28 years. Furthermore, severe, persistent antisocial behavior over time is only found in approximately 5% of males.[48]

The wide range in the prevalence of mental health disorders among youth in the juvenile justice system is indicative, in part, of the limitations of the studies in the literature. These limitations include the use of nonstandardized measures and different diagnostic tools; noncomparable sociodemographic variables; data that are not generalizable because they are specific to an individual facility, state, or other locale; variation in the timing of the evaluation from the detention setting to after adjudication; and bias when samples only include youth referred for psychiatric evaluation.[45,47,49,50] It is also important to consider the fact that for some youth, when mental health resources in the community are not sufficient, the juvenile justice system may be the placement of last resort by default.[51]

Prevalence of Psychiatric and Substance Use Disorders

Until the SYRP report, the 1991 NCCHC study was the only published study that included a national sampling of multiple juvenile custodial sites in the United States. In the NCCHC study, all of the mental health and substance use behaviors were self-reported through a modified version of the CDC's Youth Risk Behavior Surveillance instrument. The data from that survey are summarized in Table 3. The more recent SYRP study[3] found that at least half of youth reported problems with anxiety, anger, and loneliness, and approximately one-fifth had a previous suicide attempt. In addition, only 56% of the general population of 12- through 20-year-olds report a lifetime use of alcohol,

TABLE 3 Mental Health and Substance Use Data From the 1991 NCCHC Study[5]

Category	Male ($n = 1574$), %	Female ($n = 219$), %	Total Sample ($N = 1801$), %[a]
Suicidal ideation previous year	19	40	—
Suicidal plan previous year	17	37	—
Suicide attempt previous year	13	35	—
Tried smoking	—	—	87
Smoked whole cigarette by age 12 y	—	—	51
Alcohol use, >20 d lifetime	49	55	—
Cocaine use	30	42	—
Marijuana use, >40 times	—	—	40
Injected drugs	10	20	—
Use of other illegal drugs[b]	13	26	—

[a] Not all youth indicated gender on the survey.

[b] Other illegal drugs used 10 or more times in lifetime: lysergic acid diethylamide (LSD), phencyclidine (PCP), ecstasy, hallucinogenic mushrooms, speed, ice, heroin, and pills without prescription.

compared with 74% of youth in custody, and only 40% of the general population has used any illegal drug compared with 85% of youth in custody. Details from the SYRP are summarized in Table 4.

Although the NCCHC and SYRP reports have provided information on youth from multiple sites across the United States, these 2 studies are limited by only providing information based on youth self-report rather than from diagnostic evaluation tools. Between 2002 and 2006, the results of several studies that were designed to eliminate some of the previous study-design problems were published. The authors of these reports, Teplin et al,[50] Wasserman et al,[52,53] and Shufelt and Cocozza,[49] used randomly selected youth; the Diagnostic Interview Schedule for Children (DISC) as a standardized screening and assessment instrument; and included more ethnically/racially diverse samples. These studies yielded a smaller prevalence range of 45.7% to 70.4% for having either a psychiatric and/or substance use disorder (see Tables 5 and 6). The studies by Teplin et al[50] and Shufelt and Cocozza,[49] specifically, were able to show that the high rates of psychiatric illness were not just a reflection of disruptive behavior disorders. Both studies found similar results: 60.9% (Teplin et al) and 66.3% (Shufelt and Cocozza) had either a psychiatric or substance use disorder when conduct disorder was not included among the diagnoses. When Shufelt and Cocozza removed substance abuse disorders from the analysis, 45.5% of the youth still had a mental health diagnosis. In general, substance abuse is concerning, because youth who start using and abusing drugs during early adolescence are more likely to have serious delinquency and longer deviant careers, antisocial personality disorders later in life, and more risk behaviors. Overall substance abuse is associated with poor academic performance and more psychiatric disorders.[54]

Multiple studies worldwide have found that youth with psychiatric diagnoses can have more than 1 psychiatric diagnosis (comorbidity) or co-occurring psychiatric and substance abuse disorders.[39,49,50,55–61] The study by Shufelt and Cocozza[49] found that 79% of those with a psychiatric diagnosis had 2 or more diagnoses. In another study with youth in the juvenile justice system, McClelland et al[62] found that approximately half of the youth had multiple substance use disorders; 80% of those with an alcohol use disorder also abused other drugs, and half of those with a drug disorder also abused alcohol. Co-occurring psychiatric and substance use disorders were found in the Shufelt and Cocozza study, in which 60.8% of those with a psychiatric diagnosis also had a substance use disorder. In that study, co-occurring substance use and psychiatric disorders were more common when there was a history of disruptive behaviors or symptoms suggestive of mood disorders. Because co-occurring major psychiatric and substance use disorders are common and develop in a close time frame, more dual-diagnosis treatment programs are needed to simultaneously address both issues.

TABLE 4 Lifetime Substance Use Data From the SYRP[3]

Substance	% of Youth in Custody
Alcohol	74
Marijuana or hashish	84
Cocaine or crack	30
Ecstasy	26
Acid or lysergic acid diethylamide (LSD)	19
Inhalants	19
Heroin	7

Racial/Ethnic Differences

Racial/ethnic differences in the diagnosis of mental health disorders have been found in multiple studies. The well-designed study by Teplin et al[50] found that incarcerated black youth have the lowest rate of mental health diagnoses, non-Hispanic white youth have the highest rate, and the rate for Hispanic youth falls between that of these 2 groups. However, as discussed in the literature, interpreting rates of mental health diagnoses and then evaluating racial/ethnic disparity within the juvenile justice system may be problematic. Concern has been raised that minority youth may be more likely to have their behavior interpreted as criminal rather than in need of mental health service.[47] In addition, minority youth may be more reluctant to admit to experiences with mental illness, or they or their families may have a cultural bias against seeking care.[63,64]

TABLE 5 Design of Selected Studies That Evaluated Psychiatric and Substance Use Diagnoses in Youth in the Juvenile Justice System[49,50,52,53]

Author	Year Conducted	Location	No. of Subjects
Teplin et al[50]	1995–1998	Cook County Juvenile Detention Center	1829
Wasserman et al[53]	1998	Texas: probation intake in 8 counties	991
Wasserman et al[52]	2001	New Jersey and Illinois secure placement	292
Shufelt and Cocozza[49]	2006	Louisiana, Texas, and Washington: 29 programs and facilities	>1400

Gender Differences

Gender differences are also evident. Females are more likely than males to have any psychiatric diagnosis and, specifically, to have higher rates of mood and anxiety disorders (Table 6). With respect to substance use disorders, in general, males and females have similar rates, but the study by Teplin et al[50] found that females are more likely than males to use substances other than alcohol and marijuana. Although both genders experience sexual (10%–24%) and physical (11%–58%) abuse,[6] all forms of abuse, including emotional abuse, are more common in girls. As such, posttraumatic stress disorder is also more commonly diagnosed in females. Long-term outcomes for delinquent adolescent females reveal greater persistence of emotional problems and worse outcomes complicated by relationship and parenting issues, drug problems, and suicidality.[65]

Suicide

Suicide and suicidality have been a long-standing concern for juveniles in confinement. The 1991 NCCHC report and the 2003 SYRP both revealed high rates of suicidal ideation among incarcerated youth. In addition, 2 nationally representative studies explored suicidality in more detail. One study, the results of which were published in 2006,[66] found that suicide was the leading cause of death in juvenile justice facilities in the United States between 2000 and 2002. A second report, published in 2009[67] and entitled "Characteristics of Juvenile Suicide in Confinement," described the results of a retrospective evaluation of all identifiable juvenile deaths in confinement from 1995 to 1999. For the deaths related to suicide, the mechanism was hanging in all but 1 case. There were several important findings in this report. Sixty percent of the suicides occurred between 3 PM and midnight, which included a time frame in which youth were most likely to be around other people. Suicides were also most common during waking hours for those confined to their rooms. In addition, the potential for suicidality among these youth should have been recognized by staff, because 70% had been assessed by a mental health professional— half of them within the previous 6 days. Two-thirds of them had a diagnosis of depression, and half were taking a psychotropic medication. Seventy percent of the youth had a history of suicidal ideation, and almost half had had a previous suicide attempt. Precipitating factors were identified more than half of the time and included fear of transfer or placement, recent death of a family member, failure in the program, recent suicide in the facility, and parental failure or threats not to visit.

Recent studies[6,68] found that facilities with suicide-prevention training and suicide risk screening shortly after admission to the facility had a lower suicide rate. This is an area for improvement, because the 2009 study[6,67] found that only one-fifth of the facilities had the 7 key components deemed necessary for suicide prevention. These components include written protocols, intake screening, suicide-prevention training, safe housing, observation, mortality review, and cardiopulmonary resuscitation certification. The report also discussed the need to further evaluate room confinement, including the role of isolation in suicidal behavior.

TABLE 6 Estimated Rates of Mental Health Disorders in Incarcerated Youth From Studies Conducted Between 1995 and 2006[49,50,52,53]

Disorder	Rate Males %	Rate Females %
Any mental health disorder	45–69	50–81
Any mood disorder	6–19	13–29
Major depressive	5–13	11–22
Any anxiety disorder[a]	17–26	29–56
Generalized anxiety	2–7	3–7
Panic disorder	0.3–5	2–3
Obsessive compulsive	5–8	6–11
Separation anxiety disorder[b]	13–25	19–33
Any disruptive behavior[c]	20–45	20–51
ADHD	1–17	0.5–21
Oppositional-defiant	3–15	11–18
Conduct disorder	18–38	17–41
Any substance abuse	26–51	22–55

All subcategories under the "any" headings are from refs [50], [52], and [53]. ADHD indicates attention-deficit/hyperactivity disorder.

[a] Only Teplin et al[50] (2002) included "separation anxiety" in the data for the "any anxiety" category.

[b] Separation anxiety disorder subcategory data are from Teplin et al[50] (2002) and Wasserman et al[53] (2005).

[c] Teplin et al[50] (2002) did not include attention-deficit/hyperactivity disorder under the "any disruptive behavior" category; it was reported as a separate category.

Psychotropic Medications

National data are lacking on the use of psychotropic medications for youth in the juvenile justice system. However, as summarized by Desai et al,[44] 2 studies representing data from 2 states found that psychotropic medications were used for approximately half of the youth in detention facilities and more than two-thirds of youth in longer-term facilities. The fact that the majority of youth are prescribed these medications emphasizes the need for psychiatric services to appropriately diagnose and manage these youth. Mental health services are needed at the time of admission to a correctional facility for youth who are already on psychotropic medications and to evaluate youth who may need to initiate medications. In addition, subsequent evaluation is needed to decide whether ongoing use is needed during confinement. Attitudes of the parents and youth need to be considered when prescribing these medications, and continuity of care between community prescribing physicians and the juvenile justice facility is crucial.

The American Academy of Child and Adolescent Psychiatry has published a document that addresses mental health assessment and treatment for youth in the correctional system.[69] In this document, the authors recommend that psychotropic medication should only be used as part of an individually developed comprehensive treatment plan. Medication should augment other treatment interventions including individual, group, and family therapy along with behavioral interventions such as regular exercise, improved sleep hygiene, and staff/family support. The need for previously prescribed medications should be assessed on the basis of current symptoms and level of functioning. New medications should be used cautiously after review of potential risks and benefits, adverse effects, and alternatives with both the youth and the parent/guardian when the youth is a minor.

SCREENING AND ASSESSMENT FOR MENTAL HEALTH AND SUBSTANCE ABUSE DISORDERS

Ideally, youth with mental health and substance abuse problems would be identified and treated in the community rather than being first identified and addressed within the juvenile justice system. One recent study found that improvement in mental health services could reduce involvement with the juvenile justice system, particularly among youth with the most serious offenses.[70] One author[71] suggested that substance use screening before admission to detention might allow community diversion of some youth, optimize treatment choice, and minimize restrictive detention. However, optimal screening procedures have not been established, and many communities have limited availability of psychiatric and substance abuse services.

To better address the mental health needs of youth in the juvenile justice system, a panel of experts[72] was convened to create guidelines and a road map for best practices in the juvenile justice setting. The recommendations included a (1) valid and reliable mental health screening within 24 hours of admission, (2) a more extensive assessment by a mental health professional as soon as possible to determine needs, (3) use of multiple sources of information (records, family, schools, etc), (4) rescreening before release and preparation for transition out of custody, and (5) regular repeat screenings while in custody. These recommendations are consistent with existing standards from the NCCHC.

One of the commonly used screening tools for mental health and substance abuse specifically developed for the juvenile justice system is the Massachusetts Youth Screening Instrument–Second Version (MAYSI-2). This 52-item screening instrument takes 10 minutes to complete and is validated as a self-report response tool that requires no clinical expertise to administer, score, or interpret; is low cost and can be used by a range of ages, different ethnic groups, and both genders; and has good psychometric properties.[73] This tool can be completed by using audio computer-assisted technology for youth who have literacy problems. The MAYSI-2 is designed as a screening tool only, and staff trained in mental health should be available for further assessment. This tool should never take the place of well-trained staff who can recognize symptoms of mental health disorders and substance use withdrawal.

There is no standardized approach used in the juvenile justice system to screen for substance use/abuse. It is important to screen for the use or abuse of alcohol, tobacco, and the gamut of other drugs, including illicit, prescription, and nonproprietary substances. Possible methods include self-report, which is the least expensive method but requires youth to understand the questions and have accurate recall and honest disclosure. Bioassays with urine or hair are most commonly used by detention facilities and are easy to collect. However, although these tests provide objective data, urine is only sensitive for most drugs used in the previous 2 to 3 days. Hair analysis has significant problems including external contamination, which can lead to false-positive results and differences in binding for different drugs and with different types of hair.[54]

Specific screening for substance use was addressed in a recent report from the Office of Juvenile Justice and Delin-

quency Prevention.[13] Only 61% of juvenile facilities screened all youth for substance abuse, and 19% reported no screening. An additional 20% only screened youth identified by court or probation officers or facility staff. Other reasons to assess were if they had drug- or alcohol-related charges or by parent/youth request. Approximately one-third of the youth were screened on the day of admission, and another one-third were screened 1 to 7 days after admission. Three-quarters of the facilities that conducted screenings used staff-administered questions, and 55% used self-report by standardized instruments or checklist inventories. Overall, 73% of the facilities used urine-based drug screening; however, one-third of all facilities only tested a subset of admitted youth or only when use was suspected or a request was made by the court or probation officer.

ON-SITE PSYCHIATRIC AND SUBSTANCE ABUSE SERVICES

The decision to initiate or change medical treatment of psychiatric disorders in detention is challenging,[74] but acute symptoms may need to be treated with some urgency. Medications should be used to manage symptoms and minimize distress but not to manage behaviors alone. As discussed in the practice parameter from the American Academy of Child and Adolescent Psychiatry, it is ideal to determine the youth's legal disposition and placement before initiating or changing medication regimens.[69] Unlike in longer-term, postadjudication facilities, the length of stay in detention is usually too short for most counseling interventions to treat major psychiatric disorders. However, trained personnel can provide observational data, and short-term counseling interventions can provide support and facilitate the use of problem-solving strategies to prevent problem-escalating interpersonal behaviors. A more extensive evaluation may also be required before making a disposition to residential or community-based mental health treatment. Family involvement is critical at that stage, because it is the key determinant of treatment engagement and success. Whenever the youth is returning to the community, an essential part of the disposition is to include identification of a behavioral health home and care plan.

In 2002,[13] 53% of the facilities that reported mental health evaluation data had in-house mental health professionals who evaluated all admitted youth. Another one-third evaluated some youth. Facilities that provided mental health treatment on-site were more likely to also have a mental health professional evaluate all the youth. Larger facilities were more likely than smaller ones to screen all youth for suicide risk and to evaluate all youth for mental health needs. Privately operated facilities (62%) were more likely to evaluate all youth than were public facilities (41%).

Two-thirds of the facilities that reported substance abuse services provided them on-site; the majority (97%) of them provided drug education, and two-thirds provided individual or group therapy with a substance abuse treatment professional. However, it was also common (60%) for the counseling to be provided by someone not specifically trained in substance abuse treatment. Only 2 of 10 facilities had ongoing specialized treatment for substance abuse, and 1 in 10 had no substance abuse treatment services. Most facilities used in-house services, whereas only 20% relied on off-site services.[13]

HEALTH CARE STANDARDS: THE NCCHC

Standards for care of youth in a juvenile correctional facility have been published by the NCCHC, which also serves as an accreditation organization.[75,76] The latest version of the standards for youth was published in 2011.[76] These standards are used for facility accreditation but are valuable to help inform facilities about both the minimal and ideal health care for incarcerated youth. The currently published standards do not specifically distinguish between detention centers, which typically involve shorter lengths of stay, and longer-term postadjudication residential facilities. However, at a minimum, the standards state that all youth should be screened immediately on arrival at the intake facility by qualified health care professionals or health-trained staff to identify and meet *urgent health needs* and to screen for any potentially *contagious conditions* or dangerous behaviors such as *suicidal ideation*. The subsequent length of stay would determine further evaluation.

According to the standards, all youth must receive a *comprehensive health assessment within 7 days* of arrival with hands on assessment by a physician, physician assistant, or nurse practitioner. This assessment includes a complete medical, dental, and mental health history, review and update of immunizations, screening for TB, measurement of vital signs, physical examination, and genitourinary examination, including a gynecologic assessment, as indicated by gender, age, and risk factors. The need for laboratory and/or diagnostic tests for *communicable diseases*, including STIs, are determined by the responsible physician.

A *mental health screening* that provides a full assessment by qualified mental health professionals or mental health staff using a structured interview is to be conducted within 14 days of admission and includes past history, suicidal behavior, victimization,

exposure to traumatic events, substance use, violent behavior, cerebral trauma or seizures, and psychotropic medication. In addition, an oral health screening is to be performed by a dentist or health care professional trained by the dentist within 7 days of admission, and an oral examination is to be performed by a dentist within 60 days of admission.

Facilities are required to provide an opportunity for the adolescent to request health care on a daily basis, and all requests must be triaged within 24 hours. The facility must provide 24-hour emergency mental health and dental services. Discharge planning must include arrangements for follow-up or referrals to community providers and a supply of current medications to last until that follow-up can occur.

A recently published study[35] that assessed whether juvenile detention facilities follow the standards set out by the NCCHC found significant deficits when comparing reported practices to published standards. Data were analyzed from the Juvenile Residential Facilities Census (2000, 2004) and Census of Juveniles in Residential Placement (2003), which are conducted by the Office of Juvenile Justice and Delinquency Prevention of the US Department of Justice. Most juvenile correctional facilities are not accredited by the NCCHC, and in the absence of mandatory accreditation, it is not clear whether most facilities would fail to meet the standards or just choose not to be accredited. Data from 2004 showed that overall, fewer than half of the facilities were compliant with recommended health screening and assessments. Few detention facilities met even minimal levels of care, although better care was seen as the length of stay increased.

CONTINUITY OF CARE

Continuity of care, both on entering the facility and when transitioning back to the community, is crucial for youth in the juvenile corrections system. However, continuity of care is a challenge. One study[20] found that fewer than half of families showed interest in care deemed important by the on-site medical staff, and a large proportion of families were not successfully contacted. These youth had nonideal medical care before admission; only half of the youth had care in the previous year, and only one-third of them were able to identify a source of regular medical care. The juvenile justice system may be the only place where these youth have received a recent comprehensive medical history or physical examination.[15]

As custodial placement comes to an end, transitions are difficult, particularly for youth who have experienced disruption and failure and who have limited internal resiliency and external support. Transitions of communities, residences, schools, programs, therapists, friends, and family members as well as adjustment to a less restrictive environment can be difficult. Continuity of care starts at the time of admission to the facility. If the youth already has a primary care provider, it is crucial for the medical staff to be able to contact that clinician to verify previous diagnoses and treatment. For cases in which the youth does not have a primary care provider, resources to establish primary care should be provided. Providing summaries of medical care for the primary care provider, appropriate subspecialist, or mental health specialist on discharge back to the community is also extremely important. In some cases, a chronic medical condition may be first diagnosed while the youth is in custody. Facilitating the transition to a provider who can ensure continuity is key, because it is not uncommon for youth to return to the correctional facility with unmet chronic health needs. For some conditions, such as STIs or TB, public health facilities may be able to help with follow-up.[75]

COMMUNITY-BASED INTERVENTIONS FOR INCARCERATED YOUTH

Traditional cognitive behavioral therapy (CBT) is helpful for both internalizing and externalizing behaviors, including anger management, depression, and posttraumatic stress disorder. However, it may not be the best choice for many delinquent youth. There are several promising interventions that have been shown to be effective in treating youth with mental health issues. In some cases, these interventions have been shown to reduce recidivism.[77] Programs that broadly address multiple domains, including the adolescents' family, school, peers, and community, are the most effective. These programs are intensive and highly structured and include social skill development, behavior management, attitude adjustment, and cognitive perceptions. Many of these programs are community-based interventions conducted in the youth's home environment and directly engage the family members. Examples include multisystemic therapy, functional family therapy, and wraparound therapy. In another program, multidimensional treatment foster care, youth are placed with families trained to provide a structured therapeutic environment as an alternative to incarceration. The biological family is taught the system with the goal of returning the youth home. Multisystemic therapy and functional family therapy have been found to be particularly effective for youth with co-occurring mental health and substance use disorders. Some of the challenges with implementing these

programs are the high initial upfront costs and the labor-intensive nature of the interventions.

When assessing interventions, it is also important to note that the Girls Study Group[78] found that interventions for boys may not directly translate to girls. Protective factors, such as caring adults, school success, school connectedness, and religiosity, may be less effective for girls who have experienced physical and sexual assault, neglect, and neighborhood disadvantage. More research is needed to understand the interaction between risk and protective factors in girls to best design successful intervention programs. Programs for girls need to address victimization, which is commonly found in these youth.

As evidenced by the interventions described above, the approach in the juvenile court system is generally *rehabilitative* rather than *punitive*. The Office of Juvenile Justice and Delinquency Prevention[79] advocates a comprehensive strategy that includes supporting the adolescent's family and engaging core institutions, such as schools, businesses, and religious organizations, in helping to develop mature and responsible youth. This strategy utilizes the principle that delinquency prevention is the most effective approach while recognizing that there is a need for graduated sanctions that protect the community. The best prevention involves targeting risk factors for delinquency, such as drugs and firearms in the community, family conflict, abuse and neglect, poor commitment to school, and negative peer influences, while focusing on protective factors such as a resilient individual temperament; close relationships with family, teachers, other adults, and peers; and promoting school success and avoidance of drugs and crime. Reentry plans need to address education, mentoring, prosocial activities, and positive community involvement.

EDUCATIONAL NEEDS

As summarized in the recently published findings of the SYRP, educational difficulties and low commitment to academics are risk factors for delinquency.[3] In this nationally representative survey, one-fifth of the youth reported that they were not enrolled in school at the time they entered custody. This rate is 4 times higher than that for the general population. In addition, 61% had been expelled or suspended, compared with 8% of the general population. Although only 28% of youth in the general population are functioning below grade level, 48% of those in custody reported being below the level expected for their age. Similarly, a higher percentage (25%) of youth in custody reported being held back in school, compared with 11% among peers in the general population. Although the majority (92%) of youth reported attending school while in custody, only half of these youth reported that the school program was of good quality, and most youth did not spend as many hours in school as did the general population.

Learning disabilities are also much more common among youth in custody; rates of 30% have been reported by youth in custody, which is 7 times higher than that of the general population. Despite the requirements of the federal Individuals With Disabilities Education Act, which states that youth in custody must be identified and given special education services, even in short-term facilities, only 46% reportedly receive these services. The SYRP report concluded that there is a need to obtain more information on how custodial facilities address educational needs, including an assessment of the curricula used, the provision of special educational services, and whether individual educational needs are being met for each youth in custody.

JUVENILE TRANSFER LAWS/DEATH PENALTY

In the past decade, an increasing number of states have enacted laws that require that juvenile cases be transferred to adult courts for certain offenses.[80] A parallel increase has been seen in the number of juveniles incarcerated in adult facilities for certain felonies. When convicted in adult court, these juveniles commonly receive longer sentences than those sentenced in juvenile courts. Although these laws were enacted with the thought that they would be a deterrent for juvenile crimes, 6 studies, conducted in 5 different states, with approximately 500 to more than 5000 participants each, showed the opposite effect. Compared with youth retained in the juvenile court system, recidivism rates were higher for juveniles whose cases were transferred to adult criminal court. This was particularly true for violent offenders for whom transfer may actually be promoting rather than deterring further criminal involvement.

Juveniles in adult prisons report learning more about criminal behavior from adult inmates and having fear of victimization; these juveniles were least likely to say they would not reoffend. Juveniles incarcerated in adult prisons compared with juvenile facilities have an eightfold increase in suicide, fivefold increase in being sexually assaulted, and twofold increase in likelihood of being attacked with a weapon by other inmates or beaten by staff.[80] Adult facilities have much less emphasis on rehabilitation and family support than do juvenile facilities, and juveniles have expressed both resentment and a feeling of injustice when tried and punished in the adult system.

At the extreme, issues of whether to invoke the death penalty for adolescents have been debated in the past. In 2004, the American Academy of Pediatrics and the Society for Adolescent Health and Medicine issued a joint statement opposing the death penalty for juvenile offenders.[81] In 2005, the Supreme Court ruled that it was unconstitutional to impose capital punishment of individuals who committed crimes as a juvenile.[82] Age 18 was determined to be the age for death-penalty eligibility. This age was based on currently available scientific research that indicates that juveniles do not have the cognitive maturity or sense of responsibility found in adults. This was echoed in the most recent ruling by the Supreme Court in May 2010, in which life without the possibility of parole was not permitted for juveniles who committed nonhomicide crimes.[83]

FINANCING

Financing of health care for incarcerated adolescents presents many challenges.[84–86] All incarcerated persons are entitled to health care under the US Constitution (see *Estelle v Gamble*, 429 US 97); however, such a constitutional guarantee does not include access to federally funded health benefits programs such as Medicaid or the Children's Health Insurance Program (CHIP), and it does not apply to private health insurance plans. Section 1905 of the federal Social Security Act specifically prohibits federal money from being used for medical care of inmates in a federal institution and has been applied equally to adolescents.

There is also a federal prohibition on the use of Medicaid benefits for any month during which the individual is a resident of a public institution. Many states have terminated Medicaid benefits rather than suspend them to avoid improper use of federal funds. Because financing for medical care in juvenile justice facilities then largely relies on state and local resources, the extent of medical care provided can be limited. When Medicaid benefits are terminated, there is also commonly a lag in reinstatement when the youth is released back into the community. This occurs even when screening for eligibility is offered before release and application assistance is provided. Although current law allows states to suspend rather than terminate benefits for incarcerated youth, many states do not follow this procedure for administrative or other reasons.[84–86] Other states have passed legislation specifically to address this issue and require that Medicaid be suspended and not terminated for at least 6 months while in detention.[87] Ideally, continuation and utilization of active benefits while the youth is incarcerated or detained would ensure that correctional facilities can provide more comprehensive medical care. Continuation of active benefits would also facilitate continuity of care and may prevent some recidivism, especially for those with mental illnesses that require medication.[84–86] In order for Medicaid benefits to remain active for youth in the juvenile justice system, federal law must be amended to ensure both continuation of benefits and funding for the federal government share of Medicaid. Advocacy is needed at both the federal and state levels to ensure provision of necessary medical services for these youth.

RECOMMENDATIONS

The current and predicted ongoing shortage of child and adolescent psychiatrists, the separation of mental health and drug and alcohol treatment services and personnel, the limited access to health care dollars for youth in detention, and the institutional variability in procedures and human and monetary resources will continue to provide a challenge to meet a reasonable standard of health care for this population. The following recommendations are provided for caring for youth in the juvenile correctional system.

1. Delivery of Medical Care

Youth incarcerated in the juvenile corrections system should receive the same level and standards of medical and mental health care as nonincarcerated youth accessing care in their communities.

a. *Health care services should be equivalent to those recommended by guidelines of the American Academy of Pediatrics (Bright Futures [see www.brightfutures.aap.org]).* Although the extent of health services provided during the period of incarceration may be mitigated by the length of stay in the facility, shorter-term facilities, at a minimum, should focus on the identification and treatment of immediate medical and psychiatric issues such as injury; infectious diseases (TB, scabies, lice); alcohol, tobacco, and other drug use/addiction, including withdrawal; psychiatric emergencies including suicidal ideation; and identification of chronic medical or mental health problems that require continuation of daily medications.

b. *For youth incarcerated for more than 1 week or in longer-term facilities, recommended pediatric and adolescent comprehensive preventive services should be provided.* In addition to a comprehensive history and physical examination, youth should receive a dental screening and mental health screening for psychiatric illness and substance use/abuse. Assessments should focus on developmental and psychosocial issues. Immunizations should be provided as recommended by the American

Academy of Pediatrics and the Advisory Committee on Immunization Practices of the CDC. The Vaccines for Children (VFC) program is a resource from which eligible youth can access vaccines. Additional evaluation, including for neurologic, genetic, and developmental disorders, should be ordered by medical personnel as clinically indicated. Clinicians caring for incarcerated youth should have training and expertise in pediatrics or adolescent medicine.

c. *Evaluation should include screening for infectious diseases resulting from unprotected sexual activity.* In view of the high rate of risk-taking behaviors, STI screening should be included for the most common pathogens (*Neisseria gonorrhoeae*, *Chlamydia trachomatis*). The 2010 sexually transmitted disease (STD) treatment guidelines from the CDC recommend universal screening of all female adolescents for both *N gonorrhoeae* and *C trachomatis* at intake to juvenile detention facilities.[88] The 2010 STD guidelines also recommend screening sexually active young men for *C trachomatis* in clinical settings in which there is a high prevalence, such as in correctional facilities. Although not specifically recommended in the 2010 STD guidelines, periodic assessment of the local prevalence of *N gonorrhoeae* would be ideal with initiation of screening in male adolescents when prevalence rates indicate that screening would be cost-beneficial. Urine-based nucleic acid amplification testing provides a convenient, noninvasive option for screening. Depending on community prevalence, screening for syphilis should be included. HIV testing should be offered to all sexually active youth per current CDC recommendations.[36,88] Completion of the hepatitis B immunization series should be confirmed. Screening for hepatitis C with serologic testing should be considered for high-risk youth, including those who have a history of injection drug use, are HIV-positive, or have signs or symptoms of liver disease, per current CDC recommendations.[89] Juveniles with signs or symptoms of hepatitis should also be tested for serologic markers for acute infection with hepatitis A and hepatitis B. For most youth, the first Papanicolaou test is not indicated until 21 years of age . If clinically indicated per published guidelines, a pelvic examination should be performed for a Papanicolaou test (see pelvic examination and male reproductive health statements).[90,91]

d. *Screening of pubertal girls should include pregnancy testing.* Because of the high rates of sexual activity, all pubertal girls should be screened for pregnancy. Nonjudgmental counseling regarding options should be provided for pregnant youth, and accessibility to prenatal services should be provided on-site or in the community. Prenatal vitamins, including iron and folate supplementation, should be provided to all pregnant girls at the time pregnancy is diagnosed and continued throughout the course of the pregnancy. For both female and male youth who are parents, parenting classes should be included in the educational offerings.

e. *On-site mental health and substance abuse professionals should be available to provide both evaluation and treatment services.* Mental health services can be provided by staff either hired by the facilities or through a contractual arrangement with an outside community provider. Services should include psychiatric services to facilitate continuation of medications from the community mental health provider and ongoing evaluation and treatment. Psychiatrists should have training in child and adolescent psychiatry and preferably be board certified. Tobacco-, alcohol-, and drug-cessation programs should be available during the period of incarceration. Attention should be paid on an ongoing basis to the medical and mental health status of youth, because new issues can arise during their time in confinement. Correctional staff should receive training in suicide prevention, and specific attention should be paid to youth confined to their rooms in the housing unit. The practice parameter from the American Academy of Child and Adolescent Psychiatry provides specific recommendations on therovision of mental health services within the juvenile correctional system.[69]

f. *Regular physical activity and nutritionally balanced meal plans appropriate for adolescents should be provided in all facilities.* Given the current national epidemic of obesity, attention to these aspects of a healthy lifestyle is even more critical.

g. *Pediatricians should encourage all correctional care facilities to adopt and comply with the NCCHC's "Standards for Health Services in Juvenile Detention and Confinement Facilities."*[76] Accreditation is encouraged as a means to reach desired levels of health care. Information regarding accreditation can be found at www.ncchc.org.

2. Developmentally Appropriate Confinement Facilities

Children and adolescents should be housed in facilities that are able to ad-

dress their specific developmental needs.

a. Pediatricians, adolescent health care specialists, mental health professionals, and drug and alcohol treatment providers should be consulted about health care policies and procedures governing all correctional care facilities in which children and adolescents are incarcerated.

b. Children and adolescents should be detained or incarcerated only in facilities with developmentally appropriate programs and staff trained to deal with their unique social, educational, recreational, and supervisory needs.

c. If children and adolescents must be housed in adult facilities, they should have routine access to the same developmentally appropriate environment and be separated by sight and sound from the adult population.

3. Integration of Available Systems of Care

a. *Coordination between juvenile justice system health care providers and community providers is essential.* Health care information elicited in the juvenile corrections setting should, at a minimum, be shared with the adolescent and, as appropriate (when not violating confidentiality), with the parent/legal guardian to allow for continuity of care and prevent unnecessary duplication of services. Pediatricians are a crucial link in the process of ensuring continuity of care between the community and the juvenile correctional system. Information should also be shared between the relevant community providers and correctional health care staff both on admission and at the time of release to ensure continuity of care. If the youth does not have a medical home, correctional staff should make every effort to identify a medical home within the community for that youth. Pediatricians should also coordinate with probation officers who are frequently entrusted with ensuring appropriate follow-up once the youth reenters the community.

b. *Electronic medical records available within the community should also be accessible by correctional health care staff.* Existing publicly accessed databases, such as state immunization data banks, should be used to document care provided in correctional facilities. With the evolving use of electronic medical records, consideration should be given to the need to share information between correctional institutions and community providers to ensure continuity of care.

c. *All youth incarcerated in the juvenile corrections systems should maintain eligibility for their existing health insurance benefits. Uninsured youth should be able to be enrolled in Medicaid while incarcerated.* Both Medicaid and private insurance should be available for all youth without suspension or termination during incarceration and without a lag for reinstatement on reentry into the community. Youth without insurance coverage before incarceration should be automatically made eligible for Medicaid at the time of incarceration so that access to appropriate care may be facilitated. Advocacy is needed at both the federal and state levels to amend existing regulations and ensure the provision of necessary medical services for these youth.

4. Treatment and Intervention

a. *Evidence-based mental health and substance abuse treatment interventions that have been shown to reduce recidivism should be adopted to improve long-term outcomes for incarcerated youth.* Pediatricians should advocate for adequate funding for implementation of programs such as multisystemic therapy and functional family therapy with the recognition that an increased investment in the short-term will lead to cost savings in terms of improved long-term outcomes.

b. *Resources should be invested in interventions that address the risk and protective factors involved with juvenile delinquency.* There should be emphasis on investing in interventions that address the related family and community factors associated with delinquency. Specific emphasis should be placed on factors that will improve SES such as educational achievement and employment, because these factors are highly correlated with both juvenile delinquency and overall health status.

c. *More nationally representative data are needed on the health needs of youth in the juvenile justice system.* Funding is needed to collect nationally representative data on youth involved in the correctional system to better inform programming needs and desired outcomes and help guide the choice of appropriate cost-effective interventions.

5. Advocacy

Pediatricians should work with their AAP chapters, the juvenile justice sections of their state judiciary and bar associations, and state and local governmental officials.

a. Pediatricians should advocate to ensure that the appropriate legislation and funding is available to provide for medical, educational, and behavioral health needs of juve-

niles while confined and on reentry into the community.

b. Pediatricians should advocate for adequate health insurance for all medical and behavioral health services for youth both during and after incarceration to ensure that resources are available to provide adequate and continuous care.

c. Pediatricians should support both efforts to decrease the number of youth incarcerated by advocating for interventional programs in the community that address risk and protective factors and legislation that requires education of law enforcement officers about at-risk youth and teaches skills to manage interactions with these youth.

American Academy of Pediatrics
DEDICATED TO THE HEALTH OF ALL CHILDREN™

Organizational Principles to Guide and Define the Child Health Care System and/or Improve the Health of all Children

Policy Statement—Health Equity and Children's Rights

abstract

Many children in the United States fail to reach their full health and developmental potential. Disparities in their health and well-being result from the complex interplay of multiple social and environmental determinants that are not adequately addressed by current standards of pediatric practice or public policy. Integrating the principles and practice of child health equity—children's rights, social justice, human capital investment, and health equity ethics—into pediatrics will address the root causes of child health disparities.

Promoting the principles and practice of equity-based clinical care, child advocacy, and child- and family-centered public policy will help to ensure that social and environmental determinants contribute positively to the health and well-being of children. The American Academy of Pediatrics and pediatricians can move the national focus from documenting child health disparities to advancing the principles and practice of child health equity and, in so doing, influence the worldwide practice of pediatrics and child health. All pediatricians, including primary care practitioners and medical and surgical subspecialists, can incorporate these principles into their practice of pediatrics and child health. Integration of these principles into competency-based training and board certification will secure their assimilation into all levels of pediatric practice. *Pediatrics* 2010;125:838–849

INTRODUCTION

The American Academy of Pediatrics (AAP) is dedicated to reducing health disparities and increasing health care equity for children and adolescents. Toward this end, health care equity was established as a universal principle of its agenda for children in 2005. In 2008, the AAP included health equity in its strategic plan and agenda that expanded this universal principle to focus on other factors that influence children's health and well-being in addition to health care. The AAP continues to expand its programs and policies to address child health disparities through practice, advocacy, education, research, and policy formulation, primarily through initiatives related to ensuring access for all children to quality, patient-centered, and culturally effective medical care. These efforts are critical and must continue but are not sufficient to achieve health equity for all children. The fundamental determinants of children's health and well-being, and subsequently the health and well-being of the adults they will become, are rooted in social, environmental, and behavioral factors that lie beyond the purview of the health care system.[1,2]

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

Health disparities in children, as summarized in an upcoming AAP technical report on racial and ethnic disparities,[3] will remain all too prevalent until these determinants are addressed through a national agenda on child health equity—an agenda informed by the global children's rights movement.[4,5] The AAP and pediatricians have critical roles to play in designing, building, participating in, and sustaining this national agenda. To fulfill these roles, pediatrics and pediatricians must expand beyond a focus on health care and health disparities to engage the broader context of child health equity. This policy statement defines the principles and practice of child health equity as a foundation and framework to support and guide the work of pediatrics and pediatricians in the delivery of clinical services, child advocacy, and policy formulation.

BACKGROUND INFORMATION

Differences between groups in status and outcomes are referred to as disparities. Disparities are often described in relation to socioeconomic position, ethnicity, race, geography, gender, and age or in the context of a combination of these and other factors. This is particularly true with respect to child health disparities in the United States, which are routinely defined as a function of multifactorial determinants.[6–8]

The distinction between the terms "disparity" and "inequity" is critically important. Whereas the term "disparity" only defines differences between groups, "inequity" describes the causes of disparities in the context of the social, economic, civil-political, cultural, and environmental conditions that are required to generate parity and equality. Inequities result in disparities in health status that are "unfair, unjust, avoidable and unnecessary."[9] By definition, these are amenable to change.[9]

Disparities in the well-being of children in the United States are growing.[10–13] These racial, ethnic, gender, and class-based disparities have profound implications for the welfare of children in the United States and for the adults they will become.[14–19] The sources of these disparities are deeply rooted in inequities in social and environmental determinants of health (eg, poverty, income inequality, maldistribution of educational and other resources, racism, and environmental injustice) and the failure of public policies to address them.[20–26] The number of children being marginalized by our society is escalating, and child poverty and other indicators of children's well-being rank the United States among the lowest of the industrialized nations in the world.[27,28]

STATEMENT OF THE PROBLEM

If we are to succeed in our efforts to eliminate disparities in the health and well-being of children and ensure that all children reach their full potential, the root causes of health disparities must be addressed. The principles of child health equity— children's rights, social justice, human capital investment, and health equity ethics—provide insight into these root causes and reveal the tools, skills, and strategies required to eliminate health disparities through equity-based clinical care, child advocacy, and policy formulation. Pediatricians and pediatrics have important roles to play in these endeavors, which will require substantive changes in our approach to training, clinical practice, child advocacy, policy formulation, and research.

RATIONALE

Inequities in the social and environmental determinants of children's health in the United States are pervasive and cumulative, affecting children from conception through adolescence. Children who experience inequities may fail to reach their full potential,[15–19] which is detrimental not only to them, their families, and the community but also to society in general. The gradient of inequities within societies is directly related to the degree of disparities.[2,29,30] Socially divided societies pay a cost in community cohesion, drug and alcohol abuse, mental health problems, children's physical development, crime, and other social problems.[31]

Why Do Health Disparities in Children Matter?

Eliminating health disparities would make a significant difference in the overall health of children. If health disparities in the United States were eliminated, such that all children had the same risks of adverse outcomes as those of the most economically privileged, the prevalence of poor outcomes (eg, low birth weight, cerebral palsy, intellectual disabilities, psychological problems, child abuse, disabilities attributable to intentional and unintentional injuries) would be reduced by 60% to 70%.[32–37]

Inequities in children's health also lead to disparities in adult health and well-being.[15–19] These inequities contribute to chronic adult illnesses and to the intergenerational perpetuation of poverty and ill health found in many communities (eg, obesity, diabetes, cardiovascular disease, poor educational outcomes, unemployment, poverty, early death, etc).[15–19,38,39] The burden of disease in low-income children and adults is costly, which puts huge pressures on health care systems.[40] Improving health equity for children should be among our highest priorities as a national strategy for improving the health and productivity of children and adults and decreasing health care costs.

Which Children Are Most at Risk?

Many children in the United States are marginalized by socioeconomic depri-

vation, social exclusion, racism, and discrimination. Populations of children at particular risk include those who are:

- living in severe and chronic poverty[7,20–23];
- from racial and ethnic minority groups[10–13];
- affected by drug and alcohol abuse[41,42];
- in foster care and public institutions[43,44];
- disabled and living with special health care needs that impair functions[45,46];
- living with violence[46–48];
- incarcerated in adult facilities or juvenile detention[49,50];
- from homeless families and/or live as homeless teenagers[51–53];
- from immigrant and refugee families[54–56]; and
- uninsured and/or without access to health, mental health, and dental care.[57,58]

The factors that lead to marginalization, social exclusion, and poverty are often coassociated.[25] For example, disability and racial and ethnic minority status are associated with poverty[6–10]; disabled children are at higher risk of abuse[59]; and family stress that arises from poverty and poor health is associated with family breakdown, violence, and homelessness.[32,47,48,51,52] In the United States, the effects of racism beyond its association with poverty cannot be ignored.[7]

Children who experience multiple compounding risk factors are most likely to have their rights ignored and/or abused. Examples include violence against children in foster care,[60] discrimination against immigrant and refugee children,[61] inadequate mental health services for children in detention,[49,50] and the experience of children in the judicial and juvenile justice systems.[49,50,62,63]

Relevance of Child Health Equity

Life-course epidemiology and science have advanced our understanding of the mechanisms by which the complex ecology of social and environmental determinants generate and perpetuate child health disparities.[14–19] They are thought to result from the cumulative exposure to risk counterbalanced by protective factors over the life course. There seem to be critical periods in the life course, most notably during pregnancy and early childhood, when risk and protective exposures have the greatest effect on health.[14–19,25] Rapid changes in the demography of US children, transitions in the epidemiology of children's health and illness,[64] and advances in life-course epidemiology and science[14–19] establish the imperative for a new paradigm for conceptualizing and addressing the health and well-being of children. Social and environmental degradation,[20–23,31,32] discrimination and marginalization of children,[7,8] and climate change and globalization[65–68] are among the factors that contribute to this transformation of children and childhood and the millennial morbidities that affect them.[69]

The relevance and importance of child health equity to the well-being of children, families, communities, and society in the United States and throughout the world cannot be overstated. These and other societal transitions will require new and expanded roles and functions of pediatricians if pediatrics is to remain viable and relevant to the health and well-being of children.

CHILD HEALTH EQUITY

Child health equity, as conceptualized in this policy statement, is composed of 4 elements: children's rights, social justice, human capital investment, and health equity ethics. The principles encompassed within these components provide perspective and knowledge that can be integrated into the practice of primary care and subspecialty pediatrics and child health. They can be operationalized as tools, skills, and strategies for promoting children's health, address health disparities, and advance equity in child health.

Children's Rights and the United Nations Convention on the Rights of the Child

The United Nations (UN) Convention on the Rights of the Child (Convention) and the integration of its principles into the practice of pediatrics provide powerful tools and strategies to respond to the root causes of contemporary child health morbidities and disparities.[70] The articles of the Convention define the rights of children in the context of their social, economic, cultural, and civil-political status in society. In its entirety, the Convention redefines childhood, the status of children in society, and what constitutes children's health and well-being. The Convention establishes a template for child advocacy, a holistic approach to fulfilling children's needs, an inventory of optimal health outcomes, and a guide for health systems research. (See Table 1 for a list of rights contained in the Convention.) Consistent with the philosophy and policies of the AAP related to the medical home and family-centered care,[71,72] the Convention references the family as the fundamental group of society, affirms the principle of respect for family autonomy, and obligates societies to fulfill the rights of children by providing families with access to the resources they require to meet the needs of their children.[73]

The rights defined by the Convention establish the essential and holistic conditions required to ensure that children

TABLE 1 Relating the Taxonomy of Children's Rights to the Principles of Medical Ethics

Taxonomy of Rights	Inventory of Rights	Ethics Principles	Indicators
Economic	Adequate standard of living Social security Protection from economic exploitation	Justice: distributive and allocative	Is there a morally defensible system for allocating resources?
Cultural	Respect for language, culture, and religion Abolition of traditional practices likely to be prejudicial to a child's health	Autonomy	Do children feel that they are respected?
Social	Promotion of a child's best interests Life, survival, and development Best possible health and access to health care Education Play Family life or alternative care Family reunification Fullest social inclusion for disabled children Support for parents to ensure protection of children's rights	Beneficence	Do participants in the policy-making process act with charity and kindness?
Protective	Protection from abuse and exploitation Protection from armed conflict Protection from harmful drugs Protection from trafficking Rehabilitative care after abuse or neglect	Nonmaleficence	Is the dictate of "primum no nocere" adhered to in decisions made related to the child?
Civil and political	Heard and taken seriously Freedom from discrimination in the exercise of rights Freedom of religion, association, and expression Privacy and information Respect for physical and personal integrity Freedom from all forms of violence, torture, or other cruel, inhuman, or degrading treatment Due process in the law Recognition of the importance of treating the child with respect within the justice system Not to be detained arbitrarily	Autonomy	Do children consider themselves participants in their environment?

achieve an optimal state of well-being. Respect for all the rights embodied in the Convention is required to achieve this goal. No rights take priority over others.[70,74] Although the United States is 1 of only 2 countries in the world that has not ratified the Convention (Somalia being the other), the Convention's articles are, nevertheless, as relevant to American children and society as they are to children elsewhere. As presented in following sections detailing the implications of an equity-based approach to practice, the promotion and protection of children's rights can be used to guide the work of pediatricians as clinicians and child advocates and the AAP in its public-policy endeavors to improve children's health and reduce health disparities.

Social Justice

Social justice refers to the fair distribution of resources. Resource distribution results from public- and private-sector policy decisions in venues and institutions at all levels of society. Pediatricians and the AAP can work to ensure that the best interests of children (Convention, article 3) are considered whenever and wherever policy decisions are made that relate to resource distribution (eg, in clinical practice, hospitals, schools, and communities), even if these decisions seem to have little relevance to children. They also can ensure that all such decisions do not discriminate against children on the basis of race, ethnicity, economic status, gender, disability, and/or immigration status (Convention, article 2).[70] Examples of social justice issues that relate directly and indirectly to the distribution of resources that affect the health and well-being of children are listed in Table 2. Pediatricians and child health professionals, in collaboration with colleagues from other child-serving professions, community leaders, parents, children, youth, and young adults transitioning from pediatric to adult care, have critical roles to play in pol-

TABLE 2 Examples of Social Justice Issues That Affect Children's Health and Well-being

Access to healthy housing
Child-friendly neighborhood development
Land use that considers the best interest of children
Access to recreational facilities
Convenient and affordable transportation
Sufficient education resources
Freedom from gender discrimination
Required resources for disabled children
Adequate hospital budgets
Access to quality prekindergarten and early learning resources
Child- and infant-friendly hospitals
Appropriate physician reimbursement
Safe workplace conditions for adolescents

icy development if social justice related to children is to prevail.

Human Capital Investment

Capital investment in children reflects the moral and ethical commitment of society and communities to invest resources required to improve the health and well-being of all children and decrease disparities. The return on this capital investment can be measured in a traditional context of monetary value, but a new currency also must emerge as equity-based measures of health and well-being.[75,76] Capital investment in children is conceptualized as being composed of 5 forms of capital: social, economic, environmental, educational, and personal capital.

Social Capital

Social capital establishes value for human relationships that affect children. In this regard, a working definition relevant to pediatricians is that social capital relates to social relationships in the family, institutions, and communities (eg, schools, clubs, and faith-based institutions) and among peers that positively influence the health and well-being of children.

Research has shown that a higher level of social capital in families and communities is associated with better health outcomes for children. Runyan et al[77–79] have demonstrated the positive effects of social capital in moderating the impact of violence and unfavorable social environments on child health outcomes. Newly developed tools and approaches to care, including the medical home,[71,80] family-centered care,[72] psychosocial and environmental screening, Bright Futures,[81] and social capital scales,[72] can help pediatricians and others understand the concept of social capital and integrate its principles into practice.[82,83]

Economic Capital

Economic investment of a country or community's wealth in children has a direct effect on the health and well-being of children.[84–91] Children who live in poverty have poorer health and outcomes related to virtually every measure of well-being.[7,20–23] Income inequality also seems to have a negative effect on child and adult health.[84,85] Public policies that transfer wealth directly to families, and in particular to children, in the form of cash subsidies or services (eg, child care, medical care, food support, extended paid maternity leave, child allowances, housing subsidies) have a positive effect on children.[86,88] Indirect investment in children through expansion of the Earned Income Tax Credit, for example, has the potential to lift families out of poverty and improve the well-being of children.[87] Comparisons between economically developed countries consistently show a direct relationship between wealth transfer and children's well-being.[88,89] The timing of this investment is critically important, with the largest return resulting from investment in young children and families.[90,91]

Environmental Capital

The environment in which children grow and develop has a profound influence on their health and well-being as children and into adulthood. Given our rapidly advancing knowledge of early brain development,[14,19,92,93] the differential effects of the physical environment on the developing child,[94–96] epigenetics,[94,96] the prevalence of environmental injustice,[96] and the potential effects of climate change on children,[65–67,97–100] it is incumbent on society to consider the environment and environmental justice in the context of child health equity.

Educational Capital

Education is a fundamental right of children.[70] Policies related to access to quality education, particularly early learning,[90,91,101,102] and those related to children with special needs[91] reflect the transfer of educational capital (resources) to children. Such policies are important measures of equity.[28,75] The return on the investment in early education has been well defined.[90,91] The effects of education on health outcomes and measures of child and adult well-being have been similarly documented.[90,91,103]

Personal Capital

Investment in the dignity of children and ensuring that all children, without discrimination, have a legitimate and realistic expectation to enjoy optimal health and fulfill their dreams and aspirations depends on equitable public policy. Investment in the personal capital of children and families is a fundamental issue of equity, a reflection of the values of a community and a measure of its humanity. It is also an investment in the health and well-being of an individual over his or her life course—from infancy through adulthood—and an essential component of the role of pediatricians as they care for and mentor the patients whom they serve.

Translation of Principles of Human-Capital Investment Into Practice

Contextualizing child advocacy as the expansion of capital investment in children through clinical care, community development, and policy generation provides new strategies for pediatricians and the AAP to improve the health and well-being of all children. Using social capital as an example, at the clinical interface, pediatricians can include questions about the child's network of social relationships as part of routine anticipatory guidance and counsel parents about the importance of these relationships to their children. Referrals to mentoring, athletics, quality child care, and other resources

in the community can be made. At the community and policy levels, pediatricians can work with all sectors of the community to advocate for and generate public policies that ensure equitable access and quality improvements in early learning and after-school programs, scouting and Boys and Girls Clubs, community centers and recreational programs, and other resources that will increase children's social capital.

Other examples of the translation of the principles of human capital investment into practice include identifying and responding to clinical issues resulting from (1) a family's lack of access to basic needs (financial capital), (2) detrimental environmental exposures (environmental capital), (3) inadequate educational services for children with special needs (educational capital), and (4) a child's poor sense of self-efficacy and lack of a vision for the future (personal capital). Pediatricians and the AAP are in a unique position to advocate for expanded capital investments in children at the individual and community levels. At the public-policy level, the AAP can work individually and with other child advocacy organizations to ensure that all forms of capital are invested in children as a matter of public- and private-sector policy.

Health Equity Ethics

Health equity ethics adapts and applies the traditional principles of medical ethics, (eg, justice, beneficence, nonmaleficence, and autonomy) to a child rights framework.[104] It defines an expanded set of rights-based ethical principles that can be used as a tool for the consideration and analysis of issues related to the components of child health equity.

The principles of medical ethics relate directly to the 4 primary principles of children's rights, as defined by the UN Convention on the Rights of the Child: nondiscrimination (article 2), best interests (article 3), survival and development (article 6), and providing a voice and listening to children (article 12).[70] Table 3 relates the 4 core principles of children's rights to the 4 principles of medical ethics. Table 1 presents an inventory of the rights defined by the articles in the UN Convention, cross-referenced with the 4 principles of medical ethics. Table 1 also lists examples of indicators that could be used to measure policies that affect these rights. With this matrix, a rights-based perspective can be integrated into ethical decision-making, including the work of hospital ethics committees, to address issues that go beyond primarily biomedical concerns, enrich dialogue and discussion, and provide new tools for clinical practice, child advocacy, and policy formulation.[105]

TABLE 3 Relating the Core Principles of the UN Convention on the Rights of the Child to the Principles of Medical Ethics

Children's Rights Principles	Medical Ethics Principles
Article 2: Nondiscrimination	Justice
Article 3: Best interests	Beneficence
Article 6: Survival and development	Nonmaleficence
Article 12: Providing children a voice and listening to them	Autonomy

IMPLICATIONS FOR PRACTICE

The principles and practice of child health equity provide tangible knowledge, tools, skills, and strategies that can be applied by pediatricians to clinical care, child advocacy, and the formulation of public policies. The principles provide a foundation and framework to better prepare clinicians and child-serving institutions to ensure the fulfillment of children's rights to:

- child- and family-centered pediatric practices and institutions that consider the best interests of all children without discrimination when decisions are made[70–72,106–109];
- confidentiality, privacy, and dignity[70,107–109];
- have a voice and be listened to, particularly in clinical decision making and informed consent[70,107–109];
- information that is available in a language and at a developmental level they will understand[70,107–109];
- access to a full continuum of health care without discrimination on the basis of (1) insurance, refugee, and/or immigration status,[51–58] (2) disabilities,[33,36,46] and/or (3) placement in foster care, the juvenile justice system, or other public venues[43,44,49,50];
- optimal pain control and symptom management, sedation for invasive procedures, and palliative and end-of-life care that conform with international rights-based standards of care for child health practices[108,109];
- optimal nutrition, including breastfeeding, through compliance with international standards for infant nutrition[106,110] and by providing mothers with the information and resources required to ensure that they have the capacity and option to make and implement decisions that are in the best interests of their infants and children[106];
- evidence-based health care;
- access to psychosocial and mental health services, including education and recreation in the hospital setting[107–109]; and
- protection from all forms of violence and exploitation.[70,107–108]

For child-serving institutions, admission and discharge, quality improvement, and other practice and organizational policies and protocols should reflect this equity- and rights-based approach to care. All staff, including physicians, nurses, paraprofessionals, and support personnel, should be

oriented and trained to implement them. Ethics committees should integrate the principles of health equity and children's rights into their deliberations, and a children's charter, modeled after the charter adopted by the European Association for Children in Hospital (EACH),[108] should be developed and displayed by all practices and institutions that care for children.[107–109] The EACH charter enumerates the rights-based standards of care that are required to be fulfilled by health care institutions that serve children in Europe.

With respect to clinical care, pediatricians can implement the principles of health equity to address the root social and environmental causes of childhood morbidity, as well as the prevention and treatment of the illnesses they cause. An equity-based pediatric practice would approach:

- well-child care by promoting Bright Futures' emphasis on nurturing environments for all children and adolescents[81];
- asthma and lead poisoning in the context of a child's right to adequate housing and protection from environmental exposures[70,94–96];
- obesity and diabetes as a function of a child's right to breastfeed and access quality food and recreation[70,106,110];
- injury as a right to protection from environmental exposures and the consideration and promotion of the best interests of children when decisions are being made about the built environment[70,94–96,111];
- school failure as a child's right to access quality early learning environments that foster optimal development through childhood, child care, and school-based services[70,90,91];
- developmental, behavioral, and mental health problems as a child's right to nurturing home and family environments that protect them from chronic traumatic stress, and access to early prevention, diagnostic, and therapeutic services[70]; and
- dental disease as a child's right to adequate nutrition and access to dental care.[70]

The role of all pediatricians thus expands from the provision of clinical care to include child advocacy at the clinical and community levels to address root causes of childhood illnesses and morbidities. Multiple tools are available to support clinicians in this regard,[70,75,80–82,106–120] although additional training will be required to prepare them to implement this new practice paradigm. Practice standards must evolve to support this equity-based practice paradigm, and reimbursement strategies must be pursued to ensure that the economics of practice support this approach to care. Pediatricians and organized medicine must work to make this a reality, as they have succeeded in the past to advance universal health insurance systems for children, expand specialized insurance coverage and services for vulnerable populations of children, ensure reimbursement for well-child care, and, most recently, advance enhanced payment for patient-centered care.

The extent to which pediatricians become directly involved with the formulation of public policy will vary, but all must be prepared to support their peers, the AAP, and other child-serving institutions, organizations, and professional societies in their public policy endeavors in respect of children and families. Pediatricians have many available partners in these endeavors in the fields of law, social work, economics, business, and public health, as well as parents, children, youth, and transitioning adults.

RECOMMENDATIONS

The AAP and pediatricians have synergistic roles to play to ensure that social and environmental determinants of health are addressed through clinical practice, child advocacy, and policy formulation to promote health and eliminate inequities that result in child health disparities. This is an explicit goal of the US Department of Health and Human Services *Healthy People 2010* initiative.[116]

American Academy of Pediatrics

Health equity contributes to optimal child health and reduction of health disparities through the generation of appropriate public policies, health-enhancing public programs, and a clinical focus on issues of children's rights, social justice, the environment, and human capital investment. Through education and training in the relevance of the components of child health equity to clinical care, child advocacy, medical education, research, and policy formulation; and the integration of the principles and practice of child health equity into its endeavors to advance health outcomes for children, the AAP can influence all aspects of child health practice, improve children's health, and decrease health disparities.

Toward this end, the AAP, in collaboration with the public and private sector and community, state, and national organizations and institutions, will advocate at all levels of society for:

1. Integration of the principles and practice of child health equity into AAP policies and endeavors.
2. Consideration of the best interests of children by policy makers when legislation and decisions are being made that could potentially affect children.[70,106–111]
3. Access to linguistic and developmentally appropriate information

required by children and families for them to be informed decision makers concerning issues that affect them and their communities.[70,107–109]

4. Children's participation and involvement in decision making regarding issues that affect them.[70,107–109]
5. Equitable access to relevant health services for all children.[70]
6. Exploration of the use of the principles of child health equity and the articles of the UN Convention on the Rights of the Child to frame and measure private- and public-sector clinical care, advocacy, and policy formulation.[70]
7. Routine use of child health impact assessments to determine the potential effects of legislation and policy decisions on children's health and well-being.[115]
8. Examination of administrative models for protecting children's rights, such as the appointment of independent children's rights commissioners (ombudspersons) who are accessible to all children and families to ensure that children (*a*) are not discriminated against, (*b*) have their best interests considered by decision makers, (*c*) have access to information and a voice in their communities, and (*d*) have all their rights, as delineated in the UN Convention, fulfilled.[117]
9. Development of child-friendly cities. The Child Friendly Cities movement is a global effort, similar in some respects to "America's Promise," to establish communities in which the voices, needs, priorities, and rights of children are an integral part of public policies, programs, and decisions.[111,121]
10. The reduction of child poverty; racism; individual, structural, and institutional discrimination; gender inequities; and environmental injustice through legislative advocacy and policy development.[31,90,91,93,96,118]
11. Legislation to support parents and parenting at home, in the workplace, and in the community.[70,73,90,91]
12. Development of national health equity indicators that are linked to the social and environmental determinants of children's health.[75,76,113,119,120]
13. Implementation of a national child health equity research initiative to develop evidence-based interventions that target the social and environmental determinants of children's health.[122]
14. Development of competencies and curricula for training professionals in child health equity.[114]
15. Ratification of the UN Convention on the Rights of the Child.[70,123] The AAP, in collaboration with other national and international organizations, should work with the UN Committee on the Rights of the Child to ensure that the implementation of the articles of the Convention reflect new scientific knowledge and respond to the evolving needs of children.

Clinical Practice

Pediatricians have an important role to play at all levels of clinical practice and child advocacy to improve the health of children and reduce health disparities. Pediatricians can identify and intervene to shape the social and environmental determinants that affect the health of their patients. They can work with communities to provide support to families and ensure the equitable delivery of health services. As influential members of communities, pediatricians can access the media and decision makers to advocate for changes in the environments in which children live. They also can use their close links with local authorities and community services to ensure that policies are implemented and work to the benefit of all children.

Toward these ends, pediatricians can support efforts to:

1. Integrate the principles of child health equity (eg, children's rights, social justice, human-capital investment, and health-equity ethics) into their practices.
2. Use individual clinical encounters as opportunities to screen and address the social, economic, educational, environmental, and personal-capital needs of the children and families they serve.
3. Use the principles of child health equity as the foundation for child advocacy and policy development.
4. Raise awareness of the relevance of social and environmental determinants to children's health and well-being in their communities and among legislators and other policy makers.
5. Decrease child health disparities through the implementation of the principles and practice of child health equity.

SUMMARY

To eliminate discrimination and improve the health of all children, reduce child health disparities, and advance child health equity, the root social and environmental determinants of children's health must be identified and mitigated. There is an extensive evidence base that links the social epidemiology of these determinants to children's well-being. Advances in life-course sciences have expanded our knowledge of how these determinants affect the biology of children's health and the trajectory of adult health outcomes. The principles and practice of child health equity—children's rights, social justice, human capital investment, and health equity ethics—provide perspective and knowledge to

reorient pediatricians and pediatrics to the importance of social and environmental determinants to the well-being of children. They provide the tools, skills, and strategies to eliminate health disparities and ensure that every child reaches his or her full potential for health and development.

American Academy of Pediatrics
DEDICATED TO THE HEALTH OF ALL CHILDREN™

Policy Statement—Health Information Technology and the Medical Home

abstract

FREE

The American Academy of Pediatrics (AAP) supports development and universal implementation of a comprehensive electronic infrastructure to support pediatric information functions of the medical home. These functions include (1) timely and continuous management and tracking of health data and services over a patient's lifetime for all providers, patients, families, and guardians, (2) comprehensive organization and secure transfer of health data during patient-care transitions between providers, institutions, and practices, (3) establishment and maintenance of central coordination of a patient's health information among multiple repositories (including personal health records and information exchanges), (4) translation of evidence into actionable clinical decision support, and (5) reuse of archived clinical data for continuous quality improvement. The AAP supports universal, secure, and vendor-neutral portability of health information for all patients contained within the medical home across all care settings (ambulatory practices, inpatient settings, emergency departments, pharmacies, consultants, support service providers, and therapists) for multiple purposes including direct care, personal health records, public health, and registries. The AAP also supports financial incentives that promote the development of information tools that meet the needs of pediatric workflows and that appropriately recognize the added value of medical homes to pediatric care. *Pediatrics* 2011;127:978–982

INTRODUCTION

The Medical Home, the Strategic Plan of the American Academy of Pediatrics, and Health Information Management

The medical home[1] model is the central organizing principle for health care management for all children, including those with special health care needs.[2] The ideal medical home (1) translates evidence into high-quality pediatric care that is measurable, (2) provides coordinated pediatric primary and specialty care for all children, and (3) sustains pediatric practice through fair payment, cost-efficiency, and recognition of the value of pediatric primary care. The medical home model supports the strategic plan of the American Academy of Pediatrics (AAP)[3] by unifying evidence-based practice and the business of pediatric care through patient/family-provider relationships that are based on trust and effective, reliable information management.

Medical Home Information Functions

The medical home must centralize and support the primary care relationship between the patient/family and health care provider through

well-designed and well-implemented health information management. Critical information-management functions that support and enhance medical home principles include:

- establishment and maintenance of assurance (confidentiality, integrity, availability, currency, continuity, and accuracy) of patient health information;
- comprehensive organization and management of patient-care information (eg, encounter data, prescriptions, referrals, medication reconciliations) over a patient's lifetime and across all providers and services (eg, pharmacies, laboratories, imaging services, consultants, and other providers); comprehensive and accurate collection of social, demographic, and genetic histories (including family trees) with linkage to maternal and perinatal/natal data; and translation of evidence into patient-centered care plans that implement and track care;
- timely measurement of clinical effectiveness of care and effects on patient health outcomes;
- secure communication of clinical and business functions (documentation, coding, billing, accounting) among providers, the patient/family, and other members of the health care team (including insurance companies);
- education and sharing of health knowledge, information, and data for informed and shared decision-making by patients/families; and
- reuse of accrued and aggregated clinical data and experience for quality improvement, practitioner assessment, maintenance of certification, research, and program-planning in a manner that does not compromise patient confidentiality and does not require additional consent or assent.

Supporting Medical Homes With Information Technology

Improving the Continuity of Care

Medical home information-management systems must facilitate accurate, real-time collection, storage, retrieval, review, and communication of patient health information over time and across providers. For pediatrics, the core of such systems is a lifelong, electronic health record (EHR). Basic requirements for the content of an EHR for general[4] and inpatient[5] pediatric care have been articulated. Ambulatory medical home information systems must support:

- longitudinal tracking and continuity of health maintenance and chronic disease management via clinical decision-support tools that adequately meet the needs of pediatric care;
- coordination and comanagement of care provided to children with special health care needs during complex episodes that require numerous providers (primary care providers, specialists, inpatient care) via real-time communications and health information networks;
- patient transfers that span different care episodes (ie, ambulatory care to emergency care, emergency care to inpatient or critical care, critical care to rehabilitation care, inpatient care to home), including comprehensive and systematic communication of health information required for all care before, during, and after transfers between providers via structured care-transition tools and processes;
- patient-care transitions between medical homes—such as transitions from pediatric to adult medical homes[6]—via universal (ie, vendor/technology-neutral) portability standards for patient records among different medical home information systems;
- continuous quality improvement of all health care processes and provider performance over the entire patient life span via adoption and use of inclusive standardized age-specific (prenatal to elderly) data and measures; and
- information assurance: (*a*) confidentiality (authentication and authorization) as required by local and national regulations and pertinent legislation for all pediatric populations (including adolescents and children in foster care); (*b*) content and source integrity through audit trails and disaster recovery and notification protocols; and (*c*) real-time availability of patient information to care providers who need it, whenever they need it.

Real-time availability of patient information from the medical home to other entities (ie, to patients, families, pharmacies, laboratories, hospitals, emergency departments, immunization information systems, registries, other practices) requires the establishment of secure and compliant health care information communications networks. Such networks and all tools (eg, personal health records, electronic prescribing, ambulatory order entry, secure messaging, and data entry) that access patient information from the medical home must support information assurance in transit (and at rest) between entities or electronic applications.

Improving the Efficiency and Safety of Care

Medical home information systems must help enhance the efficiency and cost-effectiveness of care. Systems can help improve efficiency through reduction (if not elimination) of unnec-

essary service duplications, such as redundant laboratory testing or imaging studies, by centralizing and making available past and current results to authorized providers in a just-in-time fashion.

Automation of repetitive tasks, such as electronic prescribing and clinical decision support (electronic checklists, reminders, and alerts) for ongoing scheduled clinical tasks, such as timely immunization administration, must improve efficiency, reliability, and resilience of health care processes by removing barriers and ambiguities that lead to failures and patient harm. Medical home processes in need of this type of improvement include medication-tracking and reconciliation (especially during patient transfers and care transitions and product recalls), vaccine management and catch-up (especially during shortages), and medical and durable equipment management for children with special health care needs.

To maximize the efficiency and safety of pediatric care, information systems must connect and facilitate clear communication among all partners within the care network. In addition to having easy access to the physical networks that facilitate communication, all entities within the care network must support information-interchange standards (such as the ASTM/HL7 Continuity of Care Record/Document[7]) that include relevant concepts (eg, weight-based [mg/kg] medication dosing) that meet the needs of pediatric patients and their care.

Improving the Quality of Care

Medical home information systems must support continuous quality improvement. Systems must facilitate:

- timely translation of evidence into actionable practice protocols;
- consistent and measurable delivery of evidence-based clinical care; and
- continuous collection and reporting of quality indicators based on clinical data.

As care quality is increasingly defined by indicators on the basis of clinical practice data (as opposed to claims data) by payers and regulators, information systems must be designed and implemented to collect and display, process, and report measures derived directly from clinical care and outcomes data. To provide true measures of clinical effectiveness and cost-effectiveness, it will become necessary to design systems and measures that link performance indicators to "episodes of care" that go beyond simple "encounters."

To translate current evidence into practice, systems must support incorporation of current guidelines into actionable practice tools. Tools such as checklists and clinical decision support must be incorporated into electronic encounter forms and other clinician interfaces that can collect performance data that demonstrate the impact of guideline implementation within specific care settings.

Finally, as a potential source of ongoing accrued clinical data, medical home information systems must make such clinical data available to support quality improvement on multiple levels: to provide data for performance feedback (for continuous professional development and maintenance of certification) at the level of the individual clinician; to develop and refine clinical decision support and to assess performance (data for programs such as eQIPP [Education in Quality Improvement for Pediatric Practice][8]) at the practice level; and to pool data from individual medical home information systems (to health information exchanges) for public health research and planning at community and population levels.

RECOMMENDATIONS

The AAP supports:

1. Development, implementation, and widespread deployment of a comprehensive electronic infrastructure to support pediatric information-management functions of the family-centered medical home. These functions include (*a*) management and tracking of patient health and services over a patient's lifetime across multiple providers, (*b*) comprehensive, efficient, and timely transfer of health data for safe patient transitions among providers, institutions, and practices, (*c*) establishment of central coordination of a patient's health information among multiple repositories (including personal health records and information exchange), (*d*) translation of evidence into actionable protocols and clinical decision support, and (*e*) reuse of archived clinical data for continuous quality improvement and public health research.
2. Formal and centralized advocacy in legislative and technical arenas to promote the development, implementation, and widespread adoption of tools to support pediatric information functions in medical home information systems, including (*a*) pediatric-specific quality measures based on clinical data, (*b*) data standards that facilitate electronic collection, processing, and reporting of pediatric-specific and pediatric-appropriate clinical data from medical homes for quality improvement for practices, continuous professional development of providers, regulatory reporting, and population-based health research, and (*c*) health information exchanges that connect medical homes to other sectors of the health care environment.
3. Universal portability of health information to other entities including per-

sonal health records, pharmacy, laboratory, and imaging information systems; other patient electronic information systems (regardless of vendor); and registries for research and resource management.

4. Creation of financial incentives to (*a*) promote adoption of the medical home model in primary and specialty care, (*b*) design, implement, and deploy health information technologies that meet pediatric requirements for quality and safety, and (*c*) promote widespread universal adoption of such technologies (including education and training) into medical home information systems.

Barriers to Overcome

Challenges to these recommendations include:

- Need for universal bidirectional interoperability of systems—As interconnected systems evolve, there is increasing need to create and maintain bidirectional exchange of data from EHRs to practice-management and billing/scheduling systems, insurance information systems, and health information exchanges. Interoperability is vulnerable to loss when systems change; therefore, universal standards for maintaining data-sharing among systems are needed.
- Need for centralized leadership—As the movement to increase adoption of EHRs and associated health information technology accelerates, so does the need for a central organizing entity for pediatric-specific technical, legislative, and advocacy efforts. Such an entity must work to align incentives and help pediatric practices navigate the changes that will be required to promote family-centered medical homes and health information technology adoption. These evolving needs will require the AAP[9] to work in partnership with practices, vendors, and other stakeholders in the best interests of child health to build national and regional health information networks that meet the needs of pediatric care. An important area for initial technical work is in the development of a pediatric EHR format as part of the Child Health Insurance Reauthorization Act (CHIPRA).[10] The AAP has established the Child Health Informatics Center[11] to lead in some of these efforts.
- Financial uncertainty—Pediatric practices bear the risks and costs of health information technology adoption but do not currently see financial returns on those investments. Therefore, financial incentives and assurances that mitigate risks of adoption and that provide return on investments to practices are needed if wider pediatric adoption of health information technology is the target goal. Federal efforts include providing financial incentives for "meaningful use" of "certified products" that extend to all pediatric practices.[12]
- Privacy, security, and information ownership—Privacy laws, designed to provide patients with particular and well-recognized benefits, pose implementation challenges for providing assurance of confidentiality, integrity, and availability of pediatric patient data. In addition to jurisdictional variations in laws surrounding patient privacy, there are technical, political, and ethical issues surrounding information management for children with conditions such as HIV or rare diseases, adolescent privacy and confidentiality issues, and of confidential data stored in health information exchanges. In addition, the progressive management, regulation, and ownership of archived personal health information and its reuse as children reach the age of majority are unclear.
- Practitioner resistance—The technical challenges in implementing electronic information systems in ambulatory settings are daunting for many practices, especially smaller ones. The work and cost of selecting and implementing a system is compounded by the work and cost of converting existing practice data and infrastructure to fit an electronic record, and the loss of productivity during deployment may deter many practices from adoption. In addition, practices are vulnerable to changes in health information technology vendor choices that may require additional costly changes as markets change.

CLINICAL REPORT
Guidance for the Clinician in Rendering Pediatric Care

Tracy L. Trotter, MD; Judith G. Hall, OC, MD; and the Committee on Genetics

Health Supervision for Children With Achondroplasia

ABSTRACT. Achondroplasia is the most common condition associated with disproportionate short stature. Substantial information is available concerning the natural history and anticipatory health supervision needs in children with this dwarfing disorder. Most children with achondroplasia have delayed motor milestones, problems with persistent or recurrent middle-ear dysfunction, and bowing of the lower legs. Less often, infants and children may have serious health consequences related to hydrocephalus, craniocervical junction compression, upper-airway obstruction, or thoracolumbar kyphosis. Anticipatory care should be directed at identifying children who are at high risk and intervening to prevent serious sequelae. This report is designed to help the pediatrician care for children with achondroplasia and their families. ***Pediatrics*** **2005;116:771–783;** ***achondroplasia, short stature, children, health supervision.***

ABBREVIATIONS. OFC, occipital-frontal circumference; CT, computed tomography.

INTRODUCTION

This clinical report is designed to assist the pediatrician in caring for children with achondroplasia confirmed by radiographs and physical features. Although pediatricians usually first see children with achondroplasia during infancy, occasionally they are called on to advise a pregnant woman who has been informed of the prenatal diagnosis of achondroplasia or asked to examine a newborn to help establish the diagnosis. Therefore, this report offers advice for these situations as well.

Substantial new information has appeared since publication of the first policy statement on health supervision of children with achondroplasia.[1] In particular, a great deal has been learned about the molecular genetics of the disorder.[2] In addition, a more complete understanding of how certain serious complications can be minimized or avoided has accrued.[3] The new information is incorporated into this report, which is a revision of the original policy statement.

Achondroplasia is the most common condition associated with severe disproportionate short stature.[4] The diagnosis can usually be made on the basis of clinical characteristics and very specific features on radiographs, which include contracted base of the skull, square shape of the pelvis with a small sacrosciatic notch, short pedicles of the vertebrae, rhizomelic (proximal) shortening of the long bones, trident hands, a normal-length trunk, proximal femoral radiolucency, and (by midchildhood) a characteristic chevron shape of the distal femoral epiphysis. Other rhizomelic dwarfing disorders such as hypochondroplasia and thanatophoric dysplasia are part of the differential diagnosis, but achondroplasia usually can be distinguished from them because the changes in hypochondroplasia are milder and the changes in thanatophoric dysplasia are much more severe and invariably lethal. Achondroplasia is an autosomal dominant disorder, but approximately 75% of cases represent new dominant mutations. Achondroplasia is caused by mutation in the gene that codes for the fibroblast growth factor receptor type 3 (*FGFR3*).[5–7] Because virtually all of the causal mutations occur at exactly the same place within the gene,[7] molecular testing is straightforward. It is not necessary to perform molecular testing in every child with a clinical diagnosis of achondroplasia. However, *FGFR3* testing should be performed in children who are in any way atypical or in circumstances in which differentiation from similar disorders, such as hypochondroplasia, is not certain. Such children also should be referred for clinical genetic evaluation.

A great deal is known about the natural history of achondroplasia that can be shared with the family.[3,8] The average adult height in achondroplasia is approximately 4 ft for men and women (Figs 1 and 2).[9] The most common complication, occurring in adulthood, is related to lumbosacral spinal stenosis with compression of the spinal cord or nerve roots.[10,11] This complication is usually treatable by surgical decompression if it is diagnosed at an early stage.

Most children with achondroplasia do well. However, children affected with achondroplasia commonly have delayed motor milestones (Fig 3),[12,13] otitis media, and bowing of the lower legs.[14] Less commonly, infants and children may have serious health consequences related to hydrocephalus, craniocervical junction compression, upper-airway obstruction, or thoracolumbar kyphosis. Although they are less common, anticipatory care should be directed at identifying children who are at high risk and intervening to prevent serious sequelae. Most individuals with achondroplasia are of normal intelligence and are able to lead independent and pro-

The guidance in this report does not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

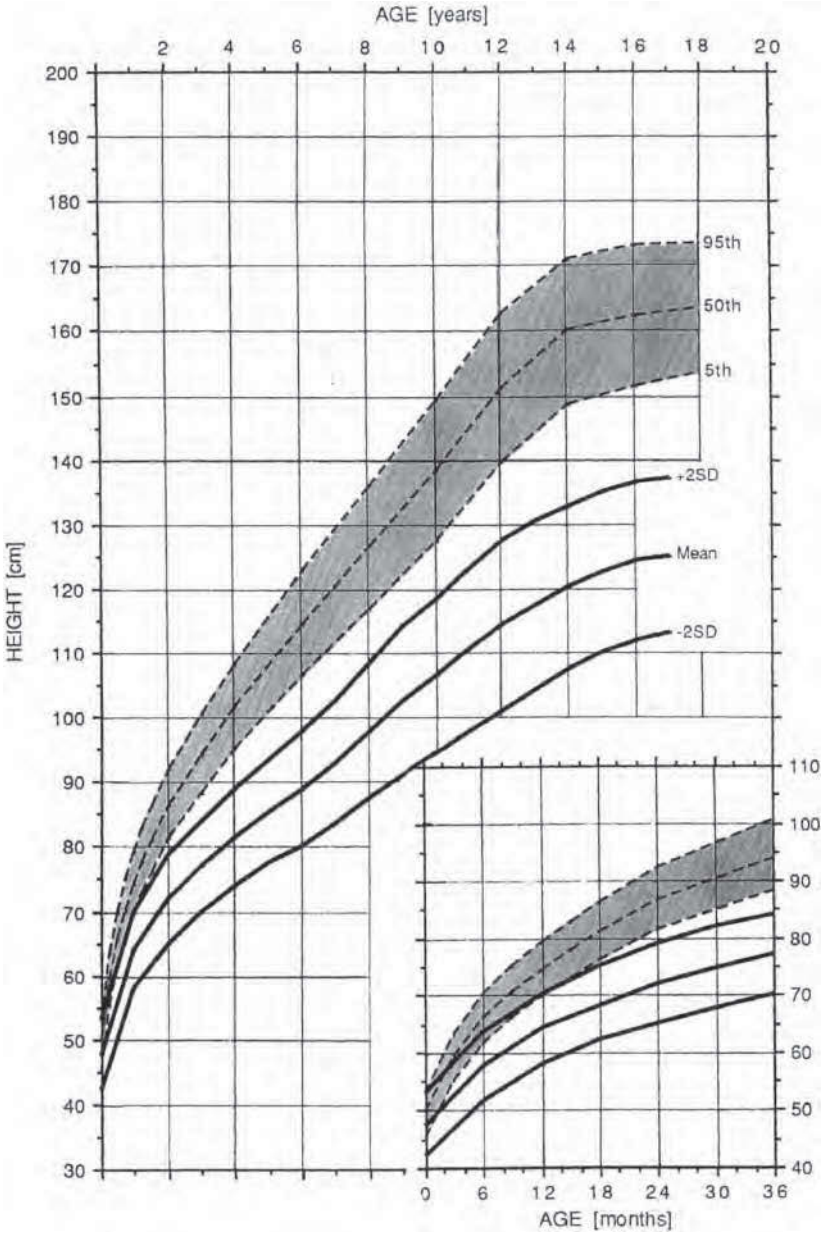

Fig 2. Height for females with achondroplasia (mean ± 2.8 standard deviation) compared with normal standard curves. The graph was derived from 214 females. (Saul RA, Seaver LH, Sweet KM, Geer JS, Phelan MC, Mills CM. *Growth References: Third Trimester to Adulthood.* 2nd ed. Greenwood, SC: Greenwood Genetic Center; 1998: 107–110.)

parents are usually knowledgeable about the disorder, the inheritance, and the prognosis for the offspring. More often, diagnosis of achondroplasia is first suspected late in gestation on the basis of long-bone foreshortening incidentally discovered by ultrasonography. With the frequent use of ultrasonography, many cases of achondroplasia are first identified prenatally (after 26 weeks of gestational age). However, disproportionately short limbs are observed in a heterogeneous group of conditions. Misdiagnosis and inaccurate prenatal counseling of families is common.[16] Confirmation of diagnosis based on ultrasonographic features characteristic of achondroplasia can be provided by molecular testing (*FGFR3* mutational testing) of prenatal specimens. If no such confirmation has yet been completed, caution should be exercised when counseling the family. In this circumstance, the pediatrician should discuss the tentative nature of the diagnosis and alternatives that may explain the identified features. The pediatrician should also discuss the natural history of achondroplasia, because it is the most likely explanation for the findings. In cases in which the diagnosis is unequivocally established either because of the familial nature of the disorder or by prenatal molecular diagnosis (chorionic villus sampling at 11–13 weeks' gestation or amniocentesis after 15 weeks' gestation), the pediatrician may consider the following steps as appropriate.

1. Review, confirm, and demonstrate laboratory or imaging studies leading to the diagnosis.
2. Explain the mechanisms for occurrence of achondroplasia in the fetus and the recurrence risk for the family.
3. Remember that at least 75% of cases of achondroplasia occur in families in which both parents have average stature. In those cases, achondroplasia in the offspring occurs because of a mutation in the gene.

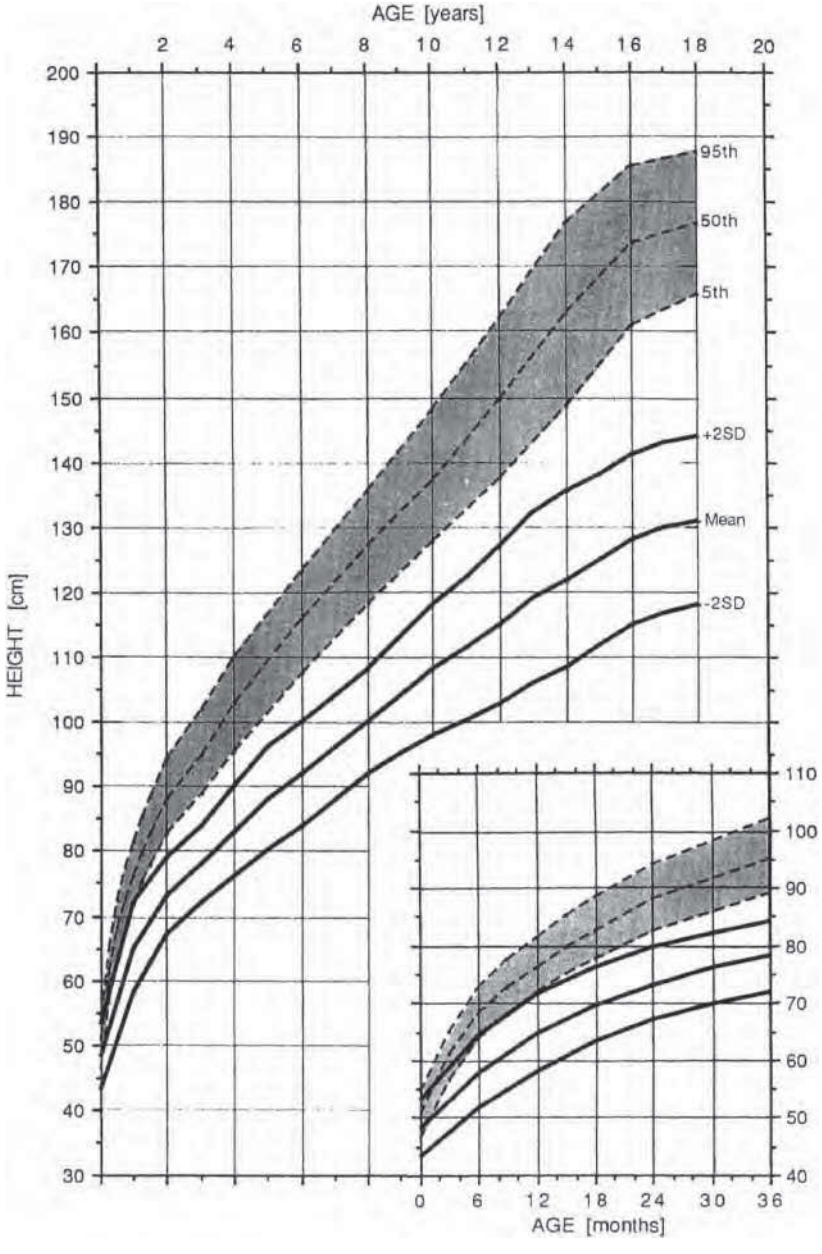

Fig 1. Height for males with achondroplasia (mean ± 2.8 standard deviation) compared with normal standard curves. The graph was derived from 189 males. (Saul RA, Seaver LH, Sweet KM, Geer JS, Phelan MC, Mills CM. *Growth References: Third Trimester to Adulthood.* 2nd ed. Greenwood, SC: Greenwood Genetic Center; 1998: 107–110.)

ductive lives.[15] Because of their disproportionate short stature, however, a number of psychosocial problems can arise. Families can benefit from anticipatory guidance and the opportunity to learn from other families with children of disproportionate short stature.

The consensus-based guidance in this report is designed to help the pediatrician care for children with achondroplasia and their families. Issues that need to be addressed at various ages are discussed (Table 1). These suggestions are not appropriate for other chondrodysplasias, because each type has its own natural history, complications, and specific guidelines. Irrespective of the availability of the guidance in this report, it is important that pediatricians and parents also consult a physician with special experience and expertise concerning achondroplasia early in the child's life, because this report only provides generally applicable suggestions that must be tailored to a particular child's condition and needs.

THE PRENATAL VISIT

Pediatricians may be called on to counsel expectant parents whose fetus has achondroplasia or is suspected to have achondroplasia because of recognition on ultrasonography of disproportionate small stature. In some settings, the pediatrician will be the primary resource for counseling a family. At other times, counseling may already have been provided to the family by a clinical geneticist and/or the obstetrician. Because of a previous relationship with the family, however, the pediatrician may be called on to review this information and assist the family in the decision-making process.

The diagnosis of achondroplasia in the fetus is made most often with certainty when 1 or both parents have this condition. In this circumstance, the

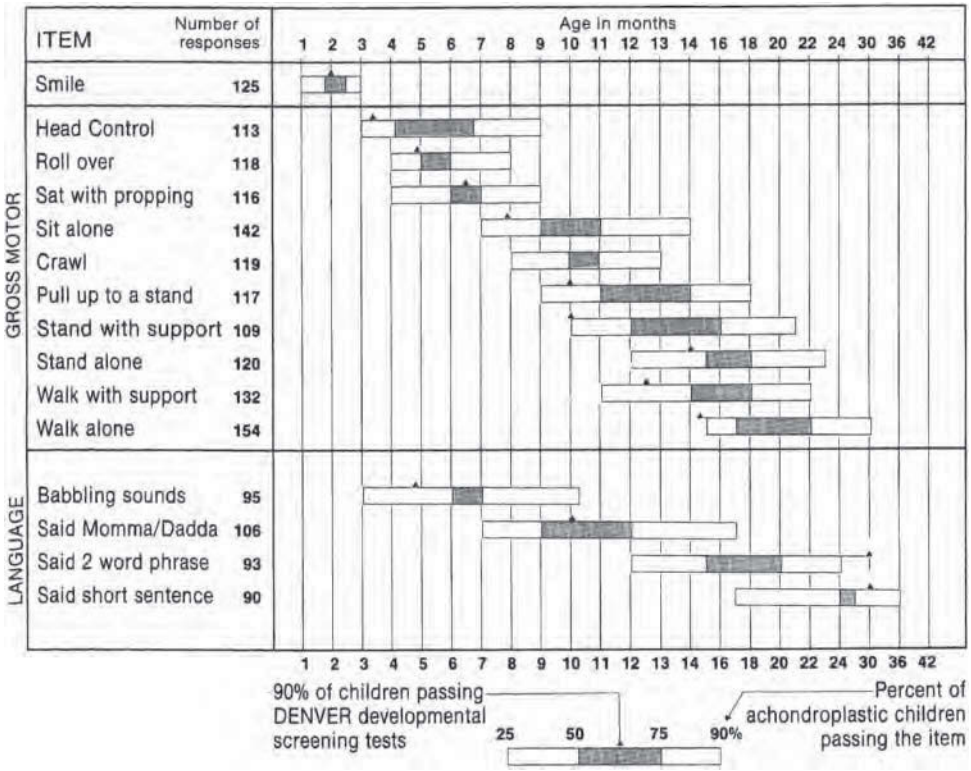

Fig 3. Developmental screening tests in achondroplasia. The bar scale shows the percentage of achondroplastic children passing the item; the black triangle on top of the bar shows the age at which 90% of normal children pass the same item. The graphs were derived from 197 affected individuals, obtained by questionnaire. (Reproduced with permission from *Am J Med Genet*. 1981;9:19-23.)

4. Review the natural history and manifestations of achondroplasia, including variability.[3]
5. Discuss additional studies that should be performed, particularly those to confirm the diagnosis in the newborn period. If miscarriage, stillbirth, or termination occurs, confirmation of diagnosis is important for counseling family members about recurrence.
6. Review currently available treatments and interventions. This discussion needs to include the efficacy, complications, adverse effects, costs, and other burdens of these treatments. Discuss possible future treatments and interventions.
7. Explore the options available to the family for the management and rearing of the child using a nondirective approach. In cases of early prenatal diagnosis, these options may include discussion of pregnancy termination, continuation of pregnancy and rearing of the child at home, foster care, or adoption. If adoption is planned to another family, contact may be made with the Little People of America adoption service.[17]
8. If the mother is affected with achondroplasia, inform her that a cesarean delivery must be performed because of the characteristic small pelvis.[18] A mother affected with achondroplasia may develop respiratory compromise during the third trimester of pregnancy, so baseline pulmonary function studies should be performed. Homozygous achondroplasia can be diagnosed prenatally with molecular testing of the fetus, by either chorionic villus sampling or amniocentesis. A pregnancy at risk of homozygosity should be followed with ultrasonographic measurements at 14, 16, 18, 22, and 32 weeks of gestation to distinguish homozygosity or heterozygosity from normal growth patterns in the fetus.
9. When both parents are of disproportionate short stature, assess the possibility of double heterozygosity[19] or homozygosity for achondroplasia. Some forms of double heterozygosity lead to life-threatening problems[19]; infants with homozygous achondroplasia usually are stillborn or die shortly after birth.[20]

HEALTH SUPERVISION FROM BIRTH TO 1 MONTH OF AGE: NEWBORNS

Examination

1. Confirm the diagnosis by radiographic studies (the diagnosis of approximately 20% of patients with achondroplasia has been delayed in the past because it was not suspected on physical examination in the newborn period, and consequently, no radiographs were obtained).
2. Document measurements, including occipitalfrontal circumference (OFC), body length, and body weight; plot these measurements on achondroplasia-specific growth charts (Figs 1, 2, and 4–7). Review the phenotype with the parents and discuss the specific findings with both parents whenever possible.
3. The OFC should be measured at every pediatric contact during the first year (Figs 4 and 5).

TABLE 1. Achondroplasia Guidelines for Health Supervision

	Prenatal	Infancy, 1 mo to 1 y of Age					Early Childhood, 1 to 5 y of Age						Late Childhood	Adolescence

These guidelines ensure compliance with AAP recommendations for preventive pediatric health care. *FGFR3* indicates fibroblast growth factor receptor type 3; X, to be performed; S, subjective, by history; O, objective, by a standard testing method; R, discuss referral to a specialist; 3 , continue to monitor.

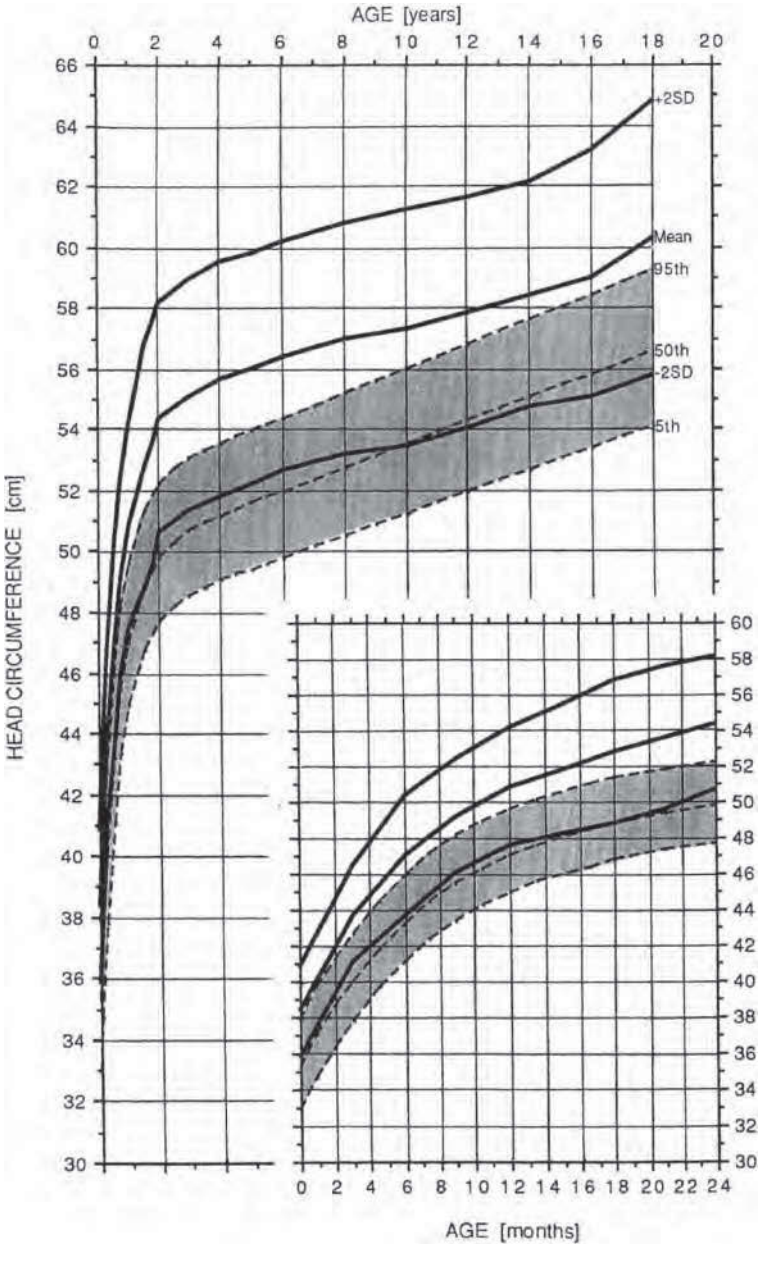

Fig 4. Head circumference for males with achondroplasia compared with normal curves (dashed lines). The graph was derived from 189 males. (Saul RA, Seaver LH, Sweet KM, Geer JS, Phelan MC, Mills CM. *Growth References: Third Trimester to Adulthood.* 2nd ed. Greenwood, SC: Greenwood Genetic Center; 1998: 107–110.)

Anticipatory Guidance

1. Discuss the specific findings of achondroplasia with the parents, including the following:
   - Autosomal dominant inheritance: approximately 75% of cases are new mutations. Germline mosaicism (in which some germ cells are derived from a normal cell line and some are from a cell line with a mutation) has been reported, but the risk of recurrence in sporadic cases is less than 1%.[21–23]
   - Most individuals with achondroplasia have normal intelligence and normal life expectancy.
   - Although serious problems may arise during infancy, such problems affect only 5% to 10% of infants with achondroplasia.
   - Growth hormones, other drug therapies, and food or vitamin supplements are not effective in significantly increasing stature. Growth-hormone therapy may result in a transient increase in growth rate. However, the salutary effects diminish with continued treatment. No study has clearly demonstrated a significant benefit with respect to ultimate adult stature.[24,25] If elected, such treatment should be considered only within a research setting. Extended limb lengthening using a variety of techniques has been used far more elsewhere than in North America. It can result in substantial increases in ultimate height.[26,27] However, it is arduous, not without risk, and costly. Most families alternatively choose to modify the environment to accommodate the child rather than the converse.
   - Special achondroplasia growth curves and infant development charts have been developed (Figs 1–7); the final expected adult height for

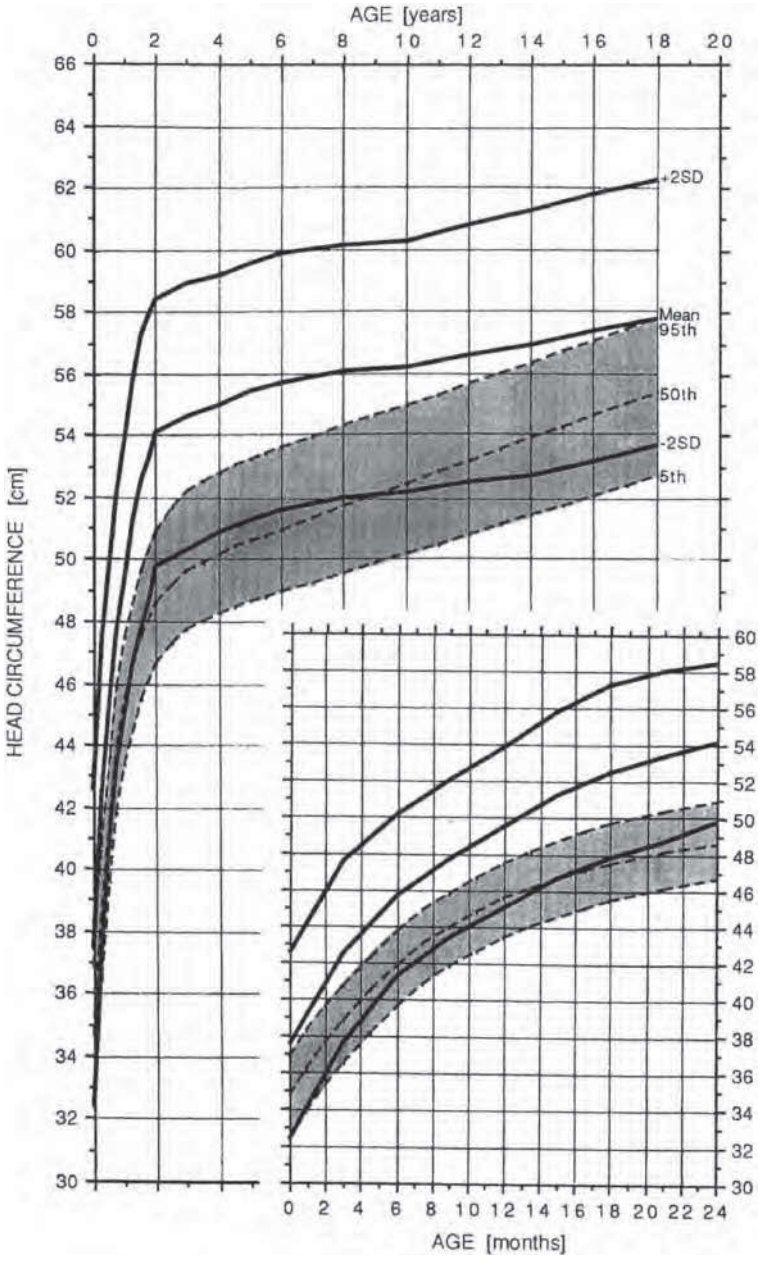

Fig 5. Head circumference for females with achondroplasia compared with normal curves (dashed lines). Data were derived from 145 females. (Saul RA, Seaver LH, Sweet KM, Geer JS, Phelan MC, Mills CM. *Growth References: Third Trimester to Adulthood.* 2nd ed. Greenwood, SC: Greenwood Genetic Center; 1998: 107–110.)

persons with achondroplasia is approximately 4 ft.[9]

2. Discuss the following possible severe medical complications and methods of prevention:
   - Unexpected infant death occurs, in the absence of aggressive evaluation, in approximately 2% to 5% of all infants with achondroplasia.[28,29] This seems to result from central apnea arising secondary to compression of arteries at the level of the foramen magnum.[28] In addition, the universally small foramen magnum may result in a high cervical myelopathy.[30,31] However, with appropriate assessment and intervention, both risks can be minimized.[31] Parents should be advised to use an infant seat or infant carrier that has a firm back that supports the neck and to use a rear-facing car safety seat for as long as possible. They should be counseled to avoid use of products like mechanical swings and carrying slings to limit uncontrolled head movement around the small foramen magnum. There are instances in which infants with achondroplasia who showed no clinical abnormality by examination and who were asymptomatic have died from this complication. Given this, and because it can be life saving, care of every infant with achondroplasia should include assessment for craniocervical junction risks, which includes careful neurologic history and examination, neuroimaging, and polysomnography.[31] Neuroimaging can be by computed tomography (CT) with thin cuts and bone windows[31] or magnetic resonance imaging (MRI),[32,33] each of which has benefits and disadvantages: CT allows direct comparison of foramen magnum size with published achondroplasia standards and often can be accomplished without sedation or anesthesia but does not allow direct visualization of the

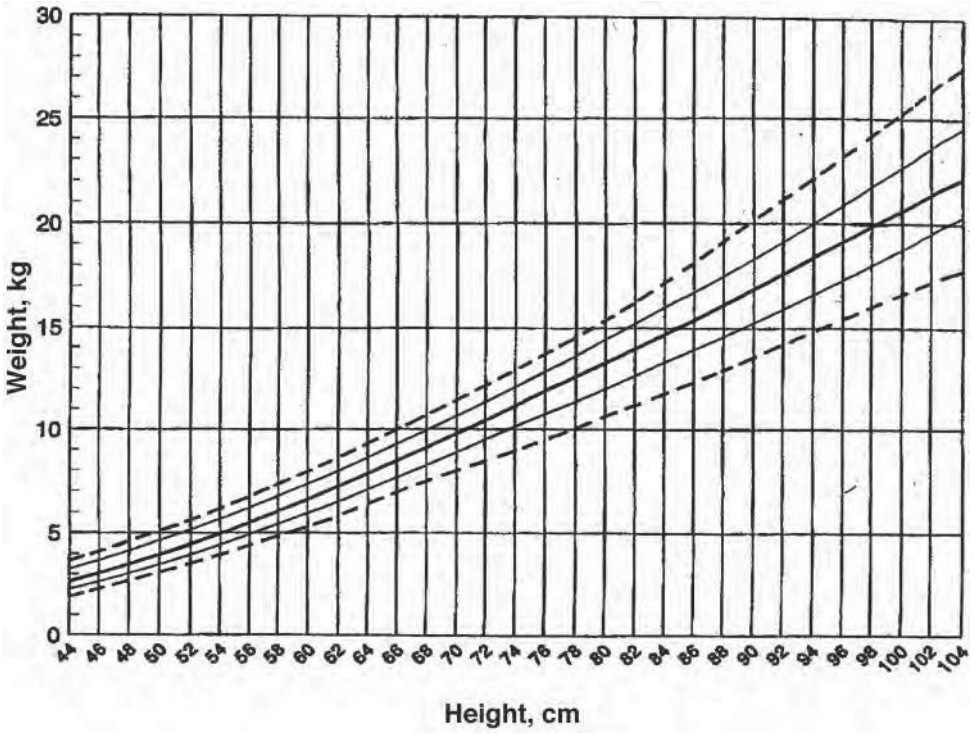

Fig 6. Height-by-weight standards in achondroplasia: males. (Reproduced with permission from *Am J Med Genet*. 1996;62:255-261.)

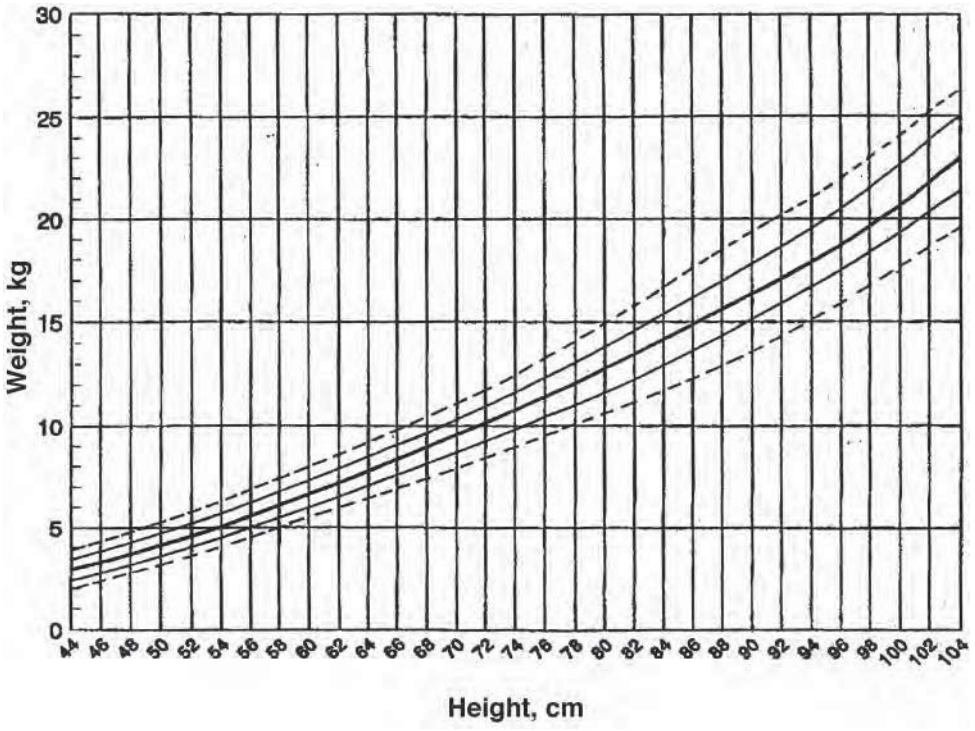

Fig 7. Height-by-weight standards in achondroplasia: females. (Reproduced with permission from *Am J Med Genet*. 1996;62:255-261.)

neural elements of interest; MRI provides such a direct assessment of the brainstem and upper cervical spinal cord, but no standards for estimation of foraminal size by MRI are available, and currently it cannot be performed routinely without sedation. Rapid development of imaging technology suggests that alternative methods may become appropriate in the future.

- If severe problems are found (eg, marked abnormality by neurologic examination, such as profound hypotonia or sustained ankle clonus; markedly diminished foramen magnum size compared with achondroplasia standard; substantial deformation of the upper cervical spinal cord; hypoxemic episodes with minimal oxygen saturations below 85%[31]), referral to a neurosur-

geon or other physician skilled and experienced in the care and treatment of neurologic problems in children with achondroplasia should be initiated.[34]

- Hydrocephalus is a lifelong risk but is most likely to develop during the first 2 years.[35] OFC should be monitored carefully during this time. If the OFC is large or crosses percentiles on the achondroplasia-specific head-circumference chart, it is appropriate to refer the infant to a pediatric neurologist or pediatric neurosurgeon. Baseline CT or MRI (performed in conjunction with imaging of the craniocervical junction) is valuable if there is concern about possible hydrocephalus. Repeating neuroimaging to assess change in ventricular size should be considered if there is acceleration of head growth compared with achondroplasia standards or if other signs like bulging, hard fontanelle, or symptoms of unusual lethargy or intractable irritability develop. Both ventriculomegaly and excessive extra-axial fluid are common benign accompaniments of achondroplasia[35] and should not be misinterpreted as indicative of need for shunt placement. Neural ultrasonography may be used to follow these clinical findings.
- Restrictive pulmonary disease occurs in less than 5% of children with achondroplasia who are younger than 3 years.[36] Living at high elevation markedly increases the risk that restrictive problems will develop. If there are signs of respiratory distress or evidence of poor weight gain despite adequate caloric intake, pulse oximetry (during feeding, when crying, and at rest) should be considered to monitor oxygenation.
- Most infants with achondroplasia develop a thoracolumbar kyphosis. More severe kyphosis is associated with unsupported sitting before there is adequate trunk muscle strength.[37,38] Parents should be counseled to avoid unsupported sitting and to avoid devices that cause curved sitting or "C sitting," such as "umbrella-style" strollers and soft canvas seats during the first year of life. Use of feeder seats for upright positioning should be recommended. If severe kyphosis appears to be developing, consider a pediatric orthopedic surgical assessment to determine if bracing is needed.[38]
- The common complication of spinal stenosis rarely occurs in childhood but manifests in older individuals with numbness, weakness, and altered deep tendon reflexes.[30] Severe thoracolumbar kyphosis is one mechanism that can give rise to spinal stenosis. It is for this reason that unsupported sitting before there is adequate trunk muscle strength is discouraged.
- Anesthesia risk:[39] if an individual with achondroplasia needs to have anesthesia and surgery, the following should be considered:
  (*a*) Care must be taken in manipulation of the neck, because uncontrolled neck movement (as may occur with intubation) could lead to unintentional spinal cord compression secondary to constriction of the foramen magnum.
  (*b*) Care should be taken to ensure that medication dosages are appropriate for size.
  (*c*) Access to veins is sometimes difficult because of lack of full extension at the elbow.
  (*d*) Generally, spinal anesthesia should be avoided, particularly when there is kyphosis or severe lumbar lordosis, because of limited space within the spinal canal.
  (*e*) General anesthesia should be strongly considered for cesarean delivery for pregnant women with achondroplasia (they will all require caesarian delivery because of contracted pelves), because use of epidural anesthesia in these women requires special skill and expertise.[40]/P

3. Discuss the potential psychosocial implications for both parent and child related to disproportionate short stature. Refer the affected individual or the parent of an affected individual to a support group such as Little People of America (also see "Resources for New Parents"). If parents do not wish to join a group, they may want to meet with or talk to other affected individuals or parents. Remind parents that most individuals with achondroplasia lead productive, independent lives.
4. Discuss with the parents how to tell their family and friends about their child's growth problem.
5. Supply the parents with educational books and pamphlets (see "Resources for New Parents").
6. Discuss the realistic functional problems for affected individuals.
7. Discuss individual resources for support, such as family, clergy, social workers, psychologists, and friends.
8. Review the prenatal diagnosis and recurrence risks for subsequent pregnancies.

HEALTH SUPERVISION FROM 1 MONTH TO 1 YEAR OF AGE: INFANCY

Examination

1. For infants not diagnosed in the newborn period, arrange for neuroimaging and polysomnography at the time of diagnosis.
2. Assess growth and development in comparison only with children with achondroplasia (Figs 1–7).
3. Perform physical examination.
4. Review head growth on achondroplasia-specific head-circumference charts.
5. Refer the infant to a pediatric neurologist or pediatric neurosurgeon if head size is disproportionately large or crosses percentiles, if there are signs or symptoms of hydrocephalus, or if there are indicators of possible craniocervical junction compression, including excessively brisk reflexes, asymmetric reflexes, ankle clonus, extreme hypotonia, or early hand preference.[10,35]
6. Consider repeating neuroimaging studies if there is acceleration of head growth, severe persisting hypotonia, or any signs of craniocervical junction compression.[31–34] Growth of the foramen magnum may be compared with achondroplasia-specific standards.[41]

7. Check motor development and discuss development; note on the milestone charts for achondroplasia. Expect motor delay but not social or cognitive delay.[12,13] Check for serous otitis media. Review risk at 6 to 12 months of age. Formal behavioral audiometric assessment should be completed at 9 to 12 months of age. Language delay may be present secondary to conductive hearing loss.
8. Continue to monitor for progression of kyphosis at the thoracolumbar junction. It is recommended that parents avoid carrying a child with achondroplasia in curled-up (C-sitting) positions. Certain types of child carriers, mechanical swings, jumpers, and umbrella-style strollers tend to increase risk for gibbus. Unsupported sitting should be avoided.[37,38] Parents and therapists should be instructed to provide back support during the first year of life. If severe kyphosis appears to be developing, consider pediatric orthopedic surgical assessment to determine if bracing is needed.[38]
9. Be aware that external rotation of the hips is commonly present and usually disappears spontaneously when the child begins to bear weight. This finding does not require bracing for the infant.

Anticipatory Guidance

1. Review the personal support available to the family.
2. Review contact with support groups.
3. Observe the emotional status of parents and intrafamily relationships.
4. Discuss early-intervention services and the importance of normal socializing experiences with other children.
5. Ask the parents whether they have educated their family members about achondroplasia; discuss sibling adjustment.
6. Review the increased risk of serous otitis media because of short eustachian tubes. Indicate that an ear examination is appropriate with any persistent or severe upper respiratory tract infection or when parents suspect that ear pain may be present.
7. Advise parents to avoid infant carriers that curl up the infant. This does not apply to car safety seats, which should always be used during automobile travel. A rear-facing car safety seat should be used to the highest weight allowed by a convertible seat (25–30 lb).
8. Discuss filing for Supplemental Security Income benefits as appropriate.

HEALTH SUPERVISION FROM 1 TO 5 YEARS OF AGE: EARLY CHILDHOOD

Examination

1. Assess the child's growth and development as plotted on the achondroplasia growth charts.
2. Continue to follow rate of head growth on the achondroplasia-specific head-circumference charts.
3. Continue to watch for thoracolumbar gibbus (kyphosis). Discuss avoiding the use of walkers, jumpers, or backpack carriers. Any kyphosis present should disappear as the child begins to bear weight. Lumbar lordosis usually develops but rarely requires specific intervention. Weight bearing and walking may occur late; however, they are expected by 2 to 2.5 years of age. When weight bearing begins, the external rotation of the hips should self-correct to a normal orientation within 6 months.
4. Anticipate some bowing of the legs. Many children will also have instability of the soft tissues surrounding the knee and internal tibial torsion. If positional deformity and instability leads to difficulty walking, a thrust at the knee (uncontrolled lateral or medial movement with weight bearing), or chronic pain, consult a pediatric orthopedist.[14]
5. Check the child's hips for hip-flexion contractures. Prescribe exercises that may decrease lumbar lordosis and hip-flexion contractures if indicated. Check the hips for external rotation. Refer the child to a pediatric orthopedist if necessary.
6. Screen hearing each year. If otologic history, hearing screening, or speech development raise concerns about hearing, formal audiologic assessment should be obtained.
7. Perform speech evaluation at no later than 2 years of age. If speech is delayed, conductive hearing loss attributable to chronic serous otitis media should be excluded.
8. Watch for obstructive sleep apnea secondary to smaller-than-average airway size plus physiologic adenoidal hypertrophy.[42–44] Most children with achondroplasia snore. However, if obstructive apnea or disordered breathing in sleep is suspected (increased retraction, glottal stops, choking, intermittent breathing, apnea, deep compensatory sighs, secondary enuresis, recurrent night-time awakening or emesis), then additional pulmonary evaluation and polysomnography are indicated.
9. Be aware that gastroesophageal reflux may be more common in children with achondroplasia and may be more common in those with neurorespiratory complications.[45] If reflux is severe, in addition to usual treatments, consider referral to a pediatric specialist with experience in treating gastroesophageal reflux in infants and children.
10. Do not misinterpret greater-than-average sweating as indicative of serious medical problems; it is normal in children with achondroplasia.
11. In rare instances in which diagnosis of achondroplasia is delayed beyond 1 year of age, determine if neuroimaging is needed on the basis of clinical signs and symptoms.

Anticipatory Guidance

1. Consider adapting the home so that the child can become independent (eg, lower the light switches, use lever door handles and lever sink faucets, make the toilet accessible, and supply step stools) (see "Resources for Parents").
2. Determine if an occupational therapy consultation is needed.

3. Discuss adapting age-appropriate clothing with snapless, easy-opening fasteners and tuckable loops.
4. Discuss adaptation of toys, especially tricycles, to accommodate short limbs.
5. Discuss adaptation of toilets to allow comfortable, independent use, with an extended wand for wiping if needed.
6. Discuss the use of a stool during sitting so that the child's feet are not hanging. Feet need support while the child is sitting at a desk, in a chair, or on the toilet. A cushion behind the child's back may be required for good posture and to prevent chronic back pain. Counsel parents for optimal protection to use a convertible rear-facing car safety seat to the highest weight and height allowed by the manufacturer of the seat.[46] A rear-facing seat provides the best support protection and positioning angle for a child with macrocephaly and skeletal dysplasia. Parents may benefit from suggestions for behavioral intervention to promote continuing the rear-facing position as long as possible.[47]
7. Review weight control and eating habits to avoid obesity, which often becomes a problem in mid- to late childhood.[48]
8. Discuss orthodontic bracing in the future and the possible need for early orthodontic assessment to consider palatal expansion.
9. Encourage the family to develop activities in which the child can take part; avoid gymnastics, diving, trampolines, and collision sports.
10. Discuss how to talk with the child and friends or family members about short stature.
11. Encourage preschool attendance so that the child can learn to socialize in an age-appropriate way, and work with parents to prepare the teacher and the other children so that the child is not given unnecessary special privileges.
12. Discuss toileting at school and special preparations needed by the school because of the child's short stature (see "Resources for Parents").

HEALTH SUPERVISION FROM 5 TO 13 YEARS OF AGE: LATE CHILDHOOD

Examination

1. Assess and review the child's growth, development, and social adaptation.
2. Plot measures on achondroplasia weight-by-height grids (Figs 6 and 7).
3. Review weight control.[48] The child may need to restrict food intake and eat less than an average-sized child eats.
4. Complete a general and neurologically oriented physical examination.
5. Check deep tendon reflexes yearly for asymmetry or increased reflexes that suggest spinal stenosis.
6. Continue to assess history for possible obstructive sleep apnea.
7. Test hearing each year.

Anticipatory Guidance

1. Determine school readiness.
2. Discuss preparation of the school and teacher for a child with short stature (see "Resources for Parents").
3. Prepare the child for others' questions and curiosity. Be sure the child can explain why he or she is short and can ask for help in an appropriate way. Children with achondroplasia usually are included in the regular education program.
4. Suggest adaptive aids for the school to cope with heavy doors, high doorknobs, reaching for the blackboard, foot support, and a regular-sized desk. Also, be sure that the child can use the restroom independently (see "Resources for Parents").
5. Counsel parents to use a child safety seat with a full harness to the highest weight allowed by the manufacturer of the seat and then to transition to the belt-positioning booster seat for optimal seatbelt positioning.[46]
6. Review socialization and foster independence.
7. Discuss contact with support groups. They are especially valuable at this age.
8. Consider obtaining an orthopedic evaluation when the child is approximately 5 years of age to make appropriate treatment plans if necessary.
9. Emphasize correct posture and encourage the child to consciously decrease lumbar lordosis by "tucking the buttocks under." If lordosis is severe, consider physical therapy referral to teach lower abdominal muscle strengthening and pelvic rotation.
10. Develop an activity program with acceptable activities such as swimming and biking. The child should avoid gymnastics and collision sports because of the potential for neurologic complications secondary to cervical spinal stenosis. If soccer is played, heading should be prohibited.
11. Review orthodontic and speech status.

HEALTH SUPERVISION FROM 13 TO 21 YEARS OR OLDER: ADOLESCENCE TO EARLY ADULTHOOD

Examination

1. Continue to record growth parameters.
2. Review weight control and diet.
3. Monitor for any signs or symptoms of nerve compression and check deep tendon reflexes, tone, and sensory findings, if indicated.
4. Continue to assess history for possible obstructive sleep apnea.

Anticipatory Guidance

1. Check on social adaptation.
2. Discuss the diagnosis with the adolescent to be sure that he or she has the vocabulary and the understanding of the genetic nature of achondroplasia.
3. Discuss contraception. The importance and use of contraception should be discussed with both males and females. Women with achondroplasia usually are fertile. Oral contraception should not be used long-term, because women with achondroplasia may have an increased risk of uterine fibroids, which may be aggravated by oral con-

traceptives. However, using a diaphragm is difficult because of the short arms in achondroplasia. Finding the appropriate long-term contraception may require consultation with a knowledgeable gynecologist. Women with achondroplasia often develop respiratory compromise late in pregnancy; thus, baseline respiratory function studies are recommended early in pregnancy. All pregnant women with achondroplasia will require caesarian delivery because of their small pelvic outlet. Because of spinal stenosis, spinal anesthesia is not recommended, and most women with achondroplasia should have general anesthesia for their cesarean delivery. If the partner of the woman with achondroplasia is of average stature, there will be a 50% risk of the infant having achondroplasia. If the partner also has short stature, the specific recurrence risk and the possibility of a severely affected infant must be determined so that the pregnancy and neonate can be managed properly. Prenatal diagnosis should be discussed to facilitate the management of the pregnancy for optimal outcome.[18]

4. Review orthodontic status.
5. Continue weight counseling.[48,49]
6. Encourage the family and affected person to set career and life goals high and appropriate, as for other members of the family. Assist in adapting to an independent life and in obtaining a driver's license. Drivers usually require a vehicle that is adapted with pedal extenders; extenders that can be easily mounted and removed as needed are available. Families may wish to work with a driver-rehabilitation specialist who is qualified to assess the driver's transportation needs and who can provide them with a list of appropriate vehicle modifications. Names of qualified evaluators can be obtained by contacting a local rehabilitation center or the Association for Driver Rehabilitation Specialists (609-844-4433).[50] For most it will be necessary to provide a letter of justification for disabling of the air bag, because even with pedal extenders, marked arm foreshortening will preclude positioning at an appropriate distance from the air bag (10–12 in).[47] Individuals who want to have an air bag on-off switch must read an informational brochure and submit an official request to the National Highway Traffic Safety Administration (888-DASH-2-DOT [www.nhtsa.dot.gov]). Approval does not guarantee, however, that the request will be honored by a vehicle dealer.[51]
7. Discuss college, vocational planning and training, and other plans after high school.
8. Foster independence.
9. Continue to encourage participation in social activities and support groups. It is particularly useful during this age period.
10. Assist in transition to adult care.

ERRATA

An error appeared in the Experience and Reason—Briefly Recorded by Tan et al, titled "Isolated Sulfite Oxidase Deficiency: A Case Report With a Novel Mutation and Review of the Literature" that was published in the September 2005 issue of *Pediatrics* (2005;116:757–766). On page 758, the last line in column 2, the authors wrote: "The patient was homozygous for a novel 4-base pair deletion (c.2037-2040delTAGA) in exon 3 that led to a frameshift and resulted in a prematurely truncated protein." This sentence should have read as follows: "The patient was homozygous for a novel 4-base pair deletion (c.1142-1145delTAGA) in exon 3 that led to a frameshift and resulted in a prematurely truncated protein." The same error appears on page 763, Table 1, column 22 in the Mutations in SUOX row. The table currently reads: "c2037-2040delTAGA." It should read: "c.1142-1145delTAGA." The authors state that to the best of their knowledge, this remains a new, previously unreported mutation, and this error in nomenclature does not alter the substance nor the importance of the publication in any way.

abstract

FREE

These guidelines are designed to assist the pediatrician in caring for the child in whom a diagnosis of Down syndrome has been confirmed by chromosome analysis. Although a pediatrician's initial contact with the child is usually during infancy, occasionally the pregnant woman who has been given a prenatal diagnosis of Down syndrome will be referred for review of the condition and the genetic counseling provided. Therefore, this report offers guidance for this situation as well. *Pediatrics* 2011;128:393–406

INTRODUCTION

Children with Down syndrome have multiple malformations, medical conditions, and cognitive impairment because of the presence of extra genetic material from chromosome 21.[1,2] Although the phenotype is variable, there typically are multiple features that enable the experienced clinician to suspect the diagnosis. Among the more common physical findings are hypotonia, small brachycephalic head, epicanthal folds, flat nasal bridge, upward-slanting palpebral fissures, Brushfield spots, small mouth, small ears, excessive skin at the nape of the neck, single transverse palmar crease, and short fifth finger with clinodactyly and wide spacing, often with a deep plantar groove between the first and second toes. The degree of cognitive impairment is variable and may be mild (IQ of 50–70), moderate (IQ of 35–50), or occasionally severe (IQ of 20–35). There is a significant risk of hearing loss (75%); obstructive sleep apnea (50%–79%); otitis media (50%–70%); eye disease (60%), including cataracts (15%) and severe refractive errors (50%); congenital heart defects (50%); neurologic dysfunction (1%–13%); gastrointestinal atresias (12%); hip dislocation (6%); thyroid disease (4%–18%)[3–6]; and, less commonly, transient myeloproliferative disorder (4%–10%) and later leukemia (1%) and Hirschsprung disease (<1%) (Table 1). The social quotient may be improved with early-intervention techniques, although the level of function is exceedingly variable. Children with Down syndrome often function more effectively in social situations than would be predicted on the basis of cognitive assessment results.

In approximately 95% of children with Down syndrome, the condition is sporadic because of nonfamilial trisomy 21, in which there are 47 chromosomes with a free extra chromosome 21 being present. In approximately 3% to 4% of persons with the Down syndrome phenotype, the extra chromosomal material is the result of an unbalanced translocation between chromosome 21 and another acrocentric chromosome, usually chromosome 14. Approximately three-quarters of these

TABLE 1 Medical Problems Common in Down Syndrome

Condition	%
Hearing problems	75
Vision problems	60
Cataracts	15
Refractive errors	50
Obstructive sleep apnea	50–75
Otitis media	50–70
Congenital heart disease	40–50
Hypodontia and delayed dental eruption	23
Gastrointestinal atresias	12
Thyroid disease	4–18
Seizures	1–13
Hematologic problems	
Anemia	3
Iron deficiency	10
Transient myeloproliferative disorder	10
Leukemia	1
Celiac disease	5
Atlantoaxial instability	1–2
Autism	1
Hirschsprung disease	<1

unbalanced translocations are de novo, and the remainder result from familial translocations. If the child has a translocation, a balanced translocation must be excluded in the parents. When there is a translocation in a parent, additional familial studies and genetic counseling should be provided. In the remaining 1% to 2% of persons with the Down syndrome phenotype, a mix of 2 cell lines is present: one normal and the other with trisomy 21. This condition is called mosaicism. Persons with mosaicism may be more mildly affected than persons with complete trisomy 21 or translocation chromosome 21, but this is not always the case, and their condition may include any of the associated medical problems and be indistinguishable from trisomy 21. Recurrence risks for families with an affected child depend on many factors, and families benefit from counseling by a clinical genetic professional.

Medical management, home environment, early intervention, education, and vocational training can significantly affect the level of functioning of children and adolescents with Down syndrome and facilitate their transition to adulthood. The following outline is designed to help the pediatrician provide care for children with Down syndrome and their families in the medical home. It is organized by the issues that need to be addressed in various age groups (see Appendix 1).

Several areas require ongoing assessment throughout childhood and should be reviewed at every physician visit and at least annually. These areas include:

- personal support available to family;
- participation in a family-centered medical home;
- age-specific Down syndrome–related medical and developmental conditions;
- financial and medical support programs for which the child and family may be eligible;
- injury and abuse prevention with special consideration of developmental skills; and
- nutrition and activity to maintain appropriate weight.

THE PRENATAL VISIT

The American College of Obstetricians and Gynecologists recommends that all pregnant women, regardless of age, be offered the option of diagnostic testing for Down syndrome and consider less invasive screening options.[7,8] Screening options have improved significantly with the introduction of first-trimester screening, which incorporates maternal age, nuchal translucency ultrasonography, and measurement of maternal serum human chorionic gonadotropin (β-hCG) and pregnancy-associated plasma protein A (PAPP-A). Second-trimester screening is available for patients who first seek medical care in the second trimester or in locations where first-trimester screening is not available. The second-trimester screening, often called the quad screen, incorporates maternal age risk with measurement of maternal serum hCG, unconjugated estriol, α-fetoprotein (AFP), and inhibin levels. The detection rate of Down syndrome by first-trimester screening is 82% to 87%, by second-trimester screening is 80%, and by combined first- and second-trimester screening (referred to as integrated screening) is approximately 95%. These screening tests are reported to have a 5% false-positive rate.[9–12]

Pediatricians may be asked to counsel a family whose fetus has been identified with or is at increased risk of Down syndrome. In some settings, the pediatrician may be the primary resource for counseling. At other times, counseling may have been provided for the family by a certified genetic counselor, a clinical geneticist, obstetrician, or developmental-behavioral pediatrician. In addition, parents may have received information from a Down syndrome program, a national Down syndrome organization, or an Internet site. Because the pediatrician often has a previous relationship with the family, he or she should be prepared to review this information and assist in the decision-making process. When asked, the pediatrician should discuss the following topics with the family:

1. The prenatal laboratory studies that lead to the diagnosis and any fetal imaging studies that have been or will be performed.
2. The mechanism for occurrence of the disorder in the fetus and the potential recurrence rate for the family as provided by genetic counseling.
3. The prognosis and phenotypic manifestations, including the wide range of variability seen in infants and children with Down syndrome. Families benefit from hearing a fair and balanced perspective, including the many positive outcomes of

children with Down syndrome and their effect on the family.

4. Any additional studies performed that may refine the estimation of the prognosis (eg, fetal echocardiogram, ultrasonographic examination for gastrointestinal tract malformations). Consultation with an appropriate medical subspecialist, such as a pediatric cardiologist or a pediatric surgeon, should occur prenatally if abnormal findings are detected.
5. Currently available treatments and interventions. This discussion needs to include the efficacy, potential complications and adverse effects, costs, and other burdens associated with treatments. Discuss early-intervention resources, parent support programs, and any appropriate future treatments.
6. The options available to the family for management and rearing of the child should be discussed using a nondirective approach. In cases of early prenatal diagnosis, this may include discussion of pregnancy continuation or termination, raising the child in the family, foster care placement, and adoption.
7. Availability of genetic counseling or meeting with a genetics professional.

If the pregnancy is continued:

1. Develop a plan for delivery and neonatal care with the obstetrician and the family. As the pregnancy progresses, additional studies should be performed if available, if recommended by subspecialty consultants, and/or if desired by the family for modifying this management plan (eg, detection of a complex heart defect by echocardiography).
2. Offer parent-to-parent contact and information about local and national support organizations.
3. Offer referral to a clinical geneticist for a more extended discussion of clinical outcomes and variability, recurrence rates, future reproductive options, and evaluation of the risks for other family members.

HEALTH SUPERVISION FROM BIRTH TO 1 MONTH: NEWBORN INFANTS

Examination

The first step in evaluating a newborn infant for trisomy 21 is a careful review of the family history and prenatal information, particularly if prenatal chromosome studies were performed. Previous children born with trisomy 21 or developmental differences or pregnancies that ended in miscarriage may be significant clues that a family may carry a balanced translocation that predisposes them to having children with trisomy 21. For children who have had the diagnosis made prenatally, a formal copy of the chromosome report should be obtained. This report allows the clinician to confirm the diagnosis, review the results with the family, and add the formal diagnosis to the child's medical record. If the results of prenatal testing are not available, a blood sample should be obtained for postnatal cytogenetic analysis to confirm the diagnosis and rule out a chromosome translocation.

A physical examination is the most sensitive test in the first 24 hours of life to diagnose trisomy 21 in an infant. If the clinician feels that enough criteria are present on physical examination, then a blood sample should be sent for chromosome evaluation. The clinician should alert the laboratory and request rapid results. A study that uses fluorescent in situ hybridization (FISH) technology should be available within 24 to 48 hours to facilitate diagnosis and parent counseling. A FISH study can only indicate that an extra copy of chromosome 21 is present; it cannot detect translocations. Therefore, a positive FISH-test result should be confirmed by a complete chromosome analysis to identify translocations that may have implications for further reproductive counseling for the parents and possibly other family members.

The mother should be allowed to recover from the immediate delivery of the infant and have her partner or support person present before the diagnosis is given. The information should be relayed in a private setting by the physicians involved, optimally by the primary care provider for the infant and the delivering physician.[13] It is recommended that hospitals coordinate the delivery of the information and offer a private hospital room pending confirmation of the diagnosis.

An important aspect of providing information about Down syndrome to families includes first congratulating parents on the birth of their infant. Obstetricians and pediatricians should coordinate their messaging and inform parents of their suspicion immediately, in a private setting and, where appropriate, with both parents together. Physicians should use their experience and expertise in providing support and guidance for families. Clinicians should ensure a balanced approach rather than their personal opinions, give current printed materials, and offer access to other families who have children with Down syndrome and support organizations if locally available. It is important that clinicians be cognizant of the realities and possibilities for healthy, productive lives of people with Down syndrome in society.[13]

Confirm the laboratory diagnosis of Down syndrome and review the karyotype with the parents when the final result is available. Discuss the specific findings with both parents whenever possible, and talk about the potential clinical manifestations associated with the syndrome. These topics

should be reviewed again at a subsequent meeting. Parents should be referred for genetic counseling if it was not conducted prenatally.

Newborn care is often provided in a hospital setting by a physician who will not be the primary care provider, and extreme care is required to be certain that a smooth transition occurs for the family.

Discuss and Review

- Hypotonia.
- Facial appearance, and acknowledge the presence of familial characteristics.
- Feeding issues. Children with Down syndrome can usually nurse, and many can breastfeed successfully. Occasionally, some will need early supplementation until a successful nursing pattern is established. Some infants will also sleep for prolonged periods and need to be awakened to feed to maintain adequate calorie intake.

Evaluate for

- Heart defects (~50% risk). Perform an echocardiogram, to be read by a pediatric cardiologist, regardless of whether a fetal echocardiogram was performed. Refer to a pediatric cardiologist for evaluation any infant whose postnatal echocardiogram results are abnormal.
- Feeding problems. Refer all infants who have marked hypotonia as well as infants with slow feeding, choking with feeds, recurrent pneumonia, or other recurrent or persistent respiratory symptoms and unexplained failure to thrive for a radiographic swallowing assessment.[14,15]
- Cataracts at birth by looking for a red reflex. Cataracts may progress slowly and, if detected, need prompt evaluation and treatment by an ophthalmologist with experience in managing the child with Down syndrome.
- Congenital hearing loss, with objective testing, such as brainstem auditory evoked response or otoacoustic emission, at birth, according to the universal newborn hearing screening guidelines. Complete any needed follow-up assessment by 3 months.[16,17]
- Duodenal atresia or anorectal atresia/stenosis by performing a history and clinical examination.
- Apnea, bradycardia, or oxygen desaturation in a car safety seat for infants who are at increased risk because they have had cardiac surgery or are hypotonic. A car safety seat evaluation should be conducted for these infants before hospital discharge.[18]
- Constipation. If constipation is present, evaluate for restricted diet or limited fluid intake, hypotonia, hypothyroidism, or gastrointestinal tract malformation, including stenoses or Hirschsprung disease, for which there is an increased risk.
- Gastroesophageal reflux, which is usually diagnosed and managed clinically. If severe or contributing to cardiorespiratory problems or failure to thrive, refer for subspecialty intervention.
- Stridor, wheezing, or noisy breathing. If severe or contributing to cardiorespiratory problems or feeding difficulty, refer to pediatric pulmonologist to assess for airway anomalies. Tracheal anomalies and small tracheal size may also make intubation more difficult.
- Hematologic abnormalities. Obtain a complete blood cell count. Leukemoid reactions, or transient myeloproliferative disorder (TMD). TMD is found almost exclusively in newborn infants with Down syndrome and is relatively common in this population (10%).[19] TMD usually regresses spontaneously within the first 3 months of life, but there is an increased risk of later onset of leukemia for these patients (10%–30%).[20] Polycythemia is also common in infants with Down syndrome (18%–64%)[21] and may require careful management. Infants with TMD and polycythemia should be followed according to subspecialty consultation recommendations. Parents of infants with TMD should be counseled regarding the risk of leukemia and made aware of the signs, including easy bruising, petechiae, onset of lethargy, or change in feeding patterns. Leukemia is more common in children with Down syndrome than in the general population but still rare (1%).
- Congenital hypothyroidism (1% risk). Obtain thyroid-stimulating hormone (TSH) concentration if state newborn screening only measures free thyroxine (T4); congenital hypothyroidism can be missed if only the T4 concentration is obtained in the newborn screening. Many children with Down syndrome have mildly elevated TSH and normal free T4 levels. Management of children with abnormal thyrotropin or T4 concentrations should be discussed with a pediatric endocrinologist.

Anticipatory Guidance Given at Least Once Between Birth and 1 Month of Age

- Discuss increased susceptibility to respiratory tract infection. Children with signs and symptoms of lower respiratory tract infection should be evaluated acutely by a medical provider, and in the presence of cardiac or chronic respiratory disease, aggressive treatment should be instituted.[14] Children with comorbid conditions who qualify should have respiratory syncytial virus prophylaxis.[22]

- Discuss with parents the importance of cervical spine-positioning precautions to avoid excessive extension or flexion to protect the cervical spine during any anesthetic, surgical, or radiographic procedure.[23,24]
- Discuss efficacy of early intervention and availability of early-intervention services and therapies in the community. Initiate referral as appropriate.[25]
- Inform the family of the availability of support and advice from parents of other children with Down syndrome.
- Supply names of Down syndrome support groups and current books and pamphlets (see "Resources for Parents").
- Discuss the strengths of the child and positive family experiences.
- Discuss the individual resources for support, such as family, clergy, and friends.
- Talk about how and what to tell siblings, other family members, and friends. Review methods of coping with long-term disabilities.
- Review the recurrence risk in subsequent pregnancies and the availability of prenatal diagnosis as provided in genetic counseling.
- Discuss treatments that are considered complementary and alternative. Parents need an opportunity to learn objectively which therapies are safe and which are potentially dangerous (eg, cell therapy that may transmit slow viruses and fat-soluble vitamins that can cause toxicity). Several articles and Internet sites evaluate the legitimacy of claims that are made.[26–28]
- Renal and urinary tract anomalies have been reported to occur at increased frequency among persons with Down syndrome, and screening for these anomalies for all children with Down syndrome has been suggested.[29] Until studies confirm this finding and document that screening improves outcomes, routine renal and urologic screening is not recommended.

HEALTH SUPERVISION FROM 1 MONTH TO 1 YEAR: INFANCY

Physical Examination and Laboratory Studies

Review the risk of serous otitis media (50%–70%). Review the previous hearing evaluation (brainstem auditory evoked response [BAER, ABR] or otoacoustic emission). If the child passed the screening study, rescreen at 6 months of age for confirmation. If the infant failed to pass screening studies, refer to an otolaryngologist who is comfortable with examining infants with stenotic external canals to determine if a middle-ear abnormality is present. Tympanometry may be necessary if the tympanic membrane is poorly visualized. Middle-ear disease should be treated promptly. Once a clear ear is established, a diagnostic BAER should be performed to accurately establish hearing status. In children with stenotic canals, in which the tympanic membranes cannot be seen, refer to an otolaryngologist for examination under an office microscope. Interval ear examinations should be performed by the otolaryngologist every 3 to 6 months until the tympanic membrane can be visualized by the pediatrician and tympanometry can be performed reliably. A behavioral audiogram may be attempted at 1 year of age, but many children will not be able to complete the study and may need additional testing by BAER.[30,31]

- At least once during the first 6 months of life, discuss with parents symptoms of obstructive sleep apnea, including heavy breathing, snoring, uncommon sleep positions, frequent night awakening, daytime sleepiness, apneic pauses, and behavior problems that could be associated with poor sleep. Refer to a physician with expertise in pediatric sleep disorders for examination and further evaluation of a possible sleep disorder if any of the above-mentioned symptoms occur.[32,33]
- At each well-child visit, discuss with parents the importance of maintaining the cervical spine in a neutral position during any anesthetic, surgical, or radiographic procedure to minimize the risk of spinal cord injury and review the signs and symptoms of myelopathy. Perform careful history and physical examination, and pay attention for myelopathic signs and symptoms.
- Within the first 6 months of life, refer to a pediatric ophthalmologist or ophthalmologist with expertise and experience with infants with disabilities to evaluate for strabismus, cataracts, and nystagmus.[34] Check the infant's vision at each visit and use developmentally appropriate subjective and objective criteria. If lacrimal duct obstruction is present, refer for evaluation for surgical repair of drainage system if not resolved by 9 to 12 months of age.[35]
- Verify results of newborn thyroid-function screen if not previously performed. Because of increased risk of acquired thyroid disease, repeat measurement of TSH at 6 and 12 months of age and then annually.
- Monitor infants with cardiac defects, typically ventricular or atrioventricular septal defects that cause intracardiac left-to-right shunts, for symptoms and signs of congestive heart failure as pulmonary vascular resistance decreases and pulmonary blood flow increases. Tachypnea, feeding difficulties, and poor weight gain may

indicate heart failure. Medical management, including nutritional support, may be needed until the infant can undergo cardiac surgery to repair the defects. For patients with large ventricular septal defects and without obstruction to pulmonary blood flow, repair should be performed before 4 months of age to limit the potential for development of pulmonary hypertension and associated complications. Infants and children with Down syndrome are also at increased risk of pulmonary hypertension even in the absence of intracardiac structural defects.

- Obtain hemoglobin concentration beginning at 1 year of age and annually thereafter. Children with Down syndrome have been shown to have significantly lower dietary intakes of iron than their typically developing peers.[36] Increased erythrocyte mean corpuscular volume (MCV) has been reported in 45% of patients with Down syndrome with and without heart disease, and when MCV is decreased, it occurs at approximately the same time as anemia.[37] Therefore, MCV is not useful in screening for the diagnoses of iron deficiency, lead toxicity, or thalassemia in children with Down syndrome. Serum ferritin concentration is a sensitive parameter for assessment of iron stores in healthy subjects but is an acute-phase reactant and may be increased in the presence of chronic inflammation or infection and should be evaluated together with C-reactive protein (CRP) concentration. An elevated CRP level is an indication that a normal ferritin level may be falsely elevated and is not a reliable indication of normal iron status. Serum ferritin and CRP or reticulocyte hemoglobin (CHr) concentrations should be obtained at annual visits for patients who are at increased risk of iron deficiency on the basis of a history of decreased iron intake.[38–42]
- Monitor for signs of neurologic dysfunction that may occur. Children with Down syndrome have an increased risk of seizures, including infantile spasms (1%–13%)[43,44] and other conditions including Moyamoya disease.[45]
- Administer immunizations, including influenza vaccine and other vaccines recommended for all children, unless there are specific contraindications.[46]

Anticipatory Guidance

- Monitor weight and follow weight-for-height trends at each health care visit. Review the infant's growth and plot it by using the standard growth charts of the National Center for Health Statistics or the World Health Organization.[47] The previously used Down syndrome-specific growth charts no longer reflect the current population styles and body proportion. Until new charts are developed, patterns of growth and weight gain should be followed on the available standard growth charts and should include use of weight for height and BMI.[48]
- Review availability of Down syndrome support groups at least once in the first year of life (see "Resources for Parents").
- Assess the emotional status of parents and intrafamilial relationships at each well-child visit. Educate and support siblings and discuss sibling adjustments.
- Review connection to early-intervention services and their relationship to the strengths and needs of the infant and family at each well-child visit.
- Review the family's understanding of the risk of recurrence of Down syndrome and the availability of prenatal diagnosis at least once in the first year of life and more often if judged necessary by the clinician. Refer for genetic counseling if not already provided.
- Be prepared to discuss and answer questions about treatments that are considered complementary and alternative at each well-child visit.

HEALTH SUPERVISION FROM 1 TO 5 YEARS: EARLY CHILDHOOD

- Obtain a history and perform a physical examination, and give attention to growth and developmental status at every well-child visit.
- Review the risk of hearing loss associated with serous otitis media. For a child who passed diagnostic hearing testing, additional screening or behavioral audiogram and tympanometry should be performed every 6 months until normal hearing levels are established bilaterally by ear-specific testing (usually after 4 years of age). Subsequently, behavioral hearing tests should be performed annually. If normal hearing is not established by behavioral testing, additional screening by otoacoustic emissions or diagnostic BAER should be performed with sedation if necessary. Children who demonstrate a hearing loss should be referred to an otolaryngologist who is comfortable with the examination of children with stenotic ear canals. The risk of serous otitis media between 3 and 5 years of age is approximately 50% to 70%.
- Check the child's vision, and use developmentally appropriate subjective and objective criteria at each well-child visit. Refer the child annually to a pediatric ophthalmologist or ophthalmologist with special expertise and experience with children with disabilities. Children with Down syndrome have a 50%

risk of refractive errors that lead to amblyopia between 3 and 5 years of age. Addressing refractive errors and strabismus at an early age can help prevent amblyopia and encourage normal visual development.[34,49–51]

Atlantoaxial Instability

Discuss with parents, at least biennially, the importance of cervical spine-positioning precautions for protection of the cervical spine during any anesthetic, surgical, or radiographic procedure. Perform careful history and physical examination with attention to myelopathic signs and symptoms at every well-child visit or when symptoms possibly attributable to spinal cord impingement are reported. Parents should also be instructed to contact their physician for new onset of symptoms of change in gait or use of arms or hands, change in bowel or bladder function, neck pain, stiff neck, head tilt, torticollis, how the child positions his or her head, change in general function, or weakness.

The Asymptomatic Child

Children with Down syndrome are at increased risk of atlantoaxial subluxation. However, the child must be 3 years of age to have adequate vertebral mineralization and epiphyseal development for accurate radiographic evaluation of the cervical spine.[52] Plain radiographs do not predict well which children are at increased risk of developing spine problems, and normal radiographs do not provide assurance that a child will not develop spine problems later.[53,54] For these reasons, routine radiologic evaluation of the cervical spine in asymptomatic children is not recommended. Current evidence does not support performing routine screening radiographs for assessment of potential atlantoaxial instability in asymptomatic children.[55–64] Parents should be advised that participation in some sports, including contact sports such as football and soccer and gymnastics (usually at older ages), places children at increased risk of spinal cord injury[65] and that trampoline use should be avoided by all children with or without Down syndrome younger than 6 years and by older children unless under direct professional supervision.[66,67] Special Olympics has specific screening requirements for participation in some sports.[68]

The Symptomatic Child

Any child who has significant neck pain, radicular pain, weakness, spasticity or change in tone, gait difficulties, hyperreflexia, change in bowel or bladder function, or other signs or symptoms of myelopathy must undergo plain cervical spine radiography in the neutral position.[55,65] If significant radiographic abnormalities are present in the neutral position, no further radiographs should be taken and the patient should be referred as quickly as possible to a pediatric neurosurgeon or pediatric orthopedic surgeon with expertise in evaluating and treating atlantoaxial instability. If no significant radiographic abnormalities are present, flexion and extension radiographs may be obtained before the patient is promptly referred.[23,62,63]

- Measure TSH annually or sooner if child has symptoms that could be related to thyroid dysfunction.
- For children on a diet that contains gluten, at each preventative care visit review for symptoms potentially related to celiac disease, including diarrhea or protracted constipation, slow growth, unexplained failure to thrive, anemia, abdominal pain or bloating, or refractory developmental or behavioral problems.[69–71] For those with symptoms, obtain a tissue transglutaminase immunoglobulin A (IgA) level and simultaneous quantitative IgA. The quantitative IgA is important, because a low IgA level will result in a false-negative tissue transglutaminase IgA result. Refer patients with abnormal laboratory values for specialty assessment. There is no evidence showing routine screening of asymptomatic individuals as being beneficial. There are neither data nor consensus that would indicate whether patients with persistent symptoms who had normal laboratory values on initial evaluation should have further laboratory tests.
- Discuss symptoms of obstructive sleep apnea, including heavy breathing, snoring, restless sleep, uncommon sleep positions, frequent night awakening, daytime sleepiness, apneic pauses, and behavior problems, that could be associated with poor sleep at each well-child visit. There is poor correlation between parent report and polysomnogram results.[33,72] Therefore, referral to a pediatric sleep laboratory for a sleep study or polysomnogram for all children with Down syndrome by 4 years of age is recommended. Refer to a physician with expertise in pediatric sleep any child with signs or symptoms of obstructive sleep apnea or abnormal sleep-study results. Discuss obesity as a risk factor for sleep apnea.[34] It is recognized that access to a pediatric sleep laboratory or specialist may be limited for some populations and geographic areas.
- Maintain follow-up with a pediatric cardiologist for patients with cardiac lesions even after complete repair to monitor for recurrent/residual lesions as well as development of pulmonary hypertension.
- Monitor for neurologic dysfunction, including seizures.
- Obtain hemoglobin concentration

annually. Also, obtain serum ferritin and CRP concentrations for any child at risk of iron deficiency.

Anticipatory Guidance

- Review early intervention, including physical therapy, occupational therapy, and speech therapy, at all health maintenance visits.
- Discuss at the 30-month visit the transition from early intervention to preschool, which occurs at 36 months of age. Help the family understand the change from the Individualized Family Service Plan (IFSP) in early intervention to the Individualized Education Plan (IEP) through public education.
- Discuss with caregivers at every visit the child's behavioral and social progress. Refer children who may have autism, attention-deficit/hyperactivity disorder, or other psychiatric or behavioral problems for appropriate evaluation and intervention as soon as suspected. Autism and other behavioral problems occur with increased frequency in children with Down syndrome, and symptoms may manifest as early as 2 or 3 years of age.[73–76]
- Provide influenza vaccine annually. Children with chronic cardiac or pulmonary disease should be given the 23-valent pneumococcal polysaccharide vaccine (PPS23) at 2 years or older.[22]
- Reassure parents that delayed and irregular dental eruption patterns are common and that hypodontia occurs with increased frequency (23%).[77,78]
- Encourage and model use of accurate terms for genitalia and other private body parts (penis, vulva) any time these body parts are discussed or examined. Model respect for body rights by reminding patients that their body is their own and explain to the child what you will do before moving into child's personal space or performing a procedure. Remind patient and family that the only reason anyone should be looking at or touching private body parts is for health (doctor office visits) or hygiene (bathing or showering).[79]
- On at least 1 well-child visit educate parents about increased risk of sexual exploitation, and remind them that likely perpetrators are people their child knows and trusts, not strangers.
- At least once between 1 and 5 years of age, as with discussion in the first year of life, discuss future pregnancy planning and review risk of recurrence of Down syndrome and availability of prenatal diagnosis.
- Assess the child's behavior and talk about behavioral management, sibling adjustments, socialization, and recreational skills.
- Encourage families to establish optimal dietary and physical exercise patterns that will prevent obesity.
- Be prepared to discuss and answer questions about treatments that are considered complementary and alternative.

HEALTH SUPERVISION FROM 5 TO 13 YEARS: LATE CHILDHOOD

- Obtain a history and perform a physical examination with attention to growth and developmental status at each annual well-child visit.
- Monitor growth patterns, especially BMI, and emphasize healthy diet and lifestyle for preventing obesity.
- Obtain annual ear-specific audiologic evaluation.
- Obtain ophthalmologic evaluation every 2 years.
- Measure TSH annually; the risk of hypothyroidism increases with age.
- Individualize cardiology follow-up on the basis of history of cardiac defects.
- Obtain hemoglobin concentration annually and serum ferritin and CRP or reticulocyte hemoglobin concentrations at annual visits for any child at risk of iron deficiency on the basis of history of decreased iron intake.
- For children on a diet that contains gluten, review for symptoms potentially related to celiac disease at every health maintenance visit and evaluate if indicated.
- At each well-child visit, discuss with parents the importance of universal precautions for protection of the cervical spine during any anesthetic, surgical, or radiographic procedure. Perform careful history and physical examination with attention to myelopathic signs and symptoms. Parents should also be instructed to contact their physician immediately for new onset of symptoms of myelopathy.
- Counsel parents that some sports place children at increased risk of spinal cord injury.[65–67]
- Monitor for neurologic dysfunction, including seizures.
- Very dry skin, which may be a sign of hypothyroidism, and other skin problems are particularly common in patients with Down syndrome. Therefore, be attentive to these dermatologic problems and discuss them with the patient and family.
- Discuss symptoms related to obstructive sleep apnea at every well-child visit, including snoring, restless sleep, daytime sleepiness, nighttime awakening, behavior problems, and abnormal sleep position. Refer to a physician with expertise in pediatric sleep any child with signs or symptoms of obstructive sleep apnea or abnormal sleep-

study results. Discuss obesity as a risk factor of sleep apnea.

Anticipatory Guidance at Every Health Maintenance Visit

- Review the child's development and appropriateness of school placement and developmental intervention.
- Discuss socialization, family status, and relationships, including financial arrangements, health insurance, and guardianship.
- Discuss the development of age-appropriate social skills, self-help skills, and development of a sense of responsibility.
- Monitor for behavior problems that interfere with function in the home, community, or school. Attention problems, attention-deficit/hyperactivity disorder, obsessive compulsive behaviors, noncompliant behavior, and wandering off are some of the common behavior concerns reported. Psychiatric disorders seen in typically developing children may also occur. Evaluate for medical problems that can be associated with behavior changes, including thyroid abnormalities, celiac disease, sleep apnea, gastroesophageal reflux, and constipation. Intervention strategies depend on the child's age, the severity of the problem, and the setting in which the problem occurs. Referral to community treatment programs, psychosocial services for consultative care, or behavioral specialists experienced in working with children with special needs may be necessary. The use of medication for behavior management should be discussed between the primary care physician and specialists involved in the child's care, because children with Down syndrome may be more sensitive to certain medications. Although there has been little research to directly address the use of psychotropic medications among children with Down syndrome, anecdotal reports indicate that such children may differ in their response to medications.
- Counsel families regarding the transition from elementary to middle school, when major change often occurs, from 1 to many teachers and from 1 class to changing classes. Prepare them to facilitate adjustment at a time when the academic disparity becomes greater and full inclusion becomes more difficult.
- Refer children who may have autism for appropriate evaluation and intervention as soon as suspected.
- Continue to assess, monitor, and encourage independence with hygiene and self-care. Encourage parents to teach, model, and respect privacy at home and in the community. Discuss appropriate management of sexual behaviors such as masturbation.
- Discuss progression of physical and psychosocial changes through puberty and issues of fertility and contraception.[79,80] Remind parents that physical development usually follows patterns similar to those found in the general population, but the child with Down syndrome will likely need more preparation in understanding and managing them.[81]
- Discuss the need for gynecologic care in the pubescent girl. Talk with the patient and her family about the recurrence risk of Down syndrome (50%) were she to become pregnant.[82,83] Although males with Down syndrome are usually infertile, there have been rare instances in which a male has reproduced.[83–85] Birth control and prevention of sexually transmitted diseases should be discussed with patients and their families. Families may wish to discuss sterilization, and the pediatrician may review the topic in the American Academy of Pediatrics policy statement "Sterilization of Minors With Developmental Disabilities."[86]
- Be prepared to discuss and answer questions regarding treatments that are considered complementary and alternative.

HEALTH SUPERVISION FROM 13 TO 21 YEARS OR OLDER: ADOLESCENCE TO EARLY ADULTHOOD

Physical Examination and Laboratory Values

- Measure hemoglobin concentration annually.
- Measure TSH concentration annually.
- Obtain annual ear-specific audiologic evaluation.
- For children on a diet that contains gluten, review for symptoms potentially related to celiac disease at every health maintenance visit, and evaluate if indicated.
- Individualize cardiology follow-up on the basis of history of cardiac defects. Discuss symptoms related to obstructive sleep apnea, including snoring, restless sleep, daytime sleepiness, nighttime awakening, behavior problems, and sleep position at every health maintenance visit. Refer to a physician with expertise in pediatric sleep any child with signs or symptoms of obstructive sleep apnea or an abnormal sleep-study result. Discuss the risk factor of obesity for sleep apnea.
- Discuss with parents and the patient at every visit the importance of cervical spine-positioning precautions for protection of the cervical spine during any anesthetic, surgical, or radiographic procedure. Perform careful history and physical

examination with attention to myopathic signs and symptoms. Parents and patients should also be instructed to contact their physician immediately for new onset of symptoms of myopathy.

- Counsel parents that some sports place children at increased risk of spinal cord injury.[65–67]
- Monitor for signs of other neurologic dysfunction, including seizures.
- Obtain ophthalmologic evaluation every 3 years. Check for onset of cataracts, refractive errors, and keratoconus, which can cause blurred vision, corneal thinning, or corneal haze and is typically diagnosed after puberty.
- Examine annually for acquired mitral and aortic valvular disease in older patients with Down syndrome. An echocardiogram should be obtained if there is a history of increasing fatigue, shortness of breath, or exertional dyspnea or abnormal physical examination findings, such as a new murmur or gallop. Discuss skin, hair, and scalp care at each preventive health care visit.

Anticipatory Guidance at Every Health Maintenance Visit

- Discuss issues related to transition into adulthood, including guardianship and long-term financial planning from early adolescence. Potential adult morbidities including apparent tendency toward premature aging and increased risk of Alzheimer disease may also be discussed.[87]
- Monitor growth patterns, especially BMI, and counsel regarding healthy diet and a structured exercise program.
- Discuss behavioral and social states and refer patients who have chronic behavioral problems or manifest acute deterioration in function for specialized evaluation and intervention.[88,89]
- Discuss appropriateness of school placement, and emphasize planning for transition to adulthood and adequate vocational training within the school curriculum.[90,91]
- Talk with the female patient and her family about the recurrence risk of Down syndrome should she become pregnant.
- Continue to assess, monitor, and encourage independence with hygiene and self-care. Provide guidance on healthy, normal, and typical sexual development and behaviors. Emphasize the need for understandable information, and encourage opportunities for advancing comprehension of sexuality. Discuss the need for contraception and prevention of sexually transmitted diseases and the degree of supervision required. Advocate for the least invasive and least permanent method of birth control and be familiar with local law and resources to assist the family in their decision-making regarding questions about sterilization.[86]
- Make recommendations and provide or refer for routine gynecologic care if not already provided. Discuss premenstrual behavioral problems and management of menses.[92]
- Discuss group homes and independent living opportunities, workshop settings, and other community-supported employment.
- Discuss intrafamily relationships, financial planning, and guardianship.
- Facilitate transition to adult medical care.[93]

FUTURE CONSIDERATIONS

Many issues related to the development and health of people with Down syndrome remain to be evaluated, and research agendas for addressing both public health and basic science topics have been developed. Knowledge in several topics of great importance to the care of children with Down syndrome could be enhanced through population-based research. A rigorous evidence-based review of screening and treatment for atlantoaxial instability, for example, is needed,[94] and continuing research is critical for directing the care for optimal outcomes of persons with Down syndrome.[1,95,96]

ACKNOWLEDGMENT

The mentoring and contributions of Dr. William Cohen have been sincerely appreciated and were integral to the development of this clinical report. His untimely death is a great loss to his patients and their families, his colleagues, and the greater medical community. This clinical report is dedicated to his memory.

APPENDIX 1 Health Supervision for Children With Down Syndrome

	Prenatal	Birth–1 mo	1 mo–1 y	1–5 y	5–13 y	13–21 y
Counseling regarding prenatal screening test & imaging results						
Plan for delivery						
Referral to geneticist						
Parent-to-parent contact, support groups, current books and pamphlets						
Physical exam for evidence of trisomy 21						
Chromosomal analysis to confirm dx						
Discuss risk of recurrence of Down syndrome						
Echocardiogram						
Radiographic swallowing assessment if marked hypotonia, slow feeding, choking with feeds, recurrent or persistent respiratory sx, FTT						
Eye exam for cataracts						
Newborn hearing screen and follow-up						
Hx and PE assessment for duodenal or anorectal atresia						
Reassure parents delayed and irregular dental eruption, hypodontia are common						
If constipation, evaluate for limited diet or fluids, hypotonia, hypothyroidism, GI malformation, Hirschsprung		**Any visit**				
CBC to R/O transient myeloproliferative disorder, polycythemia						
Hb annually; CRP & ferritin or CHr if possible risk iron deficiency or Hb <11 g.				**Annually**		
Hemoglobin						**Annually**
TSH (may be part of newborn screening)			**6 and 12 mo**	**Annually**		
Discuss risk of respiratory infection						
If cardiac surgery or hypotonic: evaluate apnea, bradycardia, or oxygen desaturation in car seat before discharge						
Discuss complementary & alternative therapies		**All health maint. visits**				
Discuss cervical spine positioning, especially for anesthesia or surgical or radiologic procedures		**All health maint. visits**				
Review signs and symptoms of myopathy		**All health maint. visits**				
If myopathic signs or symptoms: obtain neutral position spine films and, if normal, obtain flexion & extension films & refer to pediatric neurosurgeon or orthopedic surgeon with expertise in evaluating and treating atlanto-axial instability		**Any visit**				
Instruct to contact physician for change in gait, change in use of arms or hands, change in bowel or bladder function, neck pain, head tilt, torticollis, or new-onset weakness				**Biennially**		
Advise risk of some contact sports, trampolines				**All health maint. visits**		
Audiology evaluation at 6 mo						
If normal hearing established, behavioral audiogram and tympanometry until bilateral ear specific testing possible. Refer child with abnormal hearing to ot				**Every 6 mo**		
If normal ear-specific hearing established, behavioral audiogram				**Annually**		
Assess for obstructive sleep apnea Sx				**All health maint. visits**		
Sleep study by age 4 years						
Ophthalmology referral to assess for strabismus, cataracts, and nystagmus						
Refer to pediatric ophthalmologist or ophthalmologist with experience with Down syndrome				**Annually**	**Every 2 y**	**Every 3 y**
If congenital heart disease, monitor for signs & Sx of Congestive heart failure		**All visits**				
Assess the emotional status of parents and intrafamilial relationships		**All health maint. visits**				
Check for Sx of celiac disease; if Sx present, obtain tissue transglutaminase IgA & quantitative IgA				**All health maint. visits**		
Early intervention: physical, occupational, and speech therapy				**Health maint. visits**		
At 30 months, discuss transition to preschool and development of IEP						
Discuss behavioral and social progress				**Health maint. visits**		
Discuss self-help skills, ADHD, OCD, wandering off, transition to middle school					**Health maint. visits**	
If chronic cardiac or pulmonary disease, 23-valent pneumococcal vaccine at age >2 y						
Reassure regarding delayed and irregular dental eruption						
Establish optimal dietary and physical exercise patterns				**Health maint. visits**		
Discuss dermatologic issues with parents						
Discuss physical and psychosocial changes though puberty, need for gynecologic care in the pubescent female						
Facilitate transition: guardianship, financial planning, behavioral problems, school placement, vocational training, independence with hygiene and self-care, group homes, work settings						**Health maint. visits**
Discuss sexual development and behaviors, contraception, sexually transmitted diseases, recurrence risk for offspring						**Health maint. visits**
		Do once at this age				
		Do if not done previously				
		Repeat at indicated intervals				

Maint. indicates maintenance; dx, diagnosis; sx, symptoms; FTT, failure to thrive; Hx, history; PE, physician examination; GI, gastrointestinal; CBC, complete blood count; R/O, rule out; Hb, hemoglobin; ot, occupational therapy; CHr, reticulocyte hemoglobin; IgA, immunoglobulin A; IEP, Individualized Education Plan; ADHD, attention-deficit/hyperactivity disorder; OCD, obsessive compulsive disorder.

ERRATA

American Academy of Pediatrics. Health Supervision for Children with Down Syndrome. *Pediatrics.* 2011;128(2):393–406

An error occurred in the American Academy of Pediatrics clinical report "Health Supervision for Children with Down Syndrome" published in the August 2011 issue of *Pediatrics* (2011;128[2]:393-406; originally published online July 25, 2011; doi10.1542/2011-1605). In Appendix 1 on page 406, the 24th row of the first column should read "If myelopathic signs or symptoms:" rather than "If myopathic signs or symptoms:". We regret the error.

Clinical Report—Health Supervision for Children With Fragile X Syndrome

abstract

FREE

Fragile X syndrome (an *FMR1*–related disorder) is the most commonly inherited form of mental retardation. Early physical recognition is difficult, so boys with developmental delay should be strongly considered for molecular testing. The characteristic adult phenotype usually does not develop until the second decade of life. Girls can also be affected with developmental delay. Because multiple family members can be affected with mental retardation and other conditions (premature ovarian failure and tremor/ataxia), family history information is of critical importance for the diagnosis and management of affected patients and their families. This report summarizes issues for fragile X syndrome regarding clinical diagnosis, laboratory diagnosis, genetic counseling, related health problems, behavior management, and age-related health supervision guidelines. The diagnosis of fragile X syndrome not only involves the affected children but also potentially has significant health consequences for multiple generations in each family. *Pediatrics* 2011;127:994–1006

INTRODUCTION

This set of guidelines was designed to assist pediatricians in caring for children with fragile X syndrome after a diagnosis has been confirmed by DNA analysis. Fragile X syndrome (secondary to an abnormality in the fragile X mental retardation 1 [*FMR1*] gene) is the most commonly inherited form of mental retardation. The disorder affects the child and potentially the mother and other family members. These guidelines, therefore, discuss issues pertinent to the clinical manifestations of this disorder in younger and older people. The multiple manifestations in different age groups have led to fragile X syndrome being designated as one in the spectrum of *FMR1*-related disorders.[1]

Awareness that mental retardation has a sex-linked component, with an excess of males affected, has existed for more than a century.[2] This observation led to the suggestion that genes affecting cognition were located on the X chromosome. In 1943, Martin and Bell[3] reported that mental retardation segregated as an X-linked gene in a family in which both males and females were affected. Twenty-six years later, in 1969, Lubs[4] reported a distinctive fragile site on the X chromosome, which required culture media deficient in folic acid to be induced on a chromosome analysis, that segregated with mental retardation in 3 generations of a family. This is now known as the fragile X chromosome. In 1977, the relationship of this fragile site at band q27.3 on the long arm of the X chromosome (Xq27.3) to X-linked mental retardation was confirmed, and fragile X syndrome, as a clinical entity, was defined. Since

All clinical reports from the American Academy of Pediatrics automatically expire 5 years after publication unless reaffirmed, revised, or retired at or before that time.

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

that time, the clinical and molecular features of the condition have been more clearly delineated. Several literature sources are available for additional information.[1,5–7] New information regarding the role of the protein product in synaptic plasticity in the brain is under investigation.[8]

The clinical phenotype of fragile X syndrome, including cognitive abilities, is variable, and physical features often are nonspecific in nature, especially in young children. The disorder has been described in every ethnic group and has an estimated prevalence of 1 in 3700 white males and 1 in 2500 black males.[1] Clinical manifestations of fragile X syndrome also may occur in heterozygous females, in whom the prevalence is estimated to be 1 in 7000.

Molecular Basis of Fragile X Syndrome

Cytogenetic assay for fragile X syndrome is no longer regarded to be sufficiently precise for clinical diagnostic use. In 1991, the *FMR1* gene was mapped to the fragile site at Xq27.3.[5,9] *FMR1* harbors a novel, unstable CGG (cytosine-guanine-guanine) trinucleotide repeat within the 5′-untranslated region of the gene, which accounts both for the fragile site and the genetic peculiarities associated with the region. The CGG repeat is highly polymorphic in the general population. The normal range is from 5 to 40, and 30 CGG repeats represents the most common number found within the gene. Full mutations, which cause fragile X syndrome, are the consequence of unstable expansion of the repeats, which results in a CGG number that exceeds 200. A full mutation results in hypermethylation of *FMR1*, which leads to gene-silencing and a decrease in the production of the fragile X mental retardation 1 protein (FMRP). The most important factor that determines the clinical severity of fragile X syndrome is the degree of *FMR1* methylation and gene-silencing rather than the length of expansion reflected by the number of CGG repeats, which explains why 2 people with the same number of expanded CGG repeats but different FMRP levels will have different clinical presentations, because methylation may differ. Classically, in a person with a full mutation, the repeat number is massively expanded. Premutations, which have a CGG repeat number that ranges from 55 to 200, are meiotically unstable in the female. Premutations are unmethylated, are transcriptionally active, and produce FMRP, although possibly in lower amounts than normal alleles. Repeats in the range of 45 to 54 are considered to be intermediate or "gray-zone" alleles and are not considered to be predisposed to meiotic instability.[1] Molecular clinical correlations have demonstrated that variation in the clinical phenotype of affected people is related to the presence of mosaicism of methylation status, which results in preservation of some gene function and partial expression of FMRP. Although most instances of fragile X syndrome result from CGG expansion into the full mutation range, a rare point mutation within the *FMR1* gene or deletion in *FMR1* can produce the typical phenotype of fragile X syndrome as well.

Clinical Phenotype

The clinical phenotype in males with fragile X syndrome can be subtle, and its detection in the prepubertal period can be difficult. In fact, it was reported from a parent survey that 24% of families with a child in whom fragile X syndrome was diagnosed had seen a health care provider more than 10 times before fragile X testing was performed.[10] Often, it is the presence of development delay, mental retardation, or specific behavioral patterns that leads to suspicion of fragile X syndrome; mean age at diagnosis is 32 months. The classical facial appearance that includes a prominent forehead, a long, narrow face, a prominent jaw, and protuberant ears becomes more evident late in childhood or in early adolescence. The palate frequently is highly arched, and cleft palate has been reported. Dental crowding and malocclusion are common. Strabismus may be present, and refractive errors, including hyperopia and astigmatism, are present in 23% to 50% of cases. Nystagmus and ptosis also are occasional ocular findings. Macro-orchidism is observed in more than 80% of adolescent and adult males with fragile X syndrome; mean testicular volume is approximately 50 mL (normal mean testicular volume: $<$25 mL). Macro-orchidism is less common in prepubertal boys. Fragile X syndrome also has a connective tissue dysplasia, and findings may include soft velvet-like skin; joint hypermobility, especially in the fingers; pes planus; congenital hip dislocation; scoliosis and clubfoot; and, in adults, occasionally mitral valve prolapse.[6] Feeding problems are common, and gastroesophageal reflux has been reported for one-third of affected infants. Chronic otitis media, seen in 60% to 80% of cases, has its onset early in life, and recurrent otitis media is present in 23% of males with fragile X syndrome. Seizures have been reported in approximately 13% to 18% of affected males and 5% of females with a full mutation, and there may be relative macrocephaly. Birth weight in affected people typically is normal. Accelerated linear growth with tall stature is common throughout childhood; however, growth velocity tends to slow in adolescence, and 26% of adult men with fragile X syndrome have a height that is equal to or less than the 5th percentile.[6](p27–28)

A subgroup of males with the full mutation has been described in which the clinical phenotype is reminiscent of Prader-Willi syndrome.[11] Affected males have extreme obesity, short stature, stubby hands and feet, and diffuse hyperpigmentation.

Cognitive Profile

Fragile X syndrome should be suspected in a boy with developmental delay and hypotonia in early childhood. Cognitive deficits frequently result in moderate-to-severe mental retardation; the average IQ is approximately 40 in an adult man with a completely methylated full mutation. Males who are less severely affected can have incomplete methylation resulting in some gene product and present with only mild intellectual deficits or learning problems. In addition, slowing in the acquisition of cognitive skills can occur with age.

Language delay also is evident in early childhood. A child with fragile X syndrome may not begin to speak until 2 to 3 years of age. Although vocabulary and syntax may be less involved, deficits in conversational speech are frequent.

In females with a full mutation, the cognitive profile is similar to that of males, but there is wider phenotypic variability, especially in relation to IQ scores. Intellectual abilities range from normal to significant mental retardation, and the majority of females with a full mutation have a normal or borderline IQ. The milder phenotype in affected females correlates with the degree of X inactivation of the X chromosome that contains the CGG expansion during lyonization. A more severe phenotype would be anticipated when there is skewed X inactivation (eg, when the majority of X chromosomes randomly inactivated are those with a normal CGG repeat number), thus preferentially activating the X chromosome with an expanded CGG repeat number.

Neurobiology

Gross abnormalities have not been observed in the brains of people with fragile X syndrome on autopsy. Although diffuse brain atrophy and white matter abnormalities have been noted on MRI, routine neuroimaging of the brain is not indicated. At the cellular level, longer and thinner dendritic spines on which most of the synapses occur have been detected, which suggests a possible misregulation in their development and maturation. FMRP has an important role in the regulation of protein synthesis at a local level in the dendrites of neurons. Protein synthesis in dendritic spines is important for synaptic transmission, synaptic plasticity, learning, and memory. A proposed role for FMRP at the synapse is that it is a negative regulator of protein synthesis stimulated by group 1 metabotropic glutamate receptor (mGluR) activation.[8] Therefore, fragile X syndrome is at least partially a result of exaggerated responses to mGluR stimulation.

Behavioral Phenotype

Behavioral problems occur in more than 50% of affected patients and are generally out of proportion with the affected child's cognitive level, compared with children with other developmental disorders who are functioning at similar intellectual levels.[6,7] In general, behavioral difficulties can be separated into a few symptom clusters. Features of attention-deficit/hyperactivity disorder, including hyperactivity, inattentiveness, distractibility, restlessness, and impulsivity, are present in 80% of patients with fragile X syndrome. Affected children also can exhibit anxiety-related symptoms including obsessive-compulsive–like and perseverative behaviors. Emotional lability is common. Aggressive and self-injurious behaviors can occur, related to a difficult temperament, with irritability and frequent temper tantrums. Hypersensitivity to sensory stimuli can lead to heightened and prolonged arousal in situations in which there is excessive auditory, visual, or tactile stimuli. This behavior can lead to an increase in tantrums, hyperactivity, oppositionality, and restricted verbal output. On the other hand, affected males often have a good sense of humor, are persistent and hardworking, and have an endearing quality. Features of autism may be present in early childhood, including stereotypies such as hand-flapping, biting, perseverative speech, poor eye contact, and lack of interest in social interaction. Autism is present in 30% of people with a full mutation, and pervasive developmental disorder–not otherwise specified has been reported in another 20% to 30% of affected children. Fragile X syndrome also is found in approximately 2% to 6% of people with autism. Psychiatric comorbidity also is frequently observed in affected people and includes oppositional defiant disorder, separation anxiety, and obsessive-compulsive disorder. Females with a full mutation tend to have a higher risk of emotional problems compared with the general population. In fact, shyness, social avoidance, social anxiety, mood lability, and depression may be presenting features in a female with the full mutation.

Premutation

Both females and males with a CGG repeat number that ranges from 55 to 200 are considered to carry a premutation. The prevalence of a premutation has been estimated to be approximately 1 in 259 in females and 1 in 813 in males. People carrying the premutation originally were believed to be clinically normal, because the *FMR1* gene is not methylated with a CGG repeat number below 200, which results in FMRP activity. However, it is now recognized that carriers of a premutation can present with 1 or more distinct

clinical disorders: mild cognitive and/or behavioral deficits; primary ovarian insufficiency (POI); and a neurodegenerative disorder in older adult premutation carriers, especially males, called fragile X–associated tremor/ataxia syndrome (FXTAS). In contrast to decreased messenger RNA (mRNA) in people with a full mutation and absence of FMRP, mRNA levels are elevated and FMRP is present in people with a premutation.

A minority of female carriers of a premutation have mild physical features of fragile X syndrome, which can include prominent ears or hypermobile finger joints. Emotional problems also may be present, including anxiety, obsessional thinking, schizotypy, and/or depression. It was observed recently that depression and interpersonal sensitivity were more likely to occur in females with a premutation with more than 100 CGG repeats than in those with fewer repeats.[12] These emotional findings are likely to represent a mild form of the anxiety and perseverative thinking that occurs in those with a full mutation and may be the result of a mild deficit in FMRP found in the upper half of the premutation range. Males with a premutation are prone to have attentional problems, executive dysfunctions, social deficits, and obsessive-compulsive behavior.[13]

A disorder unique to female carriers of a premutation is POI (previously referred to as premature ovarian failure [POF]), in which there is cessation of menses before 40 years of age.[14–17] This disorder is seen in approximately 20% of women who carry a premutation allele, in contrast to approximately 1% in the general population. Subclinical ovarian dysfunction that leads to elevated follicle-stimulating hormone levels is seen in another 25% of adult women younger than 40 years with a premutation. An increased risk of twinning also exists for conceptions in a woman with a premutation.

Recently, a new phenotype that develops in the later years of the majority of adult men who carry a premutation (rarely reported in female premutation carriers) has emerged, designated FXTAS.[18,19] A progressive intention tremor develops after 50 years of age and is typically followed by ataxia. Associated features include a peripheral neuropathy; parkinsonian manifestations; autonomic dysfunction such as incontinence, impotence, and orthostatic hypotension; progressive cognitive impairments that involve loss of memory and deficits in executive function; and psychological features including disinhibition, anxiety, mood lability, irritability, outbursts, depression, and isolation. Some patients progress to having dementia. This neurodegenerative disorder seems pathogenetically distinct from fragile X syndrome and is probably related to *FMR1* messenger RNA levels that are elevated in premutation carriers. FXTAS has not been observed in males with a full mutation. Maternal grandfathers of affected males should be counseled and evaluated as appropriate for adult-onset movement disorders.

The expansion of the number of CGG repeats occurs during reproduction in a female with a premutation. This may be a small expansion to a slightly larger CGG repeat number in the premutation range, or it may result in a massive expansion into a full mutation. The risk of expansion to a full mutation is determined by the size of the mother's premutation. As the CGG repeat number increases, so does the risk of expansion to a full mutation (Table 1). Therefore, the larger the number of repeats, the more likely it will expand to a full mutation in an offspring. To date, no offspring with a full mutation has been described when the CGG repeat number is less than 59. Because the number of CGG repeats in a female with a premutation has the potential to increase through several generations of a family, the risk of expansion to a full mutation also increases.

TABLE 1 Risk of Expansion to a Full Mutation in Male Offspring Based on the CGG Repeat Number in the Mother[1,34]

CGG Repeat Number	Risk for Expansion to a Full Mutation, %
59–69	37
70–79	65
80–89	70
90–99	95
≥100	100

A premutation will be transmitted to all female offspring of a male with a premutation. In these females, the CGG repeat number is similar to their fathers' repeat number or may expand slightly. However, the CGG repeat number may undergo expansion when a female with a premutation reproduces, which could result in an offspring with a full mutation and fragile X syndrome. A premutation in a male will not be transmitted to his male offspring, because the son inherits his father's Y chromosome.

Who Should Be Tested for Fragile X Syndrome

Because children with fragile X syndrome may not have apparent physical features, any child who presents with developmental delay, borderline intellectual abilities, or mental retardation or has a diagnosis of autism without a specific etiology should undergo molecular testing for fragile X syndrome to determine the number of CGG repeats (Fig 1). Approximately 2% to 6% of these patient populations will be found to have an *FMR1* mutation. The family should be made aware of the implications of the testing for other family members and given the option of genetic counseling before testing. Array comparative genomic hybridization (or array

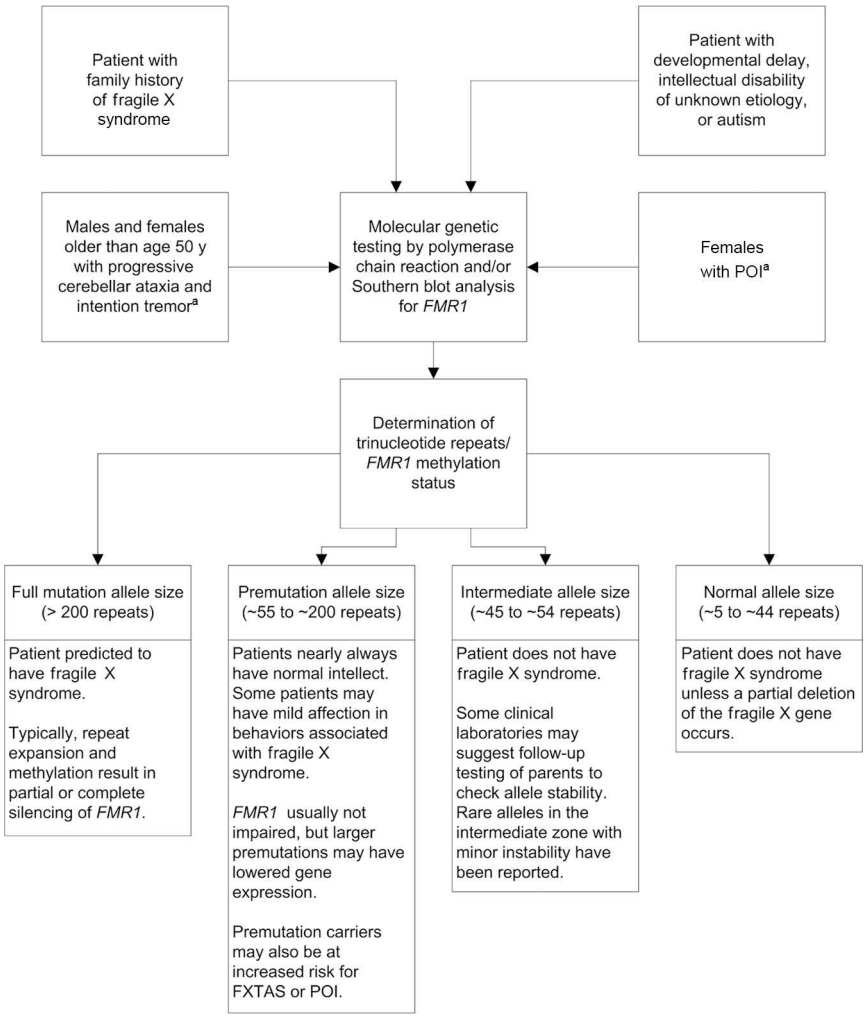

FIGURE 1

Testing algorithm for fragile X syndrome and *FMR1*-related disorders. [a] Adults to be considered for *FMR1* molecular testing. (Adapted with permission from Saul RA, Tarleton JC. *FMR1*-related disorders. *GeneReviews* [online]. October 28, 2010. Available at: www.ncbi.nlm.nih.gov/books/NBK1384. Copyright, University of Washington, Seattle, 1997–2010.)

testing) should also be considered. Phenotypic checklists have also been created for use in males with developmental delay of undetermined etiology to help identify candidates for fragile X molecular testing. These checklists slightly increase the diagnostic yield, especially when used in concert with targeted family fragile X history questionnaires. Fragile X testing should also be considered in patients in whom there is suspected, but not molecularly proven, Sotos syndrome or Prader-Willi syndrome. On the other hand, fragile X testing, is not routinely warranted for children with isolated attention-deficit/hyperactivity disorder.

When evaluating a family with fragile X syndrome, questions also should address whether there are people with mild emotional and/or learning problems, POI, and/or features of FXTAS. Because people with a premutation are at risk of having these conditions, molecular testing is suggested for asymptomatic siblings of a child with fragile X syndrome and for other family members at risk of carrying the mutation. In family members found to have a premutation allele (55–200 CGG repeats), developmental testing may be indicated, and in older people, monitoring is warranted for POI and FXTAS.

Management of a Child With Fragile X Syndrome

Diagnosing fragile X syndrome is beneficial to the family, because it establishes the reason why a child has cognitive deficits and/or behavioral problems. Establishing a diagnosis of fragile X syndrome also will allow parents and/or caregivers to gain an understanding of the disorder and how it affects the child's development and behavior. Diagnosis also will allow the family to focus on appropriate management strategies that will maximize their child's potential. Formal assessment tools are available to assist with a behavior-management plan. Current approaches to therapy are supportive and symptom based. Psychopharmacologic intervention to modify behavioral problems in a child with fragile X syndrome may represent an important adjunctive therapy when combined with other supportive strategies including speech therapy, occupational therapy, special educational services, and behavioral interventions. Medication management may be indicated to modify attentional deficits, problems with impulse control, and hyperactivity. Anxiety-related symptoms, including obsessive-compulsive tendencies with perseverative behaviors, also may be present and require medical intervention. Emotional lability and episodes of aggression and self-injury may be a danger to the child and others around him or her; therefore, the use of medication(s) to modify these symptoms also may significantly improve an affected child's ability to participate more successfully in activities in home and school settings.

Several classes of medications alone or in combination have proven to be beneficial in managing behavior problems in fragile X syndrome.[7,20] Stimulants target hyperactivity, inattention, and impulsivity, and two-thirds to three-quarters of symptomatic children with fragile X syndrome benefit from the use of methylphenidate. However, in some affected people, stimulants may exacerbate anxiety, mood lability, or aggressive tendencies. The α-2-adrenergic agonists clonidine and guanfacine have been effective in treating hyperactivity, hyperarousal to sensory stimuli, impulsivity, and aggressive behaviors in approximately 70% of young boys with fragile X syndrome. These agents may be especially helpful in a child who is younger than 5 years and does not tolerate or respond to stimulants. Clonidine also is effective for the management of sleep disturbances,[21] and melatonin may be beneficial for regulating sleep patterns.[22]

Selective serotonin-reuptake inhibitors can be useful in the management of mood disorders, anxiety, obsessive-compulsive behaviors, tantrums, and aggression in people with fragile X syndrome. Atypical antipsychotics generally are reserved for people with fragile X syndrome who exhibit more extreme behaviors, particularly aggression, marked mood lability, self-injury, and other undesired behaviors. Parent reports of improvement in mood stabilization, attention, and academic performance have been described with aripiprazole, which should be used at low doses to avoid agitation induced by higher doses.[23] However, adverse effects can include excessive weight gain, sedation, nausea, constipation, diabetes, and tardive dyskinesia.[24]

Current psychopharmacologic therapy for fragile X syndrome is supportive or symptom-based, and no therapy exists that is specifically directed at improving cognitive ability in patients with fragile X syndrome. However, because excessive mGLuR signaling plays a role in the fragile X syndrome phenotype, drugs that target mGLuR may be an effective treatment in this disorder. As more information regarding specific dendritic functions of FMRP are elucidated, pharmacologic investigations will likely be designed to address specific neurochemical and synaptic deficits generated by the absence of FMRP, targeting cognitive deficits and also leading to improvements in behavior.[7,25]

Factors in the environment also may influence adaptive behaviors, cognitive abilities, and behavioral symptoms of patients with fragile X syndrome. For instance, in 1 study, behavioral symptoms in children with fragile X syndrome who resided in a nurturing home environment displayed few autistic behaviors, better adaptive behavior, and higher IQ.[26]

Genetic Counseling

Fragile X syndrome and *FMR1*-related disorders (ie, POI and FXTAS) are inherited in an X-linked dominant manner with often complex expression. Genetic counseling is recommended for all family members who are affected or at risk of having a premutation or an offspring with a full mutation. Genetic counseling is critical to provide information regarding the inheritance pattern and variability of the clinical phenotype in people being affected with both a full mutation and premutation and to offer the option of pursuing molecular testing. Options for reproductive planning can be discussed in anticipation of family planning for adults at risk of having an affected child. In addition to seeking help from professionals who are knowledgeable of the condition, information to assist families also can be obtained from support organizations and through contact with parents who have a similarly affected child.

The mother of a child with an *FMR1* mutation is almost always a carrier of a premutation or full mutation. Females who are premutation carriers may have inherited the premutation from their father or from their mother who also carries a premutation. Women with a premutation are at risk of premature ovarian insufficiency and at small risk of FXTAS. They carry a 50% risk of transmitting an abnormal gene, which either contains a premutation copy number (55–200) or a full mutation (>200) in each pregnancy. Rarely, a decrease in the number of CGG repeats has been reported when the abnormal allele is transmitted from a woman with a premutation to her daughter. The risk of expansion of a premutation in a mother to a full mutation in her offspring correlates with the number of CGG repeats in her mutation. Therefore, the higher the number of repeats in the mother, the greater likelihood of expansion to a full mutation in her offspring (Table 1).

Males who are premutation carriers are referred to as transmitting males. During reproduction, all of their daughters will inherit a premutation, but their sons will not inherit the premutation, because they inherit a Y chromosome. All daughters of transmitting males are unaffected premutation carriers. Transmitting males also need to be aware of the risk of developing FXTAS after the fifth decade of life.

Males with a full mutation, in most instances, have mental retardation and decreased fertility. The FMRP plays a role in spermatogenesis, and in 1 study it was found that in later stages of spermatogenesis, men with fragile X syndrome had significantly malformed spermatids and a reduction in normally differentiated spermatids, which may cause reduced fertility. A full

mutation cannot be maintained during spermatogenesis; therefore, the sperm contains only expanded *FMR1* gene CGG repeat sizes in the premutation range.

Both males and females can have mosaicism as a result of either full mutation/premutation mosaicism or methylation/unmethylation mosaicism. In men, only a premutation will be transmitted to their female offspring.[27] Women with a full mutation are at 50% risk of having male or female offspring with a full mutation.

Genetic counseling is more problematic when CGG repeats are in the range of 41 to 58 in the *FMR1* allele. This is viewed as a "gray zone," because unstable alleles of this size have been reported, but expansion is unlikely. To date, the smallest repeat number to expand to a full mutation in a single generation was 59 CGG repeats.

Because fragile X syndrome can be difficult to diagnose in a child, various studies have documented that 50% of families with males with fragile X syndrome may have their second child before the diagnosis is established in the first child.[3,28–30] Families with an affected male have indicated that early diagnosis would have influenced their reproductive decision-making. After a diagnosis was made, 73% of families reported that the diagnosis of fragile X syndrome affected their decision to have another child, and 43% of the families surveyed had a second child with a full mutation. Therefore, detection of fragile X syndrome not only would enable at-risk families to receive accurate reproductive counseling for the immediate and extended family but also could allow for appropriate intervention beginning in infancy. Recently, a pilot study in South Carolina on newborn filter-paper blood screens to perform testing for fragile X syndrome was completed and established the potential feasibility of such a screening process.[31] Various policy issues still need to be considered.[32]

THE PRENATAL VISIT

In some instances, pediatricians may be called on to counsel an expectant couple whose fetus has been determined to have fragile X syndrome or when there is a family history of the condition. In some settings, the pediatrician may be the primary resource for counseling parents and family members. The pediatrician should:

1. Review the diagnostic studies that led to establishment of the diagnosis.
2. Explain the cause of fragile X syndrome in the fetus and the potential for a recurrence risk.
3. Review the clinical manifestations, the variability seen in fragile X syndrome, and the long-term prognosis.
4. Review currently available treatments and interventions. This discussion should include the efficacy, potential complications and adverse effects, and costs or other burdens of these treatments.
5. Explore, using a nondirective approach, the options available to the family for treatment and rearing of the child. In cases of prenatal diagnosis, this approach may include discussion of pregnancy continuation or termination, rearing the child at home, foster care placement, or adoption.

It is strongly encouraged that this counseling be done in conjunction with genetic counseling or referral to a genetic counselor or clinical geneticist to provide a more in-depth discussion of fragile X syndrome, including the associated medical conditions, prognosis, management strategies, recurrence risk, future reproductive options, and recommendations for evaluating at-risk family members.

Health care providers should ensure that children with fragile X syndrome are afforded the standard care for all children as outlined in the American Academy of Pediatrics "Recommendations for Preventive Pediatric Health Care"[33] and specific fragile X syndrome health supervision guidelines according to their age (Table 2).

HEALTH SUPERVISION FROM BIRTH TO 1 MONTH: NEWBORNS (TABLE 2)

Examination

1. Examine the neonate for any orthopedic abnormalities, especially congenital hip dysplasia and clubfoot.
2. Review the molecular testing results with the family. In this age group, the diagnosis will only have been made if there was a confirmed family history or if it was previously established in utero. Although the typical phenotype of fragile X syndrome generally will not be present in the neonate, review the clinical manifestations and characteristic patterns of growth and development and problems associated with this condition, which may become more apparent with time. Evaluate the neonate's occipitofrontal circumference, which may be increased, and begin to monitor head-growth velocity.
3. Monitor for feeding difficulties and symptoms of gastroesophageal reflux.

Anticipatory Guidance

1. Review the support groups and services that are available to the child and family. Supply written materials on fragile X syndrome and provide the address and telephone number of organizations involved in fragile X syndrome (eg, National Fragile X Foundation [www.

Health care providers should ensure that, in addition to the specific guidelines provided here, patients with fragile X syndrome are afforded the standard care for all children as outlined in the American Academy of Pediatrics "Recommendations for Preventive Pediatric Health Care."[33] ● indicates to be performed; —, not applicable.

[a] Strabismus may occur anytime between birth and 4 years of age.

[b] Serous otitis can occur throughout childhood, and the resulting hearing loss can further impair speech development. Pressure-equalizing tubes may be needed.

[c] Joint laxity, hip dislocation, or clubfoot may be seen.

[d] Mitral valve prolapse is possible.

[e] Irritability, hypotonia, and tantrums may begin to be seen.

[f] Seizures more commonly occur in this age group.

[g] Assess for atypical seizures, especially when any neurologic symptoms exist or if intellectual function decreases.

[h] Infants with fragile X syndrome are often described as stiff and irritable and may feed poorly.

[i] Violent outbursts may appear in this age group.

[j] Review molecular testing and discuss risks within the family; genetic counseling is strongly encouraged.

[k] Review risk to offspring of the affected person.

[l] Family support and issues of what to tell others are important at the time of diagnosis regardless of the child's age.

[m] Address sexual issues.

[n] Ask parents about violent outbursts.

[o] Review the preschool program with regard to special educational needs and future placement.

[p] Discuss the need for planning for vocational training.

FragileX.org], FRAXA Research Foundation [www.FRAXA.org]).

2. Discuss resources available for support, such as family clergy, mental health professionals, families who have an affected child residing in the area, and friends.
3. Discuss how and what to tell family members and friends about the neonate's condition.
4. Review the recurrence risk for subsequent pregnancies; discuss options for family planning, including prenatal and preimplantation genetic diagnosis; or refer for formal genetic counseling to address these issues.
5. Review the family history regarding evaluation of other family members at risk of having a premutation or full mutation, or refer for formal genetic counseling to address these issues.

HEALTH SUPERVISION FROM 1 MONTH TO 1 YEAR: INFANCY (TABLE 2)

Examination

Early growth and development may be normal, although neurologic abnormalities and delayed development may be present. Monitor the infant for the following problems:

1. Hypotonia that frequently results in mild motor delay.
2. Irritability, which is usually secondary to sensory problems, including tactile hypersensitivity.
3. Feeding problems, which are common in infancy, and the presence of vomiting secondary to gastroesophageal reflux.

Anticipatory Guidance

1. Monitor growth parameters closely.
2. If feeding problems are severe, pursue diagnostic evaluations to determine if they are the result of oral motor problems and/or gastroesophageal reflux. If gastroesophageal reflux is identified, initiate appropriate management strategies or refer the infant for further evaluation by a pediatric gastroenterologist. If oral motor problems exist, refer the infant to an appropriate

interventionist to initiate feeding therapy.

3. Review the available resources to provide the infant with early-intervention services and assist the individualized family service plan team in providing the most appropriate services to maximize the infant's developmental potential. Parents should consider applying for Supplemental Security Income (SSI) through the Social Security Administration.

HEALTH SUPERVISION FROM 1 TO 5 YEARS: EARLY CHILDHOOD (TABLE 2)

Examination

1. Perform an ophthalmologic evaluation or arrange for ophthalmologic referral to check for strabismus and refractive errors, especially hyperopia and astigmatism, which are seen in 25% to 50% of affected children. Also monitor for ptosis and nystagmus, which are seen occasionally.
2. Evaluate the child for orthopedic problems related to connective tissue dysplasia, such as pes planus (80% of affected children), hypermobile joints, and scoliosis. Pronated feet require treatment with orthotics if a gait disturbance exists or there is uneven wearing of shoes.
3. Examine the child for inguinal hernias, especially at 1 to 3 years of age.
4. Assess the child's history for seizures or staring episodes and obtain an electroencephalogram if clinically indicated.
5. Monitor the child for recurrent otitis media (60%–80% of affected children), which could be associated with conductive hearing loss, and also for recurrent sinusitis (23% of affected children). Monitor the child's audiologic status yearly.
6. Receptive and expressive communication should be monitored closely, because language delay is usually evident by 2 years of age. An occupational therapy evaluation also may be indicated and should include an assessment of sensory integration abilities. A complete psychological evaluation that includes IQ testing is an important part of the developmental evaluation of the preschool-aged child with fragile X syndrome. Affected children require early developmental services to facilitate language, motor, and cognitive skills. These services are mandated by federal law and should be followed by enrollment in a developmental preschool and supplemented with special education services. Occupational and speech-language therapy should be incorporated into the program and should include continued attention to language, motor, and cognitive skills up to and including kindergarten. Computer technology with software programs that enhance language skills and early academic abilities, including reading and mathematics, can be incorporated into special education programming. Inclusion in a preschool setting is achievable with appropriate supports.
7. Monitor the child's emotional and behavioral status closely. Tantrums and hyperactivity frequently develop in the second year of life, especially related to transitioning and excessive sensory stimuli. Evidence of anxiety and depression as well as the presence of aggression and obsessive-compulsive behaviors may develop during this time period. Manifestations of autism, such as hand-flapping, self-injury, poor eye contact, lack of social engagement, and absent joint attention may be present before 3 years of age and necessitate further evaluation. Excessive sensory stimulation should be avoided when possible, including exposure to large crowds and loud noises; earphones can be used in such settings to allow the child to listen to a favorite tape or calming music to avoid behavioral outbursts. Significant behavior problems, such as tantrums, oppositional behavior, or severe hyperactivity, usually benefit from intervention by a psychologist or other behavioral specialist. Behavioral intervention techniques that emphasize the importance of decreasing excessive sensory stimuli and using positive behavioral reinforcement and the use of behavioral charting are beneficial.
8. Psychopharmacologic interventions can be helpful. The use of stimulant medication to treat hyperactivity, short attention span, and impulsivity decreases symptoms in approximately 60% to 70% of affected children but may be more effective for a child who is of school age than of preschool age. At a younger age, antihypertensive medications, such as clonidine or guanfacine, may have a better calming effect and improve hyperactivity and hyperarousal. For treatment of anxiety, social phobia, obsessive-compulsive tendencies, depression, and aggression, use of a selective serotonin-reuptake inhibitor is safe and can be effective. Monitoring for the development of akathisia (motor restlessness) is important. In addition, in the presence of severe mood instability and/or aggression that are unresponsive to a selective serotonin-reuptake inhibitor or stimulant medication, use of an atypical antipsychotic agent to provide mood stabilization may be indi-

cated. Approximately 10% of people with fragile X syndrome develop psychotic symptoms often associated with severe paranoia, which also may lead to aggressive behavior.

9. Linear growth during this period should be monitored closely, and linear growth velocity should be similar to that of unaffected children.
10. Structural changes of the face may start to become evident in preschool years and include a long face, high forehead, high arched palate, and prominent ears. Facial changes can result in dental crowding and malocclusion, and regular dental evaluation is recommended.
11. Occasionally, in affected children, obstructive sleep apnea occurs, which may be related, in part, to facial changes but also can be the result of the connective tissue dysplasia and hypotonia of facial and pharyngeal muscles. Excessive snoring, restless sleep, or fatigue during the day should signal the need for further evaluation of the child's sleep problem with evaluation of adenoidal size and the child's sleep pattern by using polysomnography.
12. Delayed toilet-training is common during this age range and is likely to reflect the child's cognitive status.

Anticipatory Guidance

The pediatrician should review the child's preschool placement and ancillary services that complement the program. Inclusion with typically developing children should be considered when appropriate and may require supervision in that setting. Consider a formal developmental evaluation and discuss the role of behavior/psychological intervention when indicated.

1. Determine if behaviors such as hyperactivity, aggression, self-injury, and tantrums warrant medication management.
2. Seizures are an important clinical manifestation that occurs in approximately 20% of people with fragile X syndrome and usually have their onset in early childhood. Appropriate evaluation and treatment is indicated when suspicion of seizures is present.
3. Auscultation of the heart should be performed and blood pressure should be obtained at all clinic visits. The presence of a murmur or click should indicate the need for further evaluation by a pediatric cardiologist, and elevated blood pressure will require monitoring and a determination of whether medical treatment is indicated.
4. Delays in toilet-training can be helped by behavioral interventions including the use of a music video to facilitate toilet-training for people with developmental disabilities.[6](p291)
5. Review the future reproductive plans of the parents and discuss recurrence risk and family-planning options when indicated.

HEALTH SUPERVISION FROM 5 TO 12 YEARS: LATE CHILDHOOD (TABLE 2)

1. Macro-orchidism usually begins to develop at approximately 9 years of age, and the testes will increase in size throughout puberty (mean testicular volume in adulthood: ~50 mL). Testicular volume should be measured with an orchidometer, and boys should be assessed for the presence of a hernia, which occurs in approximately 15% of males with a full mutation. Assure the parents that macro-orchidism has no relation to sexual function and that it is not a sign of precocious puberty.
2. Girls with the full mutation should be monitored for the development of precocious puberty, which has been reported occasionally. Although the cause in most instances is unknown, hypothalamic dysfunction has been described with fragile X syndrome and may be the cause of precocious puberty.
3. Continuing to monitor the child's developmental status is critical for making certain that cognitive, speech and language, and motor needs are being addressed. Being provided with reports of interval progress in school is useful in determining the effectiveness of the child's programming and whether modifications or further evaluation are indicated.
4. Hyperactivity frequently will persist throughout childhood and is present in approximately 70% to 80% of affected boys and 30% to 50% of girls with a full mutation. Addressing this problem behaviorally and/or in combination with medication management may be indicated.
5. Monitor the child for obsessive-compulsive behaviors, especially because they may blend in with perseverative or repetitive behaviors and not be recognized. Anxiety—especially social anxiety—frequently is present, particularly in children who do not have hyperactivity or impulsivity. Pursuing appropriate management strategies to address the child's emotional needs is important for effective adaptation in the home and school settings.
6. Cognitive impairments result in mental retardation in most boys who have a full mutation that is fully methylated (average IQ: ~40). Occasionally, males with a full mutation are higher functioning because of incomplete methylation of FMRP as a result of mosaicism. Approximately 50% of females with a full

mutation have cognitive deficits (IQ range: 70–84). Recognition of cognitive impairments and adaptive functioning deficits should signal the need for pursuing appropriate support services in the school setting to meet the child's needs.

7. In addition to delayed toilet-training, enuresis is common in both boys and girls with fragile X syndrome. Although affected children are not considered to be at increased risk of recurrent urinary tract infections, the connective tissue dysplasia may predispose to dilatation of the ureters and vesicoureteral reflux.[6](p27) Further evaluation of the urinary tract through radiographic and ultrasonographic studies is indicated in the presence of a urinary tract infection, and referral to a nephrologist or urologist is indicated if urinary tract infections are recurrent in nature or a structural abnormality or reflux is identified. Behavioral strategies should be implemented in the presence of nighttime enuresis. In addition, treatment of enuresis may also require the use of behavior-modification techniques and an alarm system. If unsuccessful, medication management with agents such as imipramine, oxybutynin (an anticholinergic agent), or desmopressin acetate (an analog antidiuretic hormone) should be considered. Only occasionally will children require medication for this problem. Macro-orchidism will be maintained throughout adult life and does not require intervention.
8. Because of the connective tissue dysplasia, children should be monitored for scoliosis, which occurs in approximately 20% of affected children. However, when present, it is usually mild and does not require treatment.

HEALTH SUPERVISION FROM 13 TO 21 YEARS OR OLDER: ADOLESCENCE TO EARLY ADULTHOOD (TABLE 2)

1. Hyperactivity may decrease during adolescence, but attentional problems and impulsivity frequently persist and may continue to need to be addressed behaviorally and medically.
2. Assess adolescents for seizures, especially atypical seizures, particularly if intellectual performance is decreasing, although seizures tend to decrease during this time period.
3. Reassure parents that macro-orchidism will persist. Males (especially with a premutation or mosaicism) and females with fragile X syndrome can reproduce. Only a premutation will be present in the sperm of a male who has a full mutation, in contrast to other tissues, because a full mutation cannot be maintained in spermatogenesis; therefore, fertility is decreased in males.
4. The adolescent growth spurt may be slightly less compared with unaffected children, although the timing is normal. Psychosocial development, physical sexual development,[35] and fertility should be discussed, as well as the need for appropriate supervision and birth control. Counseling should be tailored appropriately to cognitive level.
5. Genetic mechanisms responsible for fragile X syndrome should be discussed with people with full mutations and premutations, and the risk of having an affected offspring should be reviewed. Males who are of reproductive age and have nonmosaic full mutations are infertile. Females with full mutations are fertile. Females with premutations are at increased risk of premature ovarian insufficiency, whereas females with full mutations are not. Males who are premutation carriers have no known fertility problems.
6. Determine if behavioral problems continue to represent a concern, and pursue behavioral/psychological intervention if indicated.
7. Discuss the availability and need for vocational training and group home placement if appropriate.
8. Monitor for a cardiac murmur or click; if either is heard, pursue a cardiology evaluation (see recommendation 1 in "Health Supervision in Adulthood").
9. Facilitate transition to adult medical care as appropriate or desired.
10. Agencies that serve people with developmental disabilities are present in most states and may provide respite for parents, adult day care programs, and personal assistance and nursing services as needed.

HEALTH SUPERVISION IN ADULTHOOD (TABLE 2)

During the transition from pediatric to adult medical care, the pediatrician can be a valuable source of information to the affected person's new primary care physician and/or obstetrician/gynecologist. The following information about fragile X syndrome can be communicated to facilitate the care of an affected adult:

1. Mitral valve prolapse occurs in approximately 50% of affected adults. Mild aortic root dilatation also has been reported, although it has not been documented to enlarge. In addition, hypertension is common in adulthood.
2. Up to 20% of women with a premutation will develop premature menopause before 40 years of age.
3. There is a greater risk of emotional problems in affected females, espe-

cially at times of hormonal changes or estrogen deficiency, such as menopause, the postpartum period, and during menstrual periods.

4. Genetic counseling should be provided to review the risk for having an offspring with either a premutation or full mutation and options available for family planning. An increased risk of twinning also should be discussed with females who have a premutation.
5. Men and, to a lesser degree, women with a premutation are at increased risk of developing FXTAS after 50 years of age. Awareness of this risk, particularly in a man with a premutation, warrants close monitoring for symptoms, especially when approaching 50 years of age.

People with fragile X syndrome and *FMR1*–related disorders face challenges throughout their entire lives. Therefore, coordinating medical, developmental, and behavioral services with available community resources can maximize the potential for affected people and minimize the stressors faced by other family members.

CLINICAL REPORT

Health Supervision for Children With Neurofibromatosis

Guidance for the Clinician in Rendering Pediatric Care

Joseph H. Hersh, MD, and the Committee on Genetics

ABSTRACT

Neurofibromatosis 1 is a multisystem disorder that primarily involves the skin and nervous system. Its population prevalence is 1 in 3500. The condition usually is recognized in early childhood, when cutaneous manifestations are apparent. Although neurofibromatosis 1 is associated with marked clinical variability, most affected children do well from the standpoint of their growth and development. Some features of neurofibromatosis 1 are present at birth, and others are age-related abnormalities of tissue proliferation, which necessitate periodic monitoring to address ongoing health and developmental needs and to minimize the risk of serious medical complications. This clinical report provides a review of the clinical criteria needed to establish a diagnosis, the inheritance pattern of neurofibromatosis 1, its major clinical and developmental manifestations, and guidelines for monitoring and providing intervention to maximize the growth, development, and health of an affected child.

All clinical reports from the American Academy of Pediatrics automatically expire 5 years after publication unless reaffirmed, revised, or retired at or before that time.

Key Words
neurofibromatosis, neurofibromatosis 1, cafe-au-lait spots, neurofibroma, optic glioma

Abbreviations
NF1—neurofibromatosis type 1
NF2—neurofibromatosis type 2
NIH—National Institutes of Health
CLS— cafe-au-lait spot
UBO— unidentified bright object

INTRODUCTION

This clinical report was designed to assist the pediatrician in caring for the child in whom the diagnosis of neurofibromatosis has been made. The pediatrician's first contact with the child is usually during infancy. However, neurofibromatosis occasionally is diagnosed in the fetus during pregnancy, and the parents are referred for advice. Therefore, guidance is also offered for the pediatrician in advising expectant parents whose fetus is affected by neurofibromatosis.

At least 2 distinct types of neurofibromatosis are recognized: neurofibromatosis 1 (NF1 [previously known as von Recklinghausen disease or generalized neurofibromatosis]) and neurofibromatosis 2 (NF2 [previously known as either central or bilateral acoustic neurofibromatosis]). Only issues concerning the diagnosis and management of NF1 are addressed in this clinical report.[1–10]

NF1 is a multisystem disorder in which some features may be present at birth and others are age-related manifestations. It affects approximately 1 in 3500 individuals.[11,12] A National Institutes of Health (NIH) Consensus Development Conference[9,13,14] regarding NF1 demarcated the following 7 features, of which 2 or more are required to establish the diagnosis of NF1:

1. six or more cafe-au-lait spots (CLSs) equal to or greater than 5 mm in longest diameter in prepubertal patients and 15 mm in longest diameter in postpubertal patients;
2. two or more neurofibromas of any type or 1 plexiform neurofibroma;
3. freckling in the axillary or inguinal regions;
4. optic glioma (optic pathway glioma);
5. two or more Lisch nodules (iris hamartomas);
6. a distinctive osseous lesion, such as sphenoid wing dysplasia or cortical thinning of the cortex of long bones, with or without pseudoarthrosis; and
7. a first-degree relative (parent, sibling, or child) with NF1 according to the aforementioned criteria.

In addition, although areas of increased T2 signal intensity are commonly identified on MRI of the brain, they do not represent an obligatory feature of NF1 and do not have any clinical significance. Therefore, the NIH Consensus Development Conference did not recommend routine neuroimaging of the brain as a means of establishing a diagnosis of NF1.[13,14]

Diagnosis in nonfamilial pediatric cases, which represent 50% of those affected with NF1, may be difficult, because certain clinical features are age dependent.[15] For the same reason, the severity of NF1 in later life may be underestimated for an affected child.

CLSs usually represent the initial clinical manifestation of NF1 and may be present at birth or first appear in infancy (Fig 1). Although approximately 80% of those with NF1 will have more than 5 CLSs by 1 year of age,[12] occasionally these characteristic lesions are not present. CLSs tend to increase in number and size throughout early childhood.

Plexiform neurofibromas, which are found in at least 25% of individuals with NF1,[16] usually are congenital and, if located on the face, trunk, or extremities, can result in disfigurement (Fig 2). Early in life, the lesions may only be recognized as soft tissue enlargement or a patch of cutaneous hyperpigmentation with or without hypertrichosis. Tibial dysplasia, when present, occurs at birth and is manifested by anterolateral bowing of the lower leg (Fig 3). Its presence requires early orthopedic intervention because of the risk of fracture and development of pseudoarthrosis that results from healing, which occurs in approximately 2% to 3% of children with NF1.[12,17] Skinfold freckling (Fig 4) that develops in early childhood, typically between the ages of 3 and 5 years, usually is the second feature noted in children with NF1 and is present in three fourths of affected individuals.[15] Dermal neurofibromata usually first appear in the prepubertal period but may develop at a much earlier age and are present in virtually all affected individuals by adulthood (Fig 5). They become evident as skin nodules or tags located in cutaneous or subcutaneous tissues, as depressions in the skin with overlying purplish discoloration, or as firm nodules or cords in the deeper subcutaneous tissue. Increase in size and number of dermal neurofibromas coincide with puberty and pregnancy, but intermittent growth can persist throughout the life of an individual with NF1.[12] Plexiform neurofibromas may present as subcutaneous masses that involve deep tissues. These lesions can be found in all

FIGURE 3
Anterior bowing of the left tibia.

organ systems, giving rise to specific symptoms depending on size, location, and degree of encroachment on surrounding tissues. Marked growth of these lesions can occur anytime in childhood, followed by long periods of quiescence.[12] Optic pathway gliomas are present in up to 15% of children with NF1 and represent the most common central nervous system tumor related to this disorder (Fig 6). They develop in children younger than 6 years. Although their natural history is often indolent, in approximately one third of patients with NF1, optic pathway tumors become symptomatic, and in approximately 5% of cases, the lesion results in visual loss, severe proptosis, and/or hydrocephalus.[18–20] Precocious puberty also can be an occasional complication when the

FIGURE 7
Multiple Lisch nodules.

optic pathway tumor involves the optic chiasm.[20,21] In the small proportion of symptomatic tumors in which clinically significant growth or progressive visual loss develops, treatment is necessary.[22] Treatment with carboplatin and vincristine sulfate has been effective in preventing further increase in tumor size and preserving remaining vision.[23] On the basis of the natural history of optic pathway tumors, the National Neurofibromatosis Foundation Optic Pathway Task Force previously has recommended against routine neuroimaging for all children with NF1; rather, yearly eye examination by either a pediatric ophthalmologist or an ophthalmologist who is knowledgeable of the ocular manifestations of NF1 has been advocated for all young children with NF1.[19,23] Lisch nodules (iris hamartomas)[12] usually develop in early adolescence, but they do not have any clinical significance (Fig 7). The sphenoid bones comprise multiple ossification centers that fuse to become the essential components of the orbits. Approximately 5% of individuals with NF1 have sphenoid wing dysplasia, which is usually unilateral. The abnormality can lead to proptosis, and approximately one half of patients with NF1 with sphenoid wing dysplasia will develop ipsilateral temporal-orbital plexiform neurofibroma.[12]

COMPLICATIONS

Although most individuals with NF1 are mildly affected, a risk of significant morbidity and life-threatening problems exists and cannot be predicted on the basis of findings in childhood. Serious complications of NF1 can result from direct involvement of multiple organ systems by plexiform neurofibromas. In addition, the lifelong risk of malignancy in affected individuals is increased. Malignant peripheral nerve sheath tumors represent the most common neoplasm, occurring in approximately 5% to 10% of individuals with NF1.[12,24] They usually develop in adulthood and are heralded by the presence of pain or rapid growth of a plexiform or deep nodular neurofibroma; however, similar manifestations can occur with a benign lesion. Other malignancies occur less frequently in patients with NF1, including pheochromocytoma, rhabdomyosarcoma, leukemia, and brain tumors other than optic gliomas.[12,25,26] Other associations exist with NF1, such as vascular changes. Macrocephaly affects most individuals with NF1.[27] Short stature occurs in one third of individuals with NF1 and does not seem to be related to disease severity. Height-growth velocity is normal for both genders during childhood, but the pubertal growth spurt is slightly reduced.[27] Growth charts made specifically for children with NF1 are available.[27,28] Neurofibromas develop in the gastrointestinal tract in a small proportion of patients with NF1 and usually present after early childhood. They may cause bleeding and anemia or signs of functional or mechanical obstruction. Rare forms of intraabdominal secretory or nonsecretory neoplasms also represent low-frequency associations. Evaluation for gastrointestinal complications should be pursued in the presence of unexplained anemia or weight loss, abdominal bloating, sudden or persistent abdominal pain, chronic diarrhea, signs of malabsorption, gastrointestinal bleeding, or recurrent emesis.[29,30] Seizures occur in 6% to 7% of cases.[12] Although electroencephalographic abnormalities are commonly reported, electroencephalography is not routinely recommended. If seizures are present, an intracranial tumor must be excluded, although usually no etiology is found. Nonossifying fibromas of the long bones and especially the distal femur and proximal tibia, on occasion, occur in adolescence or adulthood and can result in fracture. Therefore, a screening radiograph of both knees may be considered in early adolescence to provide appropriate intervention for individuals in whom lesions are detected.[31] Scoliosis is present in 10% to 30% of NF1 cases. Both idiopathic and dystrophic forms occur[12] and can lead to diminished pulmonary function. Variability in progression, however, makes it difficult to determine the prognosis once scoliosis is detected, and close monitoring is necessary after it has been discovered. An increased risk for osteoporosis in adulthood also exists.[32] Hypertension affects approximately 4% of individuals with NF1. Although essential hypertension is the most common cause of hypertension, in NF1 it can also result from renovascular disease, tumors that secrete vasoactive compounds, and coarctation of the aorta.[12] Therefore, monitoring blood pressure on a yearly basis is indicated, and if hypertension is found, additional evaluation and treatment or referral to an appropriate specialist for management is indicated.

NF1 is associated with an increased incidence of mental retardation (4%–8%)[33]; however, in most instances, intellectual abilities are in the average to low-average range. In contrast, specific learning disabilities are observed in as many as 40% to 60% of affected children,[12,34] and impaired performance on at least 1 test of academic achievement is present in 65% of children with NF1.[33] Deficits in visual-spatial-perceptual skills can result in reading and spelling difficulties. Poor fine-motor coordination can lead to problems with handwriting. Attention-deficit/hyperactivity disorder also occurs

more frequently in children with NF1. Children with NF1 have a higher likelihood of being hypotonic and of having subtle neurologic abnormalities that affect balance and gait.[33,35,36] Speech problems also may occur, and an association with velopharyngeal insufficiency exists.[37]

The reported incidence of complications in NF1 varies from study to study, mostly because of biased patient selection by age and specialty referral but also because of inconsistent diagnostic criteria and variable use of imaging techniques. Generally, complications are overestimated, because most studies involve patients in hospitals or referral clinics.[38] Approximately one third of patients with NF1 develop serious complications, and approximately one half are mildly affected. However, because of the extreme degree of variability even within a family and the progressive nature of NF1, it is not possible to determine the prognosis after establishing a diagnosis, especially at a young age.

GENETICS

NF1 is inherited in an autosomal dominant fashion. In approximately one half of patients, the condition is caused by a new mutation in that conception. In such instances, neither parent has any clinical features of NF1, and risk for recurrence of NF1 is likely not to exceed 1%. Rare instances of recurrence from phenotypically unaffected parents are attributed to germ-line or somatic mosaicism. However, individuals with NF1 caused by a new mutation are at a 50% risk of transmitting the gene to each of their offspring. The NF1 gene has a high penetrance rate; therefore, an individual who carries the mutation can be expected to have clinical manifestations of the disorder. Some individuals are mosaic for an NF1 mutation and may have localized signs, referred to as "segmental neurofibromatosis." These individuals may be at risk of transmitting the mutant gene to their offspring if the germ line includes cells with the mutation, which results in an increased risk of NF1 in their offspring.

The NF1 gene is located on the long arm of chromosome 17 at band q11.2.[39–41] Neurofibromin, the protein product of the normal gene, acts as a tumor suppressor by downregulating another cell protein, Ras, that enhances cell growth and proliferation.[12,42,43] A wide variety of mutations have been identified within the NF1 gene, which give rise to diminished function of neurofibromin in affected persons. Detection of mutations in the NF1 gene by DNA analysis has proven to be complex because of the gene's large size, presence of pseudogenes, and great variety of possible abnormalities. Molecular technology that is capable of detecting 95% of mutations in NF1 is now available,[44] but it is typically not indicated because a diagnosis of NF1 in 95% of cases can be established on the basis of clinical findings alone by 11 years of age.[28] However, when there is uncertainty regarding a definitive diagnosis, for instance, in the presence of some of the clinical manifestations of NF1, such as only CLSs, but not enough to establish a clinical diagnosis, consideration should be given to seeking genetic consultation and determining whether genetic testing is indicated at that time to expedite a diagnosis. Molecular testing also may represent an option in those instances when a couple in which one person has NF1 is seeking prenatal diagnosis. Although establishing a diagnosis is achievable when a mutation has been detected in an affected partner, determining its possible clinical effects after establishing a diagnosis in utero is not.

CLINICAL MANAGEMENT

The multiorgan occurrence of neurofibromas and their complications often requires care from a variety of medical subspecialists and surgical specialists. The medical home has the opportunity and responsibility to coordinate such care. In addition, patients with more than minimal manifestations of NF1 may benefit from referral to a multidisciplinary neurofibromatosis clinic for primary or specialty care or to a physician with expertise in the care of individuals with NF1. Such clinics and/or physicians are valuable consultation resources for medical homes that care for affected patients.

Longitudinal care for NF1 is aimed at the early detection and symptomatic treatment of complications as they occur. Some of the medical problems, such as hypertension resulting from renal artery stenosis, can be managed successfully if detected early. Enlarging plexiform neurofibromas may be managed surgically, although regrowth may occur. In addition, surgical removal of a plexiform neurofibroma, especially when it compromises an essential organ system, may not be possible because of an inaccessible site or infiltration into surrounding tissue. In most instances, management of most malignancies including leukemia is the same as for children without NF1. On the other hand, outcome of treatment of malignant peripheral nerve sheath tumors is poor. Therefore, early suspicion that there may be malignant degeneration of a plexiform neurofibroma is critical from a prognostic standpoint.

In providing medical supervision to a child with NF1, general clinical evaluation through the medical home should be provided regularly, but the frequency should increase to address disease complications. Therefore, recommendations for ongoing assessment and periodic review throughout life (Table 1), including the following:

1. Evaluate the child for new neurofibromas and progression of lesions. Examine the skin carefully for signs of plexiform neurofibromas that may impinge on or infiltrate underlying structures.
2. Check the child's blood pressure yearly to determine if there is evidence of hypertension, which occurs more frequently with NF1 and could be secondary to renal artery stenosis, aortic stenosis, and pheochromocytoma, the latter being more common in adults. A variety of vascular hypertrophic lesions may be found.
3. Evaluate neurodevelopmental progress of an affected child.
4. Obtain a formal ophthalmologic evaluation yearly.
5. Evaluate the child for skeletal changes. Look for scoliosis, vertebral angulation, and limb abnormalities,

[f] Refer to subspecialist.

particularly tibial dysplasia. Sometimes localized hypertrophy of a leg, arm, or other part of the body results from plexiform neurofibromata. Nonossifying fibromas of the long bones infrequently occur in adolescence or adulthood and have been associated with fracture; although a screening radiograph of the knees in adolescence has been suggested as a routine study, evidence is not sufficient to support routine screening at this time.

6. If any unexplained complications occur or if cutaneous lesions appear to be growing rapidly, refer the patient to the appropriate subspecialist for further evaluation.
7. Refer to the review of NF1 at www.genetests.org to obtain rapid access to updated clinical information on the condition.
8. Recommend available resources for patients with NF1 (eg, neurofibromatosis clinics, support groups, and families of children with NF1). Books, pamphlets, and Web-site addresses can be obtained from the Children's Tumor Foundation (www.ctf.org). The Children's Tumor Foundation can also provide additional information and clinic locations.

THE PRENATAL VISIT

At times, the pediatrician may be asked to counsel a family when one of the parents-to-be is affected and the fetus is at risk or has been diagnosed prenatally to have NF1 by DNA testing. In this situation, the family most likely already has been counseled about the disorder and its inheritance pattern. However, the pediatrician may be called on to review the information and assist the family in the decision-making process. When appropriate, pediatricians who have experience in the care of individuals with NF1 may wish to have a discussion with the family, or those with less experience may seek consultation from a geneticist to provide more in-depth information to:

1. review the results of the prenatal diagnostic study;
2. explain the mechanism for occurrence of the disorder in the fetus and the risk of recurrence;
3. review the clinical manifestations, variability, progressive nature, and prognosis of the disorder;
4. review the various forms of treatment and intervention that are currently available, including their efficacy, complications, and adverse effects;
5. discuss the options available to the family for management and rearing of the child (in cases of early prenatal diagnosis, this may include discussion of available options after in utero diagnosis, including continuation of the pregnancy or its termination, and discussion of appropriate management strategies and options for child rearing after delivery);
6. when appropriate, consider referral to a clinical geneticist for a more in-depth discussion of clinical findings, recurrence risk, future reproductive options, and evaluation of risks of disease for other family members; and
7. inform the family that, in many parts of the country, there are specialty neurofibromatosis clinics that are available for guidance, therapy, and consultation.

HEALTH SUPERVISION FROM BIRTH TO 1 MONTH: NEWBORN INFANTS

Examination

1. Confirm the diagnosis by the presence of cutaneous manifestations. CLSs may be present, and in 10% to 15% of neonates, a plexiform neurofibroma will be recognized. However, the clinician must be aware that a normal examination at this age does not exclude the diagnosis of NF1.
2. All first-degree relatives should be advised to have a physical examination, including a slit-lamp examination to look for Lisch nodules, which are found in >90% of adults with this disorder but are uncommon in children younger than 5 years.
3. Some specialists recommend an initial MRI study to determine if an optic glioma is present when the diagnosis of NF1 is made.[1,18] In addition to being able to identify an optic pathway glioma, if present at this age, areas of increased signal intensity on T2-weighted images, also known as unidentified bright objects (UBOs), which are present in approximately 60% of affected children, also can be detected. These lesions are well circumscribed and nonenhancing, and they are located in the brainstem, cerebellum, basal ganglia, and thalamus. An association between UBOs and learning disabilities or cognitive deficits may exist. The lesions are not space occupying and tend to disappear in adulthood. Although potentially helpful in establishing an early diagnosis when clinical findings are equivocal, because of the lack of specificity and the inability to consistently identify UBOs, the benign nature of most optic gliomas, and the need to sedate the child, neuroimaging of the brain may not be warranted. Therefore, the NIH Consensus Development Conference[13] did not recommend computed tomography or MRI studies for asymptomatic patients with NF1 and generally recommended special studies only when they were clinically indicated. Neuroimaging of the brain, on the other hand, would seem to be indicated for a small percentage of the NF1 population for whom a deletion of the entire NF1 gene and flanking DNA is found.[40,45] Affected individuals have a distinct phenotype, including facial dysmorphism, a large number of neurofibromas, severe cognitive impairment, and, frequently, evidence of structural brain anomalies.

Anticipatory Guidance

1. Review the natural history and genetics of NF1.
2. Advise the parents to report any unusual or new symptoms.

3. Stress the need for regularly scheduled visits, including careful cutaneous, skeletal, and neurologic examinations and evaluation of blood pressure.
4. Emphasize the need for a yearly ophthalmologic evaluation.

HEALTH SUPERVISION FROM 1 MONTH TO 1 YEAR: INFANCY

Examination

1. Compare the infant's growth and development with figures on growth charts.[27,28] As a group, children with NF1 are shorter than average but have a larger head size. Rarely, aqueductal stenosis can cause obstructive hydrocephalus, but in most children with NF1, the basis for macrocephaly is likely to be increased brain volume.
2. Examine the patient for the presence of CLSs. Inform the family that new ones may appear, and preexisting CLSs often increase in size. Reassure the family that CLSs have no functional significance.
3. Check for proptosis, a rapidly increasing head size, and focal neurologic signs.
4. Perform a careful physical examination and look for skeletal abnormalities, especially in the spine and legs. This is particularly important before the child begins to bear weight because of the risk of cortical thinning of the long bones, which increases the likelihood of fracture.
5. Refer the infant for formal ophthalmologic evaluation and to other appropriate specialists and subspecialists, as indicated.
6. Check the infant's neurodevelopmental progress at each visit.

Anticipatory Guidance

1. Review the family's psychological support and intrafamilial relationships.
2. Advise the parents to use sunscreen after the child reaches 6 months of age. Sun exposure deepens pigment in CLSs. Although this is usually of cosmetic significance only, melanoma and basal cell carcinoma have been reported in adults with NF1; however, the risk for developing these malignancies is not known to be increased for patients with NF1.[25]
3. If appropriate, review future pregnancy planning with the affected infant's parents.

HEALTH SUPERVISION FROM 1 TO 5 YEARS: EARLY CHILDHOOD

Examination

1. Examine the child for neurofibromata and the presence of skinfold freckling, which can appear in any intertriginous area. Assure parents that CLSs and freckling only have cosmetic significance.
2. Consider taking photographs to document lesion size for future reference.
3. Evaluate the child's vision and recommend that the child undergo an ophthalmologic examination annually throughout childhood.
4. If there are visual changes, persistent headaches, seizures, marked increase in head size, or a plexiform neurofibroma of the head, obtain a brain MRI.
5. Assess the child's speech and motor skills for deficits that require further assessment. Hypernasal speech attributable to velopharyngeal insufficiency can be present, and there may be delayed expressive language development.
6. Monitor blood pressure yearly.

Anticipatory Guidance

1. Review the child's preschool program.
2. Obtain appropriate developmental evaluations of the child for assessment of learning, speech/language, and motor abilities if developmental concerns are raised. The child may benefit from preschool services, speech/language and/or motor therapy, and special education programming to address delays. With NF1, the risk of hearing impairments is not increased appreciably.
3. Discuss indications for surgery, as appropriate. If there is a change in the size of superficial neurofibromata or evidence of a space-occupying internal lesion, refer the child to a neurofibromatosis clinic or other appropriate subspecialists.
4. Pruritus can occur in young children and may be found to be associated with cutaneous neurofibromata. However, antipruritic medications are not helpful in relieving symptoms.

HEALTH SUPERVISION FROM 5 TO 13 YEARS: LATE CHILDHOOD

Examination

1. Examine the child for skin tumors causing disfigurement and obtain a consultation with a specialist if surgery is desired to improve appearance or function. Severe cosmetic disfigurement is seen more often in adults than in children.
2. Evaluate the child for signs of puberty. Premature onset of sexual maturation or delayed puberty may occur. If sexual precocity is present, evaluate the child for the presence of an optic glioma or hypothalamic lesion.[18,21]
3. Check for signs of learning disabilities and attention-deficit/hyperactivity disorder.
4. Review the child's social adjustment.
5. Monitor the child's ophthalmologic status yearly under 8 years of age, followed by complete eye examination every 2 years.[23]

6. Monitor blood pressure yearly.

Anticipatory Guidance

1. Review the child's development and appropriateness of school placement.
2. Refer the child to a clinical psychologist or child psychiatrist for further evaluation and therapy should problems with self-esteem related to his or her physical findings or developmental problems exist.
3. Review the effects of puberty on the disease.
4. Discuss the possibility of the growth of neurofibromata during adolescence and pregnancy.
5. Counsel the parents about how and when to discuss the diagnosis with their child.

HEALTH SUPERVISION FROM 13 TO 21 YEARS OR OLDER: ADOLESCENCE TO EARLY ADULTHOOD

Examination

1. Examine the adolescent for signs of abnormal pubertal development.
2. Perform a thorough skin examination to evaluate for and determine the status of plexiform neurofibromata and a complete neurologic examination to check for findings that might suggest the presence of deep plexiform neurofibromata.
3. Obtain a surgical consultation with a specialist if signs of pressure on deep structures are found.
4. Continue monitoring blood pressure yearly.
5. Continue opthalmological examination every 2 years until 18 years of age.[23]

Anticipatory Guidance

1. Discuss the genetics of NF1 or refer the adolescent for genetic counseling.
2. Discuss sexuality.
3. Discuss birth control, including the risks and benefits of birth control pills, and reproductive options.
4. Discuss the effect of pregnancy on NF1, if appropriate. Women with NF1 may have complications during pregnancy because of enlargement of the neurofibromata[46,47] and, not uncommonly, eruption of more dermal neurofibromas.
5. Review prenatal diagnosis by using available molecular DNA studies and discuss its applicability to the patient with NF1 or refer the patient to a geneticist for further discussion of diagnostic options.
6. Facilitate transition to adult medical care.

This set of guidelines was designed to assist the pediatrician in caring for children with Prader-Willi syndrome diagnosed by clinical features and confirmed by molecular testing. Prader-Willi syndrome provides an excellent example of how early diagnosis and management can improve the long-term outcome for some genetic disorders. *Pediatrics* 2011;127:195–204

INTRODUCTION

Prader-Willi syndrome (PWS) (also Prader-Labhart-Willi syndrome) is a recognizable pattern of physical findings with significant cognitive, neurologic, endocrine, and behavioral abnormalities caused by lack of expression of genes from an imprinted region of the paternally inherited chromosome 15q11-q13, near the centromere. Originally described in 1958,[1] PWS was the first recognized disorder related to genomic imprinting in humans[2] and provides an excellent example of how early diagnosis and meticulous management can markedly improve the long-term outcome for people with some genetic disorders. PWS affects both genders equally and occurs in people from all geographic regions; its estimated incidence is 1 in 15 000 to 1 in 25 000 live births.[3,4] Affected infants uniformly have significant hypotonia, early feeding problems, and difficulty with weight gain. Later, a second phase of the disorder ensues with hyperphagia (excessive appetite for food), which leads to obesity and characteristic behavior problems. Without adequate weight control and management of eating behaviors, massive obesity and associated complications of diabetes, obstructive sleep apnea, and right-sided heart failure occur; death typically occurs in the fourth decade of life. With careful weight control, people with PWS can remain healthy well into older adult life, and some people are known to live into their seventh decade.

The findings of PWS are listed in Table 1. Clinical diagnostic criteria have been developed and validated[5] (Table 2), but now that reliable molecular testing is readily available, these clinical criteria should be considered guidelines to help define people for whom further diagnostic testing is indicated.[6] In general, PWS should be considered in any infant with significant hypotonia, particularly in the setting of poor feeding, reduced spontaneous arousal for feeding, and hypogonadism (undescended testes, small phallus, or small clitoris). In older children, the diagnosis should be considered when there is impaired satiety for food, especially with rapid weight gain. Likewise, poor linear growth, especially in the presence of excessive caloric intake, should also raise suspicion for PWS. Hypogonadism, hypotonia, developmental

TABLE 1 Clinical Findings in PWS

Fetal
Breech position
Reduced fetal activity
Polyhydramnios
Growth
Short stature
Failure to thrive in infancy
Central obesity
Head and neck
Dolichocephaly
Narrow bitemporal diameter
Almond-shaped eyes
Strabismus
Up-slanting palpebral fissures
Myopia
Hyperopia
Thin upper lip
Small-appearing mouth
Down-turned corners of mouth
Thick, viscous (reduced) saliva
Enamel hypoplasia
Early dental caries
Dental crowding and malocclusion
Ocular
Strabismus
Nystagmus
Cataracts (rare)
Retinal hypopigmentation
Foveal hypoplasia
Hyperopia
Myopia
Respiratory
Hypoventilation
Obstructive sleep apnea
Central sleep apnea
Gastrointestinal
Feeding problems in infancy
Gastroesophageal reflux
Decreased vomiting
Genitourinary
Small penis
Scrotal hypoplasia
Cryptorchidism
Hypoplastic labia minora
Hypoplastic clitoris
Skeletal
Osteoporosis
Osteopenia
Scoliosis
Kyphosis
Small hands and feet
Narrow hands with straight ulnar border
Clinodactyly
Skin, nails, hair
Hypopigmentation
Blonde to light-brown hair
Frontal hair upsweep
Neurologic
Severe neonatal hypotonia that improves with age
Poor neonatal suck and swallow reflexes
Poor gross motor coordination
Poor fine motor coordination
Mild-to-moderate mental retardation
Learning disabilities
Increased risk of seizures
Global developmental delay
Speech-articulation problems
Hyperphagia

TABLE 1 Continued

Sleep
Snoring/obstructive sleep apnea
Central apnea during sleep
Excessive daytime sleepiness
Early-morning waking
Night-awakening for food-seeking
Voice
Hypernasal speech
Weak or squeaky cry in infancy
Endocrine
Hyperinsulinemia
GH deficiency
Hypogonadotropic hypogonadism
Diabetes mellitus (type 2)
Behavior/mental health
Skin picking
Rectal picking
Food related behavioral problems
Temper tantrums
Difficulty with transitions
Stubbornness
Obsessive behaviors
Perseverant speech
Obsessive-compulsive disorder
Psychosis
Elopement
Miscellaneous
Temperature instability
High pain threshold
Unusual skill with jigsaw puzzles

delays, speech-articulation defects, and characteristic physical appearance should all raise the index of suspicion. Significant neonatal hypotonia is present in essentially all children for whom molecular testing eventually confirms the diagnosis of PWS[7]; therefore, this history should be actively sought during evaluation of older children.

These guidelines are intended to be suggestions for health care providers when assisting in the provision of a comprehensive medical home for children and adults with PWS. They are based on a thorough review of the pertinent medical literature and incorporate experimental data and the experience of clinicians with expertise in caring for people with PWS. As with all chronic medical conditions, establishing a medical home is essential to the smooth and effective provision of care to the individual person and support to his or her family, which is best achieved when the primary care provider and consultants communicate effectively and clearly delineate their respective roles in the care of the person.

GENETICS AND GENOMICS OF PWS

PWS is associated with lack of expression of several genes on the paternally inherited chromosome 15. This region contains genes that are normally "imprinted," which means that they are differentially expressed (used to make RNA and proteins) depending on whether the chromosome was inherited from the father or the mother. On the maternally inherited chromosome 15, these genes are transcriptionally silenced by hypermethylation of their promoter regions. Therefore, only the paternally inherited chromosome produces the gene products. These changes are referred to as "epigenetic," because they do not involve a

TABLE 2 Suggested Criteria for Prompting Molecular Testing for PWS

Age at Assessment	Features Sufficient to Prompt DNA Testing
Birth to 2 y	Significant hypotonia with poor suck and difficulty with weight gain
2–6 y	Congenital hypotonia with history of poor suck; global developmental delay
6–12 y	History of congenital hypotonia with poor suck (hypotonia often persists), global developmental delay, and excessive eating (hyperphagia; obsession with food) with central obesity if uncontrolled
13 y through adulthood	Cognitive impairment, usually mild mental retardation, excessive eating (hyperphagia; obsession with food) with central obesity if uncontrolled, and hypothalamic hypogonadism and/or typical behavior problems (including temper tantrums and obsessive-compulsive features)

Adapted from Gunay-Aygun M, Schwartz S, Heeger S, O'Riordan MA, Cassidy SB. *Pediatrics*. 2001;108(5). Available at: www.pediatrics.org/cgi/content/full/108/5/e92.

change in the sequence of the DNA but, instead, involve a change to the genomic structure that affects regulation of expression.

The part of chromosome 15 involved in PWS contains several segments of duplicated DNA that predispose to rearrangements, either deletion or duplication, of the PWS region. Absence of the paternally inherited contribution of the PWS region of chromosome 15 leads to lack of the gene products and causes the findings of PWS. In contrast, several other genes in the region are silenced by methylation on the paternally inherited allele. Absence of the maternally inherited contribution of this region causes Angelman syndrome, a completely different disorder caused by lack of expression of a single gene in the region (*UBE3A*).

A short sequence of DNA in the region called the "imprinting center" seems to control switching and maintenance of the imprinting pattern, which is critical, because half of a male's copies of chromosome 15 carry the silenced genes inherited from his mother. When he, in turn, passes copies of his mother's chromosome 15 to his own offspring, those genes must be reactivated, which "switches" the imprint.

It becomes clear, then, that there are multiple mechanisms by which a person may end up with no functional (transcriptionally active) copies of the genes in this critically important region of chromosome 15 and, thus, have PWS.

1. The most common situation (~70% of cases) is that the paternally inherited chromosome 15 contains a microdeletion of 3 to 4 megabases of genetic material spanning the PWS region.
2. In approximately 20% of cases, the affected infant has maternal uniparental disomy (UPD), which means that the child inherited both copies of chromosome 15 from the mother and no copy from the father.
3. Imprinting errors, which occur in 5% or fewer cases, involve a defect of the process of switching the imprint when the father passes on a copy of the chromosome 15 that he inherited from his mother.
4. Finally, PWS has been described as a result of a balanced translocation involving chromosome 15 that moves the genes in the region away from the imprinting center.

Several recent reports suggested that the essential PWS phenotype may be caused by loss of the imprinted HBII-85 cluster of small nucleolar RNAs (snoRNAs), which, if confirmed, will be one of the first developmental disorders shown to be caused by loss of microRNA.[8,9]

The PWS region of chromosome 15 is flanked by segments of duplicated DNA, which predisposes to deletion, or duplication, during recombination in meiosis. This seems to be the reason for the high frequency of the typical deletion in PWS and in some other recurrent microdeletions. It is important to recognize that the normal chromosome structure in the region plays a significant role in the development of the genetic defect; thus, PWS has been described as a "genomic disorder" to distinguish it from other genetic disorders that are specifically caused by an alteration in the sequence of the DNA.[10]

UPD is thought to result most often from meiotic nondisjunction that leads to trisomy for chromosome 15 and, thus, is associated with increased maternal age. Trisomy 15 is the most common trisomy at the time of conception but can only survive if there is a second mitotic division error after fertilization that eliminates 1 of the 3 chromosomes 15. If the paternally contributed chromosome is lost, the embryo will revert to having the normal 2 copies of chromosome 15, both of which originate from the mother. Alternatively, the sperm could have no copy of chromosome 15 as a result of a paternal meiotic error, and the resulting conceptus would have only 1 chromosome 15. Such an embryo would also be spontaneously aborted unless a second, mitotic error occurred after fertilization that duplicates the maternally contributed chromosome 15. In either case, an infant born from such a pregnancy would be missing the paternally contributed chromosome 15 and, therefore, would only have inactive, maternally imprinted copies of the genes in the PWS region.

The third mechanism, an "imprinting error," leads to a situation in which the imprinted (silenced) genes that the father inherited from his mother cannot be reactivated. The infant inherits 1 copy of chromosome 15 from each parent, but the PWS region is fully methylated on both copies of chromosome 15 and, thus, is silenced in both copies. This mechanism, although rare, is important to identify, because the inability to switch the imprint can be an inherited trait, which means that a man with an inherited imprinting defect has up to a 50% recurrence risk with each pregnancy to sire another child with PWS. The rare case of PWS attributable to a balanced translocation also may have an increased recurrence risk if the father carries the same translocation on the chromosome 15 he inherited from his mother. Neither deletion nor UPD is known to be associated with increased recurrence risk.

Although subtle differences have been shown between groups of people with deletions compared with UPD,[11–16] for the most part, there are no major differences in phenotype among the various causes. The exception is the finding of hypopigmentation, which is most notable in people with PWS who have a deletion of the *OCA2* gene (a

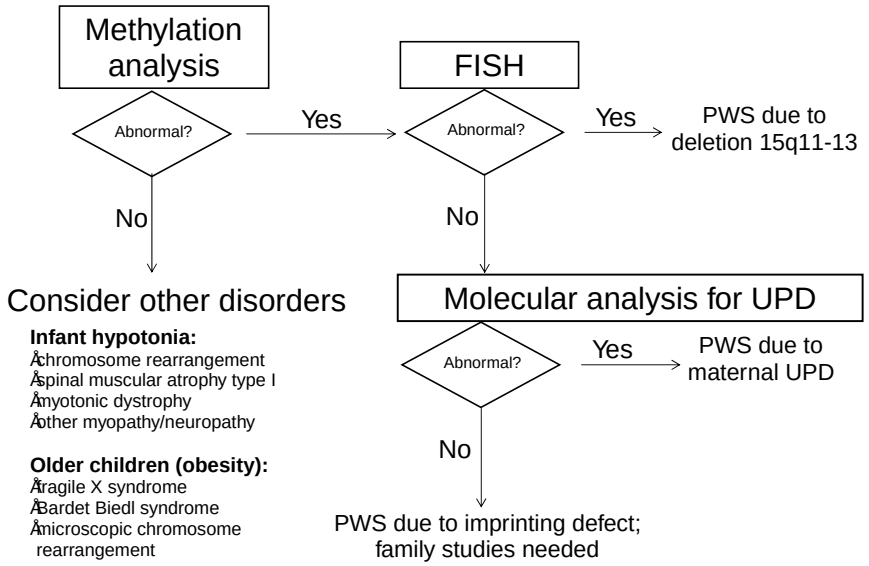

FIGURE 1
Flowchart of recommended molecular testing strategy for PWS.

nonimprinted gene in the PWS region of chromosome 15 associated with autosomal recessive oculocutaneous albinism type II).[17,18] Recently, some authors suggested that there may be subtle differences in neurocognitive development in children with deletions depending on the location of the proximal break point.[19] Others have not observed such a difference[13]; therefore, the clinical utility of defining the break points is not clear at this time.

DIAGNOSTIC TESTING

Diagnostic testing for PWS, as outlined in Fig 1, should begin with methylation analysis to confirm the absence of paternally imprinted genes in the PWS region of chromosome 15. When only a maternal methylation pattern is seen, PWS is confirmed, but additional testing is needed to identify the specific cause, which allows for appropriate counseling regarding recurrence risk. The recurrence risk for spontaneous deletions or UPD is low (<1%), whereas the recurrence risk of imprinting mutations can be as high as 50%. If the methylation analysis is consistent with PWS and the karyotype and fluorescence in situ hybridization (FISH) reveal no evidence of deletion or balanced rearrangement, the next step is to obtain blood from the parents and the child to evaluate for UPD. If biparental inheritance is discovered in the face of abnormal methylation and normal FISH results, then, by process of elimination, the cause is assumed to be an imprinting defect. The possible role of testing for defects of the HBII-85 small nucleolar RNA cluster remains to be elucidated.

SPECIAL CONSIDERATIONS FOR THE INFANT AND CHILD IN WHOM PWS IS DIAGNOSED

Nutrition

Maintenance of adequate and appropriate nutrition is central to the care of people with PWS at every age. Infants may require support of feeding for several months. Caloric needs may be, but are not always, somewhat reduced in infants with PWS, and infants with PWS typically do not spontaneously demand feedings. Therefore, the infant's diet must be adjusted as needed to maintain appropriate weight gain as determined by frequent weight checks. Increased caloric density of feedings is often helpful. Later, after hyperphagia begins, the diet must be quite calorically restricted, often to as little as 60% of the calories that similarly sized children without PWS might require for adequate growth. This diet requires careful attention to the balance of essential nutrients, which is often best achieved by referral and regular follow-up with a dietitian who is knowledgeable about PWS.

Feeding Tubes (Nasogastric or Gastrostomy Tubes)

Infants with PWS have poor feeding because of weak suck, easy fatigability, and low muscle tone. The need for assisted feeding is nearly universal in the first 4 to 6 months; use of nursing systems with 1-way valves and manual assistance of sucking, originally designed for infants with cleft palate (eg, Haberman nipple, Pigeon feeder), can greatly reduce reliance on feeding tubes. Nasogastric tubes, when needed, are generally well tolerated and rarely required for more than 3 to 6 months. The use of a gastrostomy tube (generally with placement of a button-style device) can be avoided in most cases, but if, after considering the risks and benefits of both approaches, a decision to use a gastrostomy tube is made, the device should be promptly removed when no longer needed. Poor feeding is a transient problem in PWS, and the increased abdominal fat mass with reduced muscle that characterizes this disorder ensures a cosmetically disfiguring scar at the site of the gastrostomy tube (families sometimes refer to this as the "second belly-button"). These 2 factors, relatively specific to PWS, may significantly alter the risk/benefit analysis regarding the approach to tube feedings compared with the decision-making process for children with disabilities attributable to other causes.

Endocrine Considerations and Recombinant Human Growth Hormone

Generalized hypothalamic insufficiency is characteristic of PWS and manifests as dysregulation of the hypothalamic-pituitary axis (including growth hormone [GH], thyroid function, and possibly regulation of the adrenal cortex), appetite, thermoregulation, and respiratory control. Recent work demonstrated the possibility that centrally mediated adrenal insufficiency may be an underrecognized contributor to premature deaths among people with PWS.[20,21] It is recommended that early-morning serum adrenocorticotropic hormone and cortisol concentrations be evaluated when the child is well and repeated during any severe illness. Consideration should be given to prophylactic therapy with hydrocortisone during rare episodes of critical illness in children with PWS, pending measurement of adrenocorticotropic hormone and serum cortisol. Discussion with a pediatric endocrinologist is helpful in determining whether provocative testing is indicated in early childhood.

GH insufficiency is considered to be universal in PWS, so provocative diagnostic testing is not required in the face of reduced growth velocity. In the first year of life, reduced growth velocity may not be readily identified, but both controlled clinical trials[22,23] and clinical experience have demonstrated that there is often significant response to treatment with GH, primarily in improved lean mass, improved motor development, and normalization of body habitus. Decisions about use of GH therapy and management are best made in consultation with a pediatric endocrinologist. Although GH treatment has been approved by the US Food and Drug Administration for children with PWS older than 2 years with documented growth failure, clinical experience has suggested that treatment can begin at as early as 2 to 3 months of age. It is important that parents be thoroughly informed about the potential benefits and the potential for undesired effects. Specifically, there have been several deaths in children as young as 3 years with PWS within 6 months of initiating GH therapy. The role of GH in those deaths, if any, is not known. Adenotonsillar hypertrophy and obstructive apnea may occur during GH therapy; therefore, current recommendations for management include polysomnography (sleep study) before and 6 to 10 weeks after beginning GH treatment, regardless of age. Polysomnography results are frequently abnormal in people with PWS, and both central and obstructive hypopnea are common.[24] Evidence of obstructive sleep apnea should be managed according to accepted standards of care[25] (this American Academy of Pediatrics clinical practice guideline was published in 2002 and has not been updated) and, specifically, should lead to referral to an otolaryngologist for evaluation of airway, increased effort to reduce weight, and consideration of delaying (or stopping) GH treatment until polysomnography results improve. It has also been suggested that GH could be associated with unexpected death by increasing resting energy expenditure (through increased muscle bulk) in children with underlying abnormalities of central respiratory drive attributable to PWS, although there is a suggestion in the literature that treatment with GH may be associated with modest improvement in the central respiratory drive.[26]

There is mounting evidence from controlled clinical trials that GH therapy in children improves linear growth, lean mass and lean-to-fat ratio,[27] and respiratory drive,[26,28] and there has been suggestion of beneficial effects on bone density[27,29] and possible stabilization of behavior decline.[30] Studies are in progress to evaluate the use of GH in adults with PWS.[31] However, there is nothing to suggest that endogenous GH insufficiency improves in later life; therefore, it is reasonable to consider continuing therapy into adulthood. Pretreatment laboratory evaluation to document sequelae of GH insufficiency, to exclude other causes of slow linear growth in people with PWS, and to define baseline parameters related to potential complications of therapy often includes:

- polysomnography;
- measurement of plasma insulin-like growth factor 1 (IGF1), IGF-binding protein 3 (IGFBP3), thyroxine, and thyrotropin levels, a complete blood count, and a basic metabolic profile (with calcium); and
- left hand and wrist radiography for bone age (in older children).

Follow-up should include:

- repeat polysomnography 6 to 10 weeks after initiation of therapy (consider repeating in 1 year and any time at which there are new or worsening symptoms);
- monitoring of IGF1 at least twice yearly, dosing GH to keep IGF1 in physiologic range; and
- monitoring of head circumference at each visit, because GH treatment can cause abnormal growth of the head, especially if the fontanelles are open when GH is started.

Behavioral Food Controls

After the onset of hyperphagia, children with PWS may develop a wide range of food-related behaviors, including actively seeking food, eating nonfood items (eg, animal chow, spoiled food, decorative items that look like food, searching in garbage cans, etc), stealing money to buy food, and even running away from home to

search for food in a wider area. Control of these behaviors is complex but centers on strategies to limit access to food (eg, locks on cabinets and refrigerators), limit exposures that make the child think about food (eg, birthday treats sitting on the teacher's desk during the school day), and instill confidence that the next meal will be served on time by scrupulously maintaining mealtime routines. Relatives and social contacts must be educated to realize that "sneaking" food to the child with PWS is not an appropriate method of demonstrating affection, and, in fact, undermines the child's nutritional regimen and sense of well-being.

Hypogonadism

Both males and females are affected, although the primary external manifestations in females (clitoral and labia minora hypoplasia) may not be obvious with cursory evaluation. A therapeutic trial of human chorionic gonadotropin (hCG) is indicated for treatment of undescended testes before surgery, because avoidance of general anesthesia is desirable for infants with low muscle tone and potential for underlying respiratory compromise. Added benefits of a course of hCG may include increased scrotal size and partial normalization of phallus length, thereby improving surgical outcomes for undescended testes and facilitating later standing micturition.

Behavior Management

As the child with PWS ages, there is a progression of behavioral issues, many of which can be anticipated, identified early, and managed prospectively. Early childhood is often characterized by rigidity, particularly related to daily routines and long-term persistence of temper tantrums and oppositional behaviors typical of the normally developing 2-year-old. Later, perseverant speech and compulsive behaviors, particularly skin-picking, become prominent. In later childhood and the early adolescent years, food-seeking behaviors may increase and are often associated with lying, and occasionally stealing, to obtain food. Some teenagers with PWS have a disturbing tendency to sneak off to search for food, which is potentially quite dangerous and difficult to manage. Typical of the adolescent years, the teenager with PWS is often overly confident of his or her ability to handle risks and dangerous situations. It is important to recognize that teenagers with PWS deal with many of the same neurodevelopmental and hormonal issues that all adolescents encounter, and, similar to their typically developing peers, many of their behavioral issues seem to stabilize, although not disappear entirely, as they reach adulthood.

Management of the many complex behavioral issues is best accomplished through an active partnership of the parents, the primary care provider, and a developmental/behavioral specialist (pediatrician or psychologist). Behavioral management that focuses on rewarding desired behaviors and ignoring, when possible, undesirable behaviors seems to be most effective. Early recognition of developing behavior problems is critical for maximizing the effectiveness of such an approach. Parents should be counseled that offering food as a reward or withholding food as a punishment is almost always counterproductive and should be avoided. Positive reinforcers are generally not difficult to identify, and reward systems that use small, short-term goals that progress to larger goals are quite effective.

Finally, young adults with PWS seem to be prone to a variety of compulsive behaviors including smoking cigarettes, and some of them develop frank obsessive-compulsive disorder. Likewise, a significant minority of young adults with PWS develop depression, anxiety, and, in some cases, true psychosis. Parents should be counseled to identify early indicators of these processes to facilitate appropriate medical intervention.

HEALTH SUPERVISION FROM BIRTH TO 1 MONTH: NEWBORN INFANTS

Evaluation

- Confirm the diagnosis of PWS (Fig 1) and review the implications of the molecular testing results with the parents.
- Review history for:
  - growth and development;
  - feeding problems; and
  - symptoms of obstructive apnea.
- Physical examination should include evaluation of:
  - hypotonia, and
  - hypogonadism.

Anticipatory Guidance

- Review the phenotype, discuss the specific findings with both parents whenever possible, and talk about potential clinical manifestations associated with the syndrome; these issues may have to be reviewed again at a subsequent meeting.
- Point out both early and late feeding issues and the dichotomous nature of feeding problems (ie, too little as a neonate, too much as an older child), and, as appropriate, discuss use of nasogastric feedings with increased caloric-density formula to minimize volume and use of special nipples/feeders (eg, Pigeon feeder, Haberman nipple, other nursers designed to reduce work of sucking). Special attention should be paid to:
  - avoidance of prolonged oral feeding time (usually not >20 minutes per feeding);
  - transition from tube feeding;

  - maintenance of adequate caloric intake; and
  - development of appropriate eating habits; discuss the importance of normal fat and calorie intake for brain development (some parents may start restricting too early).
- Refer infants to early-intervention services in the community.
- Discuss the importance of stimulating the infant, because he or she is likely to be undemanding.
- Inform the family of the availability of support and advice from the parents of other children with PWS.
- Supply contact information for PWS support groups (see "Resources for Parents").
- Point out the strengths of the child and positive family experiences.
- Discuss individual resources for support, such as family, clergy, and friends.
- Talk about how and what to tell other family members and friends; review methods of coping with long-term disabilities.
- Review the recurrence risk in subsequent pregnancies and the availability of prenatal diagnosis and genetic counseling.
- Give overview of the long-term management plan.

HEALTH SUPERVISION FROM 1 MONTH TO 1 YEAR: INFANCY

Evaluation

- Review and note clinical features and confirm diagnosis, if not done previously.
- Review routine health maintenance.
- Plot growth by using standard pediatric growth charts, and pay special attention to weight-for-length measurements.
- Monitor time/work of feeding and caloric density of foods to maintain appropriate growth.
- Perform developmental evaluation, and refer to early-intervention services (if not already done).
- Evaluate boys for undescended testes (or cryptorchidism) and inguinal hernia; consider trial of human chorionic gonadotropin injections (may be performed in conjunction with pediatric endocrinologist); refer to pediatric urologist or a urologist who has special expertise and experience with infants with disabilities if the infant's testes are abnormal.
- Check the infant's vision at each visit by using developmentally appropriate subjective and objective criteria; if evidence of strabismus or other concern arises, refer the infant to a pediatric ophthalmologist or an ophthalmologist who has special expertise and experience with infants with disabilities.
- Administer vaccines recommended for all children unless there are specific contraindications.
- Assess the emotional status of parents and intrafamily relationships; educate and support siblings and discuss sibling adjustments.

Anticipatory Guidance

- Review feeding issues (see above) and the infant's growth and development relative to other children with PWS.
- Review GH deficiency and review benefits and potential risks of GH therapy; consider referral to pediatric endocrinology specialist.
- Discuss:
  - need for careful dietary management later in childhood;
  - probability of mild-to-moderate cognitive impairment;
  - benefits of early behavioral monitoring and establishment of routines; and
  - importance of limit-setting and enforcement.
- At 6 to 12 months of age, review the psychological support and intrafamily relationships, including long-term planning, financial planning, and guardianship; reinforce need for parents to work in partnership, and discuss early relationship-counseling for parents if problems arise.
- Review early-intervention services relative to the strengths and needs of the infant and family.
- Review the family's understanding of the risk of recurrence of PWS and the availability of prenatal diagnosis.
- Discuss increased risk of seizures during childhood (5%–10% of those with PWS), which may be associated with fever and are generally responsive to monotherapy.

HEALTH SUPERVISION FROM 1 TO 5 YEARS: EARLY CHILDHOOD

Evaluation

- Obtain a history and perform a physical examination with attention to growth and developmental status. PWS-specific growth curves should only be used for children who are not treated with GH; regular curves should be used for children who are treated with GH.
- Feeding issues: monitor food intake and behaviors, and consider referral to dietitian who has experience with PWS; calorie needs must be based on growth rate and are usually less than those for similarly sized children without PWS.
- Annual hearing and vision screening evaluation before 3 years of age; refer the child to a pediatric ophthalmologist or ophthalmologist

who has special expertise and experience with children with disabilities for a thorough evaluation for ocular findings during the second or third year of life or earlier if there is evidence of cataracts, nystagmus, or strabismus.

- Evaluate annually for scoliosis, and regularly assess muscle tone; refer to pediatric orthopedist for management of scoliosis as indicated.
- Discuss reduced salivation and increased caries risk by 1 year of age; refer to a pediatric dentist or a general dentist who has special training to manage children with special needs; consider need for more-frequent dental cleanings (every 3–4 vs every 6 months) because of the increased caries risk.
- Ask about symptoms related to obstructive sleep apnea, including snoring, restless sleep, and excessive daytime sleepiness; refer to a sleep or pulmonary specialist as indicated.

Anticipatory Guidance

- Review early intervention, including physical therapy, occupational therapy, and speech therapy, in the preschool program and discuss future school placement and performance.
- Assess the child's behavior, discuss behavioral management, and ask specifically about common behaviors seen in those with PWS (eg, skin-picking, temper tantrums, food-seeking, etc), which may begin during this period.
- Discuss sibling adjustments, socialization, and recreational skills.
- Encourage families to establish optimal dietary and physical exercise patterns to prevent obesity; schedule annual (or more often) meetings with dietitian to review caloric intake and suggest ways to provide less calorically dense foods.
- Discuss need for all family members, child care providers, and school staff members to learn about the disorder, the need for strict food management, and development of routines.
- Discuss future pregnancy planning, risk of recurrence of PWS, and prenatal diagnosis; remind parents of positive aspects for typically functioning children of having a sibling with special needs.

HEALTH SUPERVISION FROM 5 TO 13 YEARS: LATE CHILDHOOD

Evaluation

- Obtain a history, and perform a physical examination with attention to growth and developmental status; evaluate for scoliosis.
- Specifically evaluate for behavior issues that may arise in this age group, including binge-eating, running away, and worsening of skin-picking.
- Perform vision screening annually with attention to recurrence of strabismus.
- Perform thyroid-screening tests every 2 to 3 years or if symptomatic.
- Look for signs of premature adrenarche (which often occurs without progression of other aspects of precocious puberty; thus, reassurance is often the only intervention needed).
- Discuss management of skin-picking (primarily behavioral; medications, including topiramate, are used only in the most severe cases).

Anticipatory Guidance

- Review the child's development and appropriateness of school placement and developmental intervention.
- Continue to stress the need for dietary management and daily exercise to avoid obesity.
- Discuss socialization, family status, and relationships, including financial arrangements and guardianship; begin discussion of adult living arrangements; advise parents to consider joining waiting list for placement in a group home specifically organized for people with PWS and recognize that placement may take several years (or more).
- Discuss the development of age-appropriate social and self-help skills and the development of a sense of responsibility.
- Discuss psychosexual development, physical and sexual development, menstrual hygiene and management, fertility, and contraception; explain that people with PWS often have strong feelings of desire for an infant.
- Discuss symptoms related to obstructive sleep apnea, including snoring and restless sleep, and evaluate for signs of excessive daytime sleepiness; refer to a sleep or pulmonary specialist as indicated.
- Discuss increased pain tolerance common in people with PWS, particularly with regard to evaluating for illness or injury; special attention should be given to risk of intestinal necrosis after binge-eating, because the high pain tolerance can mask symptoms and delay treatment, which can lead to death; people with PWS rarely vomit, so parents should be aware that vomiting after binge-eating can be an ominous sign.

HEALTH SUPERVISION FROM 13 TO 21 YEARS OR OLDER: ADOLESCENCE TO EARLY ADULTHOOD

Evaluation

- Perform physical examination with particular emphasis on evidence of:
  - heart failure;
  - peripheral edema;

  - skin-picking (perianal areas and intertriginous folds should be examined); and
  - scoliosis.
- Evaluate diet, caloric intake, and exercise program, and stress obesity prevention; initiate weight-loss strategy if needed.
- Vision screening should be performed annually.
- Look for early signs of developing psychosis or increasing obsessive-compulsive behaviors seen in a minority of patients (risk is apparently higher in cases attributable to UPD than deletion, but may occur with either of them).
- Evaluate pubertal status and consider referral to pediatric endocrinology for discussion about pros and cons of sex hormone therapy.

Anticipatory Guidance

- Discuss skin care, especially in the presence of truncal obesity.
- Discuss issues related to transition into adulthood.
- Discuss possible compulsive behaviors, including use of tobacco.
- Discuss appropriateness of school placement, and emphasize adequate vocational training within the school curriculum while keeping in mind the special issues related to the need to scrupulously avoid exposure to opportunities to obtain food.
- Provide information on how to recognize the signs of psychosis.
- Discuss the need for gynecologic care for pubescent girls. Talk about the risk of Angelman syndrome (attributable to deletion of maternally inherited chromosome 15q11-13) with the patient and her family if she were to become pregnant; review the fact that there have been 2 case reports in which a woman has reproduced. Men with PWS are assumed to be infertile, although the possibility of fertility should always be considered.
- Discuss sexuality and socialization, the need for and degree of supervision and/or the need for contraception.
- Explain to the patient and her family the risk of genetic abnormalities if she were to become pregnant.
- Discuss group homes and independent-living opportunities specifically for people with PWS, workshop settings, and other community-supported employment (group homes specifically designed for people with PWS are desirable, but they often have long waiting lists, so applying during the adolescent years is helpful in securing a spot for the future).
- Discuss intrafamily relationships, financial planning, and guardianship.
- Facilitate transfer to adult medical care.

TRANSITION TO ADULT CARE

- Identify health care providers in the community who are willing to learn about the special situations of people with PWS; ideally, use providers with training or experience in the care of people with special needs.
- Regular evaluation is needed for:
  - weight control (maintenance or loss);
  - diabetes;
  - hypertension;
  - sleep apnea;
  - heart failure;
  - peripheral edema; and
  - behavior management, including the use of medications such as selective serotonin-reuptake inhibitors.
- Some providers may continue to care for the person with PWS through adult life (eg, the medical geneticist); when new providers are needed, the transferring physician should clearly communicate the person's needs, and care should overlap until all providers, as well as patients and their family, are comfortable with the care needed.

Health Supervision for Children With Sickle Cell Disease

ABSTRACT. Sickle cell disease (SCD) is a group of complex genetic disorders with multisystem manifestations. This statement provides pediatricians in primary care and subspecialty practice with an overview of the genetics, diagnosis, clinical manifestations, and treatment of SCD. Specialized comprehensive medical care decreases morbidity and mortality during childhood. The provision of comprehensive care is a time-intensive endeavor that includes ongoing patient and family education, periodic comprehensive evaluations and other disease-specific health maintenance services, psychosocial care, and genetic counseling. Timely and appropriate treatment of acute illness is critical, because life-threatening complications develop rapidly. It is essential that every child with SCD receive comprehensive care that is coordinated through a medical home with appropriate expertise.

ABBREVIATIONS. SCD, sickle cell disease; HbS, sickle hemoglobin; HbF, fetal hemoglobin; HbSS, sickle cell anemia; HbSC, sickle-hemoglobin C disease; HbF, fetal hemoglobin; HPLC, high-performance liquid chromatography; AAP, American Academy of Pediatrics; CNS, central nervous system; CBC, complete blood cell; TCD, transcranial Doppler; HbA_2, hemoglobin A_2; MCV, mean corpuscular volume; Hib, *Haemophilus influenzae* type b; TIA, transient ischemic attack.

INTRODUCTION

The term sickle cell disease (SCD) describes a group of complex, chronic disorders characterized by hemolysis, unpredictable acute complications that can rapidly become life-threatening, and the variable development of chronic organ damage. Expert, comprehensive medical care decreases morbidity and prolongs life expectancy for individuals with SCD.[1–5] Many children with SCD in the United States receive much of their medical care from pediatricians. This statement is intended to provide pediatricians in primary care and subspecialty practice with an overview of the essential components of comprehensive care for children with SCD and their families. A detailed discussion of the treatment of individual acute and chronic complications of SCD is beyond the scope of these guidelines but is available elsewhere.[6–11]

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

OVERVIEW OF GENETICS AND PATHOPHYSIOLOGY

SCD is an autosomal recessive genetic disorder characterized by the presence of sickle hemoglobin (HbS) in red blood cells. Heterozygous individuals have sickle cell trait, a generally benign, asymptomatic genetic carrier state. Homozygous and compound heterozygous individuals have symptomatic disease. Four genotypes—sickle cell anemia (HbSS), sickle-hemoglobin C disease (HbSC), and 2 types of sickle β-thalassemia ($S\beta^+$-thalassemia and $S\beta^o$-thalassemia)—account for most SCD in the United States. Less common forms of SCD are caused by coinheritance of HbS with other hemoglobin variants, such as hemoglobin D-Punjab. Genes for SCD are common in persons of African, Mediterranean, Middle Eastern, and Indian ancestry and persons from the Caribbean and parts of Central and South America. SCD is the most prevalent disorder identified by neonatal blood screening, with approximately 2000 affected infants born in the United States each year.[12] Overall, the incidence of SCD exceeds that of most other serious genetic disorders, including cystic fibrosis and hemophilia.

The protean clinical manifestations of SCD result from variable degrees of hemolysis and intermittent episodes of vascular occlusion that cause tissue ischemia and acute and chronic organ dysfunction. Consequences of hemolysis may include chronic anemia, jaundice, predisposition to aplastic crisis, cholelithiasis, and delayed growth and sexual maturation. Vaso-occlusion and tissue ischemia can result in acute and chronic injury to virtually every organ of the body. Important clinical manifestations of SCD during childhood and adolescence are shown in Table 1. Generally, children with HbSS and $S\beta^o$-thalassemia are more severely affected than are children with HbSC or $S\beta^+$-thalassemia. However, each genotype is characterized by marked and largely unpredictable variability in clinical expression and severity.[13–16]

NEONATAL SCREENING AND DIAGNOSIS

Most infants with SCD are healthy at birth and become symptomatic later in infancy or childhood after fetal hemoglobin (HbF) levels decrease. Most infants with SCD born in the United States are now identified by routine neonatal screening.[9,17,18] Affected infants not identified through neonatal screening generally present clinically during infancy or early childhood with painful swelling of the hands

TABLE 1. Important Clinical Manifestations of SCD During Childhood and Adolescence

Acute Manifestations
Bacterial sepsis or meningitis*
Recurrent vaso-occlusive pain (dactylitis, musculoskeletal or abdominal pain)
Splenic sequestration*
Aplastic crisis*
Acute chest syndrome*
Stroke*
Priapism
Hematuria, including papillary necrosis
Chronic manifestations
Anemia
Jaundice
Splenomegaly
Functional asplenia

and feet (dactylitis), pneumococcal sepsis or meningitis, severe anemia and acute splenic enlargement (splenic sequestration), acute chest syndrome, pallor, jaundice, or splenomegaly. Clinical presentations in older children include anemia, severe or recurrent musculoskeletal or abdominal pain, aplastic crisis, acute chest syndrome, splenomegaly or splenic sequestration, and cholelithiasis.

Forty-four states, the District of Columbia, Puerto Rico, and the Virgin Islands currently provide universal neonatal screening for SCD; screening is available by request in the other 6 states. It is essential that pediatricians be familiar with their particular state's screening program, that a screening sample always be obtained before any blood transfusion (regardless of gestational or postnatal age),[19] and that the results of neonatal screening tests be routinely and promptly documented for all infants.[18] In states that have not yet implemented universal screening, neonatal screening for SCD should be requested for all high-risk infants (those of African, Mediterranean, Middle Eastern, Indian, Caribbean, and Central and South American ancestry). Any high-risk infant not screened at birth, or for whom neonatal screening results cannot be documented, should be screened by hemoglobin electrophoresis as soon as possible after birth. For infants with positive screening results, confirmatory testing should be accomplished before 2 months of age so that parental education, penicillin prophylaxis, and arrangements for comprehensive care can be promptly initiated.[9,18]

Confirmatory testing of infants with positive neonatal screening results and diagnosis of older patients who present with symptoms require hemoglobin separation by electrophoresis (cellulose acetate and citrate agar), isoelectric focusing, and/or high-performance liquid chromatography (HPLC).[18] In selected cases, DNA analysis or testing of parents can be helpful. Neonatal screening and diagnostic test results for the 4 most common genotypes of SCD are shown in Table 2. Solubility testing has no place in the diagnosis of SCD, because it does not differentiate SCD from sickle cell trait and because high levels of HbF cause false-negative results in infants with SCD.

OVERVIEW OF COMPREHENSIVE CARE

SCD is a complex disorder with multisystem manifestations that requires specialized comprehensive care to achieve an optimal outcome. Appropriate treatment requires the active involvement of health care professionals with expertise in the management and treatment of SCD, usually a pediatric hematologist-oncologist working in conjunction with a multidisciplinary team.

TABLE 2. SCD: Neonatal Screening and Diagnostic Test Results

Disorder	Approximate Percentage of US Patients With SCD	Neonatal Screening Results*	Hemoglobin Separation by Age 6 Weeks*	Serial CBC and Reticulocyte Counts	Hematologic Studies by Age 2 Years		
					MCV†	HbA_2‡ (%)	HbF (%)
HbSS	65	FS	FS	Hemolysis and anemia by age 6–12 mo	Normal or increased§	<3.6§	<25
HbSC	25	FSC	FSC	Mild or no anemia by age 2 y	Normal or decreased	NA‖	<15
$S\beta^+$-thalassemia	8	FSA or FS¶	FSA	Mild or no anemia by age 2 y	Normal or decreased	>3.6	<25
$S\beta^\circ$-thalassemia	2	FS	FS	Hemolysis and anemia by age 6–12 mo	Decreased	>3.6	<25

Table shows typical results—exceptions occur. Rare forms of SCD, such as SD-Punjab, SO-Arab, SC-Harlem, $S\delta\beta$-thalassemia, SE, and SLepore, not included.

* Hemoglobins reported in order of quantity (eg, FSA = F>S>A).

† Normal or reference range of MCV is > 70 fL at age 6–12 mo; lower limits of reference range subsequently increase with age to 80 fL during adolescence.

‡ HbA_2 results vary somewhat depending on laboratory methodology.

§ HbSS with coexistent α-thalassemia may show decreased MCV and HbA_2 >3.6%; however, neonatal screening results from such infants usually show Bart's hemoglobin.

‖ NA = not applicable—quantity of HbA_2 usually not measured in presence of HbC.

¶ Quantity of HbA at birth is sometimes insufficient for detection.

Medical Home

It is essential that every child with SCD receive care that is provided and coordinated through an appropriate medical home.[17] For many patients, the most appropriate medical home is a multidisciplinary sickle cell clinic that coordinates all aspects of comprehensive care in collaboration with the child's primary care pediatrician or that provides specialty and primary care in 1 setting. In other cases, the medical home may be provided by a knowledgeable primary care pediatrician or other health care professional from whom patients receive day-to-day care, with periodic referrals to sickle cell specialists for comprehensive evaluations and for the management and treatment of severe, life-threatening complications. Some SCD programs support primary care pediatricians by conducting outreach clinics in communities distant from tertiary care centers. The location of the medical home and the extent to which the care outlined in this statement is provided by the primary care pediatrician versus the multidisciplinary SCD team will vary among patients and communities and will depend in part on the expertise of the primary care pediatrician, access to a multidisciplinary SCD team, family preference, and the frequency and severity of disease manifestations. Appropriate management of many aspects of SCD requires time and expertise beyond levels provided by most primary care pediatricians. In some cases, ongoing access to the pediatric hematologist-oncologist and other subspecialists may require advocacy by the primary care pediatrician with managed care organizations or other payers.[5]

Family and Patient Education

Identification of an infant with SCD through neonatal screening provides an opportunity to educate parents and other caregivers about the child's disorder before symptoms develop.[9,18] Initially, the focus should include the genetics (including the availability of carrier testing and prenatal diagnosis) and basic pathophysiology of SCD and the importance of regularly scheduled health maintenance visits, penicillin prophylaxis, and immunizations, including pneumococcal vaccines. Education about the need for urgent medical evaluation for and treatment of febrile illness, acute splenic sequestration, aplastic crisis, and acute chest syndrome is critical. Education about splenic sequestration includes the need to seek medical attention immediately if the child is pale and listless and instruction about abdominal palpation for determining spleen size. Recognition and appropriate management of dactylitis and other painful events should be reviewed. As the child ages, other topics such as stroke, enuresis, priapism, cholelithiasis, delayed puberty, proliferative retinopathy, avascular necrosis of the hip or shoulder, and leg ulcers are introduced. During middle childhood and adolescence, education is increasingly directed toward the patient in addition to the parents, and during adolescence, it includes the genetic basis of SCD and issues related to contraception, carrier testing of partners, genetic counseling, and prenatal diagnosis. The ultimate goal is to enable families to functionally cope with the child's complex chronic illness and enhance the child's potential for successful transition to adulthood.

Health Maintenance

In addition to ensuring compliance with "Recommendations for Preventive Pediatric Health Care" of the American Academy of Pediatrics (AAP),[20] the following SCD-related issues should be addressed periodically.

Prophylactic Medications

All infants with HbSS and Sβ^o-thalassemia should receive penicillin V potassium prophylaxis, 125 mg orally, twice a day, initiated by 2 months of age.[6,9,21,22] The dose is increased to 250 mg orally, twice a day, at 3 years of age and continued at least until the fifth birthday.[22,23] Erythromycin prophylaxis may be used as an alternative for children with suspected or proven penicillin allergy. The routine use of penicillin prophylaxis for infants and children with HbSC and Sβ^+-thalassemia is controversial.[24] Folic acid supplementation is also controversial.[25]

Immunizations

Timely administration of routine immunizations recommended by the AAP is essential.[26] Children with SCD should receive the 7-valent pneumococcal conjugate and 23-valent pneumococcal polysaccharide vaccines.[22,27] Yearly influenza immunization is recommended.[28] The AAP *2000 Red Book* also recommends immunization with quadrivalent meningococcal polysaccharide vaccine.[28]

Comprehensive Medical Evaluations

All patients should have regularly scheduled comprehensive medical evaluations to review previous disease manifestations, document important baseline physical findings and laboratory values, monitor growth and development, detect early signs of chronic organ damage, and develop individualized patient care plans.[18] Blood pressure should be evaluated in light of the observation that values for persons with SCD are somewhat lower than for hematologically normal individuals.[29] Relatively elevated blood pressures have been associated with an increased risk of stroke and may warrant additional evaluation and treatment.[29] Other potential problems include splenomegaly and the detection and treatment of central nervous system (CNS) disease, proliferative retinopathy, restrictive lung disease, pulmonary hypertension, cholelithiasis, proteinuria, avascular necrosis of the hip or shoulder, and leg ulcers. School performance should be monitored for evidence of neurodevelopmental problems. Comprehensive evaluations also provide an ideal setting for providing age-appropriate family and patient education and for evaluating and addressing psychosocial issues. The frequency of comprehensive evaluations will vary somewhat depending on the patient's age, genotype, and disease manifestations.

Some patients will develop complications or show laboratory or imaging evidence of disease manifes-

tations that warrant more intense, specific therapy, such as chronic transfusions, hydroxyurea, or hematopoietic stem cell transplantation. The usual goal of chronic transfusions is to suppress erythropoiesis and provide normal red blood cells to maintain the percentage of the patient's cells (ie, those containing HbS) at less than 30%.[6,30,31] This approach significantly decreases the risk of recurrent stroke and other SCD-related complications, such as vaso-occlusive pain and acute chest syndrome.[30–32] Strategies for preventing and treating transfusion complications, including alloimmunization to minor red blood cell antigens and hemosiderosis, need to be carefully considered.[6,30,33–37] Daily oral administration of hydroxyurea increases HbF levels, decreases leukocyte counts, and decreases the frequency of episodes of pain and acute chest syndrome.[38] Hydroxyurea may be appropriate for selected children and adolescents with frequent or severe disease manifestations but requires frequent monitoring for myelotoxicity and other drug-related complications by a physician with expertise in SCD and chemotherapy.[39] Successful stem cell transplantation provides a hematologic cure for SCD,[40] but its use has been limited by the paucity of HLA-matched sibling donors and by the challenge of balancing SCD severity criteria with transplantation-related morbidity and mortality.[41] The clinical course of each patient with SCD should be regularly reviewed by a pediatric hematologist-oncologist generally at the time of comprehensive evaluations, and the possibilities of chronic transfusions, hydroxyurea, and stem cell transplantation should be considered.

Acute Illness

Acute illness characterized by relatively common childhood signs and symptoms, such as fever, cough, abdominal pain, pallor, and limp, can rapidly become life-threatening. Unfortunately, delayed or inadequate evaluation and treatment of acute illness remains an important cause of preventable morbidity and mortality.[42] Thus, it is imperative that every child with SCD have a plan for around-the-clock access to a medical facility where knowledge and perspective about SCD is available and where evaluation and treatment can be promptly delivered.[9,18] For example, a child with fever or pallor and listlessness should always be initially evaluated, if possible, at a site where complete blood cell (CBC) and reticulocyte counts, blood cultures, intravenous antibiotics, and red blood cell transfusions are readily available. Health care professionals who treat acute illness need ready access to baseline information about the patient (eg, SCD genotype, the presence or absence of splenomegaly, and baseline CBC and reticulocyte counts). Strategies for ensuring the availability of baseline information about individual patients include computerized patient databases and the provision of baseline information directly to patients and families on medical alert cards or on emergency information forms recommended by the AAP.[43] The goal of ensuring timely medical treatment for acute illness also is facilitated by providing anticipatory guidance to patients and families about early recognition, appropriate medical evaluation, and treatment of common acute complications.[9,18]

Examples of acute illnesses that require urgent evaluation and treatment are outlined briefly below. More than one of these acute complications may be present simultaneously, and the information provided here lacks many important details about the management of each. Additional details are provided in references cited throughout this statement. Because blood transfusions play a central role in the treatment of some acute complications, the patient's red blood cell antigen phenotype should be determined ahead of time if minor antigen-matched red blood cells, selected to prevent alloimmunization, are available locally.[6,30,33–35]

Fever

Because patients with SCD develop splenic dysfunction at as early as 3 months of age, they are at high risk for septicemia and meningitis with pneumococci and other encapsulated bacteria.[44] Thus, all patients with temperature greater than 38.5°C require rapid triage and physical assessment, urgent CBC and reticulocyte counts, blood culture (plus cerebrospinal fluid analysis and other cultures as indicated), and prompt administration of a broad-spectrum parenteral antibiotic, such as ceftriaxone sodium, cefuroxime, or cefotaxime sodium.[6,9,11] Because of its long half-life, ceftriaxone is usually chosen for selected cases in which outpatient management with close follow-up may be appropriate.[45] The presence of a focus of infection (eg, viral upper respiratory illness, otitis media) does not alter the urgency of administering parenteral antibiotics. Because of the prevalence of resistant pneumococci,[46] vancomycin hydrochloride should be added for proven or suspected meningitis and other severe illness. Infections such as osteomyelitis that are often caused by *Staphylococcus aureus* or other organisms, such as *Salmonella* species, should be treated with a broad-spectrum antibiotic and vancomycin pending the results of bacteriologic culture and sensitivities. Other acute complications of SCD, such as acute chest syndrome, splenic sequestration, and aplastic crisis, need to be excluded during febrile illness.

Pain

Unpredictable episodes of severe and sometimes excruciating pain are characteristic of SCD.[16,47] Many uncomplicated episodes of pain can be managed at home with oral fluids; oral analgesics, such as ibuprofen, acetaminophen, and codeine; and comfort measures, such as heating pads. When home management measures fail to adequately alleviate pain, it is essential that patients receive rapid triage, physical assessment, and aggressive, appropriately monitored analgesia.[47] For severe pain, parenteral opioids, such as morphine, are indicated and usually administered by scheduled around-the-clock dosing or patient-controlled analgesia.[6,47] Opioids should not be withheld because of the unfounded fear of addiction. Other issues include maintenance of adequate (but avoidance of excessive) hydration, monitoring of oxygenation and cardiopulmonary status,

use of incentive spirometry to encourage deeper inspiratory effort,[48] and close observation for the development of other complications, particularly acute chest syndrome.[49,50] During episodes of severe pain, life-threatening complications may develop rapidly and often are heralded by relatively sudden clinical changes, such as an increasing oxygen requirement, altered mental status, or decreasing hemoglobin level or platelet count.[49–51]

Acute Chest Syndrome

Acute chest syndrome is an illness characterized by a new infiltrate identified on a chest radiograph, accompanied or preceded by lower respiratory tract symptoms and/or hypoxemia.[49,50] The syndrome may be present initially during an acute illness or may develop after 2 to 3 days of severe vaso-occlusive pain. Acute chest syndrome is also a common complication of general anesthesia and surgery.[52] Causes include infection (viral and bacterial, including *Mycoplasma* or *Chlamydia* species), pulmonary infarction, and pulmonary fat embolism.[50] Patients may deteriorate rapidly with progression to pulmonary failure and death. Early recognition and aggressive treatment with oxygen, analgesics, antibiotics, and often simple or exchange transfusions are essential and may be life saving.[6,30,49,50,53] The availability of a pediatric intensive care unit is critical in some cases.

Splenic Sequestration

Splenic sequestration is an acute illness characterized by an acutely enlarging spleen and hemoglobin level more than 2 g/dL below the patient's baseline value.[6,9] Mild to moderate thrombocytopenia is often present. Severe cases progress rapidly to shock and death. Prompt recognition and treatment with red blood cell transfusions may be life saving.[30] Surgical splenectomy to prevent recurrence is often recommended after recovery from life-threatening or recurrent episodes of sequestration.[6]

Aplastic Crisis

Aplastic crisis is characterized by an exacerbation of the patient's baseline anemia with a substantially decreased reticulocyte count, typically less than 1%.[6,9] Most cases are caused by acute infection with human parvovirus B19, usually without the characteristic rash. Less commonly, parvovirus infection causes other acute complications of SCD that may occur with aplastic crisis, including severe pain, bone marrow necrosis, acute chest syndrome, splenic sequestration, and stroke.[6] Recognition requires comparison of CBC and reticulocyte counts obtained during acute illness with baseline values. Red blood cell transfusions are often needed to prevent heart failure in patients with uncomplicated aplastic crisis or to urgently treat other coexistent complications.[30] Because parvovirus is contagious, isolation from at-risk persons,[28] such as pregnant health care professionals and those with immunodeficiency or chronic hemolysis, and testing of siblings with SCD for concurrent and subsequent aplastic crisis are recommended.

Stroke

Any acute neurologic symptom other than mild headache, even if transient, requires urgent evaluation. Common presenting symptoms and signs of stroke include hemiparesis, aphasia or dysphasia, seizures, monoparesis, severe headache, cranial nerve palsy, stupor, and coma.[54] Initial evaluation includes CBC and reticulocyte counts and noncontrast computed tomography or magnetic resonance imaging to exclude hemorrhage.[6] Red blood cell minor antigen phenotype, if not previously documented, should be determined so that transfusions can be matched to prevent alloimmunization.[29,30,33–35] Magnetic resonance angiography to document large vessel vasculopathy is often performed. Treatment includes anticonvulsants if necessary, other supportive care for seizures or increased intracranial pressure if present, and a program of chronic transfusions, usually initiated acutely by partial exchange transfusion or erythrocytapheresis.[6,30] Ischemic CNS injury can also present with nonfocal or "soft" signs, such as developmental delays or poor school performance.[55] Children at highest risk of stroke can be identified by screening with transcranial Doppler (TCD) ultrasonography.[56] Those with positive findings on TCD ultrasonography may be candidates for primary stroke prevention with chronic transfusions.[57]

Priapism

Priapism is a prolonged painful erection of the penis that commonly occurs in children and adolescents with SCD, often starting during the early morning hours.[58] It occurs in 2 forms: 1) stuttering episodes that last fewer than 2 to 4 hours but are often recurrent and may precede a severe episode, and 2) severe episodes that last more than 2 to 4 hours and may eventually result in impotence. Severe episodes require urgent evaluation and treatment that may include hydration, analgesics, aspiration and irrigation by a urologist, and sometimes blood transfusions.[59]

Psychosocial Care

Comprehensive care includes periodic psychosocial assessments and access to services needed to optimize the patient's and family's adaptation to chronic illness.[6,18] Personal and cultural beliefs about illness and existing stresses and support systems may greatly impact the ability to cope with SCD. Patient support groups and community-based organizations can be important resources. Relevant issues include health insurance coverage, transportation for health care, and education of school personnel about SCD.

GENETIC EDUCATION AND COUNSELING

The pediatrician may be called on to provide education and counseling to a couple at risk of having a child with SCD. In some cases, such couples will be identified by the diagnosis of SCD, sickle cell trait, hemoglobin C trait, or β-thalassemia minor in a previous child. In other cases, couples may be identified

because of ethnic background or previous laboratory testing. It is important that education and genetic counseling be provided by professionals with expertise in genetics and in the clinical manifestations and treatment of SCD.[9,18] The availability of prenatal diagnosis using DNA analysis of samples obtained from chorionic villous sampling or amniocentesis should be discussed. In many cases, referral to a hematologist-oncologist or a clinical geneticist or obstetrician associated with a prenatal diagnosis center is appropriate. The pediatrician may be called on to review the information and to support the family in the decision-making process.

Education and counseling should include review of autosomal recessive inheritance and the provision of accurate information about genetic risk and the clinical course, medical complications, and treatment of the specific SCD genotype relevant to the family. Genetic risk cannot be assumed from the diagnosis of SCD in a previous child or from the family's memory of test results; documentation of adequate parental testing is essential. Such testing includes a CBC count and hemoglobin separation by electrophoresis (cellulose acetate and citrate agar), isoelectric focusing, and/or HPLC.[18] Most individuals with heterozygous β-thalassemia show a decreased mean corpuscular volume (MCV) and increased levels of hemoglobin A_2 (HbA_2) and/or HbF. Thus, accurate quantitation of HbF by alkali denaturation, radial immunodiffusion, or HPLC and of HbA_2 by column chromatography or HPLC is needed if the MCV is decreased or borderline decreased.[18] Solubility testing is inadequate and should never be used for carrier testing, in part because it will not identify individuals with hemoglobin C trait or β-thalassemia. The results of parental testing should be reviewed by an individual with expertise in the diagnosis of hemoglobinopathies.

Adolescents with SCD should receive accurate information about the genetic transmission of SCD and the availability of carrier testing for partners, genetic counseling, and prenatal diagnosis. They should be counseled about avoiding unwanted pregnancies and offered appropriate contraceptive services. When an adolescent with SCD becomes pregnant, comanagement by a hematologist with expertise in SCD and by a high-risk obstetrician is essential. Options for partner testing, genetic counseling, and prenatal diagnosis should be reviewed. Pregnancy is often associated with an increased frequency of complications of SCD, but most appropriately managed pregnancies in women with SCD have a successful outcome for the mother and infant.[60,61]

HEALTH SUPERVISION FROM BIRTH TO 1 YEAR OF AGE: INFANCY

Family Education

1. Review the results of neonatal screening and confirmatory testing (Table 2).
2. Discuss the basic pathophysiology and genetics of SCD, including the availability of carrier testing and prenatal diagnosis.
3. Review the importance of regularly scheduled health maintenance visits, penicillin prophylaxis, and immunizations, including pneumococcal vaccines.
4. Discuss the need for urgent medical evaluation for and treatment with parenteral antibiotics of febrile illness (temperature greater than 38.5°C).
5. Discuss signs and symptoms of acute splenic sequestration and teach abdominal palpation for determining spleen size.
6. Discuss recognition and appropriate management of dactylitis and other painful events.
7. Discuss the significance of respiratory symptoms possibly indicative of acute chest syndrome.
8. Recommend avoidance of exposure to pet reptiles to decrease the risk of salmonellosis.[62]
9. Discuss medical home options (primary care pediatrician vs comprehensive sickle cell program). Stress the need for coordinated care and communication among the family, pediatrician, and subspecialists. The roles and responsibilities of family and providers should be discussed and defined.
10. Provide written materials to reinforce education.

Health Maintenance

1. Begin prophylactic administration of penicillin V potassium, 125 mg orally, twice a day, by 2 months of age for infants with HbSS and Sβ^o-thalassemia.[6,9,21,22,27] The routine use of penicillin prophylaxis for infants with HbSC and Sβ^+-thalassemia is controversial.[24]
2. Provide routine immunizations, including *Haemophilus influenzae* type b (Hib) and 7-valent pneumococcal conjugate vaccines, beginning at 2 months of age.[22,26–28] Yearly influenza immunization is recommended for children 6 months and older.[28]
3. Provide comprehensive medical evaluations every 2 to 4 months. Critical issues during the first year include the documentation of spleen size and baseline CBC and reticulocyte counts, which may change significantly as HbF levels decrease. Baseline information should be provided to parents. Red blood cell minor antigen phenotype should be determined if transfusions that may be needed for treatment of acute illness can be matched to prevent alloimmunization.[30,34,35] Develop and modify as needed an individualized patient care plan.

Acute Illness

1. Develop a plan for around-the-clock access to a medical facility that can provide urgent evaluation for and treatment of acute illness characterized by fever (temperature greater than 38.5°C), pallor, lethargy, abdominal distention or enlarging spleen size, or tachypnea or other signs of respiratory illness.
2. Arrange immediate access at the acute care facility to baseline information about the patient.
3. Anticipate and address any insurance barriers to the receipt of appropriate care for acute illness.

Psychosocial Care

1. Explore personal beliefs about illness and existing sources of stress and support.
2. Review insurance coverage and provide assistance with application for public support, if applicable.
3. Discuss transportation issues, particularly for episodes of acute illness.
4. Provide information regarding support groups and other community-based organizations.

HEALTH SUPERVISION FROM 1 TO 5 YEARS OF AGE: EARLY CHILDHOOD

Family Education

1. Review disease manifestations to date, if any, and the parents' response.
2. Review the importance of penicillin prophylaxis, if applicable, and of urgent medical evaluation for and treatment of febrile illness (temperature greater than 38.5°C).
3. Review signs, symptoms, and appropriate management of splenic sequestration and other anemic crisis, dactylitis and other manifestations of pain, and acute chest syndrome.
4. Discuss CNS manifestations of SCD and stress the importance of urgent evaluation for signs or symptoms suggestive of stroke or transient ischemic attack (TIA). Discuss screening with TCD ultrasonography, if available.
5. Discuss enuresis and relationship to SCD.
6. Discuss activities, including the need to avoid temperature extremes and to maintain adequate hydration.
7. Recommend avoidance of exposure to pet reptiles to decrease the risk of salmonellosis.[62]
8. Reinforce the rationale and importance of periodic comprehensive evaluations.
9. Reconsider the patient's medical home model depending on family preference and frequency and severity of complications.

Health Maintenance

1. Continue prophylactic administration of penicillin V potassium, 125 mg orally, twice a day, for children with HbSS and $S\beta^0$-thalassemia.[6,9,21,22,27] At 3 years of age, increase the dosage to 250 mg orally, twice a day.[22,27] The routine use of penicillin prophylaxis for children with HbSC and $S\beta^+$-thalassemia is controversial.[24]
2. Complete immunization with Hib and 7-valent pneumococcal conjugate vaccines.[22,26–28] Administer the 23-valent pneumococcal polysaccharide vaccine at 2 and 5 years of age but no earlier than 6 to 8 weeks after the last dose of pneumococcal conjugate vaccine.[22,27] Yearly influenza immunization is recommended.[28]
3. Provide comprehensive medical evaluations at least every 6 to 12 months and modify the patient's care plan as needed. Important issues include growth and development; jaundice; sleep apnea; cardiopulmonary status, including systemic hypertension and functional heart murmurs; spleen size; and neurologic status.
4. Document baseline CBC and reticulocyte counts (every 6–12 months for patients with HbSS and $S\beta^0$-thalassemia and at least yearly for patients with HbSC and $S\beta^+$-thalassemia).
5. Baseline renal and liver function tests, urinalysis, chest radiography, pulse oximetry, electrocardiography, echocardiography, and/or TCD ultrasonography may be indicated.

Acute Illness

1. Develop a plan for around-the-clock access to a medical facility that can provide urgent evaluation for and treatment of acute illness characterized by fever (temperature greater than 38.5°C), pallor, lethargy, abdominal distention or enlarging spleen size, tachypnea or other signs of respiratory illness, or any neurologic sign or symptom.
2. Arrange immediate access at the acute care facility to baseline information about the patient.
3. Anticipate and address any insurance barriers to the receipt of appropriate care for acute illness.

Psychosocial Care

1. Explore personal beliefs about illness and existing sources of stress and support.
2. Review insurance coverage and provide assistance with application for public support, if applicable.
3. Discuss transportation issues, particularly for episodes of acute illness.
4. Provide information regarding support groups and other community-based organizations.
5. Discuss child care or preschool arrangements and offer to assist in educating child care providers or educators about SCD.

HEALTH SUPERVISION FROM 5 TO 13 YEARS OF AGE: LATE CHILDHOOD

Patient and Family Education

1. Review disease manifestations to date and patient's and family's response.
2. Stress the continued importance of urgent medical evaluation for and treatment of febrile illness (temperature greater than 38.5°C).
3. Review home management of painful events.
4. Reinforce anticipatory guidance regarding anemic crisis (including splenic sequestration for patients with HbSC and $S\beta^+$-thalassemia), acute chest syndrome, stroke, and TIA. Discuss screening with TCD ultrasonography, if available.
5. For boys, discuss priapism, initial home management, and the need for urgent evaluation for and treatment of prolonged episodes.
6. Discuss enuresis, if applicable, and its relationship to SCD.
7. Discuss issues related to activity, including participation in athletics, avoidance of temperature extremes, and maintenance of hydration.
8. Recommend avoidance of exposure to pet reptiles to decrease the risk of salmonellosis.[62]

9. Reinforce the rationale and importance of periodic comprehensive evaluations.
10. Reconsider the patient's medical home model depending on family preference and frequency and severity of complications.

Health Maintenance

1. Continuation of prophylactic administration of penicillin V potassium, 250 mg orally, twice a day, after the fifth birthday may be appropriate in selected patients, including those with a history of invasive pneumococcal infection or surgical splenectomy.[22,23,27,28]
2. Administer Hib and 7-valent pneumococcal conjugate vaccines if not previously immunized. Administer second 23-valent pneumococcal polysaccharide vaccine at 5 years of age but no earlier than 3 years after the first pneumococcal polysaccharide vaccine and 6 to 8 weeks after the last pneumococcal conjugate vaccine.[22,27] A third dose of pneumococcal polysaccharide vaccine may be given no earlier than 5 years after the second pneumococcal polysaccharide vaccine and 6 to 8 weeks after the last pneumococcal conjugate vaccine. Yearly influenza immunization is recommended.[28]
3. Provide comprehensive medical evaluations every 6 to 12 months and modify the patient's care plan as needed. Important issues include growth and development; sleep apnea; cardiopulmonary status, including systemic hypertension and functional heart murmurs; hepatosplenomegaly; cholelithiasis; proteinuria; pubertal development; enuresis; avascular necrosis of the hip and shoulder; and neurologic status. Screening for proliferative retinopathy with periodic retinal examinations beginning at 10 years of age is often recommended, especially for patients with HbSC.
4. Document baseline CBC and reticulocyte counts at least yearly.
5. Baseline pulse oximetry, renal and hepatic function tests, chest radiography, pulmonary function tests, electrocardiography, echocardiography, and/or TCD ultrasonography may be indicated.
6. Abdominal ultrasonography to detect cholelithiasis may be indicated.

Acute Illness

1. Develop a plan for around-the-clock access to a facility that can provide urgent evaluation for and treatment of acute illness characterized by fever (temperature greater than 38.5°C), pallor, lethargy, abdominal distention or enlarging spleen size, tachypnea or other signs of respiratory illness, prolonged priapism, or any neurologic sign or symptom.
2. Arrange immediate access at the acute care facility to baseline information about the patient.
3. Anticipate and address any insurance barriers to the receipt of appropriate care for acute illness.

Psychosocial Care

1. Explore personal beliefs about illness and existing sources of stress and support.
2. Review insurance coverage and provide assistance with application for public support, if applicable.
3. Discuss transportation issues, particularly for episodes of acute illness.
4. Provide information regarding support groups and other community-based organizations.
5. Review school attendance and performance and consider formal neurocognitive testing.
6. Offer assistance with education of school personnel about SCD.

HEALTH SUPERVISION FROM 13 TO 21 YEARS AND OLDER: ADOLESCENCE TO EARLY ADULTHOOD

Patient and Family Education

1. Review disease manifestations to date and patient's and family's response.
2. Discuss the nature of SCD with the patient and review concerns and issues related to the impact of the disease throughout adolescence.
3. Review principles of pain management.
4. Review need for urgent medical evaluation for and treatment of febrile illness (temperature greater than 38.5°C).
5. Provide anticipatory guidance regarding anemic crisis (including splenic sequestration for HbSC and $S\beta^+$-thalassemia), acute chest syndrome, stroke, TIA, and priapism.
6. Discuss sexuality and the availability of contraception options, such as barriers, intramuscular medroxyprogesterone, and low-dose estrogen oral contraceptives.
7. Discuss genetics, including partner testing, genetic counseling, and prenatal diagnosis.
8. Discuss issues related to physical activity, including athletics, avoidance of temperature extremes, and maintenance of hydration.
9. Discuss the importance of avoiding drugs, such as alcohol, tobacco, and cocaine, which may precipitate or exacerbate complications of SCD.
10. Discuss chronic manifestations of the disease, including proliferative retinopathy, cholelithiasis, avascular necrosis of the hip and shoulder, leg ulcers, and delayed growth and puberty.
11. Recommend avoidance of exposure to pet reptiles to decrease the risk of salmonellosis.[62]
12. Reinforce rationale and importance of periodic comprehensive evaluations.
13. Reconsider patient's medical home model depending on patient and family preference and frequency and severity of complications.
14. Discuss options for adult-oriented health care providers and develop with the patient a plan for transition from pediatric to adult medical care.

Health Maintenance

1. Yearly influenza immunization is recommended.[28]
2. Provide comprehensive medical evaluations every 6 to 12 months and modify the patient's care

plan as needed. Important issues include adolescent maturation and development; sleep apnea; cardiopulmonary status, including systemic hypertension, restrictive lung disease, and pulmonary hypertension; hepatosplenomegaly; cholelithiasis; proteinuria; pubertal development; avascular necrosis; and neurologic status. Periodic retinal examinations are often recommended, especially for patients with HbSC.
3. Document baseline CBC and reticulocyte counts at least yearly.
4. Baseline pulse oximetry, renal and liver function tests, chest radiography, pulmonary function tests, electrocardiography, and/or echocardiography may be indicated.
5. Abdominal ultrasonography to detect cholelithiasis may be indicated.

Acute Illness

1. Develop a plan for around-the-clock access to a facility that can provide urgent evaluation for and treatment of acute illness characterized by fever (temperature greater than 38.5°C), pallor, lethargy, abdominal distention or enlarging spleen size, tachypnea or other signs of respiratory illness, prolonged priapism, or any neurologic sign or symptom.
2. Arrange immediate access at the acute care facility to baseline information about the patient.
3. Anticipate and address any insurance barriers to the receipt of appropriate care for acute illness.

Psychosocial Care

1. Explore personal beliefs about illness and existing sources of stress and support.
2. Review insurance coverage and provide assistance with application for public support, if applicable.
3. Discuss transportation issues, particularly for episodes of acute illness.
4. Provide information regarding support groups and other community-based organizations.
5. Review school attendance and performance and consider formal neurocognitive testing.
6. Offer assistance with education of school personnel about SCD.
7. Discuss educational and vocational goals.

Clinical Report—Hearing Assessment in Infants and Children: Recommendations Beyond Neonatal Screening

abstract

Congenital or acquired hearing loss in infants and children has been linked with lifelong deficits in speech and language acquisition, poor academic performance, personal-social maladjustments, and emotional difficulties. Identification of hearing loss through neonatal hearing screening, regular surveillance of developmental milestones, auditory skills, parental concerns, and middle-ear status and objective hearing screening of all infants and children at critical developmental stages can prevent or reduce many of these adverse consequences. This report promotes a proactive, consistent, and explicit process for the early identification of children with hearing loss in the medical home. An algorithm of the recommended approach has been developed to assist in the detection and documentation of, and intervention for, hearing loss. *Pediatrics* 2009;124:1252–1263

KEY POINTS

1. Every child with 1 or more risk factors on the hearing risk assessment should have ongoing developmentally appropriate hearing screening and at least 1 diagnostic audiology assessment by 24 to 30 months of age.
2. Periodic objective hearing screening of all children should be performed according to the recommendations for preventive periodic health care.[1]
3. Any parental concern about hearing loss should be taken seriously and requires objective hearing screening of the patient.
4. All providers of pediatric health care should be proficient with pneumatic otoscopy and tympanometry. However, it is important to remember that these methods do not assess hearing.
5. Developmental abnormalities, level of functioning, and behavioral problems (ie, autism/developmental delay) may preclude accurate results on routine audiometric screening and testing. In this situation, referral to an otorhinolaryngologist and a pediatric audiologist who has the necessary equipment and expertise to test infants and young children should be made.
6. The results of abnormal screening should be explained carefully to parents, and the child's medical record should be flagged to facilitate tracking and follow-up.

doi:10.1542/peds.2009-1997

All clinical reports from the American Academy of Pediatrics automatically expire 5 years after publication unless reaffirmed, revised, or retired at or before that time.

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

7. Any abnormal objective screening result requires audiology referral and definitive testing.
8. A failed infant hearing screening or a failed screening in an older child should always be confirmed by further testing.
9. Abnormal hearing test results require intervention and clinically appropriate referral, including otolaryngology, audiology, speech-language pathology, genetics, and early intervention.

INTRODUCTION

Failure to detect congenital or acquired hearing loss in children may result in lifelong deficits in speech and language acquisition, poor academic performance, personal-social maladjustments, and emotional difficulties. Early identification of hearing loss and appropriate intervention within the first 6 months of life have been demonstrated to ameliorate many of these adverse consequences and facilitate language acquisition.[2] Supportive evidence is outlined in the Joint Committee on Infant Hearing's "Year 2007 Position Statement: Principles and Guidelines for Early Hearing Detection and Intervention Programs," which was endorsed by the American Academy of Pediatrics (AAP).[3] This evidence also is part of the rationale for the AAP statement "Newborn and Infant Hearing Loss: Detection and Intervention,"[4] which endorses universal hearing screening and reviews the primary objectives, important components, and recommended screening methods and parameters that characterize an effective universal hearing screening program. Furthermore, the AAP statement "Recommendations for Preventive Pediatric Health Care"[1] promotes objective newborn hearing screening as well as periodic hearing screening for every child through adolescence (Table 1).

[a] To be performed.
[b] Risk assessment, with appropriate action to follow if positive.

All providers of pediatric health care need to recognize children who are at risk of or who suffer from congenital or acquired hearing loss, be prepared to screen their hearing, and assist the family and arrange for proper referral and treatment by identifying available hearing resources within their communities. In addition, the pediatric health care professional can play an important role in communication with the child's schoolteacher and/or nurse and special education professionals to facilitate proper accommodation and education once a hearing deficit has been confirmed.

This clinical report replaces the previous 2003 clinical report and seeks to promote a proactive, consistent, and explicit process for the early identification of children with hearing loss in the medical home. To assist in the detection and documentation of and intervention for hearing loss, an algorithm of the recommended approach with key points has been developed (Fig 1), as have several tables.

RISK INDICATORS FOR HEARING LOSS

Some degree of hearing loss (Table 2) is present in 1 to 6 per 1000 newborn infants.[5] Most children with congenital hearing loss are potentially identifiable by newborn and infant hearing screening. However, some congenital hearing loss may not become evident until later in childhood. Hearing loss also can be acquired during infancy or childhood for various reasons. Infectious diseases, especially meningitis, are a leading cause of acquired hearing loss. Trauma to the nervous system, damaging noise levels, and ototoxic drugs can all place a child at risk of developing acquired hearing loss.[6,7] Otitis media is a common cause of usually reversible hearing loss. Certain physical findings, historical events, and developmental conditions may indicate a potential hearing problem. These conditions include, but are not limited to, anomalies of the ear and other craniofacial structures, significant perinatal events, and global developmental or speech-language delays. All older infants and children should be screened for risk factors involving hearing problems. A summary of high-risk indicators for hearing loss and developmental milestones are included in Tables 3 and 4, respectively. All infants with a risk indicator for hearing loss, regardless of surveillance findings, should be referred for an audiologic assessment at least once by 24 to 30 months of age, even if the child passed the newborn hearing screening. Children with risk indicators that are highly associated with delayed-onset hearing loss, such as hav-

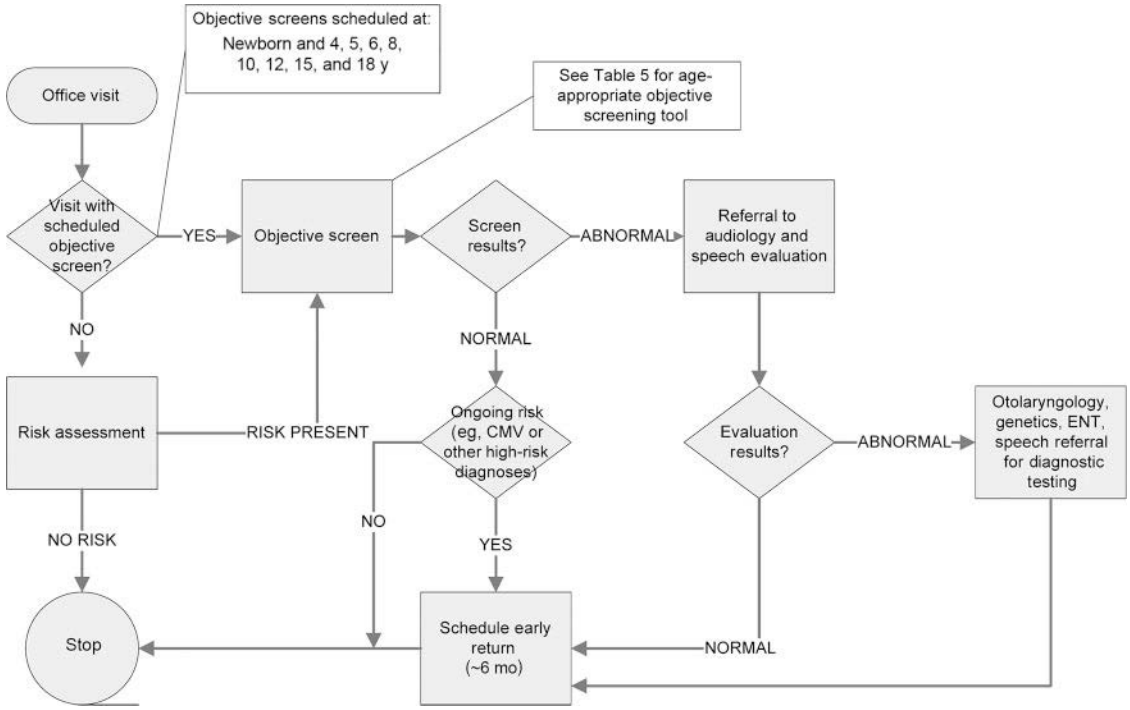

FIGURE 1
Hearing-assessment algorithm within an office visit. CMV indicates cytomegalovirus; ENT, ear, nose, and throat.

ing received extracorporeal membrane oxygenation or having cytomegalovirus infection, should have more frequent audiological assessments. Key point 1: Every child with 1 or more risk factors on the hearing risk assessment should have ongoing developmentally appropriate hearing screening and at least 1 diagnostic audiology assessment by 24 to 30 months of age (Table 1).

Although questionnaires and checklists are useful for identifying a child at risk of hearing loss, studies have shown that only 50% of children with hearing loss are identified by the comprehensive use of such questionnaires.[8,9] Key point 2: Periodic objective hearing screening of all children should be performed according to the recommendations for preventive periodic health care[1] (Table 1).

If a parent or caregiver is concerned that a child might have hearing loss, the pediatrician needs to assume that such is true until the child's hearing has been evaluated objectively. Parental concern is of greater predictive value than the informal behavioral examination performed in the physician's office.[10] Parents often report suspicion of hearing loss, inattention, or erratic response to sound before hearing loss is confirmed.[11] One study showed that parents were as much as 12 months ahead of physicians in identifying their child's hearing loss.[3] Key point 3: Any parental concern about hearing loss should be taken seriously and requires objective hearing screening of the patient.

TABLE 2 Definitions of Hearing Loss

Hearing Loss	Definition
Mild	On average, the most quiet sounds that people can hear with their better ear are between 20 and 40 dB. People who suffer from mild hearing loss have some difficulties keeping up with conversations, especially in noisy surroundings.
Moderate	On average, the most quiet sounds heard by people with their better ear are between 40 and 70 dB. People who suffer from moderate hearing loss have difficulty keeping up with conversations when not using a hearing aid.
Severe	On average, the most quiet sounds heard by people with their better ear are between 70 and 95 dB. People who suffer from severe hearing loss will benefit from powerful hearing aids, but often they rely heavily on lip reading, even when they are using hearing aids. Some also use sign language.

PHYSICAL EXAMINATION

Thorough physical examination is an essential part of evaluating a child for hearing loss. Findings on head and neck examination associated with potential hearing loss include heterochromia of the irises, malformation of the auricle or ear canal, dimpling or skin tags around the auricle, cleft lip or palate, asymmetry or hypoplasia of the facial structures, and microcephaly.[12] Hypertelorism and abnormal pig-

TABLE 3 American Academy of Pediatrics Joint Committee on Infant Hearing Year 2007 Position Statement[3]: Risk Indicators Associated With Permanent Congenital, Delayed-Onset, and/or Progressive Hearing Loss in Childhood

1	Caregiver concern[a] regarding hearing, speech, language, or developmental delay.
2	Family history[a] of permanent childhood hearing loss.
3	Neonatal intensive care of more than 5 days or any of the following regardless of length of stay: ECMO[a], assisted ventilation, exposure to ototoxic medications (gentamicin and tobramycin) or loop diuretics (furosemide/Lasix), and hyperbilirubinemia[19] that requires exchange transfusion.
4	In utero infections such as CMV[a], herpes, rubella, syphilis, and toxoplasmosis.
5	Craniofacial anomalies, including those that involve the pinna, ear canal, ear tags, ear pits, and temporal bone anomalies.
6	Physical findings, such as white forelock, that are associated with a syndrome known to include a sensorineural or permanent conductive hearing loss.
7	Syndromes associated with hearing loss or progressive or late-onset hearing loss[a], such as neurofibromatosis, osteopetrosis, and Usher syndrome; other frequently identified syndromes include Waardenburg, Alport, Pendred, and Jervell and Lange-Nielson.
8	Neurodegenerative disorders[a], such as Hunter syndrome, or sensory motor neuropathies, such as Friedreich ataxia and Charcot-Marie-Tooth syndrome.
9	Culture-positive postnatal infections associated with sensorineural hearing loss[a], including confirmed bacterial and viral (especially herpes viruses and varicella) meningitis.
10	Head trauma, especially basal skull/temporal bone fracture[a] that requires hospitalization.
11	Chemotherapy[a].
12	Recurrent or persistent otitis media for at least 3 months.

Risk indicators that are marked with [a] are of greater concern for delayed onset hearing loss. ECMO indicates extracorporeal membrane oxygenation; CMV, cytomegalovirus.

Reproduced with permission from: American Academy of Pediatrics, Joint Committee on Infant Hearing. *Pediatrics*. 2007; 120(4):898–921.

mentation of the skin, hair, or eyes also may be associated with hearing loss, as in Waardenburg syndrome. The presence of renal abnormalities (Alport syndrome), cardiac anomalies (prolonged QT interval in Jervell and Lange-Nielsen syndrome), and other syndromes should also prompt evaluation of hearing. Abnormalities of the eardrum should alert the physician to the possibility of hearing loss. Cerumen impactions can obscure the tympanic membrane, preventing an accurate examination, and may cause hearing loss. Dense cerumen impactions should be removed before diagnostic testing. A leading cause of acquired hearing loss is otitis media with effusion. Temporary hearing loss has been demonstrated during episodes of acute otitis media. The child with repeated or chronic otitis media with effusion is at high risk of acquired hearing loss and should undergo comprehensive hearing evaluation.[13,14] Key point 4: All providers of pediatric health care should be proficient with pneumatic otoscopy and tympanometry. However, it is important to remember that these methods do not assess hearing.

TOOLS FOR OBJECTIVE HEARING SCREENING

In addition to universal newborn hearing screening and regular surveillance of developmental milestones, auditory skills, parental concerns, and middle-ear status, objective screenings for hearing loss should be performed periodically on all infants and children in accordance with the schedule outlined in the AAP statement "Recommendations for Preventive Pediatric Health Care"[1] (Table 1). The technology used for hearing screening should be age appropriate. The child also should be comfortable with the testing situation; young children may need preparation. A variety of objective tools have been developed for screening tests. The choice of tool to use in screening depends on the child's age, degree of cooperation, and available resources. Screenings should be conducted in a quiet area where visual and auditory distractions are minimal. For children for whom screening is not possible because of developmental level, referral to a pediatric audiologist should be initiated for appropriate physiologic and/or behavioral audiological assessment. Various tests performed by audiologists are outlined in Table 5.

Tympanograms

Conductive hearing loss may be the most common cause of infant hearing screening failures.[15] Objective middle-ear assessment can best be performed by tympanometry. Tympanometry measures relative changes in tympanic membrane movement as air pressure is varied in the external auditory canal. Tympanograms (Fig 2) can most simply be classified as types A, B, and C depending on the curve shape relative to 0 as the pressure is changed (www.audiologyonline.com/askexpert/display_question.asp?question_id=451).

The presence of a type A, high-peaked tympanogram significantly decreases the probability that middle-ear effusion is the cause of hearing loss. A type B, flat tympanogram has the highest probability of the presence of middle-ear effusion or tympanic membrane perforation, which are both likely to cause some degree of hearing loss. A type C tympanogram, with a peak shifted toward negative pressure, has a low probability of middle-ear fluid and associated hearing loss. Type B and C tympanograms require clinical correlation and possibly further evaluation and treatment. Traditionally, tympanograms have been obtained by using low-frequency probe tones. These tones have been historically inaccurate for infants younger than 6 months. The use of a high-frequency probe tone (1000 Hz) was recently shown to be a better measure of middle-ear status in infants and young

TABLE 4 Developmental Milestones in the First 2 Years of Life

Milestone	Average Age of Attainment, mo	Developmental Implications

Head steady in sitting	2.0	Allows more visual interaction
Pull to sit, no head lag	3.0	Muscle tone
Hands together in midline	3.0	Self-discovery
Asymmetric tonic neck reflex gone	4.0	Child can inspect hands in midline
Sits without support	6.0	Increasing exploration
Rolls back to stomach	6.5	Truncal flexion, risk of falls
Walks alone	12.0	Exploration, control of proximity to parents
Runs	16.0	Supervision more difficult
Fine motor		
Grasps rattle	3.5	Object use
Reaches for objects	4.0	Visuomotor coordination
Palmar grasp gone	4.0	Voluntary release
Transfers object hand to hand	5.5	Comparison of objects
Thumb-finger grasp	8.0	Able to explore small objects
Turns pages of book	12.0	Increasing autonomy during book time
Scribbles	13.0	Visuomotor coordination
Builds tower of 2 cubes	15.0	Uses objects in combination
Builds tower of 6 cubes	22.0	Requires visual, gross, and fine motor coordination
Communication and language		
Smiles in response to face, voice	1.5	Child more active social participant
Monosyllabic babble	6.0	Experimentation with sound, tactile sense
Inhibits to "no"	7.0	Response to tone (nonverbal)
Follows 1-step command with gesture	7.0	Nonverbal communication
Follows 1-step command without gesture (eg, "Give it to me")	10.0	Verbal receptive language
Speaks first real word	12.0	Beginning of labeling
Speaks 4–6 words	15.0	Acquisition of object and personal names
Speaks 10–15 words	18.0	Acquisition of object and personal names
Speaks 2-word sentences (eg, "Mommy shoe")	19.0	Beginning grammaticization, corresponds with vocabulary of ≥50 words
Cognitive		
Stares momentarily at spot where object disappeared (eg, yarn ball dropped)	2.0	Lack of object permanence (out of sight, out of mind)
Stares at own hand	4.0	Self-discovery, cause and effect
Bangs 2 cubes	8.0	Active comparison of objects
Uncovers toy (after seeing it hidden)	8.0	Object permanence
Egocentric pretend play (eg, pretends to drink from cup)	12.0	Beginning symbolic thought
Uses stick to reach toy	17.0	Able to link actions to solve problems
Pretend play with doll (gives doll bottle)	17.0	Symbolic thought

Modified from: Behrman RE, Jenson HB, Kliegman R, eds. *Nelson Textbook of Pediatrics*. 16th ed. Philadelphia, PA: Saunders; 2003.

children. These tympanograms are generally not classified as A, B, or C but rather as peak or no peak.

Evoked Otoacoustic Emissions

Evoked otoacoustic emissions (OAEs) are acoustic signals generated from within the cochlea that travel in a reverse direction through the middle-ear space and tympanic membrane out to the ear canal. These signals are generated in response to an auditory stimulus, either clicks or tone bursts. The signals may be detected with a very sensitive microphone/probe system placed in the external ear canal. The OAE test allows for individual ear assessment, can be performed quickly at any age, and does not depend on whether the child is asleep or awake. Mild degrees of motion artifact do not interfere with test results; however, screening results are frequently influenced by the presence of middle-ear pathologic abnormalities. The OAE test is an effective screening measure for middle-ear abnormalities and for moderate or more severe degrees of hearing loss, because normal OAE responses are not obtained if hearing thresholds are approximately 30- to 40-dB hearing levels or higher. The automated OAE screener provides a pass-fail report; no test interpretation by an audiologist is required. The OAE test does not further quantify hearing loss or hearing threshold level. The OAE test also does not assess the integrity of the neural transmission of sound from the eighth nerve to the brainstem and, therefore, will miss auditory neuropathy and other neuronal abnormalities. Infants with such abnormalities will have normal OAE test results but abnormal auditory brainstem response (ABR) test results. A "failed" OAE test only implies that a hearing loss of more than 30 to 40 dB may exist or that the middle-ear status is abnormal.

Automated ABR

One objective physiologic means of screening hearing is the automated ABR. This instrument measures cochlear response in the 1- to 4-kHz range with a broadband click stimulus in each ear. Many ABR screening instruments incorporate built-in artifact rejection for myogenic, electrical, and environmental noise interference, which ensures that data collection is halted if testing conditions are unfavorable. The automated screener provides a pass-fail report; no test interpretation by an audiologist is required. A "fail" report on an automated ABR implies a hearing level of worse than 40 dB. Automated ABR can test each ear individually and can be performed on children of any age. Motion artifacts interfere with test results. For this reason, the test

TABLE 5 Audiologic Tests for Infants and Children

Developmental Age of Child	Auditory Test/ Average Time	Type of Measurement	Test Procedures	Advantages	Limitations
All ages	Evoked OAEs/10-min test	Physiologic test specifically measuring cochlear (outer hair cell) response to presentation of a stimulus; stimuli may be clicks (transient evoked OAEs) or tone pairs (distortion product OAEs)	Small probe containing a sensitive microphone is placed in the ear canal for stimulus delivery and response detection	Ear-specific results; not dependent on whether patient is asleep or awake; quick test time; screening test	Infant or child must be relatively inactive during the test; not a comprehensive test of hearing, because it does not assess cortical processing of sound; OAEs are very sensitive to middle-ear effusions and cerumen or vernix in the ear canal
Birth to 9 mo	Automated ABR/15-min test	Electrophysiologic measurement of activity in auditory nerve and brainstem pathways	Placement of electrodes on child's head detects neurologic response to auditory stimuli presented through earphones or ear inserts 1 ear at a time	Ear-specific results; responses not dependent on patient cooperation; screening test	Infant or child must remain quiet during the test (sedation is often required); not a comprehensive test of hearing, because it does not assess cortical processing of sound
9 mo to 2.5 y	VRA/15- to 30-min test	Behavioral tests measuring responses of the child to speech and frequency-specific stimuli presented through speakers or insert earphones	Technique conditions the child to associate speech or frequency-specific stimuli with a reinforcer, such as a lighted toy or video clips; VRA requires a calibrated, sound-treated room	Assesses auditory perception of child; diagnostic test.	When performed with speakers, only assesses hearing of the better ear; not ear specific; if VRA is performed with insert, earphones can rule out a unilateral hearing loss
2.5 to 4 y	Play audiometry/ 15–30 min	Behavioral test of auditory thresholds in response to speech and frequency-specific stimuli presented through earphones and/ or bone vibrator	Child is conditioned to respond when stimulus tone is heard, such as to put a peg in a pegboard or drop a block in a box	Ear-specific results; assesses auditory perception of child; screening or diagnostic test.	Attention span of child may limit the amount of information obtained
4 y to adolescence	Conventional audiometry/ 15- to 30-min test	Behavioral test measuring auditory thresholds in response to speech and frequency-specific stimuli presented through earphones and/ or bone vibrator	Patient is instructed to raise his or her hand when stimulus is heard	Ear-specific results; assesses auditory perception of patient; screening or diagnostic test	Depends on the level of understanding and cooperation of the child
All ages	Diagnostic ABR	Electrophysiologic measurement of activity in auditory nerve and brainstem pathways	Placement of electrodes on child's head detects auditory stimuli presented through insert earphones 1 ear at a time	Ear-specific results; multiple frequencies are tested, creating a map of hearing loss similar to an audiogram; responses not dependent on patient cooperation; diagnostic test	Infant or child must remain quiet during the test (sedation is often required); not a true test of hearing, because it does not assess cortical processing of sound
All ages	Tympanometry	Relative change in middle-ear compliance as air pressure is varied in the external auditory canal	Small probe placed in the ear canal and pressure varied in the ear canal	Tests for possible middle-ear pathology and pressure-equalization tube function	Not a test of hearing; depends on ear canal seal; high-frequency tone probe needed for infants younger than 6 mo

Adapted with permission from: Bachmann KR, Arvedson JC. *Pediatr Rev.* 1998;19(5):155–165.

is performed best in infants and young children while they are sleeping. If the test cannot be performed because of motion artifact, sedation may be necessary. The ABR is currently used in many newborn screening programs.

ABR and OAEs are tests of auditory pathway structural integrity but are not true tests of hearing. Even if ABR or OAE test

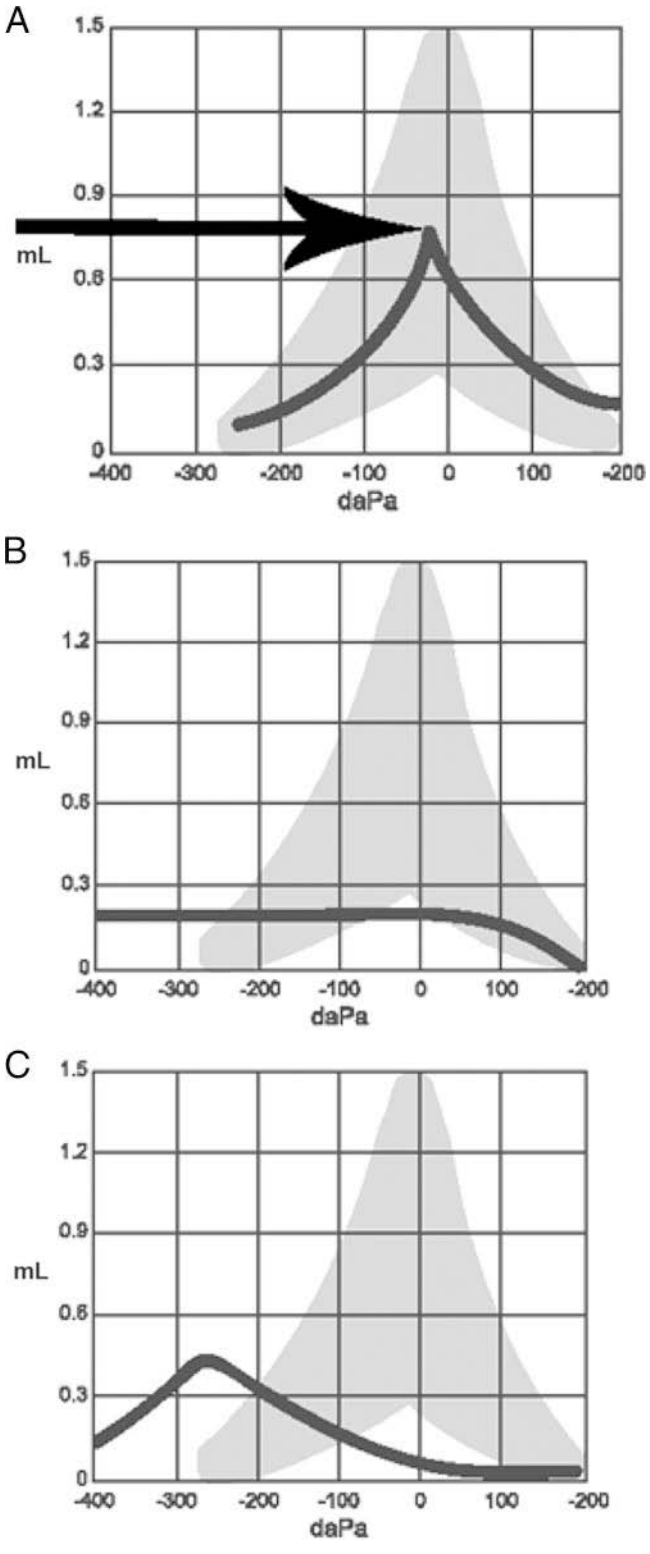

FIGURE 2
Tympanograms. Type A: normal. Type B: abnormal, needs medical attention. Type C, borderline normal; monitor; may need medical attention.

results are normal, hearing cannot be definitively considered normal until a child is mature enough for a reliable behavioral audiogram to be obtained. Behavioral pure-tone audiometry remains the standard for hearing evaluation. Hearing thresholds at specific frequencies can be determined, and the degree of hearing loss can be assigned. If there are distractions or the room is not sound treated, pure-tone audiometry in the office should be considered solely a screening test.

Play Audiometry

Children 2 to 4 years of age are screened or tested more appropriately by play audiometry. These children are conditioned to respond to an auditory stimulus through play activities, such as dropping a block when a sound is heard through earphones. Air-conduction hearing threshold levels of greater than 20 dB at any of these frequencies indicate possible hearing loss, and referral to a pediatric audiologist should be made.

Conventional Screening Audiometry

For children aged 4 years and older, conventional screening audiometry can be used. The child is asked to raise his or her hand when a sound is heard. The test should be performed in a quiet environment using earphones, because ambient noise can affect test performance significantly, especially at lower frequencies (ie, 500 and 1000 Hz). Each ear should be tested at 500, 1000, 2000, and 4000 Hz. Air-conduction hearing threshold levels of greater than 20 dB at any of these frequencies indicate possible hearing loss, and referral to a pediatric audiologist should be made.

If the child does not pass the screening, earphones should be removed and instructions carefully repeated to the child to ensure proper understanding and attention to the test and then rescreened with the earphones repositioned. A child whose repeat test shows hearing thresholds of greater than 20 dB at any of these frequencies, especially if there is no pathologic abnormality of the middle ear on physical

examination, should be referred for formal hearing testing. Key point 5: Developmental abnormalities, level of functioning, and behavioral problems (ie, autism/developmental delay) may preclude accurate results on routine audiometric screening and testing. In this situation, referral to an otorhinolaryngologist and a pediatric audiologist who has the necessary equipment and expertise to test infants and young children should be made (Table 5). Key point 6: The results of abnormal screening should be explained carefully to parents, and the child's medical record should be flagged to facilitate tracking and follow-up.

It is important to remember that a "fail" report on any 1 of a combination of tests warrants additional testing. It is also important to remember that failure of speech, language, and hearing screening assessments warrants additional testing (Tables 6–9).

TABLE 6 Ten Ways to Recognize Hearing Loss: Adolescents (11- to 21-Year Visits)

1.	Do you have a problem hearing over the telephone?
2.	Do you have trouble following the conversation when two or more people are talking at the same time?
3.	Do people complain that you turn the TV volume up too high?
4.	Do you have to strain to understand conversation?
5.	Do you have trouble hearing in a noisy background?
6.	Do you find yourself asking people to repeat themselves?
7.	Do many people you talk to seem to mumble (or not speak clearly)?
8.	Do you misunderstand what others are saying and respond inappropriately?
9.	Do you have trouble understanding the speech of women and children?
10.	Do people get annoyed because you misunderstand what they say?

Comprehensive Audiological Evaluation Using Physiologic and/or Behavioral Testing

The ABR test may be used as a diagnostic tool by audiologists for more definitive diagnosis of hearing loss. Usually performed in children in natural sleep up to approximately 3 to 6 months of age and then under sedation for older infants, diagnostic ABR can provide not only a general level of hearing but also frequency-specific hearing data. Diagnostic ABR is performed with different frequency tone bursts and across varying sound levels to effectively estimate an audiogram. Diagnostic ABR can also be performed with bone conduction to separate conductive from sensorineural hearing loss. Diagnostic ABR is often the definitive test used by audiologists in children and infants who are unable to cooperate with other methods of hearing testing. Audiologic evaluation using ABR or auditory steady-state response provides frequency-specific hearing thresholds by air and bone conduction in each ear separately. ABR is the gold standard for determination of hearing thresholds in infants younger than 6 months and in children who cannot be tested behaviorally.

Children as young as 6 to 24 months can be tested by means of visual reinforced audiometry (VRA). This technique conditions the child to associate speech or frequency-specific sound with a reinforcement stimulus such as a lighted toy or animated toy or video clips. VRA is performed by an audiologist with experience testing young children. This testing is not readily applied in screening programs, because infants younger than 6 months' developmental age cannot perform the task, and sound-treated rooms are needed. The results of VRA can approximate those of conventional audiometry.

Children with unilateral or mild hearing loss also should be evaluated further. Studies have shown such children to be similarly at risk of adverse communication skills as well as difficulties with social, emotional, and educational development.[16]

FOLLOW-UP AND DIAGNOSTIC TESTING

Key point 7: Any abnormal objective screening result requires audiology referral and definitive testing. Screening will only result in benefit for the patient if abnormal test results are confirmed and appropriate intervention is provided. Most studies that have evaluated the success rate of infant hearing screening programs have described a fairly high rate of failure to confirm a failed screen with definitive testing. A similar problem could also occur in screening older infants and children. Improving the physician's involvement not only in screening but also in arranging and confirming appropriate follow-up testing and intervention is necessary to achieve optimal speech, language, and hearing.

Key point 8: A failed infant hearing screening or a failed screening in an older child should always be confirmed by further testing. Audiologists may repeat the audiometric test as described above in a sound booth and using a variety of other tests. ABR can also be used for definitive testing of the auditory system. A diagnostic ABR is usually performed under sedation or general anesthesia in children aged approximately 3 to 6 months and older. The test is performed with frequency-specific stimuli and presentation levels to approximate hearing threshold levels. Diagnostic ABR provides information that is accurate enough to allow for therapeutic intervention. Hearing aids can be fitted with information obtained from a diagnostic ABR. Audiologic assessment and intervention is

TABLE 7 Developmental/Behavioral Screening Tools

Resource	Description	Age Range	Where to Find
General developmental screening tools			
Ages & Stages Questionnaire (ASQ)	A series of 19 questionnaires used to screen infants and young children for developmental delays during the first 5 y of life	4–60 mo	www.brookespublishing.com/tools/asq/index.htm
Ages & Stages Questionnaire: Social-Emotional (ASQ:SE)	A series of 19 questionnaires used to screen infants and young children at risk for social or emotional difficulties, to identify behaviors of concern to caregivers, and to identify any need for further assessment	6–60 mo	www.brookespublishing.com/tools/asqse/index.htm
Parents' Evaluation of Developmental Status (PEDS)	A method for detecting developmental and behavioral-emotional problems in children	Birth to 8 y	www.pedstest.com
Parents' Evaluation of Developmental Status-Developmental Milestones (PEDS:DM)	A collection of 6–8 items per age/encounter designed to replace informal milestones checklists with highly accurate items known to predict developmental status	Birth to 11 y	www.pedstest.com/dm
Autism-specific screening tools			
Checklist for Autism in Toddlers (CHAT)	A screening tool for early detection of autism	18 to ≥24 mo	www.autismresearchcentre.com/tests/chat_test.asp
Checklist for Autism in Toddlers (CHAT), Denver Modifications	CHAT scoring modifications	18 to ≥24 mo	
Checklist for Autism in Toddlers-23 (CHAT-23)	Combination of M-CHAT and CHAT items	16–86 mo	
Childhood Asperger Syndrome Test (CAST)	A parental questionnaire to screen for autism spectrum conditions	4–11 y	www.autismresearchcentre.com/tests/cast_test.asp
Modified Checklist for Autism in Toddlers (M-CHAT)	23-item scale pointing to express interest, responsiveness to name, interest in peers, showing behavior, response to joint attention, social imitation	16–48 mo	http://depts.washington.edu/dbpeds/Screening%20Tools/MCHAT.doc
Pervasive Developmental Disorders Screening Test-II, Primary Care Screener (PDDST-II PCS)	A parental questionnaire to screen for autism spectrum conditions	18–48 mo	www.pearson-uk.com/product.aspx?*n*=1315&skey=2960
Autism-specific or psychosocial screening tools			
Pediatric intake form from *Bright Futures*	Questionnaire to help gather a general understanding of the history, functioning, questions and concerns of the family	Birth to 21 y	www.brightfutures.org/mentalhealth/pdf/professionals/ped_intake_form.pdf
ADHD screening tools			
Vanderbilt rating forms	Parent- and teacher-completed forms that help a clinician diagnosis ADHD and to categorize the problem into 1 of its various subtypes	6–12 y	www.brightfutures.org/mentalhealth/pdf/professionals/bridges/adhd.pdf
AAP ADHD toolkit	A comprehensive toolkit developed from evidence-based guidelines for the diagnosis and treatment of children with ADHD; this resource toolkit contains a wide array of screening, diagnosis, treatment, and support materials for clinicians and other health care professionals	6–12 y	www.aap.org

ADHD indicates attention-deficit/hyperactivity disorder.

an ongoing process. The child requires regular audiologic reevaluations to determine if there is fluctuating or progressive hearing loss. Middle-ear monitoring is also essential. Hearing aid selection, fitting, verification, and validation require ongoing and regular visits with the audiologist. Candidacy for cochlear implantation should be considered when there is limited residual hearing or when progress with amplification is insufficient. Recommendations to the family regarding cochlear implantation should be based on a team evaluation that includes audiology, otology, psychology, speech-language pathology, and other intervention personnel.

Most providers of pediatric health care realize the importance of referring to an otolaryngologist, an audiologist, and a speech-language pathologist. Less recognized is the potential

TABLE 8 Guidelines for Children with Abnormal Speech Development

Age, mo	Referral Guidelines for Children With "Speech" Delay
12	No differentiated babbling or vocal imitation
18	No use of single words
24	Single-word vocabulary of ≤10 words
30	Fewer than 100 words; no evidence of 2-word combinations; unintelligible
36	Fewer than 200 words; no use of telegraphic sentences; clarity <50%
48	Fewer than 600 words; no use of single sentences; clarity ≤80%

TABLE 9 Guidelines for Children With Suspected Hearing Loss

Age, mo	Normal Development
0–4	Should startle to loud sounds, quiet to mother's voice, momentarily cease activity when sound is presented at a conversational level
5–6	Should correctly localize to sound presented in a horizontal plane, begin to imitate sounds in own speech repertoire or at least reciprocally vocalize with an adult
7–12	Should correctly localize to sound presented in any plane, should respond to name, even when spoken quietly
13–15	Should point toward an unexpected sound or to familiar objects or persons when asked
16–18	Should follow simple directions without gesture or other visual cues; can be trained to reach toward an interesting toy at midline when a sound is presented
19–24	Should point to body parts when asked; by 21 mo, can be trained to perform play audiometry

Source: Matkin ND. *Pediatr Rev.* 1984;6:151.

benefit of genetic and ophthalmologic evaluation of children and infants with sensorineural hearing loss.[17]

Especially in young infants and children, referral to an otolaryngologist for a complete diagnostic assessment is essential. More than 90% of the children with permanent hearing loss are born to "hearing" parents, resulting in a sense of urgency for parents of newly identified children with hearing loss to seek out answers regarding etiology, risk of progression, implications, and other questions. If children are indeed identified with sensorineural hearing loss, a variety of diagnostic tests can be recommended depending on the patient's history and physical examination. Otolaryngologists may play a role in diagnosis and treating middle-ear fluid or other middle-ear disorders as well as assisting in the definitive diagnosis of the cause of sensorineural hearing loss.[18] Diagnostic testing may include imaging of the temporal bone to identify structural defects; genetic tests, such as for abnormalities of the *Connexin* gene; and, occasionally, evaluation for other metabolic defects. Evaluation by a geneticist and genetic testing can be important for diagnosis as well as for providing the family with information for future planning purposes.

The hearing health care team (comprising the audiologist, otolaryngologist, teachers of the child with hearing impairment, speech-language pathologists, and other educational and medical personnel) should assist the family with intervention for hearing loss. Interventions may include observation with increased attention to speech and language development, hearing aids, auditory-assisted systems for the school environment, or more invasive surgical hearing devices such as cochlear implants or bone-anchored hearing aids. The goal is to provide families with appropriate options so that they may make well-informed decisions. Interventions should be driven by family desires and guided by accurate and timely information from all hearing-related health care professionals. Family goals and expectations are influenced by culture, parental education, level of income, availability of local resources, language in the home, and more. The role of the hearing health care team is to assist families in identifying all the options available to them and to support them throughout the ongoing decision-making processes that will occur throughout the child's development. All members of the hearing health care team, in conjunction with parents and on the basis of informed choice, should recognize that no decision regarding intervention is "final," and periodic opportunities should be identified for discussion regarding progress, alternative interventions, and new developments.

Medical follow-up includes ongoing evaluation and management of the adequacy of hearing rehabilitation; observation for potential complications of hearing rehabilitation, such as otitis externa and cerumen impactions; and monitoring for appropriate speech and language development.

Speech and language evaluation by a speech-language pathologist with training in working with children with hearing loss is also important for documentation of baseline speech and language skills and implementing a program of intervention that reflects the family's choice regarding language development.

At least one third of children with hearing loss will have an additional coexisting condition.[3] Because many causes of hearing loss are associated with abnormal ophthalmologic findings, formal ophthalmologic evaluation is appropriate, not only to assist with the diagnosis but also to optimize vision. A diagnosis of Usher syndrome with associated progressive hearing and vision loss may influence communication choices.

Children with hearing loss should also be monitored for developmental and behavioral problems (attention-deficit/hyperactivity disorder, autism, learning disabilities) and referred for

additional evaluation when necessary. Health care professionals can use screening tools to evaluate young children periodically for such concerns (Table 7) and refer for additional evaluation when concerns arise.

A medical professional should participate as an active member of a family's hearing health care team after diagnosis and provide input to assist in the adequacy of the rehabilitative efforts to monitor the child for progression and additional disabilities.

HEARING REFERRAL RESOURCES

Key point 9: Abnormal hearing test results require intervention and clinically appropriate referral, including otolaryngology, audiology, speech-language pathology, genetics, and early intervention. Pediatric health care professionals should maintain a list of referral resources available in their community for children with hearing loss and should advocate for increasing options and choices for families. Otolaryngologists, audiologists, and speech-language pathologists with special training and experience in treating children should be consulted for specific diagnosis, counseling, and treatment. Pediatric health care professionals should collaborate to refer the child for comprehensive educational counseling and treatment services. Communication among professionals caring for a child with hearing loss is essential to ensure appropriate case management.

Helicobacter pylori Infection in Children: Recommendations for Diagnosis and Treatment

*Benjamin D. Gold, ÀRichard B. Colletti, ÿMyles Abbott, ÄSteven J. Czinn, ||Yoram Elitsur, ÆEric Hassall, #Colin Macarthur, **John Snyder, and ÀÀPhilip M. Sherman

*Division of *Pediatric Gastroenterology and Nutrition, Department of Pediatrics, Emory University School of Medicine, Atlanta, Georgia; ÀPediatric Gastroenterology, University of Vermont, Fletcher Allen Health Center, Burlington, Vermont; ÿBerkeley California; ÄPediatric Gastroenterology, Rainbow Babies and Childrenôs Hospital, Cleveland, Ohio; ||Division of Gastroenterology, Marshall University School of Medicine, Huntington, West Virginia; ÆDivision of Gastroenterology, BC Childrenôs Hospital, Vancouver, British Columbia, Canada; Divisions of #General Pediatrics and ÀÀGastroenterology and Nutrition, The Hospital for Sick Children, Toronto, Ontario, Canada; and **Pediatric Gastroenterology, University of California San Francisco, San Francisco, California, U.S.A.*

Helicobacter pylori infects at least 50% of the worldôs human population (1). However, most individuals infected with *H. pylori* do not experience symptoms or have signs of recognizable disease. In most children, the presence of *H. pylori* infection does not lead to clinically apparent disease, even when the organism colonizing the gastric mucosa causes chronic active gastritis (2). Knowledge about *H. pylori* infection is evolving, particularly in the pediatric age group for which there are still large gaps in knowledge.

Additional multicenter, randomized, placebo-controlled treatment trials in children infected by *H. pylori* are critically needed to definitively characterize the effect of *H. pylori* eradication treatment during childhood on symptoms and gastroduodenal mucosal disease.

There is compelling evidence that this organism is associated with a significant proportion of duodenal ulcers and, to a lesser extent, with gastric ulcers in children (3). There are epidemiologic data linking chronic *H. pylori* infection, probably beginning in childhood, with the development of gastric adenocarcinoma and gastric lymphoma (4). Findings in recently reported animal models support the role of *H. pylori* in the pathogenesis of gastric cancers (5).

There are many studies describing the prevalence of *H. pylori* infection. Most epidemiologic studies of *H. pylori* infection have been performed in adults who had been infected for many years before clinical symptoms appeared (6). The incidence of *H. pylori* infection in industrialized countries is estimated to be approximately 0.5% of the susceptible population per year. In contrast, there is a significantly higher estimated incidence of *H. pylori* infection in developing countries of approximately 3% to 10% per year (7). The limited data on the incidence of *H. pylori* infection in children consist largely of retrospective seroprevalence studies.

Humans appear to be the primary natural reservoir of *H. pylori* infection. Other reservoirs that have been proposed include water, domestic cats, and houseflies (8ï 10). The risk factors described for acquiring infection include residence in a developing country, poor socioeconomic conditions, family overcrowding, and possibly an ethnic or genetic predisposition. In North America, the prevalence rates of *H. pylori* among Asian-Americans, African-Americans and Hispanics are similar to those of residents of developing countries (11). The route of transmission of *H. pylori* in humans is not known but is postulated to be fecal-oral, gastric-oral (in vomitus), or oral-oral (12).

Although *H. pylori* infection may be acquired during childhood, there are limited guidelines regarding its diagnosis and treatment in children and adolescents. Such evidence-based consensus guidelines are needed for both primary care and specialty medical providers to ensure judicious use of diagnostic testing and appropriate therapeutic regimens for the management of children with *H. pylori* infection. Therefore, the North American Society for Pediatric Gastroenterology and Nutrition (NASPGN) appointed the *Helicobacter pylori* Infection Guideline Committee to develop a clinical practice guideline for the child with *H. pylori* infection.

Received and accepted September 8, 2000.

Address correspondence and reprint requests to Dr. Benjamin Gold, Emory University School of Medicine, 2040 Ridgewood Drive, NE, Atlanta, GA 30322, U.S.A.; or to Dr. Richard B. Colletti, University of Vermont, Department of Pediatrics, A-121 Given Medical Building, Burlington, VT 05405-5557, U.S.A.

These clinical practice guidelines are designed to assist primary care physicians, nurse practitioners, physician assistants, and pediatric gastroenterologists in the evaluation and treatment of suspected or diagnosed *H. pylori*ï associated disease. The desired outcomes of these recommendations are the detection of children and adolescents with *H. pylori* who need treatment. These recommendations are applicable to children in developed countries where the prevalence of infection is low but may not be directly relevant to children living in communities where there is a higher frequency of gastric colonization by *H. pylori*. These recommendations have been endorsed by the Executive Council of NASPGN and by the American Academy of Pediatrics. They are general guidelines to assist medical care providers in the diagnosis and treatment of *H. pylori* infection in children. They are not intended as a substitute for clinical judgment or as a protocol for the management of all patients.

In its deliberations, the committee addressed four issues about *H. pylori* infection in children: How reliable are tests to detect *H. pylori*? When is testing for *H. pylori* indicated? When is treatment of *H. pylori* infection indicated? What is the preferred treatment of *H. pylori*? A summary of the recommendations of the *H. pylori* Infection Guideline Committee is presented in Table 1.

METHODS

The *H. pylori* Infection Guideline Committee consisted of a primary care pediatrician, a clinical epidemiologist, and seven pediatric gastroenterologists. To develop evidence-based guidelines, articles published in English from January 1966 through May 1999 on *H. pylori* in children were searched. Articles on diagnosis and treatment were sought separately. Letters, editorials, case reports, abstracts, and reviews were excluded. Evidence tables were prepared based on 16 articles on clinical presentation, 9 articles on diagnostic studies, and 30 articles on therapy. Subsequently, additional articles were identified and reviewed. When the pediatric literature was insufficient, the adult literature was also considered. Articles were evaluated using published criteria (13). The Committee based its recommendations on an integration of a review of the medical literature and expert opinion. Consensus was achieved by using the nominal group technique, a structured quantitative method, as described previously (14,15). By using the methods of the Canadian Preventive Services Task Force (16), the quality of evidence of each of the recommendations made by the committee was determined and is summarized (Table 1).

HOW RELIABLE ARE TESTS FOR *H. PYLORI* INFECTION?

Several invasive and noninvasive tests are available to detect *H. pylori* infection (Table 2). An ideal test for *H. pylori* is noninvasive or minimally invasive, highly accurate, inexpensive, and readily available and enables differentiation between active or past infection with the

TABLE 1. *Summary of recommendations and the quality of the supporting evidence*

Recommendations	Quality of evidence[a]
How reliable are tests for *H. pylori* infection?	
Currently, the diagnosis of *H. pylori*-mediated disease can be made reliably only through the use of endoscopy with biopsy.	II, III
Presently available commercial serologic tests are frequently unreliable for screening children for the presence of *H. pylori* infection.	II
Urea breath testing, although promising, has not been studied sufficiently in children.	II
When is testing indicated?	
It is recommended that testing be performed in children with endoscopically diagnosed, or radiographically definitive, duodenal or gastric ulcers.	I
It is recommended that children with recurrent abdominal pain, in the absence of documented ulcer disease, not be tested for *H. pylori* infection.	II
Testing for *H. pylori* infection is not recommended in asymptomatic children.	II
Routine screening of children with a family history of gastric cancer or recurrent peptic ulcer disease is not recommended.	II
Testing following treatment of documented *H. pylori* is recommended, especially with complicated peptic ulcer disease (i.e., bleeding, perforation, or obstruction). For patients who remain symptomatic after treatment, it is recommended that endoscopy and biopsy be performed to evaluate for the persistence of *H. pylori*-associated peptic ulcer disease.	I, II
If pathological evidence of MALT lymphoma is documented, then testing for *H. pylori* is recommended.	II
When is treatment of *H. pylori* infection indicated?	
Eradication treatment is recommended for children who have a duodenal ulcer or gastric ulcer identified at endoscopy and *H. pylori* detected on histology.	I
A prior history of documented duodenal or gastric ulcer disease is an indication for treatment if active *H. pylori* infection is documented.	I
There is no compelling evidence for treating children with *H. pylori* infection and non-ulcer dyspepsia or functional recurrent abdominal pain.	III
Treatment is not recommended for *H. pylori*-infected children residing in chronic care facilities; children with unexplained short stature; or children at increased risk for acquisition of infection, including asymptomatic children who have a family member with either peptic ulcer disease or gastric cancer.	III
What is the preferred treatment of *H. pylori* infections in children?	
It is recommended that treatment consist of three or four medications, given once or twice daily, for one to two weeks.	I

[a] Categories of the quallity of evidence: I Evidence obtained from at least one properly designed randomized controlled study. II-1 Evidence obtained from well-designed cohort or case-controlled trials without randomization. II-2 Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group. II-3 Evidence obtained from multiple time series with or without the intervention. Dramatic results in uncontrolled experiments (such as the results of the introduction of penicillin treatment in the 1940ôs) could also be regarded as this type of evidence. III Opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.

organism. In addition, such a test enables discrimination between the presence of *H. pylori* infection and *H. pylori*ï associated disease. Because no such ideal test currently exists, the advantages and drawbacks of tests that are available require critical appraisal and must be assessed for their suitability for use in children.

Failure to reach an accurate diagnosis carries considerable financial and social costs including the expense of more tests, repeated visits to health care providers, inappropriate treatment, and missed school or work. A definitive test, even if it is expensive, may result in overall cost savings (17).

It is important to emphasize that the accuracy of a diagnostic test is greatly impacted by the prevalence of *H. pylori* in the population tested. There is a need for studies to assess the accuracy and potential utility of various noninvasive diagnostic tests in populations in North America that differ in demographic factors that may influence the prevalence and natural history of *H. pylori* infection (18).

Invasive Testing Through Endoscopy

Biopsies and Histopathology

The definitive diagnosis of *H. pylori* and the evidence of the consequences of infection can be made reliably only by endoscopy with multiple biopsy specimens obtained in one or more regions of the stomach including antrum, body, and transition zones (i.e., cardia and incisura). Histology provides information regarding the presence of *H. pylori* and the severity and topographic distribution of gastritis including the presence of atrophic gastritis, intestinal metaplasia, and mucosa-associated lymphoid tissue (MALT) lymphoma (3). As in adults, biopsy specimens obtained in the prepyloric antrum have the highest yield in *H. pylori* infection. Tissue specimens often are also obtained from the body and the transition zones of the stomach, particularly if the patient has recently taken acid-suppressing medication (19). It is recommended that multiple biopsies be performed in children with endoscopically documented peptic ulcer disease or peptic ulcer suspected as a result of radiographic study. The optimal staining of biopsy sections is best determined by local expert pathologists. Endoscopic examination of and specimens obtained in the esophagus, stomach, and duodenum also provide information about other upper gastrointestinal disorders that may be the cause of clinical symptoms including, for example, esophagitis and peptic ulcer disease that is not due to *H. pylori*.

There are drawbacks to diagnostic gastrointestinal endoscopy. It is a relatively invasive procedure requiring sedation or anesthesia. Furthermore, the test remains relatively expensive in many centers, and access to an endoscopist with specific pediatric expertise is limited in many geographic areas.

Rapid Urease Testing of Biopsy Tissues

Urease testing (CLO, TriMed, Kansas City, MO; *Hp*-Fast, GI Supply, Division of ChekMed Systems Inc., Camphill, PA; PyloriTek, Horizons International, Aguadilla, Puerto Rico) provides indirect identification of *H. pylori* infection within a few hours of endoscopy (20). However, these tests have a poor positive predictive value (as low as 50%) in children, even though the negative predictive value is high (97ï 98%) (20,21). The accuracy of the test is dependent on the number of tissue specimens tested, the location of biopsy sites, bacterial load, and previous usage of antibiotics and proton pump inhibitors, as well as the prevalence of *H. pylori* in the population tested.

Bacterial Culture

Culture of *H. pylori* from the gastric mucosa provides an opportunity to obtain a profile of antibiotic sensitivity that could identify potential treatment failure due to antibiotic resistance (22). Culture also provides a bacterial strain for use in epidemiologic studies to examine associations of virulence characteristics with disease outcome. However, bacterial culture for *H. pylori* is relatively expensive and success rates for recovery of the organism in many clinical laboratories are low (23). Currently, standardization of culture procedures has not been established, and bacterial cultures are only obtained routinely in research settings.

Polymerase Chain Reaction

Polymerase chain reaction (PCR) is a highly sensitive technique that can be used to detect the presence of *H. pylori* in body fluids (e.g., gastric juice and stool), tissues (e.g., gastric mucosa), and water (24). Testing of *H. pylori* genomic DNA by PCR can be used to advance knowledge at the molecular levelð for example, by providing information about point mutations conferring resistance to antibiotics and about putative bacterial virulence factors. However, PCR is expensive, the assay

is difficult to set up, specificity may be compromised by inadvertent contamination, and it is not widely available outside the research laboratory.

Noninvasive Testing

Immunoassay Tests to Detect H. pylori *Antibodies*

Enzyme-linked immunosorbent assays (ELISAs) to detect *H. pylori* antibodies are relatively inexpensive and easy to implement in the clinical setting. Many tests are available for use to test whole blood, plasma, or serum. However, compared with histology, the sensitivity and specificity of serologic assays are poor in both adults and children unless used in the populations in which they were initially developed (25). In general, the accuracy of serum-based immunoassays and whole-blood tests for use in the physicianôs office in symptomatic children in developed countries is poor, with a range of sensitivity of only 60% to 70% (26ï 28). Furthermore, age-related cutoff values for commercial immunologic tests have not been established for children. One immunoassay developed in a research center to detect *H. pylorii* specific immunoglobulin (Ig)G in children was 91% sensitive compared with sensitivity of less than 70% in three commercially available assays (28). In areas with low prevalence of *H. pylori* infection, such as in developed countries, testing of serum and whole blood is not sufficiently accurate to diagnose *H. pylori* infection in children. Accordingly, treatment regimens based on the results of these tests cannot be recommended. Serologic tests may not be used reliably to verify eradication of *H. pylori*, because antibody titers can remain positive for months, despite resolution of infection.

Saliva and Urine Tests for H. pylori *Antibodies*

Similar to serologic tests, saliva-based tests also detect the presence of *H. pylorii* specific IgG antibodies. The tests are easy to perform, painless, and inexpensive. Saliva tests are less sensitive than assays of serum or whole blood (29). The protein concentration of saliva appears to affect the accuracy of test results. Urine-based assays are easy to perform, require minimal labor for collection, and are painless (30). However, these assays are highly variable and are not yet commercially available. Therefore, saliva and urine assays for the detection of *H. pylori* antibodies cannot be recommended.

Stool Test for H. pylori *Antigens*

Testing of *H. pylori* antigens in stools has shown promising results in adults for the noninvasive diagnosis of gastric infection using a commercially available kit (31). Testing for *H. pylori* antigens in feces also appears to be accurate for use in monitoring the success of eradication therapy. However, patients may be reluctant to collect stool specimens. In addition, refrigerated stools are more difficult to test. Additional pediatric studies evaluating the accuracy of stool antigen testing for both initial diagnosis and posttreatment follow-up are required before specific recommendations can be considered (32).

Urea Breath Testing

Urea breath tests are noninvasive and have high sensitivity and specificity (>95%) both in adults (33) and children (34,35). The test requires the ingestion of either radiolabeled ^{14}C-urea or urea tagged with the stable isotope ^{13}C. Test results may be influenced by concurrent use of antibiotics and acid-suppressing medications and by the presence of other urease-producing organisms present in the oral cavity. Test parameters are currently laboratory-specific (e.g., dosages for differing ages of children, cutoff values, duration of fasting, use of a test meal, times of sampling, and timing of posttherapy testing) and have not been well standardized for children (36). In addition, urea breath testing is technically more difficult to perform in small children and infants, with failure rates in collection up to 10%, especially outside the clinical research setting (34).

In summary, the diagnosis of *H. pylorii* associated diseases currently can be made reliably only by endoscopy with biopsies. The most commonly used noninvasive test to screen adults for *H. pylori* infection is serology. Unfortunately, currently available commercial serologic tests are frequently unreliable for screening children for the presence of *H. pylori* infection. Current whole-blood, saliva, and urinary immunoassays are insufficiently sensitive or specific to be effective as diagnostic tools. Insufficient data are available in children to confirm the accuracy of the recently approved *H. pylori* stool antigen test. The urea breath test has the promise to provide noninvasive and accurate diagnosis of *H. pylori* infection; but currently, there is insufficient evidence that it can be used to reliably diagnose or exclude *H. pylorii* associated diseases.

WHEN IS TESTING INDICATED?

The primary goal of testing is to diagnose the cause of clinical symptoms and not simply to detect the presence of *H. pylori* infection. Testing is not helpful unless it will alter the management of the disease.

A variety of invasive and noninvasive tests exist for the detection of *H. pylori* infection, but their degree of sensitivity and specificity vary, as do their suitability for clinical use in children. Thus, there is potential for inappropriate testing or misuse of tests in children.

Endoscopically Diagnosed or Radiographically Definitive Peptic Ulcer

The causal relationship between *H. pylori* infection and primary duodenal ulcers is compelling (37). Therefore, it is recommended that testing for the presence of *H. pylori* infection be performed in children with endoscopically diagnosed or radiographically definitive duodenal ulcer. Although the data in children are less complete, evidence from studies in adults (38) supports the recommendation that testing for *H. pylori* also be performed in subjects with a documented gastric ulcer.

Abdominal Pain Unrelated to Peptic Ulcers

Several lines of evidence, including serologic surveys, endoscopic evaluations, and treatment trials indicate that *H. pylori* is not a frequent cause of recurrent abdominal pain in children. There have been six studies performed in North America, Europe, and Australia, with 2715 children evaluated by esophagogastroduodenoscopy and biopsy, serology, or urea breath test (39ï 44). Although 5% to 17% of children with abdominal pain had evidence of infection with *H. pylori*, 5% to 29% of children without abdominal pain were also infected with *H. pylori*. There are no convincing data to support routine testing of children with recurrent abdominal pain (39ï 45). Investigators have also looked for specific symptom patterns in *H. pylori*ï infected children, but none so far has been detected (46ï 50). Future studies are needed to determine whether subsets of children with abdominal pain can be identified in whom signs and symptoms are caused by *H. pylori* infection. It is recommended that children with recurrent abdominal pain, in the absence of documented ulcer disease, not be tested for *H. pylori* infection.

Asymptomatic Children, Including Those at Increased Risk of Acquiring *H. pylori* Infection

There are no compelling data to support routine testing in asymptomatic children. Testing for *H. pylori* infection is not recommended in children without clinical symptoms, including those residing in long-term care facilities, children with short stature, and those at increased risk of acquiring *H. pylori* infection. In addition, purported extraintestinal manifestations of *H. pylori* infection have not been demonstrated in a convincing fashion (51). Accordingly, a test-and-treat approach is not recommended in these circumstances.

Family History of Gastric Cancer or Recurrent Peptic Ulcer Disease

No currently available data support routine testing in children with a positive family history of diseases related to *H. pylori* infection (52). Epidemiologic evidence indicates that there is a link between gastric cancers (both adenocarcinoma and lymphoma) and *H. pylori* infection. However, no studies have shown that *H. pylori* eradication during childhood prevents subsequent development of gastric malignancies. Until evidence is available to better define the role of *H. pylori* in a variety of gastric cancers and the role of *H. pylori* eradication in disease prevention, routine screening of children with a family history of gastric cancer or recurrent peptic ulcer disease is not recommended.

Histologic Evidence of Lymphoma

In the rare circumstance in which histopathologic evidence of MALT lymphoma is documented in a child, testing for *H. pylori* is recommended.

Follow-up of Therapy for *H. pylori* Infection

Testing to confirm eradication of infection and the resolution of associated symptoms and disease sequelae is advisable in selected children. Guidelines in adults recommend testing after treatment of complicated peptic ulcer (52), but studies in children are limited. As such, few data are available on the effectiveness of therapy in children, testing after treatment is recommended in those with complicated peptic ulcer disease (i.e., bleeding, perforation, or obstruction) or lymphoma. For patients who remain symptomatic, it is recommended that endoscopy and biopsy be performed to evaluate for the persistence of *H. pylori*-associated peptic ulcer disease. For patients with an uncomplicated ulcer who are asymptomatic after completion of eradication therapy, testing for persistence of infection is not necessary. However, some physicians advocate the use of urea breath testing in this clinical setting.

WHEN IS TREATMENT OF *H. PYLORI* INFECTION INDICATED?

Eradication therapy is recommended for children who have both known active *H. pylori* infection and symptomatic gastrointestinal disease. Known active *H. pylori* infection is defined as identification of the organisms by histopathologic examination or as a positive culture from endoscopic gastric biopsy. Serology is not a reliable test for active disease, because it may indicate past but not current infection with *H. pylori*.

There are no randomized controlled trials in children that determine the precise clinical settings in which eradication therapy is indicated. Although additional studies in children are needed (53), the available evidence supports the following recommendations.

Duodenal and Gastric Ulcers

Eradication treatment is recommended for children who have a duodenal ulcer or gastric ulcer identified at endoscopy and *H. pylori* documented by histopathology. A prior history of duodenal or gastric ulcer disease is also an indication for treatment if active *H. pylori* infection is documented. If a definitive ulcer is present on contrast radiography (e.g., an ulcer crater is present), eradication therapy is indicated if either a noninvasive or invasive test result is positive for *H. pylori*.

Lymphoma

The rare child with pathologic evidence of MALT lymphoma and *H. pylori* infection should be treated with eradication therapy. Further studies of pediatric patients with lymphoma should be performed to monitor the recurrence, progression, or remission of the tumor after therapy.

Atrophic Gastritis With Intestinal Metaplasia

Eradication treatment is recommended for the rare child who has pathologically proven atrophic gastritis with intestinal metaplasia, according to the updated Sydney classification of gastritis (54), plus coexisting *H. pylori* infection. Because of the preneoplastic nature of these pathologic changes, follow-up endoscopy is recommended to confirm that the *H. pylori* infection has been eradicated and to ensure that there is no subsequent progression of gastric mucosal disease.

Gastritis Without Peptic Ulcer Disease

The finding of *H. pylori*ï associated gastritis in the absence of peptic ulcer disease during diagnostic endoscopy poses a dilemma for the endoscopist. The decision to treat *H. pylori*ï associated gastritis without duodenal or gastric ulcer in this situation is subject to the judgment of the clinician and deliberations with the patient and family. Studies in adults on the effect of eradication treatment on abdominal symptoms have produced conflicting results (55ï 58). There are no randomized controlled trials in children. The long-term impact of the eradication of *H. pylori* and the healing of gastritis on the subsequent development of peptic ulcer disease, adenocarcinoma, or lymphoma is uncertain. Although there is a small lifetime risk of development of peptic ulcer disease associated with *H. pylori* gastritis, there are no randomized controlled trials demonstrating that eradication of *H. pylori* results in prevention of peptic ulcer disease. In addition, there are no data showing that eradication therapy influences the long-term risk for development of gastric cancers. Antibiotic treatment can result in adverse drug reactions, promote antibiotic resistance, and increase the cost of care. Therefore, the *H. pylori* Infection Guideline Committee concludes that there is insufficient evidence to support either initiating or withholding eradication treatment in this situation.

Recurrent Abdominal Pain and Asymptomatic Children

There is no compelling evidence, at the present time, for treating children with *H. pylori* infection and either nonulcer dyspepsia or functional recurrent abdominal pain. There is also no convincing evidence currently available that asymptomatic children who have a family member with *H. pylori* infection, peptic ulcer, or gastric cancer need treatment.

WHAT IS THE PREFERRED TREATMENT OF *H. PYLORI* INFECTION IN CHILDREN?

The optimum treatment regimen for eradicating *H. pylori* in children has not been determined (59). Effective therapy in adults is defined as successful eradication of *H. pylori* infection in a minimum of 80% of treated subjects (60). Although it appears that treatment options that have been effective in adults will also be efficacious in children, controlled studies in pediatric populations are needed to confirm or refute this supposition. Unfortunately, the limited data currently available in children are open-label, case series and uncontrolled, anecdotal observations that do not meet the minimum criteria for determining efficacy. In vitro sensitivity of *H. pylori* to a specific drug does not guarantee that the bacterium will be effectively eradicated from the human stomach. Therefore, current treatment strategies to eradicate *H. pylori* have been developed primarily by trial-and-error methodology (61).

The single most important determinant of successful eradication therapy is compliance with the prescribed combination treatment regimen (62). There are well-described treatment failures due to suboptimal compliance. To enhance adherence to the treatment regimen, the number of medications prescribed, the frequency of administration, and the duration of therapy are best kept to the minimum required for successful treatment.

It is recommended that initial treatment consist of three medications, administered twice daily, for 1 to 2 weeks (63). Specifically, as shown in Table 3, three first-line therapy options are recommended for use in children and adolescents. For patients in whom initial treatment has failed, two other options are recommended, including one option with four medications. It is recommended that monotherapy and two-drug regimens be avoided, because they are ineffective and increase the likelihood

TABLE 3. *Recommended eradication therapies for* H. pylori *disease in children*

First-line options	Medications	Dosage
1	amoxicillin	50 mg/kg/day up to 1 g bid
	clarithromycin	15 mg/kg/day up to 500 mg bid
	proton pump inhibitor: omeprazole (or comparable acid inhibitory doses of another PPI)	1 mg/kg/day up to 20 mg bid
2	amoxicillin	50 mg/kg/day up to 1 g bid
	metronidazole	20 mg/kg/dayï 500 mg bid
	proton pump inhibitor: omeprazole (or comparable acid inhibitory doses of another PPI)	1 mg/kg/day up to 20 mg bid
3	clarithromycin	15 mg/kg/day up to 500 mg bid
	metronidazole	20 mg/kg/day up to 500 mg bid
	proton pump inhibitor: omeprazole (or comparable acid inhibitory doses of another PPI)	1 mg/kg/day up to 20 mg bid
Second-line options		
4	bismuth subsalicylate	1 tablet (262 mg) qid *or* 15 ml (17.6 mg/mL qid)
	metronidazole	20 mg/kg/dayï 500 mg bid
	proteon pump inhibitor: omeprazole (or comparable acid inhibitory doses of another PPI)	1 mg/kg/day up to 20 mg bid
	pus, an additional antibiotic: amoxicillin	50 mg/kg/day up to 1 g bid
	or tetracycline[a]	50 mg/kg/day up to 1 g bid
	or clarithromycin	15 mg/kg/dayï 500 mg bid
5	ranitidine bismuth-citrate	1 tablet qid
	clarithromycin	15 mg/kg/dayï 500 mg bid
	metronidazole	20 mg/kg/dayï 500 mg bid

Initial treatment should be provided in a twice daily regimen (to enhance compliance) for 7 to 14 days.

[a] Only for children 12 years of age or older.

bid, twice daily; qid, four times daily.

of acquired antibiotic resistance (64). Primary antimicrobial resistance also can result in treatment failure even when a three- or four-drug regimen is used. Resistance of *H. pylori* to nitroimidazoles causes an increase in the rate of treatment failures in regimens using metronidazole. An increasing prevalence of resistance to clarithromycin, documented in the past few years, particularly in Europe, could eventually impair the therapeutic effectiveness of this antibiotic in *H. pylori* treatment regimens. Results in some studies suggest that prior therapy with a proton pump inhibitor also reduces the effectiveness of eradication treatment protocols. Studies are needed to determine the relative importance of these risk factors in pediatric populations.

AMERICAN ACADEMY OF PEDIATRICS

CLINICAL REPORT

Guidance for the Clinician in Rendering Pediatric Care

George J. Cohen, MD, and the Committee on Psychosocial Aspects of Child and Family Health

Helping Children and Families Deal With Divorce and Separation

ABSTRACT. More than 1 million children each year experience their parents' divorce. For these children and their parents, this process can be emotionally traumatic from the beginning of parental disagreement and rancor, through the divorce, and often for many years thereafter. Pediatricians are encouraged to be aware of behavioral changes in their patients that might be signals of family dysfunction so they can help parents and children understand and deal more positively with the issue. Age-appropriate explanation and counseling is important so children realize that they are not the cause of, and cannot be the cure for, the divorce. Pediatricians can offer families guidance in dealing with their children through the troubled time as well as appropriate lists of reading material and, if indicated, can refer them to professionals with expertise in the emotional, social, and legal aspects of divorce and its aftermath.

INTRODUCTION

Each year, more than 1 million children experience the divorce of their parents. In 1995, less than 60% of US children were living with both biologic parents, almost 25% were living with their mother only, approximately 4% were living with their father only, and the rest were living with stepfamilies, adoptive families, or foster families (including other relatives). It is estimated that there are 500 000 new divorced fathers each year. Divorce rates peaked in 1979–1981 at 5.3 per 1000 persons and decreased by 1995 to 4.4 per 1000 persons. Approximately 50% of first marriages and 60% of second marriages end in divorce.[1,2]

Divorce and separation may be solutions to a discordant marriage, and any decrease in intrafamily hostility may be constructive; however, for many children and their parents, tensions continue and the entire divorce process is a long, searing experience. Divorce is the termination of the family unit, and thus, it is often characterized by painful losses.[3] Approximately half of all children do not see their fathers after divorce, and relatively few have spent a night in their fathers' homes in the past month.[4]

The divorce itself is usually not the first major change in the affected child's life. Parental conflict before the separation often leads to internalizing and externalizing behavior problems, even in preschoolers.[5] Children's sense of loss is ongoing and may increase, especially on holidays, birthdays, and special school events and when trying to integrate new family relationships. Other losses for the child or adolescent relate to changes in home, extended family, school, playmates, financial status, and parental work schedules.[6,7]

Up to half of children show a symptomatic response during the first year after their parents divorce. Risk factors for continuing childhood difficulty include ongoing parental discord, maternal depression, psychiatric disorders in either parent, and poverty.[5,7–10] Long-term follow-up studies indicate that divorce may limit or delay children's capacity for intimacy and commitment as young adults.[11–13]

CHILDREN'S REACTIONS

The clinical manifestations of divorce in children depend on many variables, including the child's age; the predivorce level of the family's psychosocial functioning; the parents' ability in the midst of their own anger, loss, and discomfort to focus on their child's feelings and needs; and the child's temperament and temperamental fit of parents with their children.[5,10,14,15]

- Infants and children younger than 3 years may reflect their caregivers' distress, grief, and preoccupation; they often show irritability, increased crying, fearfulness, separation anxiety, sleep and gastrointestinal problems, aggression, and developmental regression.[8,14,16]
- At 4 to 5 years of age, children often blame themselves for the breakup and parental unhappiness, become more clingy, show externalizing behavior (acting out), misperceive the events of the divorce situation, fear that they will be abandoned, and have more nightmares and fantasies.[10,17]
- School-aged children may be moody or preoccupied; show more aggression, temper, and acting-out behavior; seem uncomfortable with gender identity; and feel rejected and deceived by the absent parent. School performance may decrease, and they may agonize about their divided loyalties and feel that they should be punished.[9,10,14,16]

- Adolescents may feel decreased self-esteem and may develop premature emotional autonomy to deal with negative feelings about the divorce and their deidealization of each parent. Their anger and confusion often lead to relationship problems, substance abuse, decreased school performance, inappropriate sexual behavior, depression, and aggressive and delinquent behavior.[18–20]
- At all ages, children frequently have psychosomatic symptoms as a response to anger, loss, grief, feeling unloved, and other stressors. They may try to play 1 parent against the other because they need to feel in control and test rules and limits. However, they are likely to feel guilty and responsible for the separation and feel that they should try to restore the marriage.

PARENTS' REACTIONS

Parents also suffer detrimental effects from divorce and manifest a variety of negative and uncomfortable reactions. Mothers are likely to react to daily stressors as well as untoward major events; to consume more alcohol; to use more mental health services for depression, anxiety, or feelings of humiliation; and to feel overwhelmed and less capable as parents. Fathers often feel pushed away, are likely to seem less accepting of their children, and also may develop depression, anxiety, and substance abuse. Grandparents as well often perceive a decreased quality of relationship with their grandchildren, with custody arrangements being more influential in determining visiting schedules than is geographic distance.[10,18,21–25]

MODIFYING FACTORS

Although divorce may be associated with a variety of negative reactions in all members of the family, protective and risk factors have been identified. Predivorce parental rancor, along with children's misunderstanding of the significant changes in their lives and their feelings of guilt for the separation, are likely to lead to greater emotional difficulties. Poor education, poverty, and parents' mental health problems may be more important negative factors than the separation itself. Inconsistent discipline, the child's sense of vulnerability, and rejection by a parent are likely to cause adjustment problems, particularly in children with difficult temperament traits, such as low emotionality or high impulsivity. Factors that lead to better outcomes include positive child temperament and an optimistic view of the future, consistent parental discipline, parental acceptance and warmth, and maintenance of as normal a routine as possible.[5,8,10,17,18,24,26–29]

THE PEDIATRICIAN'S ROLE

Prevention

Pediatricians may only be able to learn about divorce or separation from the children's behavioral changes, family moves, and changes in family financial responsibility. Inquiring about family stressors, including marital difficulties, can be a routine part of the pediatric health supervision visit. When pediatricians counsel the family regarding issues of child development and behavior, areas of marital discord or stress are often uncovered. Addressing these stressors directly or referring for marital counseling is appropriate and may preserve the marital relationship. Pediatricians must consider their own attitudes and ethical positions concerning divorce, especially if they have experienced divorce in their own families, and they must be as objective as possible in counseling children and parents. If the marriage is to end, early interventions can aim to decrease parental hostility and assist the child and parents in coping with family disruptions to come.

In cases of marital discord, the potential role of pediatricians in the area of prevention cannot be underestimated. The pediatrician faces 2 preventive tasks: preserving the intact family when appropriate or decreasing morbidity related to separations that occur.

Anticipatory Guidance

The pediatrician can assess the child's reactions, the parents' reactions and levels of hostility, their abilities to meet the child's physical and emotional needs, their support systems, and any indication of parental mental illness.[30,31]

Understanding the child's experience of divorce is essential if the pediatrician is to advise the family. The works of several authors can be particularly helpful.[17,20,32–35] Wallerstein[36] correctly notes that the family divorce is a process, not simply a single event. Consequently, a child's adjustment occurs in stages.

The event of acute parental separation, which precedes the legal divorce by months or years, is typically the time of highest vulnerability for the child. Parental distress is high. One parent is absent and often temporarily lost to the child. The custodial parent may find parenting responsibilities more difficult because of his or her own distress. At a time when children's needs are increased, parents are at an emotional disadvantage and are often less able to address the needs of their children.

Decreasing school performance, behavioral difficulties, social withdrawal, and somatic complaints are common reactions of children and accompaniments of divorce that require intervention. Profound sadness is typical, and depression is not uncommon.

A parent conference at this stage might be scheduled. The pediatrician can meet with the parents together ideally, or separately if necessary, to assess the current situation, assist in future planning for the children's needs, and reestablish an ongoing, working doctor-patient relationship with each parent. If one parent is not able or willing to confer with the pediatrician, the conference must be with the custodial parent. The pediatrician may offer the noncustodial parent an opportunity to discuss the separation as it affects the child. It is important that the pediatrician understand and respect possible individual parent preferences for a man or woman as the counselor, whether the counselor is the pediatrician or an expert to whom the pediatrician refers the family.

The discussion can begin by inquiring how each member of the family is doing at this time of family stress. Do both parents have adequate support systems, such as extended family, clergy, or a personal physician to help meet their own physical and emotional needs? Are there supports that can help parents in their parenting roles? What is the apparent emotional reaction of the children? It may be helpful to interpret these reactions to the parents on the basis of the child's developmental level and perspective.

Pediatricians can help parents understand their children's reactions and encourage them to discuss the divorce process with their children. Parents can be helped to answer the children's questions honestly at their level of understanding. The children's routines of school, extracurricular activities, contact with family and friends, discipline, and responsibilities should remain as normal as possible. Children should be given permission for their feelings and opportunities to express them. They must understand that they did not cause the divorce and cannot bring the parents back together. Hopefully, they can be told that each parent will continue to love and care for them. The pediatrician can offer families pertinent written material on divorce directed at parents and children (see reading lists at the end of this report).

Custody options can be discussed, and the parents' plan may be explored. It is often helpful to remind parents that they together know better than anyone else their children's needs after divorce and that their knowledge of their own children makes them remarkably more qualified than outsiders, including those in the legal system, to develop a good plan. When consensus cannot be reached or disagreement exists, methods of conflict resolution can be discussed. The pediatrician must insist on being the child's advocate and not take the side of either parent. However, if living with either parent seems to present a risk of abuse or neglect for the child, the pediatrician must contact child protective services and possibly seek advice from his or her own attorney. Seductive behavior by a parent toward the pediatrician can be rebuffed politely but firmly. Custody arrangements should be planned always with the children's best interests in mind. Legal custody and parental rights and responsibilities can vary in their physical and legal arrangements from sole 1-parent custody, to various forms of shared arrangements, to equal or joint custody.[35] Varying statutory requirements exist to protect the interests of children. The reader is referred to the American Academy of Pediatrics statement "The Child in Court."[37]

More important for the child's mental health than the type of custody is the quality of parenting that the child receives through the divorce and postdivorce periods as well as the child's own resilience. Regardless of the type of custody arrangement, it is important that the pediatrician be given a copy of the divorce decree or be informed in writing by both parents of who is responsible for informed consent, who is to pay for the child's health care, and with whom the pediatrician may discuss health information about the child. If the noncustodial parent has visiting rights, it is important that immunization and other pertinent health records be given to both parents in case of an emergency or urgent situation. Parents should inform the child's school of the change in the family structure, request that report cards be sent to both parents, and identify which parent has authority to grant permission for the child's school-related activities.

Long-term Follow-up

Although many children have long-lasting emotional and adjustment problems associated with their parents' divorce, most adjust and function well over time, particularly those who have supportive relationships and a positive temperament and receive professional counseling.[2,20,32–34] Pediatricians must recognize that a divorce is a process and not an event; substantive periods of change during the process can demand new adjustments on the part of children. Although the legal divorce is an important event for parents, it may be an insignificant event to a younger child who knows little of the legal process or a very significant event for the older child who experiences further proof that his parents will not reconcile. Among troublesome issues for children may be the parents' dating and sexual activities. Parental discretion and truthfulness are important for the maintenance of respect for the parents. Stepfamilies introduce another adjustment challenge for children and their parents.

As children develop and mature, their emotions, behaviors and needs with regard to the divorce are likely to change. A custody arrangement that made sense for a younger child may need adjustment for a preadolescent or adolescent. In addition, Wallerstein[36] describes the "sleeper effect" on some early adolescents. With their advancing maturity, awakening sexuality, and important steps toward their own adulthood, their parents' divorce is reinterpreted and requires rediscussion and readjustment. Many behavioral and emotional reactions from the separation can be reawakened at times of subsequent loss, at anniversaries, with the child's advancing maturity, and with the need to adjust to new and different family structures.[36] Ideally, the pediatrician will be able to maintain a professional relationship with both parents so as to continue to help them care for their children in a comfortable and positive manner.

ADVICE FOR ASSISTING CHILDREN AND FAMILIES

- Be alert to warning signs of dysfunctional marriage and impending separation.
- Discuss family functioning in anticipatory guidance and offer advice pertinent to divorce as appropriate.
- Always be the child's advocate, offering support and age-appropriate advice to the child and parents regarding reactions to divorce, especially guilt, anger, sadness, and perceived loss of love.
- Try to maintain positive relationships with both parents rather than taking sides. If there is evidence of an abusive situation, referral to child protective services is indicated.

- Encourage open discussion about separation and divorce with and between parents, emphasizing ways to deal with children's reactions and identifying appropriate reading materials.
- Refer families to mental health resources with expertise in divorce if necessary.
- Become familiar with the *Diagnostic and Statistical Manual for Primary Care (DSM-PC) Child and Adolescent Version*[38] and review the diagnostic criteria carefully so that a specific and appropriate diagnosis is used when helping children and families deal with separation and divorce (Appendix 1).

Diagnostic and Statistical Manual for Primary Care (DSM-PC) Child and Adolescent Version.* Wolraich ML, Felice ME, Drotar D, eds. Elk Grove Village, IL: American Academy of Pediatrics; 1996

Appendix 1. Reimbursement and *DSM-PC* Diagnoses Related to Family Divorce

The *Diagnostic and Statistical Manual for Primary Care (DSM-PC) Child and Adolescent Version*[38] provides diagnoses appropriate to the management of family divorce in pediatric practice. The *DSM-PC* defines diagnoses regarding specific problems of the child as well as situations that impact the child's health and well-being. The *DSM-PC* diagnostic codes are consistent with codes found in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)*. All *DSM-PC* codes conform to the coding of the *International Classification of Diseases, Ninth Revision (ICD-9)*.

The situational diagnosis code for family divorce is v61.0. Additional situations may also be managed within the context of the pediatric encounter with the child and can be specifically coded, such as marital discord (v61.1) or domestic violence (v62.8).

Multiple diagnoses for children impacted by family divorce can be found in *DSM-PC*. Clinicians are encouraged to review the diagnostic criteria carefully so that a specific and appropriate diagnosis is used.

If the child's difficulty appears to be acutely related to issues of adjustment and the adjustment to stress is marked by specific symptoms, various adjustment disorders might be considered appropriate diagnoses, including the following:

- Adjustment disorder with depressed mood (309.0);
- Adjustment disorder with anxiety (309.24);
- Adjustment disorder with mixed anxiety and depressed mood (309.28); and
- Adjustment disorder with disturbance of conduct (309.3).

Newly occurring symptoms suggestive of attention-deficit/hyperactivity disorder at the time of parental separation might, with time and further evaluation, more properly be diagnosed as adjustment disorder with anxiety.

Many children will endure their family change with varying levels of sadness. Some will meet the diagnostic criteria for depression, depressive disorder (NOS 311.0), or major depressive disorder (296.12 × or 293.3 ×). The *DSM-PC* also defines a "sadness variation" (v65.45) or "sadness problem" (v40.3).

Appropriate current procedural terminology codes to bill for work performed with children with these diagnoses might be 99213–5 (expanded, detailed, or complex problem). These codes are time sensitive. Note that these codes may be used whether or not the patient is present; thus, they can be used for time spent speaking with parents alone. Telephone case management codes (99371–3) and preventive counseling codes (99401–4) may also be appropriate procedure codes, although many primary care practitioners report difficulty in obtaining reimbursement for these services from third-party payers.

Appropriate diagnostic and procedure coding as well as documentation are essential to reimbursement for the important additional services that primary care and specialty pediatricians provide to children and families in the context of family divorce.

Helping the Student with Diabetes Succeed

A Guide for School Personnel

U.S. Department of Health and Human Services

A Joint Program of the National Institutes of Health and the Centers for Disease Control and Prevention

NATIONAL DIABETES EDUCATION PROGRAM

This guide was produced by the National Diabetes Education Program (NDEP), a federally sponsored partnership of the National Institutes of Health, the Centers for Disease Control and Prevention, and more than 200 partner organizations. The following organizations support its use by school personnel:

American Academy of Pediatrics

American Association for Health Education

American Association of Diabetes Educators

American Diabetes Association

American Dietetic Association

American Medical Association

Barbara Davis Center for Childhood Diabetes

Centers for Disease Control and Prevention

Indian Health Service

Juvenile Diabetes Research Foundation International

Lawson Wilkins Pediatric Endocrine Society

National Association of Elementary School Principals

National Association of School Nurses

National Association of Secondary School Principals

National Association of State Boards of Education

Acknowledgments

Many National Diabetes Education Program partners contributed to the development of this guide. A core writing and review team helped research, write, and refine drafts of the manuscript and enlisted the involvement of school personnel and parents in reviewing the guide. Their dedication and assistance were invaluable (their names appear below).

Guides developed by state departments of health and education in New York, Rhode Island, Vermont, Virginia, and Washington to address the issue of diabetes in schools and materials from the National Association of State Boards of Education provided additional background information and direction for developing this document.

Foreword

Major research advances have been made in diabetes management and control during the past decade. Several landmark research studies have proved conclusively that aggressive treatment to lower blood glucose (sugar) levels can help prevent or delay diabetes-related complications affecting the eyes, kidneys, nerves, and cardiovascular system. In addition, advances in medical research and technology have produced an array of treatment and management tools that have made it easier for people with diabetes to check their blood glucose levels and to control them.

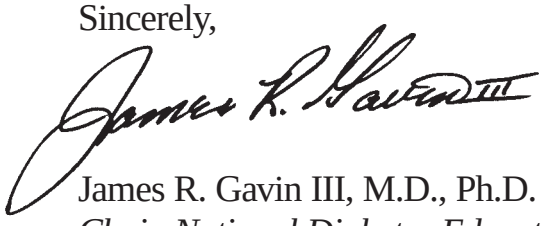
For young people with diabetes, these advances mean a brighter and healthier future. Blood glucose levels that are well managed have the potential to help young people not only to stave off the long-term complications of diabetes but also to feel better and to be happier and more productive at school and at play. Accordingly, students with diabetes need a supportive environment to help them take care of their diabetes throughout the school day and at school-sponsored activities.

The National Diabetes Education Program (NDEP) developed this guide to educate and inform school personnel about diabetes, how it is managed, and how each member of the school staff can help meet the needs of students with the disease. School principals, administrators, nurses, teachers, coaches, bus drivers, health care, and lunchroom staff all play a role in making the school experience safe and sound for students with diabetes.

The NDEP convened an expert panel comprised of health care professionals, federal agency staff, and representatives from key diabetes, pediatric medicine, and educational organizations to develop this comprehensive guide and to help disseminate it throughout the country.

We hope that schools will take advantage of the important information contained in this guide, share it with school staff, parents, and students, and use it to ensure that all students with diabetes are educated in a medically safe environment and have the same access to educational opportunities as their peers.

Sincerely,



James R. Gavin III, M.D., Ph.D.
Chair, National Diabetes Education Program
May 2003

Introduction

More than 17 million Americans have diabetes. In your work with children and youth in the school setting, it is likely that you already have, or will have, a student with diabetes in your care. Diabetes is one of the most common chronic diseases in school-aged children, affecting about 151,000 young people in the United States, or about 1 in every 400 to 500 young people under 20 years of age. Each year, more than 13,000 youths are diagnosed with type 1 diabetes. In addition, health care providers are finding more and more children and teens with type 2 diabetes, even though the disease is usually diagnosed in adults over age 40.

Diabetes is a serious chronic disease that impairs the bodyôs ability to use food for energy. It is the sixth-leading cause of death by disease in the United States. Long-term complications include heart disease, stroke, blindness, kidney disease, and amputation of the foot or leg. Although there is no cure, the disease can be managed and complications delayed or prevented.

Diabetes must be managed 24 hours a day, 7 days a week. For students with type 1 diabetes, and for some with type 2 diabetes, that means careful monitoring of their blood glucose (sugar) levels throughout the school day and administering multiple doses of insulin therapyð now prescribed for most young people with diabetes. As a result, the school health team, which includes the school nurse, teachers, office personnel, and other school staff members, plays an important role in helping students manage their diabetes.

Effective diabetes management is crucial

- for the immediate safety of students with diabetes
- for the long-term health of students with diabetes
- to ensure that students with diabetes are ready to learn and to participate fully in school activities and
- to minimize the possibility that diabetes-related emergencies will disrupt classroom activities.

The school nurse, teachers, office personnel, and other school staff members play an important role in helping students manage their diabetes.

The purpose of this guide is to educate school personnel about diabetes and to share a set of practices that enable schools to ensure a safe learning environment for students with diabetes.

The purpose of this guide is to educate school personnel about diabetes and to share a set of practices that enable schools to ensure a safe learning environment for students with diabetes, particularly the student who uses insulin to control the disease (all students with type 1 and some with type 2 diabetes). **The team approach to school-based diabetes management presented in this guide builds on what schools already are doing for children with other chronic diseases.** Current practices and use of existing resources have been adapted for the student with diabetes.

The practices shared in this guide are not necessarily required by the federal laws enforced by the U.S. Department of Education for each student with diabetes. This guide can be used, however, in determining how to address the needs of students with diabetes. The individual situation of any particular student with diabetes will affect what is legally required for that particular student. Additionally, the guide does not address state and local laws, as the requirements of these laws may vary from state to state and school district to school district. This guide should be used in conjunction with federal as well as state and local laws.

At its core, effective school-based diabetes management requires two things:

- **All school staff members who have responsibility for a student with diabetes should receive training that provides a basic understanding of the disease** and the studentôs needs, how to identify medical emergencies, and which school staff members to contact with questions in case of an emergency.
- **A small group of school staff members should receive training from a qualified health care professional such as a physician or a nurse in student-specific routine and emergency care** so that a staff member is always available for younger or less-experienced students who require assistance with their diabetes management (e.g., administering insulin, checking their blood glucose, or choosing an appropriate snack) and for all students with diabetes in case of an emergency. This group may be comprised of the school nurse and other school staff who are not health care professionals. The non-medical personnel are called ñtrained diabetes personnelò in this guide. Other terminology may be used in your school.

Organized in four sections, the guide includes background information and tools for school personnel to help students manage diabetes effectively.

SECTION 1, Diabetes Primer for School Personnel, provides overview information about diabetes, describes how the disease is managed, and reviews the components for planning and implementing effective diabetes management in school. **The Primer should be copied and distributed to all school personnel who may be responsible for the safety of students with diabetes.** School nurses are the likely leaders in distributing this information and providing the background and education that other school personnel will need. This leadership may vary, however, from one school system to another because of state laws, staffing levels, and other considerations.

SECTION 2, Actions for School Personnel, Parents, and Students, lays out the roles and responsibilities of individual school personnel, parents, and students. **The pages in this section should be copied and distributed to school staff members, parents, and students with diabetes** so that they understand their respective roles in diabetes management.

SECTION 3, Tools for Effective Diabetes Management, contains two important tools for helping schools implement effective diabetes management, a sample Diabetes Medical Management Plan and a sample Quick Reference Emergency Plan for a student with diabetes. **The Quick Reference Emergency Plan should be distributed to all personnel who have responsibility for the student with diabetes** during the school day and during school-sponsored activities.

SECTION 4, School Responsibilities Under Law, was developed by the U.S. Department of Education. This section provides an overview of federal laws that address schoolsôresponsibilities to students with diabetes, including confidentiality requirements. In applying the laws, schools must consider each student on an individualized basis; what is appropriate for one student may not be appropriate for another student.

The **APPENDICES** contain additional resources and information for diabetes management in the school setting. The **Resources** section lists government, professional, and voluntary organizations that can be contacted for more information about diabetes and youth. The **Glossary** provides additional explanations of the medical and technical terms used in this guide. The **American Diabetes Associationôs position statement** on ñCare for Children with Diabetes in the School and Day Care Settingò lays out the diabetes medical communityôs recommendations that are the basis for this guide.

School personnel are encouraged to **visit the National Diabetes Education Programôs website, www.ndep.nih.gov**, to download a comprehensive online resource directory on Diabetes in Children and Adolescents.

www.ndep.nih.gov

To obtain additional copies of this guide and other diabetes information, please call the National Diabetes Education Program at 1-800-438-5383 or visit the programôs website at www.ndep.nih.gov to download copies.

Section 1 DIABETES PRIMER

Copy and distribute this section to all school personnel who may be responsible for the safety of students with diabetes.

Section 1 DIABETES PRIMER FOR School Personnel

WHAT IS DIABETES?

Diabetes is a chronic disease in which the body does not make or properly use insulin, a hormone needed to convert sugar, starches, and other food into energy. People with diabetes have increased blood glucose (sugar) levels because they lack insulin, have insufficient insulin, or are resistant to insulinôs effects. High levels of glucose build up in the blood and spill into the urine; as a result, the body loses its main source of fuel.

When insulin is no longer made, it must be obtained from another sourceð insulin shots or an insulin pump. When the body does not use insulin properly, oral medications may be taken instead of, or in addition to, insulin shots. **Neither insulin nor other medications, however, are cures for diabetes: they only help control the disease.**

Taking care of diabetes is important. If not treated, diabetes can lead to serious health problems. The disease can affect the blood vessels, eyes, kidneys, nerves, gums, and teeth, and it is the leading cause of adult blindness, lower limb amputations, and kidney failure. People with diabetes also have a higher risk of heart disease and stroke. Some of these problems can occur in teens and young adults who develop diabetes during childhood. The good news is that research shows that these problems can be greatly reduced or delayed by keeping blood glucose levels near normal.

Taking care of diabetes is important. If not treated, diabetes can lead to serious health problems.

WHAT ARE THE TYPES OF DIABETES?

There are two main types of diabetes: type 1 and type 2 are described below. A third typeð gestational diabetesð occurs only during pregnancy and ends after delivery. Women who have had gestational diabetes, however, are more likely to develop type 2 diabetes later in life.

Type 1 Diabetes

Type 1 diabetes is a disease of the immune system, the bodyôs system for fighting infection. In people with type 1 diabetes, the immune system attacks the beta cells (the insulin-producing cells of the pancreas) and destroys them. Because the pancreas can no longer produce insulin, people with type 1 diabetes need to take insulin daily to live. Type 1 diabetes can occur at any age, but it occurs most often in children and young adults.

- **Symptoms.** The symptoms of type 1 diabetes usually develop over a short period of time. They include increased thirst and urination, constant hunger, weight loss, and blurred vision. Affected children also may feel very tired all the time. If not diagnosed and treated with insulin, the child with type 1 diabetes can lapse into a life-threatening condition known as diabetic ketoacidosis (KEY-toe-asi-DOE-sis), or DKA.
- **Risk factors.** Although scientists have made much progress in predicting who is at risk for type 1 diabetes, they do not yet know what triggers the immune systemôs attack on beta cells. They believe that type 1 diabetes is due to a combination of genetic and environmental factors. Researchers are working to identify these factors and to stop the autoimmune process that leads to type 1 diabetes.

Type 1 Diabetes INFO

Symptoms:

- Increased thirst and urination
- Constant hunger
- Weight loss
- Blurred vision
- Fatigue

Risk Factors:

- Genetics
- Environment

Type 2 Diabetes

INFO

Symptoms:

- Fatigue
- Increased thirst and urination
- Nausea
- Rapid weight loss
- Blurred vision
- Frequent infections
- Slow healing of wounds or sores

Risk Factors:

- Being overweight
- Having a family member who has type 2 diabetes
- Being African American, Hispanic/Latino American, American Indian, Asian American or Pacific Islander American

Type 2 Diabetes

The first step in the development of type 2 diabetes is often a problem with the bodyôs response to insulin, or insulin resistance. For reasons scientists do not completely understand, the body cannot use its insulin very well. This means that the body needs increasing amounts of insulin to control blood glucose. The pancreas tries to make more insulin, but after several years, insulin production may drop off.

Type 2 diabetes used to be found mainly in overweight adults ages 40 or older. Now, as more children and adolescents in the United States become overweight and inactive, type 2 diabetes occurs more often in young people. To control their diabetes, children with type 2 diabetes may need to take oral medication, insulin, or both.

- **Symptoms.** Type 2 diabetes develops slowly in some children, but quickly in others. Symptoms may be similar to those of type 1 diabetes. A child or teen can feel very tired, thirsty, or nauseated and have to urinate often. Other symptoms include rapid weight loss, blurred vision, frequent infections, yeast infections, and slow healing of wounds or sores. High blood pressure may be a sign of insulin resistance. In addition, physical signs of insulin resistance, such as acanthosis nigricans (A-can-tho-sis NIG-reh-cans), may appear; here the skin around the neck or in the armpits or groin appears dark, thick, and velvety.

  On the other hand, some children or adolescents with type 2 diabetes show no symptoms at all when they are diagnosed. For that reason, it is important for parents and caregivers to talk to their health care providers about screening children or teens at high risk for diabetes.

- **Risk factors.** Being overweight and having a family member who has type 2 diabetes are the key risk factors for type 2 diabetes. In addition, type 2 diabetes is more common in certain racial or ethnic groups, such as African Americans, Hispanic/Latino Americans, American Indians, and some Asian Americans and Pacific Islander Americans. For children and teens at risk, health care providers can encourage, support, and educate the entire family to make lifestyle changes that may delayð or preventð the onset of type 2 diabetes. Such changes may include reaching a healthy weight and then maintaining it and engaging in regular physical activity.

WHAT IS EFFECTIVE DIABETES MANAGEMENT?

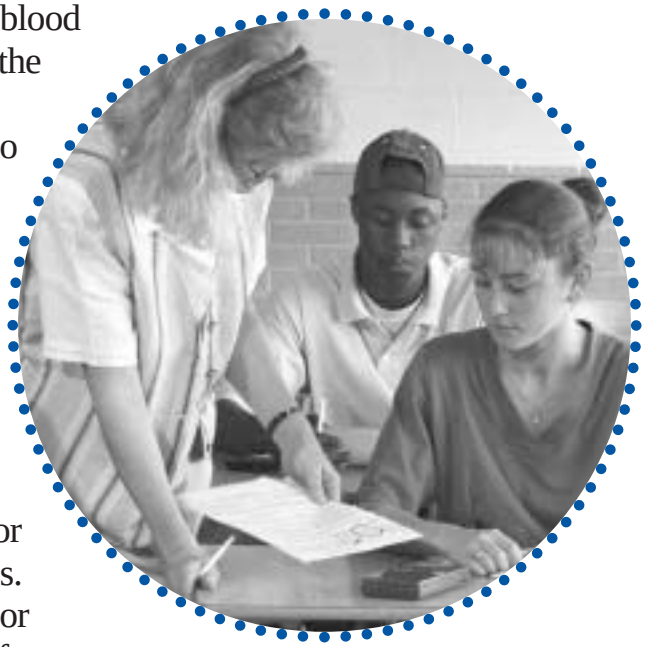
The goal of effective diabetes management is to control blood glucose levels by keeping them within a target range that is determined for each child. Optimal blood glucose control helps to promote normal growth and development and allows for optimal learning. Effective diabetes management is needed to prevent the immediate dangers of blood glucose levels that are too high or too low. As noted earlier, research has shown that maintaining blood glucose levels within the target range can prevent or delay the long-term complications of diabetes, such as heart attack, stroke, blindness, kidney failure, nerve disease, and amputations of the foot or leg.

The key to optimal blood glucose control is to carefully balance food, exercise, and insulin or medication. As a general rule, food makes blood glucose levels go up, and exercise and insulin make blood glucose levels go down. Several other factors, such as growth and puberty, mental stress, illness, or injury also can affect blood glucose levels.

The key to optimal blood glucose control is to carefully balance food, exercise, and insulin or medication.

3 **With all of these factors coming into play, maintaining good blood glucose control is a constant juggling actð 24 hours a day, 7 days a week.**

Students with diabetes must check (or test) their blood glucose levels throughout the day by using a blood glucose meter. The meter gives a reading of the level of glucose in the blood at the time it is being checked. If blood glucose levels are too low (hypoglycemia) or too high (hyperglycemia), students can then take corrective action, such as eating, modifying their activity level, or administering insulin. **Low blood glucose levels, which can be life-threatening, present the greatest immediate danger to people with diabetes (see hypoglycemia, pages 17i 19).**



Many students will be able to handle all or almost all of their diabetes care by themselves. Others, because of age, developmental level, or inexperience, will need help from school staff.

The school nurse is the most appropriate person in the school setting to provide care for a student with diabetes.

The school nurse is the most appropriate person in the school setting to provide care for a student with diabetes. Many schools, however, do not have a full-time nurse, and sometimes a single nurse must cover a large number of schools. Moreover, even when a nurse is assigned to a school full time, this staff member may not always be available during the school day, during extracurricular activities, or on field trips. Yet, because diabetes management is needed 24 hours a day, 7 days a weekð and diabetes emergencies can happen at any timeð school personnel should be prepared to provide diabetes care at school and at all school-sponsored activities in which a student with diabetes participates. In this case, the school nurse or another qualified health professional should be involved with training of appropriate staff and providing professional supervision and consultation regarding routine and emergency care of the student.

3 All students with diabetes will need help with emergency medical care.

Effective school-based diabetes management requires two things:

1. **All school staff members who have responsibility for students with diabetes should receive training that provides a basic understanding of the disease** and the studentsôneeds, how to identify medical emergencies, and whom to contact in case of an emergency.
2. **A few school staff members should receive training from a qualified health care professional in student-specific routine and emergency diabetes care tasks** so that at least one staff member is always available for younger, less experienced students and for any student with diabetes in case of an emergency.

The diabetes medical community has found that nonmedical personnel (called ñtrained diabetes personnelò in this guide) can be trained and supervised to safely provide and assist with diabetes care tasks in the school setting, including blood glucose monitoring, insulin and glucagon administration, and urine ketone testing. These nonmedical school staff members should be trained and monitored by the school nurse or a qualified health professional. Assignment of diabetes care tasks must take into account state laws that may be relevant in determining what tasks may be performed by nonmedical personnel.

HOW CAN A SCHOOL PLAN AND IMPLEMENT EFFECTIVE DIABETES MANAGEMENT?

Collaboration, cooperation, and planning are key elements in developing and implementing successful diabetes management at school. **As is true for children with other chronic diseases, students with diabetes are more likely to succeed in school when students, parents, school nurses, principals, teachers, other school personnel, and the studentôs health care providers (or personal health care team) work together to ensure effective diabetes management.** Your school probably has similar plans and systems in place for children with other health considerations.

To work collaboratively, a school health team should be assembled that includes people who are knowledgeable about diabetes, the school environment, and federal and state education and nursing laws. Team members could include the student, parents/guardian, the school nurse and other health personnel, administrators, the principal, the studentôs teacher(s) and guidance counselor, and other relevant staff.

The school health team works together to implement the Diabetes Medical Management Plan (see pages 49-52) developed by the studentôs personal health care team and family. The team decides who needs to receive appropriate medical information about the child, who will be the trained diabetes personnel and who will monitor them, and what tasks will be delegated. In addition, the school health team should be part of the group that develops and implements the studentôs Section 504 Plan, Individualized Education Program (IEP), or other education plan that addresses the studentôs developmental and educational needs so that diabetes can be managed safely and effectively in school.

Three federal laws address the schoolôs responsibilities to help students with diabetes:

- Section 504 of the Rehabilitation Act of 1973 (Section 504)
- Americans with Disabilities Act of 1990 (ADA)
- Individuals with Disabilities Education Act (IDEA)

These federal laws provide a framework for planning and implementing effective diabetes management in the school setting. School administrators and nursing personnel also should determine whether there are applicable state and local

School Health TEAM

- Student with diabetes
- Parents/guardian
- School nurse
- Other school health personnel
- Principal
- Office staff
- Studentôs teacher(s)
- Guidance counselor
- Other relevant staff

laws that should be factored into helping the student with diabetes (see pages 14ï 15 and Section 4 for additional information on these federal laws).

Written plans outlining each studentôs diabetes management help students, their families, school staff, and the studentôs health care providers know what is expected of them. These expectations should be laid out in writing in the following documents:

- *Diabetes Medical Management Plan,* developed by the studentôs personal health care team and family, contains the prescribed diabetes health care regimen, tailored for each student.
- *Quick Reference Emergency Plan,* based on the information provided in the studentôs Diabetes Medical Management Plan, describes how to recognize hypoglycemia and hyperglycemia and what to do as soon as signs or symptoms of these conditions are observed.
- *Education plans, such as the Section 504 Plan or Individualized Education Program (IEP),* explain what accommodations, education aids, and services are needed for each student with diabetes.
- *Other documents may be generated when a school nurse is involved,* such as a nursing care plan and instructions to staff (see page 36).

The Diabetes Medical Management Plan describes the diabetes regimen developed by the student's personal health care team and family.

Diabetes Medical Management Plan

The Diabetes Medical Management Plan describes the diabetes care regimen developed by the studentôs personal health care team and family and should be signed by the studentôs physician or other member of the health care team (see Section 3 for a sample plan). Although this guide uses the term ñDiabetes Medical Management Plan,ò school districts may use other terms for this document. While this plan is not required by Section 504, the ADA, or the IDEA, the information in it can be useful in addressing the requirements of these federal laws.

Information in the Diabetes Medical Management Plan may include the following:

- Date of diagnosis
- Current health status

- Emergency contact information
- Studentôs willingness and ability to perform self-management tasks at school
- List of diabetes equipment and supplies
- Specific medical orders
  - Blood glucose monitoring
  - Insulin, glucagon, and other medications to be given at school
  - Meal and snack plan
  - Exercise requirements
  - Additional monitoring
- Typical signs, symptoms, and prescribed treatment for hypoglycemia
- Typical signs, symptoms, and prescribed treatment for hyperglycemia

The Diabetes Medical Management Plan should be reviewed and updated each school year or upon a change in the studentôs prescribed regimen, level of self-management, school circumstances (e.g., a change in schedule), or at the request of the student or parents/guardian. Information from this plan is used by the school nurse to develop the studentôs nursing care plan and may be incorporated into the 504, IEP, or other education plan.

Quick Reference Emergency Plan

The Quick Reference Emergency Plan is based on the information provided in the studentôs Diabetes Medical Management Plan; the school nurse will usually coordinate its development. The plan summarizes how to recognize and treat hypoglycemia and hyperglycemia and should be distributed to all personnel who have responsibility for students with diabetes (see Section 3 for a sample plan). Although this guide uses ñQuick Reference Emergency Plan,ò school districts might use other names.

The Quick Reference Emergency Plan summarizes how to recognize and treat hypoglycemia and hyperglycemia.

Education Plans

The school health team, including the student and parents/guardian, must agree on how the Diabetes Medical Management Plan will be implemented and what medical accommodations, educational aids, and services may be needed for the student. This information might be included in a Section 504 Plan, an IEP, or other education plan.

A ñ504 Planò is the commonly used term for a plan of services developed under Section 504 of the Rehabilitation Act. An IEP is required for students who receive special education and related services under the Individuals with Disabilities Education Act (IDEA). The information in the Diabetes Medical Management Plan can be used in developing either a Section 504 Plan or an IEP, but should not be a substitute for these plans.

3 The 504 Plan, IEP, or other education plan lays out what medical accommodations, educational aids, and services the student may need.

Each student with diabetes has different needs, but the education-related plans developed for such students are likely to address the following common elements:

- Where and when blood glucose monitoring and treatment will take place
- Identity of trained diabetes personnel who are trained to conduct blood glucose checking, insulin and glucagon administration, and treatment of hypoglycemia and hyperglycemia
- Location of the studentôs diabetes management supplies
- Free access to the restroom and water fountain
- Nutritional needs, including provisions for meals and snacks
- Full participation in all school-sponsored activities and field trips, with coverage provided by trained diabetes personnel
- Alternative times for academic exams if the student is experiencing hypoglycemia or hyperglycemia
- Permission for absences, without penalty, for doctorsôappointments and diabetes-related illness
- Maintenance of confidentiality and the studentôs right to privacy

It is strongly recommended that this information be agreed upon before each school year begins (or upon diagnosis of diabetes) and that it be written down and signed by a representative of the school and the parents/guardian. This assures that school staff members, parents, and students know their responsibilities. Parents must be notified in a timely manner of any proposed changes in the provision of services and be included in related discussions.

This approach to planning and implementing effective diabetes management in school can promote a better understanding of schoolsôresponsibilities and can prepare staff members to act in the best interest of students with diabetes.

WHAT ARE THE ELEMENTS OF EFFECTIVE DIABETES MANAGEMENT IN SCHOOL?

Diabetes management means monitoring or checking blood glucose levels throughout the day, following an individualized meal plan, getting regular physical activity, and administering insulin and/or medications to help keep blood glucose levels in the target range and to help prevent the onset of hypoglycemia or hyperglycemia. Additional elements of diabetes management in school include planning for events outside the usual school day, planning for appropriate disposal of materials that come in contact with blood, and dealing with the emotional and social aspects of living with diabetes.

Monitoring Blood Glucose

One of the most important parts of diabetes management is regular monitoring or checking of blood glucose levels. Monitoring involves pricking the skin with a lancet at the fingertip, forearm, or other test site to obtain a drop of blood and placing the drop on a special test strip that is inserted in a glucose meter. The meter gives the current blood glucose level.

Physicians generally recommend that students check their blood glucose during the school day, usually before eating snacks or lunch, before physical activity, or when there are symptoms of hypoglycemia or hyperglycemia. In young children, symptoms may be subtle; blood glucose should be checked whenever symptoms are suspected. Many students can check their own

Elements of Effective DIABETES MANAGEMENT

- Monitoring blood glucose
- Understanding hypoglycemia
- Understanding hyperglycemia
- Following an individualized meal plan
- Getting regular physical activity
- Administering insulin
- Planning for special events
- Planning for disasters and emergencies
- Dealing with emotional and social issues

blood glucose level; others will need supervision; and others will need to have this task performed by a school nurse or trained diabetes personnel.

It is extremely important for students to be able to check their blood glucose levels and respond to levels that are too high or too low as quickly as possible. Accordingly, if recommended by the studentôs physician, **it is medically preferable to permit students to check their blood glucose level and respond to the results in the classroom, at any other campus location, or at any school activity.** Taking immediate action is important so that the symptoms donôt get worse and the student doesnôt miss time in the classroom.

Blood glucose monitoring does not present a danger to other students or staff members when there is a plan for proper disposal of lancets and other materials that come into contact with blood. The family and the school should agree on the plan, which should be consistent with standard Universal Precautions and local waste-disposal laws. Disposal may be in a container kept at school or in the studentôs personal container, a heavy-duty plastic or metal container with a tight-fitting lid. Check with the studentôs personal health care team about health and safety requirements in your area.

Students Usually Check Their

BLOOD GLUCOSE

- Before eating snacks or meals
- Before physical activity
- When they have symptoms of high or low blood glucose

Advantages of Checking Blood Glucose Levels Any Time and Any Place

- The student can achieve better blood glucose control to prevent long-term complications of high blood glucose and acute complications of high and low blood glucose.
- It is safer for students because less time is lost between recognizing symptoms, confirming low blood glucose, and obtaining treatment with a fast-acting sugar source followed by a snack or meal.
- The student gains independence in diabetes management when the blood glucose meter is easily accessible and checks can be conducted as needed.
- The student experiences less stigma as blood glucose monitoring loses its mystery when handled as a regular occurrence.
- The student spends less time out of class.

Understanding Hypoglycemia (Low Blood Glucose)

HYPOglycemia means LOW blood glucose.

Hypoglycemia, also called ñlow blood glucoseò or ñlow blood sugar,ò is one of the most frequent complications of diabetes and can happen very suddenly. Hypoglycemia occurs when a studentôs blood glucose level falls too low, usually as a result of administering too much insulin, skipping or delaying meals or snacks, not eating enough food as prescribed in the meal plan, exercising too long or too intensely, or a combination of two or more of these factors. It is more likely to occur before lunch, at the end of the school day, or during or after physical education classes.

3 Hypoglycemia, which often cannot be prevented, is the greatest immediate danger to students with diabetes.

Hypoglycemia usually can be treated easily and effectively. If it is not treated promptly, however, hypoglycemia can lead to unconsciousness and convulsions and can be life threatening. Early recognition of its symptoms and prompt treatment, in accordance with the studentôs Diabetes Medical Management Plan, are necessary for preventing severe symptoms that may place the student in danger. This information, contained in the Quick Reference Emergency Plan, should be provided to all school personnel who have responsibility for the student with diabetes (see sample plan on page 53).

Hypoglycemia is not always completely preventable, and not all students, especially young children, will recognize its symptoms with every episode. Therefore, school personnel should be familiar with the symptoms and treatment so that an urgent problem can be handled appropriately.

Hypoglycemia can impair thinking abilities and sometimes can be mistaken for misbehavior. If a student has a sudden change in behavior, becomes lethargic, combative, or unconscious, or is having a seizure or convulsion, presume that the student has hypoglycemia. Treat the situation as a hypoglycemic emergency and check the studentôs blood glucose level immediately. If a blood glucose meter

Hypoglycemia occurs when a student's blood glucose level falls too low, usually as a result of

-] Administering too much insulin
-] Skipping or delaying meals or snacks
-] Not eating enough food as prescribed in the meal plan
-] Exercising longer and more intensely
-] Or a combination of these factors

is not available in the immediate area, or if the blood glucose level is otherwise unknown, treat the student for hypoglycemia.

3 The student should never be left alone or sent anywhere alone when experiencing hypoglycemia.

As soon as symptoms of hypoglycemia are observed, give the student a quick-acting sugar product equivalent to 15 grams of carbohydrate, as specified in the Quick Reference Emergency Plan. This may include: 3 or 4 glucose tablets, 3 teaspoons (or three-fourths of a tube) of glucose gel, 4 ounces of juice, or 6 ounces (half a can) of non-diet soda. Recheck the studentôs blood glucose level 10 to 15 minutes after treatment. Repeat treatment if the blood glucose level still falls below the studentôs target range.

Symptoms of hypoglycemia, which are different for each student and may vary from episode to episode, can include:

Mild/Moderate Symptoms

-] shaky
-] sweaty
-] hungry
-] pale
-] headache
-] blurry vision
-] sleepy
-] dizzy
-] confused
-] disoriented
-] uncoordinated
-] irritable or nervous
-] changed personality
-] inability to concentrate
-] weak
-] lethargic
-] changed behavior

Severe Symptoms

-] inability to swallow
-] having a seizure or convulsions
-] unconscious

Severe hypoglycemia is rare at school and generally can be prevented with prompt treatment when the early signs of low blood glucose are recognized. When hypoglycemia is severe, the school nurse or trained diabetes personnel must respond immediately. Symptoms may include inability to swallow, unconsciousness, unresponsiveness, seizure activity, convulsions, or jerking movements. At this point, never attempt to give the student food or a drink or to put anything in the mouth because it could cause choking.

If students become unconscious or experience convulsions or seizures, position them on their side to prevent choking. Immediately contact the school nurse or trained diabetes personnel, who will administer an injection of glucagon (see next page), if

How to Treat Hypoglycemia

Mild/Moderate Symptoms:

As soon as symptoms are observed, give the student a quick-acting sugar product, such as:

-] 3 or 4 glucose tablets
-] 3 teaspoons of glucose gel
-] 4 ounces of juice
-] 6 ounces of non-diet soda

Severe Symptoms:

-] Position the student on his/her side
-] Contact the school nurse or trained diabetes personnel
-] Administer glucagon, as prescribed
-] Call 911
-] Call studentôs parents

indicated in the studentôs Diabetes Medical Management Plan. While the glucagon is being administered, another school staff member should call for emergency medical assistance and then notify the parents/guardian. If glucagon is not authorized, staff should call 911 immediately.

Glucagon is a hormone that raises blood glucose levels by causing the release of glycogen (a form of stored carbohydrate) from the liver. It is administered when the studentôs blood glucose level gets so low that the student passes out, experiences seizures, or cannot swallow. Although it may cause nausea and vomiting when the student regains consciousness, glucagon can be a life-saving treatment that cannot harm a student.

The studentôs parents/guardian should supply the school with a glucagon emergency kit. This kit usually contains a bottle (vial) of glucagon in powder form and a pre-filled syringe with special liquid; the two are mixed just before a glucagon injection is given. Glucagon may be stored at room temperature. The school nurse and trained diabetes personnel must have ready access to the glucagon emergency kit at all times.

Understanding Hyperglycemia (High Blood Glucose)

HYPERglycemia means HIGH blood glucose.

Hyperglycemia, also called ñhigh blood glucose,ò is a serious manifestation of diabetes that may be caused by too little insulin, illness, infection, injury, stress or emotional upset, ingestion of food that has not been covered by the appropriate amount of insulin, or decreased exercise or activity. High blood glucose symptoms include increased thirst, frequent urination, nausea, blurry vision, and fatigue. Over a long period of time, even moderately high blood glucose levels can lead to serious complications, such as heart disease, blindness, kidney failure, and amputations. In the short term, hyperglycemia can impair cognitive abilities and adversely affect academic performance.

Hyperglycemia does not usually result in acute problems. If, however, the student fails to take insulin, if a pump malfunctions and delivers less insulin, or if either physical or emotional stress

Hyperglycemia INFO

Symptoms:

-] Increased thirst
-] Frequent urination
-] Nausea
-] Blurry vision
-] Fatigue

causes the insulin not to work effectively, there will be a breakdown of fat, causing ketones to form (see below).

At first, ketones will be cleared by the kidneys into the urine, but if there are more than the kidneys can handle, they will build up in the blood and may result in diabetic ketoacidosis (DKA). This complication will cause a fruity breath odor, nausea, vomiting, stomach pain, and, if untreated, deep breathing and increasing sleepiness. Students who use insulin pumps can go into DKA within hours if their pumps stop delivering insulin appropriately.

DKA can be prevented if the student's urine is checked for ketones during times of illness, especially if vomiting occurs, or whenever the blood glucose level exceeds the target range provided in the Diabetes Medical Management Plan. The test involves dipping a special strip into the urine and comparing the resulting color to a color chart.

Treatment of hyperglycemia may involve drinking extra water or diet drinks or administering supplemental insulin in accordance with the Diabetes Medical Management Plan.

How to Treat Hyperglycemia

-] Drink extra water or diet drinks
-] Administer supplemental insulin
-] Monitor blood glucose levels closely

3 **Free and unrestricted access to liquids and the restroom must be provided, as high blood glucose levels increase urination and may lead to dehydration if the student cannot replace the fluids.**

The student's blood glucose level should be monitored closely until it returns to the target range, as outlined in the Diabetes Medical Management Plan. If treatment does not lower blood glucose levels and clear the ketones, if vomiting occurs, or if the student is lethargic or experiences breathing difficulties, call the parents/guardian or call for medical assistance if they cannot be reached. Treatment guidelines for ketones and when to call parents should be listed in the student's Diabetes Medical Management Plan. Information about the symptoms and treatment of hyperglycemia, contained in the Quick Reference Emergency Plan, should be provided to all school personnel who have responsibility for the student with diabetes (see sample plan on page 54).

Administering Insulin

Students with type 1 diabetes, and some students with type 2 diabetes, require insulin to be given at regular times each day. Some students may need additional or corrective dosages of insulin to treat hyperglycemia or to cover a rise in blood glucose levels. The Diabetes Medical Management Plan specifies the dosage, delivery system, and schedule for insulin administration, which will differ for each student. The nursing care plan, 504, IEP, or other education plan, which are based on the Diabetes Medical Management Plan, specify who will administer prescribed insulin and under what circumstances.

Today, new types of insulin and new delivery systems help keep blood glucose levels within the target range. These options may require closer monitoring and possibly more assistance for the student with diabetes.

Insulin has three characteristics:

Onset is the length of time before insulin reaches the bloodstream and begins lowering blood glucose.

Peak time is the time during which insulin is at its maximum strength in terms of lowering blood glucose.

Duration is the number of hours insulin continues to lower blood glucose levels.

There are several types of insulin that are used in combination to treat people with diabetes. These different types of insulin have been manufactured either to have immediate (rapid-acting or short-acting insulin), intermediate, or long (basal insulin) onset of action and duration of action in the body. A coordinated combination of insulins is used to allow for adequate treatment of diabetes at meals, snacks, during periods of physical activity, and through the night.

Opened vials of insulin may be left at room temperature for 30 days after opening, but will keep for 3 months if refrigerated. Unopened vials should be stored in the refrigerator and are good until the expiration date.

The **three most common ways to administer insulin** are with a syringe, an insulin pen, or an insulin pump.

Insulin syringes available today make it easier to draw up the proper dosage, and shorter, smaller needles make injections easier and relatively painless.

Insulin has three characteristics:

-] Onset
-] Peak time
-] Duration

The three most common ways to deliver insulin:

-] Insulin syringe
-] Insulin pen
-] Insulin pump

An insulin pen looks like a fountain pen. The pen holds a cartridge of insulin, and a needle is screwed onto its tip just before use. Insulin pens are convenient and most appropriate when children need a single type of insulin.

An insulin pump is a computerized device that looks like a pager and is usually worn on the studentôs waistband or belt. The pump is programmed to deliver small, steady doses of insulin throughout the day; additional doses are given to cover food or high blood glucose levels. The pump holds a reservoir of insulin that is attached to a system of tubing called an infusion set. Most infusion sets are started with a guide needle, then the plastic cannula (a tiny, flexible plastic tube) is left in place, taped with dressing, and the needle is removed. The cannula is usually changed every 2 or 3 days or when blood glucose levels remain above target range. More students are opting for insulin pump therapy as a means to keep blood glucose levels in better control.

Some students who need insulin during the school day are able to administer it on their own; others will need supervision; and others will need someone to administer the insulin for them. The school nurse and/or trained diabetes personnel should provide this help in accordance with the Diabetes Medical Management Plan and the nursing care plan. School personnel who are responsible for the studentôs care should be knowledgeable about the use and operation of that studentôs insulin delivery system. Information about insulin administration should appear in the studentôs Diabetes Medical Management Plan, nursing care plan, and education plan (504, IEP, or other education plan).

In the event a school nurse is not available to administer insulin, a nurse or another qualified health care professional should teach, monitor, and supervise trained diabetes personnel to administer insulin. Further, when the school nurse is not available to administer insulin and insulin is administered by other trained diabetes personnel, additional safety precautions may be taken, such as verification of the dose by two trained diabetes personnel before administration.

Following an Individualized Meal Plan

The nutritional needs of a student with diabetes do not differ from the needs of a student without diabetes. Both should eat a variety of foods to maintain normal growth and development. The major difference is that the timing, amount, and content of the food that the student with diabetes eats are carefully matched to the action of the insulin.

The studentôs meal plan is designed to balance nutritional needs with the insulin regimen and physical activity level. **There are usually no forbidden foods for people with diabetes.** The family and personal health care team create an individualized meal plan based upon carbohydrate counting or an exchange system.

Carbohydrate counting involves calculating the number of grams of carbohydrate or choices of carbohydrate the student eats. This information, which can be obtained from nutrition information on food labels, is used to determine the amount of insulin the student needs to control blood glucose for any given meal or snack.

The **exchange system** groups foods in six different lists, each with a set nutritional value. A meal plan is prepared that recommends several exchanges or servings from each food group for each meal and snack. The exchange list ensures that the meal plan is consistent in portion size and nutrient content while offering a wide variety of foods from each group. Students using this approach consume a prescribed number of exchanges at meal and snack times.

The student's meal plan is designed to balance the student's nutritional needs with his or her insulin routine and physical activity level.

The exchange lists include the following food groups:

] Bread/starch] Fruit] Milk] Vegetables
] Meat/protein foods] Fats

With some insulin regimens, it is important to maintain consistency in the timing and content of meals and snacks. The student should eat lunch at the same time each day. Snacks are often necessary for a child with diabetes and must be eaten to balance the peak times of insulin action. **A missed or delayed snack could result in hypoglycemia.** The student also must have immediate access to a quick-acting form of glucose, such as juice, glucose

tablets or gel, or regular soda to treat hypoglycemia. The student's nursing care plan or education plan (504, IEP, or other education plan) should show the timing of meals and snacks and an alternative plan for unusual or unforeseen circumstances.

Getting Regular Physical Activity

Exercise and physical activity are critical parts of diabetes management. Everyone can benefit from regular exercise, but it is even more important for a student with diabetes. In addition to maintaining cardiovascular fitness and controlling weight, physical activity can help to lower blood glucose levels.

Students with diabetes should participate fully in physical education classes and team sports. To maintain blood glucose levels within their target ranges during extra physical activity, students will make adjustments in their insulin and food intake. To prevent hypoglycemia, they also may need to check their blood glucose levels more frequently while engaging in physical activity.

3 Students with diabetes should participate fully in physical education classes and team sports.

Physical education instructors and sports coaches must be able to recognize and assist with the treatment of hypoglycemia. A quick-acting source of glucose and the student's glucose meter should always be available, along with plenty of water.

Students using pumps may disconnect from the pump for sports activities. If they keep the pump on, they may set a temporary, reduced rate of insulin while they are playing. School personnel should provide the student with a safe location for storing the pump when the student does not wear it. The student's Diabetes Medical Management Plan, nursing care plan, 504 Plan, IEP, or other education plan should include specific instructions.

Planning for Special Events, Field Trips, and Extracurricular Activities

With proper planning, students with diabetes can participate fully in all school-related activities.

Meeting the needs of students with diabetes requires advance planning for special events, such as classroom parties, field trips, and school-sponsored extracurricular activities held before or after school. With proper planning for coverage by trained diabetes personnel and possible adjustments to their insulin regimen and meal plan, students with diabetes can participate fully in all school-related activities.

While there are usually no forbidden foods in a meal plan for children or teens with diabetes, school parties often include foods high in carbohydrates and fats. Providing more nutritious snacks will be healthier for all students and encourage good eating habits. The parents/guardian should decide whether the student with diabetes should be given the same food as other students or food the parents provide. Parents should be given advance notice of parties to incorporate special foods in the meal plan or to adjust the insulin regimen.

Students often view a field trip as one of the most interesting and exciting activities of the school year, and students with diabetes must be allowed to have these school-related experiences. Although it is not unusual to invite parents to chaperone field trips, parental attendance is **not** a prerequisite for participation by the student with diabetes. **Trained diabetes personnel should accompany the student with diabetes** and ensure that all the studentôs supplies are brought along with the student and that there are snacks and supplies to treat hypoglycemia.

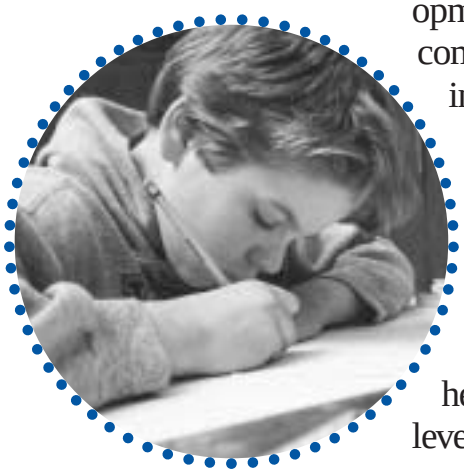
The plan for coverage and care during extracurricular activities sponsored by the school that take place outside of school hours should be carefully set out in the studentôs 504, IEP, or other education plan. As with field trips, trained diabetes personnel must be available at these activities.

Planning for Disasters and Emergencies

To be prepared in the event of natural disasters or emergencies when students need to stay at school, the parents/guardian must provide an emergency supply kit. This kit should contain enough supplies for 72 hours, including the following items as appropriate:

- Blood glucose meter, testing strips, lancets, and batteries for the meter
- Urine ketone strips
- Insulin and supplies
- Insulin pump and supplies, including syringes
- Other medications
- Antiseptic wipes or wet wipes
- Fast-acting source of glucose
- Carbohydrate-containing snacks
- Hypoglycemia food supplies (enough for 3 episodes): quick-acting sugar and carbohydrate/protein snacks
- Glucagon emergency kit

Dealing with Emotional and Social Issues



Students with diabetes must deal not only with the usual developmental issues of growing up but also with learning to manage this complex disease. Diabetes can affect every facet of life, complicating the task of mastering normal developmental challenges.

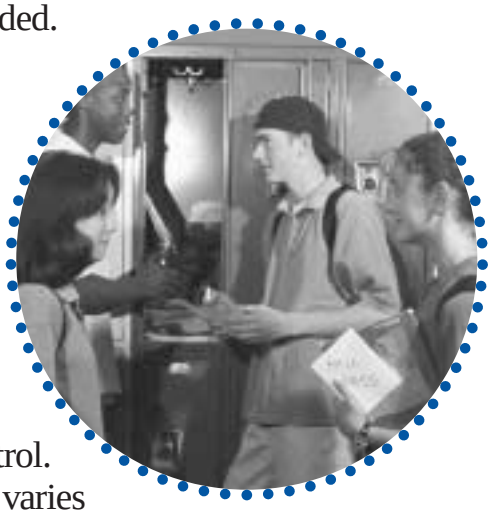
For the most part, children do not want to be singled out or made to feel different from their peers. Diabetes care tasks, however, can set them apart and make them feel angry or resentful about their disease. Sometimes, children and teens feel pressured to please caretakers and yet cannot consistently comply with their requests. To appease concerned parents or health care providers, some children report fictitious glucose levels or do not take all their insulin.

Children react differently to having diabetes. They may be accepting, resentful, open to discussing it, or attempt to hide it. Often, the same child will experience all of these feelings over time. School personnel should be aware of the studentôs feelings about having diabetes and identify ways to ensure the student is treated the same as others.

Diabetes can be a focal point for conflict within families. One of the biggest tasks for children and adolescents is to become increasingly independent from their parents, but diabetes may compromise independence because parents are concerned about their childrenôs ability to perform self-care and take responsibility for it. Parents, who are ultimately responsible for their childrenôs well-being, may be reluctant to allow normal independence in children or teens who have not been able to take care of themselves properly. This parental concern can lead to increasing struggles with dependence, oppositional behavior, and rebellion. Some adolescent girls, for example, may rebel by not following their insulin regimen because they want to lose weight or avoid gaining weight.

Diabetes care tasks can set children and teens apart from their peers and make them feel resentful or angry about their disease.

Increasingly, depression is being recognized as quite common among children and teens generally, and even more so in those with diabetes. Health care providers and school personnel must be aware of emotional and behavioral issues and refer students with diabetes and their families for counseling and support as needed.



WHY IS DIABETES SELF-MANAGEMENT IMPORTANT?

While it is very important to provide students with assistance and supervision of their diabetes care as needed, it is equally important to enable students to take on the responsibility of learning diabetes self-management and control. The age for transfer of responsibility from caregiver to child varies from child to child and from task to task because children develop and mature at different rates. Studentsôability to participate in self-care also depends upon their willingness to do so. As students are ready, they can assume more responsibility for their care.

Studentsô competence and capability for performing diabetes-related tasks are determined by the school health care team and the parents/guardian. **Diabetes care depends upon self-management.** Ultimately, each person with diabetes becomes responsible for all aspects of self-care, including blood glucose monitoring and insulin administration. Regardless of their level of self-management, however, all students with diabetes may require assistance when blood glucose levels are out of the target range.

WHY IS DIABETES MANAGEMENT TRAINING ESSENTIAL FOR SCHOOL PERSONNEL?

Diabetes management training teaches school nurses and staff members how to provide necessary care for students with diabetes during the school day and school-sponsored extracurricular activities. Training should occur before the beginning of the school year, when a student is diagnosed with diabetes, when a student with diabetes is enrolled in the school, or when appropriate. There also should be regular refresher sessions.

There are two levels of training appropriate for school personnel. The first level of training is for school staff members who have primary responsibility for students with diabetes (e.g., teachers and coaches), but who donôt perform diabetes care tasks such as blood glucose monitoring or insulin or glucagon administration. This training should include:

- General overview of diabetes and typical health care needs of a student with diabetes
- Recognition of hypoglycemia and hyperglycemia
- Identity of school nurses and/or trained diabetes personnel and how to contact them for help

The second level of training is for school personnel who will perform routine and emergency care (school nurses and trained diabetes personnel) and should include the following content based on current standards of care for children and youth with diabetes recommended by the American Diabetes Association:

- General overview of typical health care needs of a student with diabetes and how these needs are addressed in the studentôs written care plans

- Explanation/overview of type 1 and type 2 diabetes
- The effect of balancing insulin, food, and exercise upon a studentôs blood glucose levels
- Procedures for routine care of individual students, including blood glucose monitoring, insulin administration, urine ketone testing, and recording results
- Signs and symptoms of hypoglycemia and hyperglycemia and the short- and long-term risks of these conditions
- Treatment of hypoglycemia and hyperglycemia
- Glucagon administration
- Managing nutrition and exercise in the school setting
- Tools, supplies, and equipment required for diabetes care and their storage
- Legal rights and responsibilities of schools and parents/guardian

More information on diabetes can be found in the Resource List beginning on page 61.

WHERE CAN I LEARN MORE ABOUT DIABETES?

The Resource List beginning on page 61 includes a list of the major organizations (and their websites) that offer related information, resources, and training.

Section 2 ACTIONS

Section 2 ACTIONS

FOR School Personnel, Parents, and Students

The health, safety, and educational progress of a student with diabetes depend on cooperation and collaboration between the family and school staff members. Working together, they form the school health team that implements the provisions of the studentôs written plans and provides the necessary assistance in the school environment (see Diabetes Primer, page 11).

When available, the school nurse is the most appropriate person to plan diabetes care in the school and oversee implementation of the studentôs written plans. When a school nurse is not available, the diabetes medical community has found that nonmedical personnel (ñtrained diabetes personnelò) can be trained and supervised to safely provide and assist with diabetes care tasks in the school setting, including blood glucose monitoring, insulin and glucagon administration, and urine ketone testing. Assignment of diabetes care tasks must take into account state and local laws addressing what tasks may be performed by nonmedical school personnel.

The responsibilities of each key school staff member are described in the pages that follow, along with those of the parents/guardian and the student. One person may fill more than one role. For example, a teacher or a coach also may be one of the trained diabetes personnel. The recommended actions on the following pages do not represent legal checklists of what people must do to comply with relevant federal, state, and local laws. Rather, they are steps that school personnel, parents, and students should take to ensure effective diabetes management.

The following pages should be copied and distributed to everyone involved along with the studentôs Quick Reference Emergency Plan (see pages 53ï54). All substitute and appropriate after-school personnel should receive information relevant to their position.

ACTIONS for the School District Administrator

(Superintendent, 504 coordinator, or other school administrator responsible for coordinating student services)

- **Provide leadership** in developing district policy related to all aspects of diabetes management at school that is consistent with the standards of care* recommended for children with diabetes, including delegation of responsibilities, required staff training, medication administration policy, and blood glucose monitoring. Obtain input from local or regional experts.
- **Support implementation of district policy.** Support school district health professionals and other school administrators regarding: 1) development, coordination, and implementation of diabetes management training; 2) ongoing quality control and improvement of these training programs; and 3) development and implementation of a program to monitor the performance of those who receive training.
- **Arrange for training of school personnel.** Arrange for a health care professional, such as the school nurse or a diabetes-trained public health nurse, to provide training and ongoing monitoring for trained diabetes personnel.
- **Allocate sufficient resources** to manage students with diabetes.
- **Monitor schools** attended by students with diabetes for compliance with district policy.
- **Meet with members of the school health team as needed.** Address issues of concern about the provision of diabetes care by the school district, as appropriate.
- **Respect the studentôs confidentiality and right to privacy.**
- **Learn about diabetes** by reviewing the materials contained in this guide.
- **Understand and implement the federal and state laws** that may apply to students with diabetes, including Section 504 of the Rehabilitation Act of 1973, the Americans with Disabilities Act, and the Individuals with Disabilities Education Act (see Section 4).

*The American Diabetes Association (ADA) publishes ñStandards of Care for Diabetes Managementò annually in the journal *Diabetes Care*. These standards also appear on the associationôs website, www.diabetes.org. See the ADAôs position statement on ñCare of Children with Diabetes in the School and Day Care Settingò on pages 73ï 77.

Please copy and distribute to the Principal, School Administrator, or Designee.

ACTIONS for the Principal, School Administrator, or Designee

- **Participate in developing and implementing school policy** related to diabetes management at school and implement school district policy.
- **Allocate sufficient resources to manage students with diabetes.**
- **Develop and implement a system to inform school health services** of the pending enrollment of a student with diabetes.
- **Promote a supportive learning environment** for students with diabetes. Treat these students the same as other students except to respond to medical needs.
- **Meet annually with the school health team.** Arrange and attend a meeting of the school health team members (student, family, school nurse, 504/IEP coordinator, teacher(s), and other staff members who have primary responsibility for the student) before the school year starts, or when the child is newly diagnosed, to discuss medical accommodations and educational aids and related services the student needs.
- **Identify all staff members** who have responsibility for the student with diabetes.
- **Arrange for diabetes management training** for the school nurse, trained diabetes personnel, and other staff members with responsibility for students with diabetes. Inform staff members about how and when they should contact trained diabetes personnel. Ensure that trained diabetes personnel are available at all times when the student is on or off campus for school-sponsored activities and events.
- **Alert all school-related staff members** who teach or supervise a student with diabetes. Ensure that they, including the bus driver, are familiar with the accommodations and emergency procedures contained in the studentôs Diabetes Medical Management Plan, 504 Plan, IEP, or other education plan.
- **Alert all substitute personnel.** Ensure that they are aware of the needs and emergency procedures for students with diabetes.
- **Work with the school health team to implement the studentôs written plans,** including the Diabetes Medical Management Plan, and monitor compliance.

Continued on next page

ACTIONS for the Principal, School Administrator, or Designee *Continued*

- **Implement school policy on availability of trained staff.** The school nurse or at least one of the schoolôs trained diabetes personnel must be available when the student with diabetes is on campus or is a participant in off-campus school-sponsored activities and events.
- **Respect the studentôs confidentiality and right to privacy.**
- **Help develop and implement on-campus as well as off-campus emergency protocols.**
- **Include diabetes awareness as part of health or cultural education.**
- **Support and facilitate** ongoing communication between parents/guardian of students with diabetes and school staff.
- **Learn about diabetes** by reviewing the materials contained in this guide.
- **Be able to recognize and respond to signs and symptoms of hypoglycemia and hyperglycemia** in accordance with the studentôs Quick Reference Emergency Plan, which includes knowing when and how to contact the school nurse or trained diabetes personnel.
- **Understand the federal and state laws** that may apply to students with diabetes, including Section 504 of the Rehabilitation Act of 1973, the Americans with Disabilities Act, and the Individuals with Disabilities Education Act; understand procedures for implementation (see Section 4).

Please copy and distribute to the School Nurse.

ACTIONS for the School Nurse

When a school nurse is assigned to the school (or school district), that person is the key school staff member who coordinates provision of health care services for a student with diabetes at school and at school-related activities. When notified that a student with diabetes is enrolled in the school, annually or more often as necessary, the school nurse will:

- **Obtain and review the studentôs current Diabetes Medical Management Plan** from the personal health care provider and pertinent information from the family.
- **Facilitate the initial school health team meeting** to discuss implementing the studentôs Diabetes Medical Management Plan and participate in the development and implementation of the studentôs 504 Plan, IEP, or other education plan. Monitor compliance with these plans and facilitate follow-up meetings of the school health team to discuss concerns, receive updates, and evaluate the need for changes to the studentôs plans, as appropriate.
- **Conduct a nursing assessment of the student and develop a nursing care plan.** Many school nurses already have systems set up to develop nursing care plans for students with chronic diseases. The plan for students with diabetes is based on assessment of the student, input from the parents/guardian and the student, and the Diabetes Medical Management Plan. For example, the nursing care plan will identify specific functional problems, establish a goal to overcome each problem, and delineate tasks or interventions to help reach the goals.
- **Conduct ongoing, periodic assessments of students with diabetes and update the nursing care plans.**
- **Coordinate development of the studentôs Quick Reference Emergency Plan** and provide copies to staff members who have responsibility for the student throughout the school day (e.g., teachers, coach, PE instructor, lunchroom staff, and bus driver).
- **Obtain materials and medical supplies necessary for diabetes care tasks** from the parents/guardian and arrange a system for notifying the student or parents/guardian when supplies need to be replenished.
- **Plan and implement diabetes management training** for the trained diabetes personnel and any other staff members with responsibility for the student with diabetes who require such training. Ensure that all those mentioned in the 504 Plan, IEP, or other education plan know their roles in carrying out the plan, how their roles relate to each other, and when and where to seek help.
- **Participate in diabetes management training** provided by health care professionals with expertise in diabetes and attend other continuing education offerings to attain and/or maintain knowledge about current standards of care for children with diabetes.

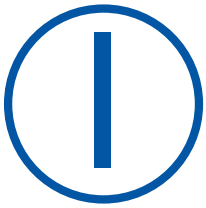
Continued on next page

ACTIONS for the School Nurse *Continued*

- **Review the information about diabetes in this guide.**
- **Distribute the Diabetes Primer in this guide to all school personnel** who have responsibility for students with diabetes.
- **Train (or oversee training of), assess competence, and monitor trained diabetes personnel** in carrying out the health care procedures defined in the Diabetes Medical Management Plan, 504 Plan, IEP, or other education plan.
- **Perform routine and emergency diabetes care tasks,** including blood glucose monitoring, urine ketone testing, insulin administration, and glucagon administration.
- **Practice universal precautions and infection control procedures** during all student encounters.
- **Maintain accurate documentation** of contacts with students and family members; communications with the student's health care provider; any direct care given, including medication administration; and the training and monitoring of trained diabetes personnel.
- **Collaborate with other co-workers** (e.g., food service) and agencies (e.g., outside nursing agencies, school bus transportation services) as necessary to provide health care services.
- **With parental permission, act as liaison between the school and the student's health care provider** regarding the student's self-management at school.
- **Communicate to parents/guardian any concerns about the student's diabetes management or health,** such as acute hypoglycemia episodes, hyperglycemia, general attitude, and emotional issues.
- **Promote and encourage independence and self-care** consistent with the student's ability, skill, maturity, and developmental level.
- **Respect the student's confidentiality and right to privacy.**
- **Act as an advocate** for students to help them meet their diabetes health care needs.
- **Provide education and act as a resource on managing diabetes** at school to the student, family, and school staff. Establish and maintain an up-to-date resource file of pamphlets, brochures, and other publications for school personnel.
- **Assist the classroom teacher** with developing a plan for substitute teachers.
- **Assist the PE instructor** with managing the student's exercise program at school.
- **Be knowledgeable about federal, state, and local laws and regulations** that pertain to managing diabetes at school (see Section 4).

Please copy and distribute to Trained Diabetes Personnel.

ACTIONS for Trained Diabetes Personnel



With proper supervision and training, and where state laws do not prohibit it, nonmedical personnel can help students manage their diabetes safely at school. This guide uses the term ñtrained diabetes personnel,ò but some schools use other names. Trained diabetes personnel may include school staff members, health aides, and licensed practical nurses. Depending on the size of the school, at least two people should be trained to perform diabetes care tasks and be trained diabetes personnel.

If a school has a nurse, the nurse takes the lead in providing diabetes care. Either the school nurse or at least one of the trained diabetes personnel should be on site throughout the school day and during school-sponsored activities that take place before or after school in which a student with diabetes participates.

- **Understand the studentôs Diabetes Medical Management Plan, 504 Plan, IEP, or other education plan.**
- **Understand the studentôs Quick Reference Emergency Plan.**
- **Attend the studentôs school health team meetings** to gain understanding of the overall goal of care.
- **Participate in diabetes management training.**
- **Learn about diabetes** by reviewing materials contained in this guide.
- **Perform routine and emergency diabetes care tasks,** including blood glucose monitoring, urine ketone testing, insulin administration, and glucagon administration after receiving training under the direction of the school nurse or other assigned health care professional.
- **Practice universal precautions and infection control procedures** in all student encounters.
- **Participate in planned evaluations of care.**
- **Document care provided** according to standards and requirements outlined by school policy.
- **Observe and record student health and behavior,** noting any changes over time.
- **Communicate directly and regularly with the school nurse or the supervising health care professional.**
- **Consult with appropriate members of the studentôs school health team** when questions arise or the studentôs health status changes.

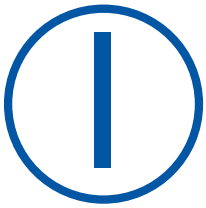
Continued on next page

ACTIONS for Trained Diabetes Personnel *Continued*

- **Respect the studentôs confidentiality and right to privacy.**
- **Be available** on campus during regular school hours and when the student participates in school-sponsored extracurricular activities held before or after school.
- **Accompany the student on field trips or off-campus school-sponsored sports events** and activities, as determined by the 504 Plan, IEP, or other education plan.
- **Provide support and encouragement to the student.**
- **Help ensure that the student has a supportive learning environment** and is treated the same as students without diabetes, except to respond to medical needs.

Please copy and distribute to the Teacher.

ACTIONS for the Teacher



- **Participate in the school health team meeting(s).** The teacher(s) who has primary responsibility for the student participates in the school health team meeting(s) when the Diabetes Medical Management Plan, 504 Plan, IEP, or other education plans are discussed.
- **Work with the school health team to implement written care plans,** including the Diabetes Medical Management Plan, 504 Plan, IEP, or other education plan.
- **Recognize that a change in the studentôs behavior could be a symptom of blood glucose changes.** Be aware that a student who has low blood sugar, even mildly low, may briefly have some cognitive impairment. If changes occur, respond in accordance with the studentôs Quick Reference Emergency Plan.
- **Be prepared to recognize and respond to the signs and symptoms of hypoglycemia and hyperglycemia** in accordance with the studentôs Quick Reference Emergency Plan, which specifies when and how to contact the school nurse or trained diabetes personnel.
- **Provide a supportive environment for the student** to manage diabetes effectively and safely at school, which includes eating snacks for routine diabetes management and to treat low blood glucose levels, having bathroom privileges and access to drinking water, monitoring blood glucose, and administering insulin and other medications.
- **Provide classroom accommodations for the student with diabetes,** as indicated in the studentôs 504 Plan, IEP, or other education plan.
- **Provide instruction to the student** if it is missed because of absence for diabetes-related care.
- **Provide information for substitute teachers** that communicates the day-to-day needs of the student and the Quick Reference Emergency Plan.
- **Notify the parents/guardian in advance of changes in school schedule,** such as class parties, field trips, and other special events.
- **Communicate with the school nurse, trained diabetes personnel, or parents regarding any concerns about the student.**
- **Attend diabetes management training,** if designated as trained diabetes personnel.
- **Learn about diabetes** by reviewing the materials contained in this guide.
- **Treat the student with diabetes the same as other students,** except to meet medical needs.
- **Respect the studentôs confidentiality and right to privacy.**

*Please copy and distribute to the Coach and Physical Education Instructor.**

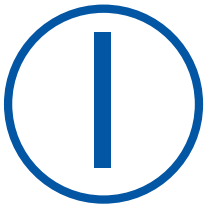
ACTIONS for the Coach and Physical Education Instructor

- **Encourage exercise and participation in physical activities and sports for students with diabetes** as well as for other students.
- **Treat the student with diabetes the same as other students,** except to meet medical needs.
- **Encourage the student to have personal supplies readily accessible.** Make sure blood glucose monitoring equipment is available at all activity sites.
- **Allow the student to check blood glucose levels** as outlined in the 504 Plan, IEP, or other education plan.
- **Understand and be aware that hypoglycemia can occur during and after physical activity**.
- **Recognize that a change in the studentôs behavior could be a symptom of blood glucose changes.**
- **Be prepared to recognize and respond to the signs and symptoms of hypoglycemia and hyperglycemia** and take initial actions in accordance with the studentôs Quick Reference Emergency Plan, which specifies when and how to contact the school nurse or trained diabetes personnel.
- **To treat hypoglycemia, provide the student with immediate access to a fast-acting form of glucose,** as outlined in the Quick Reference Emergency Plan.
- **Consider taping a fast-acting form of glucose (e.g., 3 or 4 glucose tablets or hard candies) to a clipboard or include it in the First Aid pack** that goes out to physical education activities, practices, and games.
- **Learn about diabetes** by reviewing materials contained in this guide.
- **Provide input to the studentôs school health team as needed.**
- **Communicate with the school nurse and/or trained diabetes personnel regarding any observations or concerns about the student.**
- **Provide information for the substitute PE instructor** that communicates the daily needs of the student and the Quick Reference Emergency Plan.
- **Respect the studentôs confidentiality and right to privacy.**

*If appropriate, please distribute this information to the playground/campus supervisor.

Please copy and distribute to the Food Service Manager, Lunchroom Staff, or Lunchroom Monitor.

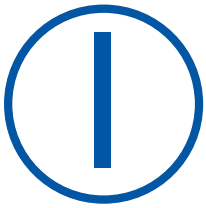
ACTIONS for the Food Service Manager, Lunchroom Staff, or Lunchroom Monitor



- **Obtain a copy of the studentôs written meal plan** from the Diabetes Medical Management Plan.
- **Obtain a copy of the studentôs Quick Reference Emergency Plan** and keep it in a known, yet secure, place in the lunchroom.
- **Provide a lunch menu and lunch schedule in advance to parents** along with the nutrition content of menu selections, including grams of carbohydrate and fat.
- **Understand and be aware that hypoglycemia can occur before lunch.** Supervisory lunch personnel may need to encourage the student to eat appropriate foods.
- **Be prepared to recognize and respond to the signs and symptoms of hypoglycemia and hyperglycemia** and take actions in accordance with the studentôs Quick Reference Emergency Plan.
- **Recognize that a studentôs behavior change could be a symptom of blood glucose changes.**
- **Learn about the various kinds of diabetes meal and snack plans.** Know which type of meal plan the student follows.
- **Recognize that eating meals and snacks on time is a critical component of diabetes management.** Failure to eat lunch on time could result in low blood glucose, especially if a student has missed a morning snack or has had a physically strenuous or otherwise active morning at school.
- **Ensure that the student has timely access to food and sufficient time to finish.**
- **Know where supplies to treat hypoglycemia are kept** (e.g., with the student or another place).
- **Treat the student with diabetes the same as other students,** except to respond to medical needs.
- **Provide input to the studentôs school health team when requested.**
- **Communicate with the school nurse and/or trained diabetes personnel regarding any concerns about the student.**
- **Respect the studentôs confidentiality and right to privacy.**

Please copy and distribute to the Bus Driver.

ACTIONS for the Bus Driver



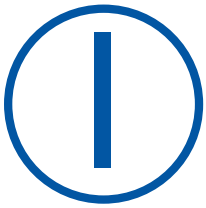
- **At the beginning of the school year, identify any students on the bus who have diabetes.**
- **Obtain a copy of the studentôs Quick Reference Emergency Plan** and keep it on the bus in a known, yet secure, place. Leave the plan readily available for substitute drivers.
- **Understand and be aware that although hypoglycemia normally occurs at the end of the day, it may happen at the beginning of the day** if the student has not eaten breakfast.
- **Recognize that a studentôs behavior change could be a symptom of blood glucose changes.**
- **Be prepared to recognize and respond to the signs and symptoms of hypoglycemia and hyperglycemia** and take initial actions in accordance with the studentôs Quick Reference Emergency Plan, which specifies when and how to contact trained diabetes and emergency personnel.
- **Keep supplies to treat low blood glucose on the bus and be aware of where the students with diabetes normally keep their supplies.**
- **Treat the student with diabetes the same as other students,** except to respond to medical needs.
- **Allow the student to eat snacks on the bus.**
- **Provide input to the studentôs school health team when requested.**
- **Communicate with the school nurse and/or trained diabetes personnel regarding any concerns about the student.**
- **Respect the studentôs confidentiality and right to privacy.**

Please copy and distribute to the Guidance Counselor or School Psychologist.

ACTIONS for the Guidance Counselor or School Psychologist

- **Work with school staff to promote a supportive learning environment.**
- **Ensure that the student with diabetes is treated the same as students without diabetes,** except to respond to medical needs.
- **Be aware of and be prepared to respond to the emotional needs of the student.** Children react differently to having diabetes. Some are accepting and open to discussing it; others are resentful and may attempt to hide it. Often, a single child will experience both kinds of feelings. Be aware of the studentôs feelings about having diabetes and identify ways to ensure the student is treated the same as other students.
- **Recognize that students with chronic illnesses such as diabetes may rebel by discontinuing all or part of their medical regimen.** Adolescent girls, for example, may not follow their insulin regimen because they want to lose weight or to avoid gaining weight.
- **Be aware that some students may not wish to share information about their diabetes with other students or school staff,** particularly if it makes them feel different from others.
- **Promote and encourage independence and self-care** that are consistent with the studentôs ability, skill, maturity, and development.
- **Provide input to the studentôs school health team** when requested.
- **Communicate with the school nurse and/or trained diabetes personnel regarding any concerns about the student.**
- **Respect the studentôs confidentiality and right to privacy.**

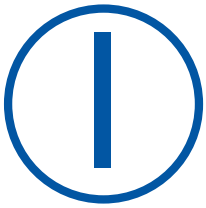
ACTIONS for the Parents or Guardian



- **Inform the school principal that your child has diabetes** when the student enrolls in school or is newly diagnosed with the disease.
- **Provide accurate and current emergency contact information.**
- **Provide the signed Diabetes Medical Management Plan** to the school nurse or other member of the school health team.
- **Attend and participate in the initial and annual meetings of the school health team** (includes student, parents, school nurse, principal, 504 coordinator, teachers, and other school personnel who have responsibility for the student with diabetes) to discuss implementing the studentôs Diabetes Medical Management Plan, to review medical accommodations and educational aids the student may need, and to develop a 504 Plan, IEP, or other education plan.
- **Provide specific information about your childôs diabetes** and performance of diabetes-related tasks at home to the school health team.
- **Permit sharing of medical information** necessary for the studentôs safety between the school and the studentôs personal health care providers.
- **Inform school staff of any changes in the studentôs health status.**
- **Provide all supplies and equipment necessary for implementing your childôs Diabetes Medical Management Plan, 504 Plan, IEP, or other education plan,** including blood glucose monitoring equipment, supplies for insulin administration and urine ketone testing, snacks, fast-acting glucose, and a glucagon emergency kit. As appropriate, provide these supplies to school personnel. Replenish supplies as needed.
- **Provide and maintain all supplies and equipment necessary to accommodate the studentôs long-term needs (72 hours) in case of an emergency.**
- **Inform appropriate school staff (principal, teachers, coaches, and others) when the student plans to participate in school-sponsored activities** that take place before or after school so that health care coverage can be coordinated to ensure the health and safety of the student with diabetes.
- **Understand the federal, state, and local laws** that address the schoolôs responsibilities to students with diabetes.

Please copy and distribute to Students with Diabetes who are able to take responsibility for their self-management.

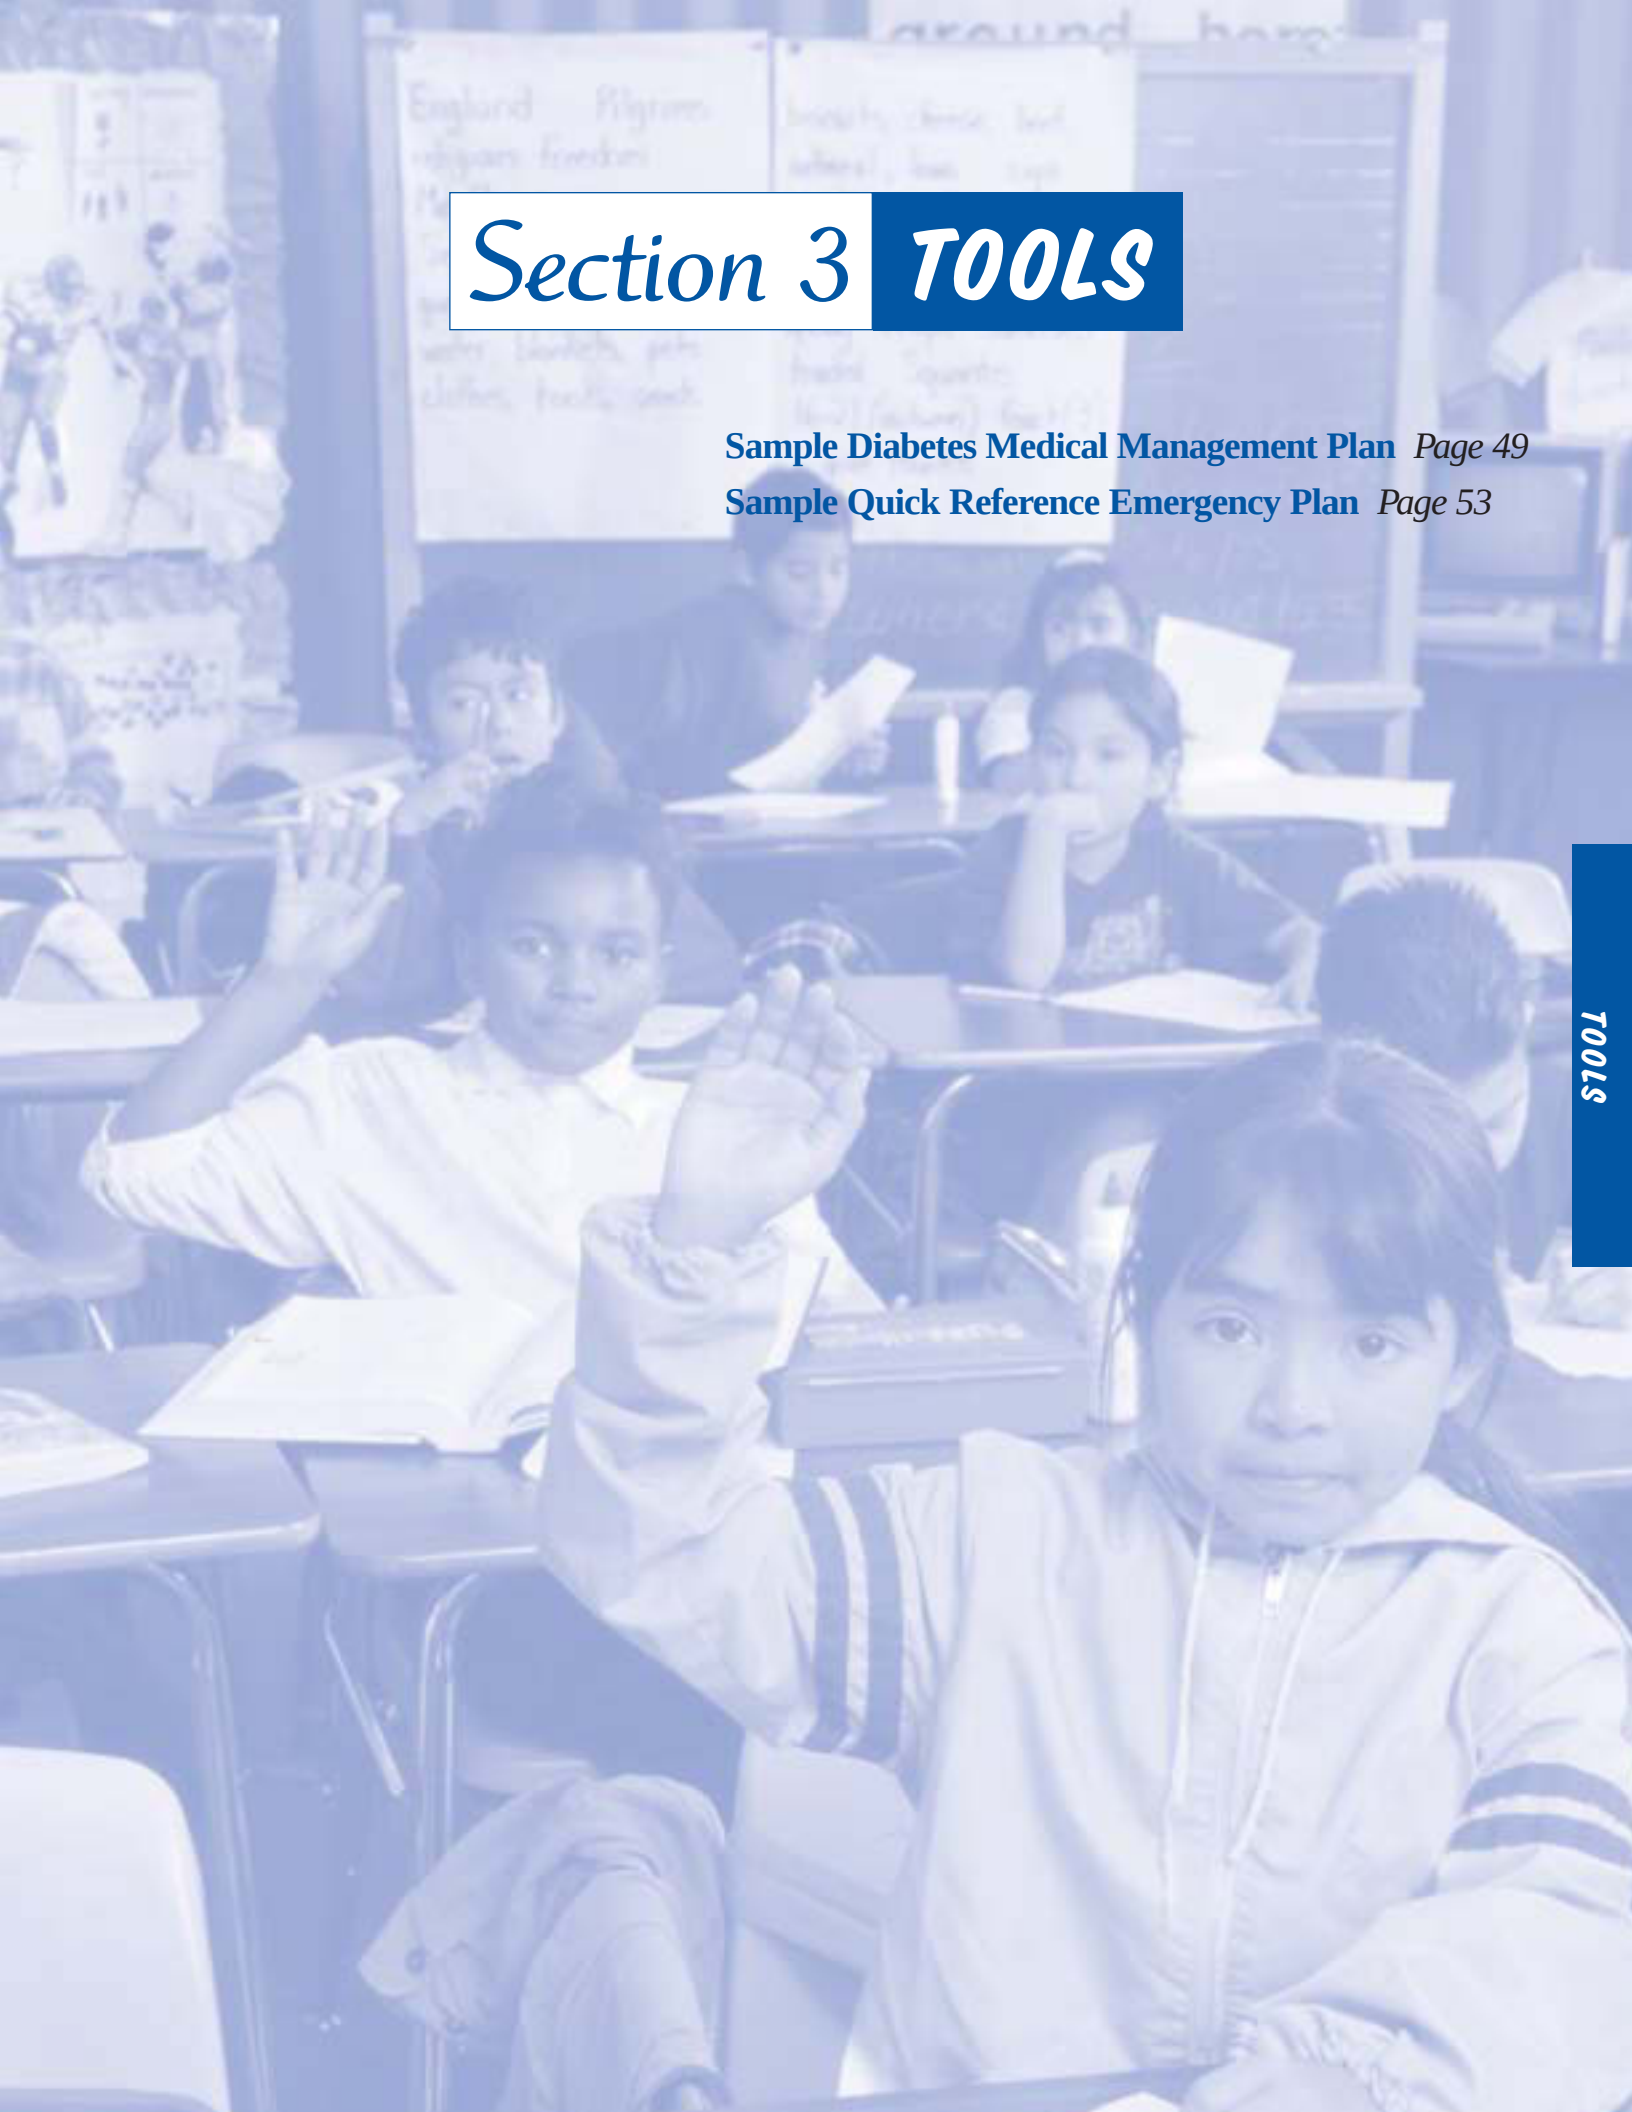
ACTIONS for the Student with Diabetes



- **Participate in the school meeting** to discuss your Diabetes Medical Management Plan, 504 Plan, IEP, or other education plan, as appropriate.
- **Always wear a medical alert ID** and carry a fast-acting source of glucose.
- **Tell teachers and other school staff members if you feel symptoms** of low or high blood glucose, especially if you need help.
- **Work with school staff members if you need help** checking your blood glucose, getting insulin, or eating the right amount of food at the right time during the school day.
- **Take charge of your diabetes care at school** if your written school plans allow you to. This may include:
  -] checking and writing down blood glucose levels
  -] figuring out the right insulin doses
  -] giving yourself insulin
  -] throwing away needles, lancets, and other supplies you have used in the right place
  -] eating meals and snacks as planned
  -] treating low blood sugar
  -] carrying diabetes equipment and supplies with you at all times

Things You Need to Know:

1. **What** your written school plans say to help you manage your diabetes, which person at school will help you, and what is expected of you.
2. **Who** to contact and what to do when you are having a low blood sugar reaction.
3. **When** you should check your blood glucose levels, give yourself insulin, have a snack, and eat lunch.
4. **Where** your diabetes supplies are stored, if you donôt carry them, and who to contact when you need to use them.



Section 3 TOOLS

Section 3 TOOLS FOR Effective Diabetes Management in Schools

This section contains examples of two important tools to help the school health team in managing the student with diabetes:

The **Sample Diabetes Medical Management Plan** is completed by the studentôs parents/guardian and personal health care team and can be used as the basis for developing education plans and nursing care plans for students with diabetes.

The **Sample Quick Reference Emergency Plan** addresses management of hypoglycemia and hyperglycemia emergencies. This plan should be completed for each student with diabetes and both pages should be copied and distributed to all relevant personnel, in accordance with the studentôs Diabetes Medical Management Plan, 504 Plan, IEP, or other education plan.

Date of Plan: _____

Diabetes Medical Management Plan

Effective Dates: _____

This plan should be completed by the studentôs personal health care team and parents/guardian. It should be reviewed with relevant school staff and copies should be kept in a place that is easily accessed by the school nurse, trained diabetes personnel, and other authorized personnel.

Studentôs Name: _____

Date of Birth: _____ Date of Diabetes Diagnosis: _____

Grade: _____ Homeroom Teacher: _____

Physical Condition: a Diabetes type 1 a Diabetes type 2

Contact Information

Mother/Guardian: _____

Address: _____

_____

Telephone: Home _____ Work _____ Cell _____

Father/Guardian: _____

Address: _____

_____

Telephone: Home _____ Work _____ Cell _____

Studentôs Doctor/Health Care Provider:

Name: _____

Address: _____

_____

Telephone: _____ Emergency Number: _____

Other Emergency Contacts:

Name: _____

Relationship: _____

Notify parents/guardian or emergency contact in the following situations:

_____

_____

_____

Blood Glucose Monitoring

Target range for blood glucose is a 70-150 a 70-180 a Other _____

Usual times to check blood glucose _____

Times to do extra blood glucose checks (*check all that apply*)

a before exercise
a after exercise
a when student exhibits symptoms of hyperglycemia
a when student exhibits symptoms of hypoglycemia
a other (explain):_____

Can student perform own blood glucose checks? a Yes a No

Exceptions: _____

Type of blood glucose meter student uses: _____

Insulin

Usual Lunchtime Dose

Base dose of Humalog/Novolog /Regular insulin at lunch (circle type of rapid-/short-acting insulin used) is _____ units or does flexible dosing using _____ units/ _____ grams carbohydrate.
Use of other insulin at lunch: (circle type of insulin used): intermediate/NPH/lente _____ units or basal/Lantus/Ultralente _____ units.

Insulin Correction Doses

Parental authorization should be obtained before administering a correction dose for high blood glucose levels. a Yes a No

_____ units if blood glucose is _____ to _____ mg/dl
_____ units if blood glucose is _____ to _____ mg/dl
_____ units if blood glucose is _____ to _____ mg/dl
_____ units if blood glucose is _____ to _____ mg/dl
_____ units if blood glucose is _____ to _____ mg/dl

Can student give own injections? a Yes a No
Can student determine correct amount of insulin? a Yes a No
Can student draw correct dose of insulin? a Yes a No

_____ Parents are authorized to adjust the insulin dosage under the following circumstances:_____

_____

For Students With Insulin Pumps

Type of pump:_____ Basal rates: _____ 12 am to _____
_____ _____ to _____
_____ _____ to _____

Type of insulin in pump:_____

Type of infusion set:_____

Insulin/carbohydrate ratio:_____ Correction factor: _____

Diabetes Medical Management Plan *Continued*

Student Pump Abilities/Skills:	*Needs Assistance*
Count carbohydrates	a Yes a No
Bolus correct amount for carbohydrates consumed	a Yes a No
Calculate and administer corrective bolus	a Yes a No
Calculate and set basal profiles	a Yes a No
Calculate and set temporary basal rate	a Yes a No
Disconnect pump	a Yes a No
Reconnect pump at infusion set	a Yes a No
Prepare reservoir and tubing	a Yes a No
Insert infusion set	a Yes a No
Troubleshoot alarms and malfunctions	a Yes a No

For Students Taking Oral Diabetes Medications

Type of medication:_____ Timing: _____

Other medications:_____ Timing: _____

Meals and Snacks Eaten at School

Is student independent in carbohydrate calculations and management? a Yes a No

Meal/Snack	*Time*	*Food content/amount*
Breakfast	_____	_____
Mid-morning snack	_____	_____
Lunch	_____	_____
Mid-afternoon snack	_____	_____
Dinner	_____	_____

Snack before exercise? a Yes a No

Snack after exercise? a Yes a No

Other times to give snacks and content/amount:_____

Preferred snack foods: _____

Foods to avoid, if any: _____

Instructions for when food is provided to the class (e.g., as part of a class party or food sampling event):

_____

_____

Exercise and Sports

A fast-acting carbohydrate such as_____ should be available at the site of exercise or sports.

Restrictions on activity, if any:_____

Student should not exercise if blood glucose level is below_____ mg/dl or above_____ mg/dl or if moderate to large urine ketones are present.

Hypoglycemia (Low Blood Sugar)

Usual symptoms of hypoglycemia: _____

_____

Treatment of hypoglycemia: _____

_____

Glucagon should be given if the student is unconscious, having a seizure (convulsion), or unable to swallow. Route_____, Dosage_____, site for glucagon injection: _____arm, _____thigh, _____other.

If glucagon is required, administer it promptly. Then, call 911 (or other emergency assistance) and the parents/guardian.

Hyperglycemia (High Blood Sugar)

Usual symptoms of hyperglycemia: _____

_____

Treatment of hyperglycemia: _____

_____

Urine should be checked for ketones when blood glucose levels are above _____ mg/dl.

Treatment for ketones: _____

Supplies to be Kept at School

_____Blood glucose meter, blood glucose test strips, batteries for meter
_____Lancet device, lancets, gloves, etc.
_____Urine ketone strips
_____Insulin vials and syringes
_____Insulin pump and supplies
_____Insulin pen, pen needles, insulin cartridges
_____Fast-acting source of glucose
_____Carbohydrate containing snack
_____Glucagon emergency kit

Home phone	Work phone	Cell	Home phone	Work phone	Cell

School Nurse/Trained Diabetes Personnel **Contact Number(s)**

Never send a child with suspected low blood sugar anywhere alone.

Causes of Hypoglycemia
- ÅToo much insulin
- ÅMissed food
- ÅDelayed food
- ÅToo much or too intense exercise
- ÅUnscheduled exercise

Onset
- ÅSudden

Symptoms

Mild
- ÅHunger
- ÅShakiness
- ÅWeakness
- ÅPaleness
- ÅAnxiety
- ÅIrritability
- ÅDizziness
- ÅSweating
- ÅDrowsiness
- ÅPersonality change
- ÅInability to concentrate
- ÅOther: _____ _____

Circle studentôs usual symptoms.

Moderate
- ÅHeadache
- ÅBehavior change
- ÅPoor coordination
- ÅBlurry vision
- ÅWeakness
- ÅSlurred Speech
- ÅConfusion
- ÅOther _____ _____

Circle studentôs usual symptoms.

Severe
- ÅLoss of consciousness
- ÅSeizure
- ÅInability to swallow

Circle studentôs usual symptoms.

Actions Needed

Notify School Nurse or Trained Diabetes Personnel. If possible, check blood sugar, per Diabetes Medical Management Plan. When in doubt, always TREAT FOR HYPOGLYCEMIA.

Mild
- ÅStudent may/may not treat self.
- ÅProvide quick-sugar source.
  3-4 glucose tablets
  or
  4 oz. juice
  or
  6 oz. regular soda
  or
  3 teaspoons of glucose gel
- ÅWait 10 to 15 minutes.
- ÅRecheck blood glucose.
- ÅRepeat food if symptoms persist or blood glucose is less than _____.
- ÅFollow with a snack of carbohydrate and protein (e.g., cheese and crackers).

Moderate
- ÅSomeone assists.
- ÅGive student quick-sugar source per MILD guidelines.
- ÅWait 10 to 15 minutes.
- ÅRecheck blood glucose.
- ÅRepeat food if symptoms persist or blood glucose is less than _____.
- ÅFollow with a snack of carbohydrate and protein (e.g., cheese and crackers).

Severe
- ÅDonôt attempt to give anything by mouth.
- ÅPosition on side, if possible.
- ÅContact school nurse or trained diabetes personnel.
- ÅAdminister glucagon, as prescribed.
- ÅCall 911.
- ÅContact parents/guardian.
- ÅStay with student.

Quick Reference Emergency Plan

Studentôs Name

Grade/Teacher Date of Plan

Emergency Contact Information:

Mother/Guardian			**Father/Guardian**		
Home phone	Work phone	Cell	Home phone	Work phone	Cell

School Nurse/Trained Diabetes Personnel **Contact Number(s)**

Causes of Hyperglycemia

- ÅToo much food
- ÅToo little insulin
- ÅDecreased activity
- ÅIllness
- ÅInfection
- ÅStress

Onset

- ÅOver timeð several hours or days

Symptoms

Mild

- ÅThirst
- ÅFrequent urination
- ÅFatigue/sleepiness
- ÅIncreased hunger
- ÅBlurred vision
- ÅWeight loss
- ÅStomach pains
- ÅFlushing of skin
- ÅLack of concentration
- ÅSweet, fruity breath
- ÅOther: _____

Circle studentôs usual symptoms.

Moderate

- ÅMild symptoms plus:
- ÅDry mouth
- ÅNausea
- ÅStomach cramps
- ÅVomiting
- ÅOther:_____

Circle studentôs usual symptoms.

Severe

- ÅMild and moderate symptoms plus:
- ÅLabored breathing
- ÅVery weak
- ÅConfused
- ÅUnconscious

Circle studentôs usual symptoms.

Actions Needed

- ÅAllow free use of the bathroom.
- ÅEncourage student to drink water or sugar-free drinks.
- ÅContact the school nurse or trained diabetes personnel to check urine or administer insulin, per studentôs Diabetes Medical Management Plan.
- ÅIf student is nauseous, vomiting, or lethargic, ____ call the parents/guardian or ____ call for medical assistance if parent cannot be reached.

Section 4 LAWS

School Responsibilities Under Federal Law

The federal laws described in this section apply to a schoolôs responsibility to help students manage diabetes, including confidentiality requirements. A particular student with diabetes could be covered under only one law or more than one law. For information on getting copies of the laws, see page 57.

Section 504 of the Rehabilitation Act of 1973 (Section 504) and Americans with Disabilities Act of 1990 (ADA)

Section 504 prohibits recipients of federal funds from discriminating against people on the basis of disability. Title II of the ADA prohibits discrimination on the basis of disability by public entities, regardless of whether the public entities receive federal funds. Public school districts that receive federal funds are covered by both Title II and Section 504 and the obligations of public schools to students with disabilities under each law are generally the same. For schools, these laws are enforced by the Office for Civil Rights (OCR) in the U.S. Department of Education.

Section 504 outlines a process for schools to use in determining whether a student has a disability and in determining what services a student with a disability needs. This evaluation process must be tailored individually, since each student is different and his or her needs will vary. Historically, students with diabetes have been covered by Section 504 and the ADA.

Under Section 504, students with disabilities must be given an equal opportunity to participate in academic, nonacademic, and extracurricular activities. The regulations also require school districts to identify all students with disabilities and to provide them with a free appropriate public education (FAPE). Under Section 504, FAPE is the provision of regular or special education and related aids and services designed to meet the individual educational needs of students with disabilities as adequately as the needs of nondisabled students are met.

However, a student does not have to receive special education services in order to receive related aids and services under Section 504. Administering insulin or glucagon, providing assistance in checking blood glucose levels, and allowing the student to eat snacks in school are a few examples of related aids and services that schools may have to provide for a particular student with diabetes. The most common practice is to include these related aids

and services as well as any needed special education services in a written document, sometimes called a ñSection 504 Plan.ò

Private schools that receive federal funds may not exclude an individual student with a disability if the school can, with minor adjustments, provide an appropriate education to that student. Private, nonreligious schools are covered by Title III of the ADA.

Individuals with Disabilities Education Act (IDEA)

IDEA provides federal funds to assist state educational agencies and, through them, local educational agencies in making special education and related services available to eligible children with disabilities. IDEA is administered by the Office of Special Education Programs (OSEP) in the Office of Special Education and Rehabilitative Services (OSERS) in the U.S. Department of Education.

A child with a disability must meet the criteria of one or more of 13 disability categories and need special education and related services. The IDEA category of ñother health impairmentò includes diabetes as one of the health conditions listed. To qualify under IDEA, the studentôs diabetes also must adversely affect educational performance to the point that the student requires special education and related services, as defined by state law. An example of a child with diabetes who may qualify under IDEA is a student who may have difficulty paying attention or concentrating in the learning environment because of recurring high or low blood glucose levels that adversely affect the studentôs educational performance.

IDEA requires school districts to find and identify children with disabilities and to provide them a free appropriate public education (FAPE). Under IDEA, FAPE means special education and related services that meet state standards and are provided in conformity with an individualized education program (IEP). The IDEA regulations specify how school personnel and parents, working together, develop and implement an IEP.

Each childôs IEP must include the supplementary aids and services to be provided for, or on behalf of, the child and a statement of the program modifications or supports for school personnel that will be provided for the child to make progress and be involved in the general curriculum. Administering insulin or glucagon, providing assistance in checking blood glucose levels, and allowing the student to eat snacks in school are a few examples of related services, supplementary aids and services, or program modifications or supports that schools could provide for a particular student with diabetes who is eligible under IDEA.

Generally, if a child with diabetes needs only a related service and not special education services as defined by state law, that child is not a child with a disability under IDEA and therefore is not eligible for any services under IDEA. Such a child might still be eligible for services under Section 504.

Family Education Rights and Privacy Act (FERPA)

FERPA generally prohibits schools from disclosing personally identifiable information in a studentôs education record, unless the school obtains the consent of the studentôs parent or the eligible student (a student who is 18 years old or older or who attends an institution of postsecondary education). FERPA does allow schools to disclose this information, without obtaining consent, to school officials, including teachers, who have legitimate educational interests in the information, including the educational interests of the child. Schools that do this must include in their annual notification to parents and eligible students the criteria for determining who constitutes a school official and what constitutes a legitimate educational interest. Additionally, under FERPA, schools may not prevent the parents of students, or eligible students themselves, from inspecting and reviewing the studentôs education records.

How can I get copies of the federal laws?

The statutes are found in the United States Code (U.S.C.). The regulations implementing the statutes are found in the Code of Federal Regulations (CFR).

- Section 504 of the Rehabilitation Act of 1973, 29 U.S.C. 794, implementing regulations at 34 CFR Part 104. Available at www.ed.gov/ocr/disability.html.
- Title II of the Americans with Disabilities Act of 1990, 42 U.S.C. 12134 et seq., implementing regulations at 28 CFR Part 35. Available at www.ed.gov/ocr/disability.html.
- To obtain copies of the Section 504 and Title II regulations, you also may contact the Customer Service Team of the Office for Civil Rights, U.S. Department of Education, at (202) 205ï 5413 or toll-free at 1ï 800ï 421ï 3481. For TTY, call 1ï 877ï 521ï 2172.
- Individuals With Disabilities Education Act, 20 U.S.C. 111 et seq., implementing regulations at 34 CFR Part 300. Available at www.ed.gov/offices/OSERS/OSEP.
- For copies of the IDEA regulations, you also may contact EdPubs at 1ï 877ï 433ï 7827.
- Family Education Rights and Privacy Act (FERPA), 20 U.S.C.1232g, implementing regulations at 34 CFR Part 99. Available at www.ed.gov/offices/OM/fpco.

How can I get more information?

The Office for Civil Rights (OCR) and the Office of Special Education Programs (OSEP) in the U.S. Department of Education can answer questions and provide technical assistance. For more information from OCR, contact OCRôs Customer Service Team at (202) 205ï 5413 or toll-free at 1ï 800ï 421ï 3481. For TTY, call 1ï 877ï 521ï 2172. Information is also available on the OCR website, www.ed.gov/ocr. You may also contact one of OCRôs 12 Enforcement Offices around the country. Contact information is available from the OCR Customer Service Team and from the OCR website. For more information from OSEP, call (202) 205ï 5507 or (202) 205ï 5637 for TTY. More information about FERPA is available at www.ed.gov/offices/OM/fpco.

APPENDICES

RESOURCE LIST
Help for Students with Diabetes

American Academy of Family Physicians (AAFP)
The AAFP is the national member organization of family doctors. Its website includes articles about the link between obesity and diabetes in young people and how to help children lose weight.

11400 Tomahawk Creek Parkway
Leawood, KS 66211
Phone: (913) 906ï 6000

GLOSSARY
of Diabetes Terms

A

Americans with Disabilities Act. A federal law enacted in 1990 to protect people with disabilities from discrimination. Under this law, diabetes can be considered a disability.

Autoimmune disease. A disorder in which the immune system mistakenly attacks and destroys body tissue that it believes to be foreign. In type 1 diabetes, an autoimmune disease, the immune system attacks and destroys the insulin-producing beta cells.

B

Blood glucose level. The amount of glucose in the blood. The recommended blood glucose levels for most people with diabetes are from about 80 to 120 before a meal, 180 or less after a meal, and between 100 and 140 at bedtime.

Blood glucose meter. A device that measures how much glucose is in the blood. A specially coated test strip containing a fresh sample of blood (obtained by pricking the skin, usually the finger, with a lancet) is inserted in the meter, which then measures the amount of glucose in the blood.

Blood glucose monitoring. The act of checking the amount of glucose in the blood. Also called self-monitoring of blood glucose.

C

Carbohydrates. One of the three main classes of foods and a source of energy for the body. Carbohydrates are mainly sugars and starches that the body breaks down into glucose. Foods high in carbohydrates raise blood glucose levels. Carbohydrate foods include: breads, crackers, and cereals; pasta, rice, and grains; vegetables; milk and yogurt; fruit, juice, and sweetened sodas; and table sugar, honey, syrup, and molasses.

Complications of diabetes. Harmful effects that may happen when a person has diabetes. Short-term complications resulting from poorly controlled or uncontrolled diabetes include hypoglycemia (low blood glucose) and hyperglycemia (high blood glucose). Long-term complications, which may develop when a person has had diabetes for a long time, include blindness, amputation of feet or legs, kidney disease, heart disease, stroke, and nerve damage.

D

Diabetes Medical Management Plan. Describes the medical orders or diabetes regimen developed by the student's health care provider and family.

Diabetic Coma. A severe emergency in which a person is not conscious because his or her blood glucose is too low or too high. See also hyperglycemia; hypoglycemia; and diabetic ketoacidosis.

Diabetic ketoacidosis (DKA). A condition that occurs due to insufficient insulin in the body. This can be due to illness, incorrect doses of insulin, or omitting insulin injections. The acidic state that follows causes fruity smelling breath, deep and rapid breathing, stomach pain, nausea, vomiting, and sleepiness. DKA can lead to coma and death if not treated promptly.

Fast-acting glucose. Foods containing simple sugar that are used to raise blood glucose levels quickly during a hypoglycemic episode.

Glucagon. A hormone that raises the level of glucose in the blood. Glucagon, given by injection, is used to treat severe hypoglycemia.

Glucose. A simple sugar found in the blood. It is the bodyôs main source of energy.

Glucose tablets or gel. Special products that deliver a pre-measured amount of pure glucose. They are a fast-acting form of glucose used to counteract hypoglycemia.

Hormone. A chemical produced by an organ that travels in the blood to affect other organs.

Hyperglycemia. A high level of glucose in the blood. High blood glucose can be due to a mismatch in insulin, food, and exercise. Symptoms include thirst, frequent urination, blurred vision, and fatigue.

Hypoglycemia. A low level of glucose in the blood. Low blood glucose is most likely to occur during or after exercise, if too much insulin is present, or not enough food is consumed. Symptoms include feeling shaky, having a headache, or being sweaty, pale, hungry, or tired.

Individualized Education Program (IEP). A program designed for students covered by the Individuals with Disabilities Education Act (IDEA).

Individuals with Disabilities Education Act (IDEA). A federal law that provides funds to states to support special education and related services for children with disabilities, administered by the Office of Special Education Programs in the U.S. Department of Education. To be eligible for services under IDEA, a studentôs diabetes must impair his or her educational performance so that he or she requires special education and related services.

Insulin. A hormone produced by the pancreas that helps the body use glucose for growth and energy. There are several types of insulin that are used in combination to treat people with diabetes. These different types of insulin have been manufactured either to have immediate (rapid-acting or short-acting insulin), intermediate, or long

(basal insulin) onset of action and duration of action in the body. A coordinated combination of insulins is used to allow for adequate treatment of diabetes at meals, snacks, during periods of physical activity, and through the night.

Insulin injections. The process of putting insulin into the body with a needle and syringe or an insulin pen.

Insulin pen. A pen-like device used to put insulin into the body.

Insulin pump. A device that delivers a continuous supply of insulin. The insulin is delivered in a steady, measured dose through a system of plastic tubing (infusion set). Most infusion sets are started with a guide needle, then the plastic cannula (a tiny, flexible plastic tube) is left in place, taped with dressing, and the needle is removed.

Insulin resistance. A condition in which the body does not respond normally to the action of insulin. Many people with type 2 diabetes have insulin resistance.

Ketoacidosis. See Diabetic ketoacidosis.

Ketones (ketone bodies). Chemicals that the body makes when there is not enough insulin in the blood and the body must break down fat for its energy. Ketones can poison and even kill body cells. When the body does not have the help of insulin, ketones build up in the blood and ñspillò over into the urine so that the body can get rid of them. Ketones that build up in the body for a long time lead to serious illness and coma. See also: Diabetic ketoacidosis.

Lancet. A fine, sharp-pointed needle used by people with diabetes for pricking their skin to obtain a sample of blood for blood glucose monitoring.

Metabolism. The term for the way cells chemically change food so that it can be used to keep the body alive.

Medical alert identification. An identification card and necklace or bracelet indicating the student has diabetes and giving an emergency number to call.

Mg/dL. Milligrams per deciliter. This term is used in blood glucose monitoring to describe how much glucose is in a specific amount of blood.

Nursing Care Plan. A plan developed by the school nurse used to implement the studentôs diabetes medical management plan. The plan describes functional problem areas, sets goals for overcoming problems, and lists tasks/interventions to meet the goals.

P

Pallor. Abnormal paleness of the skin.

Palpitations. Abnormally rapid or violent beating of the heart.

Pancreas. The organ behind the lower part of the stomach that makes insulin.

Peak effect time. Time when insulin has its major impact on reducing blood glucose levels. See also Insulin.

Q

Quick Reference Emergency Plan. This plan provides school personnel with essential information on how to recognize and treat hypoglycemia or hyperglycemia.

S

Section 504 of the Rehabilitation Act. A federal law that prohibits recipients of federal funds from discriminating against people on the basis of disability.

Syringe. A device used to inject medications such as insulin into body tissue.

T

Target range. A selected level for blood glucose values that the person with diabetes tries to maintain. The target range is usually determined by the physician in consultation with the patient (or parents, if the patient is a child). See also blood glucose levels.

Test strips. Specially designed strips used in blood glucose meters or in urine testing.

Trained Diabetes Personnel. Nonmedical personnel who have basic diabetes knowledge and have received training in diabetes care, including the performance of blood glucose monitoring, insulin and glucagon administration, recognition and treatment of hypoglycemia and hyperglycemia, and performance of urine ketone testing.

U

Urine ketone testing. A procedure for measuring the level of ketones in the urine.

Care of Children With Diabetes in the School and Day Care Setting

AMERICAN DIABETES ASSOCIATION

Diabetes is one of the most common chronic diseases of childhood, with a prevalence of ~1.7 affected individuals per 1,000 people aged <20 years (1–4). In the U.S., ~13,000 new cases are diagnosed annually in children (4–7). There are about 125,000 individuals <19 years of age with diabetes in the U.S. (8). The majority of these young people attend school and/or some type of day care and need knowledgeable staff to provide a safe school environment (9–12). Both parents and the health care team should work together to provide school systems and day care providers with the information necessary to allow children with diabetes to participate fully and safely in the school experience.

DIABETES AND THE LAW

— Federal laws that protect children with diabetes include Section 504 of the Rehabilitation Act of 1973, the Individuals with Disabilities Education Act of 1991 (originally the Education for All Handicapped Children Act of 1975), and the Americans with Disabilities Act. Under these laws, diabetes has been considered to be a disability, and it is illegal for schools and/or day care centers to discriminate against children with disabilities. In addition, any school that receives federal funding or any facility considered open to the public must reasonably accommodate the special needs of children with diabetes. Indeed, federal law requires an individualized assessment of any child with diabetes. The required accommodations should be provided within the child's usual school setting with as little disruption to the school's and the child's routine as possible and allowing the child full participation in all school activities.

Despite these protections, children in the school and day care setting still face discrimination. For example, some day care centers may refuse admission to children with diabetes, and children in the classroom may not be provided the assistance necessary to monitor blood glucose and may be prohibited from eating needed snacks. The American Diabetes Association works to ensure the safe and fair treatment of children with diabetes in the school and day care setting (13–15).

Diabetes care in schools

Appropriate diabetes care in the school and day care setting is necessary for the child's immediate safety, long-term well being, and optimal academic performance. The Diabetes Control and Complications Trial showed a significant link between blood glucose control and the later development of diabetes complications, with improved glycemic control decreasing the risk of these complications (16,17). To achieve glycemic control, a child must monitor blood glucose frequently, follow a meal plan, and take medications. Insulin is usually taken in multiple daily injections or through an infusion pump. Crucial to achieving glycemic control is an understanding of the effects of physical activity, nutrition therapy, and insulin on blood glucose levels.

To facilitate the appropriate care of the student with diabetes, school and day care personnel must have an understanding of diabetes and must be trained in its management and in the treatment of diabetes emergencies. Knowledgeable trained personnel are essential if the student is to avoid the immediate health risks of low blood glucose and to achieve the metabolic control required to decrease risks for later development of diabetes complications. Studies have shown that the majority of school personnel have an inadequate understanding of diabetes and that parents of children with diabetes lack confidence in their teachers' ability to manage diabetes effectively (12,18,19). Consequently, diabetes education must be targeted toward day care providers, teachers, and other school personnel who interact with the child, including school administrators, school coaches, school nurses, health aides, bus drivers, secretaries, etc.

The purpose of this position statement is to provide recommendations for the management of children with diabetes in the school and day care setting.

GENERAL GUIDELINES FOR THE CARE OF THE CHILD IN THE SCHOOL AND DAY CARE SETTING

I. Diabetes Health Care Plan

An individualized Diabetes Health Care Plan should be developed by the parent/guardian, the student's diabetes care team, and the school or day care provider. Inherent in this process are delineated responsibilities assumed by all parties, including the parent/guardian, the school personnel, and the student. These responsibilities are outlined in this position statement. The Diabetes Health Care Plan should address the specific needs of the child and provide specific instructions for each of the following:

1. Blood glucose monitoring, including the frequency and circumstances requiring testing.

The recommendations in this paper are based on the evidence reviewed in the following publications: Diabetes Control and Complications Trial Research Group: The effect of intensive treatment of diabetes on the development and progression of long-term complications in insulin-dependent diabetes mellitus. *N Engl J Med* 329:977–986, 1993; and Diabetes Control and Complications Trial Research Group: The effect of intensive diabetes treatment on the development and progression of long-term complications in adolescents with insulin-dependent diabetes mellitus. *J Pediatr* 125:177–188, 1994.

The initial draft of this paper was prepared by Georgeanna Klingensmith, MD, Francine Kaufman, MD, *Desmond Schatz*, MD, and *William Clarke*, MD. The paper was peer-reviewed, modified, and approved by the Professional Practice Committee and the Executive Committee, November 1998. Most recent review/ revision, 2000.

2. Insulin administration (if necessary), including doses/injection times prescribed for specific blood glucose values and the storage of insulin.
3. Meals and snacks, including food content, amounts, and timing.
4. Symptoms and treatment of hypoglycemia (low blood glucose), including the administration of glucagon if recommended by the student's treating physician.
5. Symptoms and treatment of hyperglycemia (high blood glucose).
6. Testing for ketones and appropriate actions to take for abnormal ketone levels, if requested by the student's health care provider.

Figure 1 includes a sample Diabetes Health Care Plan. For detailed information on the symptoms and treatment of hypoglycemia and hyperglycemia, refer to the *Medical Management of Type 1 Diabetes* (20). A brief description of diabetes targeted to school and day care personnel is included in the APPENDIX; it may be helpful to include this information as an introduction to the Diabetes Health Care Plan.

II. Responsibilities of the various care providers

A. The parent/guardian should provide the school or day care provider with the following:

1. All materials and equipment necessary for diabetes care tasks, including blood glucose testing, insulin administration (if needed), and urine or blood ketone testing. The parent/guardian is responsible for the maintenance of the blood glucose testing equipment (i.e., cleaning and performing controlled testing per the manufacturer's instructions) and must provide materials necessary to ensure proper disposal of materials. A separate logbook should be kept at school with the diabetes supplies for the staff or student to record test results; blood glucose values should be transmitted to the parent/guardian for review as often as requested.
2. Supplies to treat hypoglycemia, including a source of glucose and a glucagon emergency kit, if indicated in the Diabetes Health Care Plan.
3. Information about diabetes and the performance of diabetes-related tasks.
4. Emergency phone numbers for the parent/guardian and the diabetes care team so that the school can contact these individuals with diabetes-related questions and/or during emergencies.
5. Information about the student's meal/snack schedule. The parent should work with the school to coordinate this schedule with that of the other students as closely as possible. For young children, instructions should be given for when food is provided during school parties and other activities.

B. The school or day care provider should provide the following:

1. Training to all adults who provide education/care for the student on the symptoms and treatment of hypoglycemia and hyperglycemia and other emergency procedures. An adult and back-up adult(s) trained to *1*) perform fingerstick blood glucose monitoring and record the results; *2*) take appropriate actions for blood glucose levels outside of the target ranges as indicated in the student's Diabetes Health Care Plan; and *3*) test the urine or blood for ketones, when necessary, and respond to the results of this test.
2. Immediate accessibility to the treatment of hypoglycemia by a knowledgeable adult. The student should remain supervised until appropriate treatment has been administered, and the treatment should be available as close to where the student is as possible.
3. If indicated by the child's developmental capabilities and the Diabetes Health Care Plan, an adult and back-up adult(s) trained in insulin administration.
4. An adult and back-up adult(s) trained to administer glucagon, in accordance with the student's Diabetes Health Care Plan.
5. A location in the school to provide privacy during testing and insulin administration, if desired by the student and family, or permission for the student to check his or her blood glucose level and to take appropriate action to treat hypoglycemia in the classroom or anywhere the student is in conjunction with a school activity, if indicated in the student's Diabetes Health Care Plan.
6. An adult and back-up adult(s) responsible for the student who will know the schedule of the student's meals and snacks and work with the parent/guardian to coordinate this schedule with that of the other students as closely as possible. This individual also will notify the parent/guardian in advance of any expected changes in the school schedule that affect the student's meal times or exercise routine. Young children should be reminded of snack times.
7. Permission for the student to see school medical personnel upon request.
8. Permission for the student to eat a snack anywhere, including the classroom or the school bus, if necessary to prevent or treat hypoglycemia.
9. Permission to miss school without consequences for required medical appointments to monitor the student's diabetes management. This should be an excused absence with a doctor's note, if required by usual school policy.
10. Permission for the student to use the restroom and have access to fluids (i.e., water) as necessary.
11. An appropriate location for insulin and/or glucagon storage, if necessary.

An adequate number of school personnel should be trained in the necessary diabetes procedures (e.g., blood glucose monitoring, insulin and glucagon administration) and in the appropriate response to high and low blood glucose levels to ensure that at least one adult is present to perform these procedures in a timely manner while the student is at school, on field trips, and during extracurricular activities or other school-sponsored events. These school personnel need not be health care professionals.

The student with diabetes should have immediate access to diabetes supplies at all times, with supervision as needed. Provisions similar to those described above must be available for field trips, extracurricular activities, other school-sponsored events, and on transportation provided by the school or day care facility to enable full participation in school activities.

It is the school's legal responsibility to provide appropriate training to school

Diabetes Care Plan for _____ **(name of student)** _____ **School** _____ **Effective Dates:** _____

_____ After exercise
_____ Other (explain): _____
_____ When student exhibits symptoms of hyperglycemia
_____ When student exhibits symptoms of hypoglycemia
Can student perform own blood glucose tests? Yes No Exceptions: _____
School personnel trained to monitor blood glucose level and dates of training: _____

Insulin
Times, types, and dosages of insulin injections to be given during school:

Time	Type(s)	Dosage
_____	_____	_____
_____	_____	_____
_____	_____	_____

School personnel trained to assist with insulin injection and dates of training: _____
Can student give own injections? Yes No
Can student determine correct amount of insulin? Yes No
Can student draw correct dose of insulin? Yes No

For Students with Insulin Pumps:
Type of pump: _____
Insulin/carbohydrate ratio: _____
Correction factor: _____
Is student competent regarding pump? Yes No
Can student effectively troubleshoot problems (e.g., ketosis, pump malfunction)? Yes No
Comments: _____

Meals and Snacks Eaten at School (The carbohydrate content of the food is important in maintaining a stable blood glucose level.)

	Time	Food content/amount
Breakfast	_____	_____
A.M. snack	_____	_____
Lunch	_____	_____
P.M. snack	_____	_____
Dinner	_____	_____

Snack before exercise? Yes No _____
Snack after exercise? Yes No _____
Other times to give snacks and content/amount: _____
A source of glucose, such as _____, should be readily available at all times.
Preferred snack foods: _____
Foods to avoid, if any: _____
Instructions for when food is provided to the class, e.g., as part of a class party or food sampling: _____

Hypoglycemia (Low Blood Sugar)
Usual symptoms of hypoglycemia: _____
Treatment of hypoglycemia: _____
School personnel trained to administer glucagon and dates of training: _____
Glucagon should be given if the student is unconscious, having a seizure (convulsion), or unable to swallow. If required, glucagon should be administered promptly and then 911 (or other emergency assistance) and parents should be called.

Hyperglycemia (High Blood Sugar)
Usual symptoms of hyperglycemia: _____
Treatment of hyperglycemia: _____
Circumstances when urine or blood ketones should be tested: _____
Treatment for ketones: _____

Exercise and Sports
A snack such as _____ should be readily available at the site of exercise or sports.
Restrictions on activity, if any: _____
Student should not exercise if blood glucose is below _____ mg/dl.

Supplies and Personnel
Location of supplies: Blood glucose monitoring equipment: _____ Insulin administration supplies: _____
Glucagon emergency kit: _____ Ketone testing supplies: _____
Snack foods: _____
Personnel trained in the symptoms and treatment of low and high blood sugar and dates of training: _____

staff on diabetes-related tasks and in the treatment of diabetes emergencies. This training should be provided by health care professionals with expertise in diabetes unless the student's health care provider determines that the parent/guardian is able to provide the school personnel with sufficient oral and written information to allow the school to have a safe and appropriate environment for the child. If appropriate, members of the health care team should provide instruction and materials to the parent/guardian to facilitate the education of school staff. Educational materials from the American Diabetes Association and other sources targeted to school personnel and/or parents are available. Table 1 includes a listing of appropriate resources.

III. Expectations of the student in diabetes care

Children and youths should be able to implement their diabetes care at school with parental consent to the extent that is appropriate for the student's development and his or her experience with diabetes. The extent of the student's ability to participate in diabetes care should be agreed upon by the school personnel, the parent/guardian, and the health care team, as necessary. The ages at which children are able to perform self-care tasks are very individual and variable, and a child's capabilities and willingness to provide self-care should be respected.

1. *Preschool and day care.* The preschool child is usually unable to perform diabetes tasks independently. By 4 years of age, children may be expected to generally cooperate in diabetes tasks.
2. *Elementary school.* The child should be expected to cooperate in all diabetes tasks at school. By age 8 years, most children are able to perform their own fingerstick blood glucose tests with supervision. By age 10, some children can administer insulin with supervision.
3. *Middle school or junior high school.* The student should be able to administer insulin with supervision and perform self-monitoring of blood glucose under usual circumstances when not experiencing a low blood glucose level.
4. *High school.* The student should be able to perform self-monitoring of blood glucose under usual circumstances when not experiencing low blood glucose levels. In high school, adolescents should be able to administer insulin without supervision.

At all ages, individuals with diabetes may require help to perform a blood glucose test when the blood glucose is low. In addition, many individuals require a reminder to eat or drink during hypoglycemia and should not be left unsupervised until such treatment has taken place and the blood glucose value has returned to the normal range.

MONITORING BLOOD GLUCOSE IN THE CLASSROOM — It is best for a student with diabetes to obtain a blood glucose level and to respond to the results as quickly and conveniently as possible. This is important to avoid medical problems being worsened by a delay in testing/treatment and to minimize educational problems caused by missing instruction in the classroom. Accordingly, as stated earlier, a student should be permitted to monitor his or her blood glucose level and take appropriate action to treat hypoglycemia in the classroom or anywhere the student is in conjunction with a school activity, if preferred by the student and indicated in the student's Diabetes Health Care Plan. However, some students desire privacy during testing and this preference should also be accommodated.

In summary, with proper planning and the education and training of school personnel, children and youth with diabetes can fully participate in the school experience. To this end, the family, the health care team, and the school should work together to ensure a safe learning environment.

APPENDIX: BACKGROUND INFORMATION ON DIABETES FOR SCHOOL PERSONNEL — Diabetes is a serious, chronic disease that impairs the body's ability to use food. Insulin, a hormone produced by the pancreas, helps the body

convert food into energy. In people with diabetes, either the pancreas does not make insulin or the body cannot use insulin properly. Without insulin, the body's main energy source—glucose—cannot be used as fuel. Rather, glucose builds up in the blood. Over many years, high blood glucose levels can cause damage to the eyes, kidneys, nerves, heart, and blood vessels.

The majority of school-aged youth with diabetes have type 1 diabetes. People with type 1 diabetes do not produce insulin and must receive insulin through either injections or an insulin pump. Insulin taken in this manner does not cure diabetes and may cause the student's blood glucose level to become dangerously low. Type 2 diabetes, the most common form of the disease typically afflicting obese adults, has been shown to be increasing in youth (21). This may be due to the increase in obesity and decrease in physical activity in young people. Students with type 2 diabetes may be able to control their disease through diet and exercise alone or may require oral medications and/or insulin injections. All people with type 1 and type 2 diabetes must carefully balance food, medications, and activity level to keep blood glucose levels as close to normal as possible.

Low blood glucose (hypoglycemia) is the most common immediate health problem for students with diabetes. It occurs when the body gets too much insulin, too little food, a delayed meal, or more than the usual amount of exercise. Symptoms of mild to moderate hypoglycemia include tremors, sweating, lightheadedness, irritability, confusion, and drowsiness. A student with this degree of hypoglycemia will need to ingest carbohydrates promptly and may require assistance. Severe hypoglycemia, which is rare, may lead to unconsciousness and convulsions and can be life-threatening if not treated promptly.

High blood glucose (hyperglycemia) occurs when the body gets too little insulin, too much food, or too little exercise; it may also be caused by stress or an illness such as a cold. The most common symptoms of hyperglycemia are thirst, frequent urination, and blurry vision. If untreated over a period of days, hyperglycemia can cause a serious condition called diabetic ketoacidosis (DKA), which is characterized by nausea, vomiting, and a high level of ketones in the blood and urine. For students using insulin infusion pumps, lack of insulin supply may lead to DKA more rapidly. DKA can be life-threatening and thus requires immediate medical attention.

POLICY STATEMENT

High-Deductible Health Plans and the New Risks of Consumer-Driven Health Insurance Products

Organizational Principles to Guide and Define the Child Health Care System and/or Improve the Health of All Children

Committee on Child Health Financing

ABSTRACT

Consumer-driven health care is the most noteworthy development in health insurance since the widespread adoption of health maintenance organizations and preferred provider organizations in the 1980s. The most common consumer-driven health plan is the high-deductible health plan, which is essentially a catastrophic health insurance plan, often linked with tax-advantaged spending accounts, with very high deductibles, fewer benefits, and higher cost-sharing than conventional health maintenance organization or preferred provider organization plans. The financial risks are significant under high-deductible health plans, especially for low- to moderate-income families and for families whose children have special health care needs. Of concern for pediatricians are the potential quality risks that are predictable in high-deductible health plans, in which families are likely to delay or avoid seeking care, especially preventive care (if it is not exempted from the deductible), when they are faced with paying for care before the deductible is met. This policy statement provides background information on the most common consumer-driven health plan model, discusses the implications for pediatricians and families, and offers recommendations pertaining to health plan product design, education, practice administration, and research.

INTRODUCTION

Consumer-driven health care is the most noteworthy development in health insurance since the widespread adoption of health maintenance organizations (HMOs) and preferred provider organizations (PPOs) in the 1980s. Faced with unsustainable premium increases and heightened competition, employers are experimenting with new products, referred to as consumer-driven health plans (CDHPs).[1] The potential benefit of a CDHP is to increase the control consumers have over their health care spending and to empower them to use published information to guide their care options. The most commonly sold CDHP is a high-deductible health plan (HDHP), which essentially is a catastrophic health insurance plan, often linked with tax-advantaged spending accounts, with very high deductibles, fewer benefits, and higher cost-sharing than conventional HMO and PPO plans. HDHPs offer a new strategy for sharing risk and responsibility for health care costs among employers and employees.[2] HDHPs also represent a major shift from defined benefits to defined contributions.[3] At this time, there is insufficient information to ascertain the specific effects of HDHPs on children's access to care and the operation of the medical home; however, there is concern that

children from low- to moderate-income families and children with special health care needs may be at risk if covered under HDHPs.

This policy statement provides background information on the most common CDHP model—the HDHP paired with a tax-advantaged spending account—and the latest research on these new insurance products. The statement also discusses the implications for pediatricians and families and offers recommendations pertaining to product design, education, practice administration, and research.

BACKGROUND

HDHPs were established by the Medicare Prescription Drug Improvement and Modernization Act of 2003. Currently, qualified HDHPs are health insurance plans with at least a $2000 deductible for family coverage and a total annual out-of-pocket maximum, including deductible, copays, and other cost-sharing, that cannot exceed $10 000 per family.[4] The spending account—either a health reimbursement account (HRA) or a health savings account (HSA)—is used to pay for a portion of health care expenses until the plan's high deductible is met; then, the HDHP functions like a PPO plan.[5]

The 2 common spending accounts differ in terms of ownership, requirements to be tied to an HDHP, discretion to carry over unused amounts into subsequent years, and portability (see Table 1). Briefly, the HRA is owned and solely funded by the employer.[6] It is typically offered with an HDHP but also can be offered with an HMO or PPO. The employer has discretion about the amount of funds to be carried over, and HRAs are not portable.[7] The HSA is owned by the employee, although the employer can contribute. It can only be used with an HDHP that has a deductible up to $5150 per family.[7] Money can be carried over from year to year, and the HSA is portable.[7]

Research shows that very large and very small employers as well as individuals in the nongroup market are most interested in offering and purchasing HDHPs. Early research suggests that healthier and wealthier individuals are more likely to purchase HDHPs than their counterparts. Individuals and families in higher tax brackets, especially those who are healthy, can benefit from this method to save for medical expenses, and possibly retirement, with pretax dollars.

According to the 2005 National Employers Health Benefits Survey[8] sponsored by the Kaiser Family Foundation and the Health Research and Education Trust, 20% of employers are offering an HDHP, up from only 5% in 2003. A minority of firms that offer HDHPs (1 in 5) offer either an HRA contribution (10%) or an HSA-qualified plan (12%). In firms that offer HRAs, approximately 25% of employees participate (1.6 million employees or 2% of all covered workers). On average, employer contributions to HRAs amount to $1556. In firms that offer HSAs, approximately 15% of employees participate (810 000 employees or 1.2% of all covered workers). Average annual employer contributions to HSAs amount to $1185, with one third of employers making no contributions. It is unclear what the average amount that employees contribute is.

Table 2 illustrates the cost differences between HDHPs and PPOs for an average family. Although the proportion of employers currently offering HDHPs with spending accounts is small, the expected growth is predicted to be sizeable. According to the 2005 National Employer Health Benefits Survey, 2% to 4% of firms reported that they were very likely to offer HDHPs next year, and 22% to 25% reported that they were somewhat likely to offer them.[9]

PREVENTIVE CARE AND HDHPs

Generally, an HDHP cannot provide any benefits before the deductible is satisfied, but there is an exception for preventive care. Referred to as the "safe harbor for preventive benefits," HDHPs with HSAs are permitted, but not required, to offer preventive care without meeting the deductible.[9] According to the Internal Revenue Code, preventive care is defined as routine well-child care and immunizations; periodic health evaluations, including tests and diagnostic procedures ordered in conjunction with routine examinations, such as annual physicals; mental health and substance abuse screening; vision and hearing screening; screenings for various pediatric conditions (ie, developmental delay, congenital hypothyroidism, lead concentration, phenylketonuria, and scoliosis); metabolic, nutritional, and endocrine screening; infectious disease screening; and maintenance drugs used by chronically ill patients.[10] Despite this important provision, the 2005 National Employer Health Benefits Survey found that only 30% of employers who offer an HDHP with an HSA covered preventive care before the deductible was met, thus eroding the relationship between the medical home and the family.[9]

TABLE 1 **Comparison of HRA and HSA**

Plan	Tax Savings	Funded by	Annual Rollover of Unused Funds	Portable
HRA	Yes	Employer	At the employer's discretion	At the employer's discretion
HSA	Yes (funds may be invested and earn interest tax free)	Can be both employer and employee	Yes	Yes

TABLE 2 **Comparison of Premiums and Deductibles in HDHP and PPOs**

Plan for Average Family of 4 Members	Average Annual Premiums, $	Average Annual Deductible, $
HDHP with HRA	8530	3686
HDHP with HSA	7909	4070
PPO	11 090	646

IMPLICATIONS FOR PEDIATRICIANS AND FAMILIES

HDHPs carry potentially significant coverage, financial, quality, and practice risks for pediatricians as well as families. Among the coverage restrictions, HDHPs typically offer less generous coverage for certain services (eg, drugs, mental health) compared with PPOs or HMOs.[10] Physician and hospital coverage is likely to be the same, although not necessarily in terms of cost-sharing.[8] It is often difficult to assess the coverage risks associated with preventive care, because the service may or may not be exempt from the deductible; also, information on periodicity and content may not be extensively described in consumer materials. Another more significant coverage risk of HDHPs is the potential for "destabilization" of employer-sponsored health insurance if more employers and families purchase HDHPs instead of HMOs and PPOs, which typically offer more comprehensive benefits.

The financial risks are significant under HDHPs, especially for low- to moderate-income families and for families whose children have special health care needs.[7] Because visits by children with special health care needs to specialists are not considered preventive care, parents will need to tap into their HSA or HRAs to pay for these visits as well as any laboratory tests, imaging, therapies, and other essential health care services. Once the HSA or HRA is depleted, parents will need to pay out-of-pocket until they have reached their deductible. Thus, children with special health care needs may not receive all their recommended care, and/or their families may have considerable out-of-pocket expenses. Clearly, families face greater exposure to financial risk with higher deductibles, use of coinsurance versus copays, and higher out-of-pocket maximums.[11] In addition, families may face higher per-service charges because there is not a "middle man" negotiating provider discounts.[12] Under managed care plans, discounted fees are provided in exchange for the potential for increased volume, prompt payment, and streamlined claims processing. These favorable discounts may not be available under HDHPs. In general, HDHPs with spending accounts could potentially be advantageous only if certain conditions were met—for example, if the family had few health problems, the premium was priced low, preventive care was not counted toward the deductible, benefits needed by the family were covered with affordable cost-sharing, and few services were used by the family.[13]

Of concern to pediatricians are the potential quality risks that are predictable in HDHPs in which families are likely to delay or avoid seeking care when they are faced with paying for care before the deductible is met.[14] Lower rates of preventive care and immunizations, less compliance with recommended treatment, less continuity of care, and lower use of acute and chronic care services are very real concerns.[15] HDHPs have the potential to adversely decrease access to medical homes and result in more episodic, high-priced care. Faced with difficult choices, families may seek to "load up" on a scheduled visit to save money or delay care until after the deductible is met. In the end, families will have to make many more decisions about the cost-versus-quality trade-offs, relying on Internet-based information, online patient support tools, and nurse help lines.[1]

Although decision-support tools have been identified as a special feature of HDHPs, a recent US Government Accountability Office report[16] noted that tools provided by insurance carriers to assist consumers in assessing the price and quality of health care providers and services do not provide sufficient information to allow enrollees to fully assess the cost and quality trade-offs of health care–purchasing decisions. Of concern are the methods that insurers and third-party agencies use to rate the quality of care of providers. Relying on claims data, for example, represents a flawed approach to judging quality.

A variety of pediatric practice risks are starting to emerge with HDHPs. Among them are greater administrative and collection costs and bad debt for practices.[17] This is attributable in part to the fact that some HDHP administrators have notified families not to pay the physician charges at the time of service, instead waiting for explanation of benefit statements to assess deductibles and savings account balances. Importantly, pediatricians are likely to be asked more about the costs of their services as well as the content and value of specific services.[13] In addition, families in these plans will likely request more telephone and e-mail assistance to avoid making in-person visits.

RECOMMENDATIONS

The following recommendations focus on the different groups of people and organizations affected by CDHPs. These groups include the insurance companies and third-party payers designing the plans, the families purchasing the plans, and the employers providing the plans. Also included are recommendations for physicians and practices to prepare for CDHPs.

HDHP Design

- Coverage should be provided for preventive services including, but not limited to, well-child care, immunizations, and appropriate screenings.

- Preventive services should be "first-dollar" coverage (ie, covered before the deductible is met).
- Allowed reimbursement amounts for preventive services should be age adjusted to provide adequate payment for preventive health care recommended by the American Academy of Pediatrics (AAP).
- Physicians should be allowed to collect copays and payment for nonpreventive services at the time of visit. Methods to make this simpler, such as real-time debit cards for HSAs, should be developed. Vendors should implement integrated, real-time claims-adjudication processes to help clinicians obtain payment for services from the patient more quickly.
- Payment for services before the deductible has been met should be at billed charges. If a contracted fee schedule is used, it should be adjusted to reflect the increased billing and administration costs incurred by the physician.
- Consideration should be given to payment for telephone and e-mail services, because telephone and e-mail advice will be in greater demand.

Education

- Increase pediatricians' awareness of the prevalence of HDHPs in their geographic area and their varied cost-sharing requirements and benefit designs.
- Communicate to employers the importance of covering preventive care outside the deductible and the importance of receiving preventive care in the medical home.
- Publicize to employers, patients, and the public the average costs of preventive care services, including the increased frequency of examinations and number of vaccines required during the first 2 years of life and the increased amount of time required for adolescent care.
- Consider new educational strategies to assist families when insurance decisions are made, and focus on deductible levels, preventive care coverage, cost-sharing protections, provider networks, spending accounts, and payment arrangements.

Practice Management

- Publicize the practice's policy about collecting payment for services at the time of the visit.
- Communicate the costs and reasons for preventive, acute, follow-up, and chronic medical care.
- Establish billing policies for telephone and e-mail services.
- Prepare for greater administration/collection burdens and bad debts.
- Use AAP Hassle Factor forms (available online at the Member Center at www.aap.org/moc [under "more resources"]) to inform state and national AAP leaders of issues and problems.

Quality Improvement Measures

- HDHPs should adhere to providing quality data information to consumers on the basis of measurement standards developed by accrediting organizations.
- Quality data should be based on measures that are evidence based, relevant to patient outcomes, and statistically valid and reliable.

Research

- Encourage, support, and promote research to assess the value and benefits of preventive pediatric services and promote research to evaluate the effects that HDHPs have on children's and adolescents' access to care and family satisfaction with care and cost of care.
- Examine the effect of HDHPs on the use of medical services, including preventive, acute, and chronic care.

CONCLUSIONS

CDHPs offer the opportunity of more consumer involvement in the decision to purchase specific health care items. However, of notable concern are the effects of this process on children receiving necessary and highly cost-effective preventive care and on lower- or middle-income parents, who will have to pay for a substantial amount of their children's health care out-of-pocket.

DEDICATED TO THE HEALTH OF ALL CHILDREN™

POLICY STATEMENT

HIV Testing and Prophylaxis to Prevent Mother-to-Child Transmission in the United States

Organizational Principles to Guide and Define the Child Health Care System and/or Improve the Health of All Children

Committee on Pediatric AIDS

ABSTRACT

Universal HIV testing of pregnant women in the United States is the key to prevention of mother-to-child transmission of HIV. Repeat testing in the third trimester and rapid HIV testing at labor and delivery are additional strategies to further reduce the rate of perinatal HIV transmission. Prevention of mother-to-child transmission of HIV is most effective when antiretroviral drugs are received by the mother during her pregnancy and continued through delivery and then administered to the infant after birth. Antiretroviral drugs are effective in reducing the risk of mother-to-child transmission of HIV even when prophylaxis is started for the infant soon after birth. New rapid testing methods allow identification of HIV-infected women or HIV-exposed infants in 20 to 60 minutes. The American Academy of Pediatrics recommends documented, routine HIV testing for all pregnant women in the United States after notifying the patient that testing will be performed, unless the patient declines HIV testing ("opt-out" consent or "right of refusal"). For women in labor with undocumented HIV-infection status during the current pregnancy, immediate maternal HIV testing with opt-out consent, using a rapid HIV antibody test, is recommended. Positive HIV antibody screening test results should be confirmed with immunofluorescent antibody or Western blot assay. For women with a positive rapid HIV antibody test result, antiretroviral prophylaxis should be administered promptly to the mother and newborn infant on the basis of the positive result of the rapid antibody test without waiting for results of confirmatory HIV testing. If the confirmatory test result is negative, then prophylaxis should be discontinued. For a newborn infant whose mother's HIV serostatus is unknown, the health care professional should perform rapid HIV antibody testing on the mother or on the newborn infant, with results reported to the health care professional no later than 12 hours after the infant's birth. If the rapid HIV antibody test result is positive, antiretroviral prophylaxis should be instituted as soon as possible after birth but certainly by 12 hours after delivery, pending completion of confirmatory HIV testing. The mother should be counseled not to breastfeed the infant. Assistance with immediate initiation of hand and pump expression to stimulate milk production should be offered to the mother, given the possibility that the confirmatory test result may be negative. If the confirmatory test result is negative, then prophylaxis should be stopped and breastfeeding may be initiated. If the confirmatory test result is positive, infants should receive antiretroviral prophylaxis for 6 weeks after birth, and the mother should not breastfeed the infant. *Pediatrics* 2008;122:1127–1134

INTRODUCTION

Continuing technologic and medical advances in the diagnosis, prevention, and treatment of pediatric HIV infection require ongoing assessment and review of recommendations relating to pediatric HIV infection, including recommendations regarding prenatal and perinatal HIV counseling and testing. Current guidelines are consistent in their recognition of the importance of universal HIV testing of pregnant women in the United States as the key to prevention of mother-to-child transmission (MTCT) (also referred to as vertical or perinatal transmission) of HIV. The American Academy of Pediatrics (AAP) continues to support these guidelines. This policy statement updates the data that support the guidelines and suggests ways to continue improving the implementation of the recommendations for universal testing during routine prenatal care.

WHY IS A NEW STATEMENT NEEDED NOW?

There is continued MTCT of HIV in the United States; 397 infants were infected through MTCT in 1999–2001 in areas conducting enhanced perinatal surveillance.[1] These infant infections occurred despite the availability of efficacious

interventions for preventing such transmission (antiretroviral [ARV] prophylaxis to mother and infant, elective cesarean delivery before the onset of labor and before rupture of membranes, and complete avoidance of breastfeeding).[2] In recent years, lack of identification of maternal HIV-infection status has been the primary reason for new infant HIV infections; effective interventions cannot be implemented unless maternal HIV status is known. Rapid HIV antibody testing methods now allow identification of HIV-infected women or HIV-exposed infants in 20 to 60 minutes[3–5] (see also www.cdc.gov/hiv/topics/testing/rapid/index.htm). Studies have demonstrated the effectiveness of ARV prophylaxis for preventing MTCT of HIV, even when prophylaxis is initiated after the birth of the infant.[6–10] New guidelines from the Centers for Disease Control and Prevention (CDC) strengthen the recommendations for routine HIV testing during pregnancy.[11] This report summarizes the recommendations of the AAP regarding HIV testing and prophylaxis to prevent MTCT of HIV, which are consistent with and supportive of the CDC recommendations.

HIV TESTING

For adults and children 18 months or older, "conventional testing" of blood for the presence of antibodies against HIV is performed by using a screening enzyme immunoassay (EIA). If the initial EIA result is positive, the laboratory repeats the EIA on the same blood sample, and if the repeat result is positive, the remainder of the blood is used to perform a confirmatory test, either immunofluorescent antibody (IFA) or Western blot assay. Because children younger than 18 months may have a positive HIV antibody test result because of the presence of passively acquired maternal antibody, assays that directly detect HIV DNA or RNA (generically referred to as HIV nucleic acid amplification tests) are required for diagnosis of HIV infection in children younger than 18 months.[12,13] Results of conventional HIV antibody tests and HIV nucleic acid amplification tests usually require hours to days to be returned.

"Rapid" HIV antibody tests have been available since 2002.[3,5,14] These are screening tests, which means that a positive test result requires confirmation with an IFA or Western blot assay. The rapid antibody test is more sensitive and more specific than the conventional EIA, so a conventional EIA is not used as the confirmatory test for a rapid HIV antibody test.[15] In 1 study of the feasibility and benefit of use of the rapid test in pregnant women already in labor when they presented to health care professionals, the positive predictive value of the rapid test was shown to be higher than that of the conventional EIA.[4] That study of 4849 women (HIV prevalence: 7 in 1000) demonstrated that for the conventional EIA, the sensitivity was 100%, specificity was 99.8%, and the positive predictive value was 76%, whereas for the rapid HIV test, the sensitivity was 100%, specificity was 99.9%, and the positive predictive value was 90%.[4]

Although it is usually recommended that all HIV antibody screening tests be confirmed before HIV-specific treatments are started, this can take several weeks, because there is often a delay between availability of the results of the screening test and results of the confirmatory IFA or Western blot assay. This is not problematic for a woman identified early in pregnancy, because initiation of ARV prophylaxis against MTCT generally is not started until the second trimester. However, it is a problem for a woman who is late in pregnancy or in labor or is being tested immediately postpartum. In such instances, time is of the essence in initiating ARV prophylaxis to prevent MTCT. Therefore, when women have positive results of rapid antibody screening late in pregnancy, during labor, or within the first few hours of delivery of the infant, ARV prophylaxis to prevent MTCT should be instituted promptly on the basis of the positive results of the screening test. A maternal blood sample for a confirmatory HIV antibody assay should be obtained and sent for testing.[4,16,17] Prophylaxis should be stopped if the confirmatory test result is negative.

BENEFITS OF HIV TESTING

HIV testing during pregnancy allows identification of HIV infection in women who might not know they are infected. This is important for the health of the woman, because knowledge of her HIV-infection status will allow appropriate evaluation, including $CD4^+$ T-lymphocyte count and HIV viral load quantification, initiation of comprehensive care, and appropriate ARV treatment. HIV antibody testing early in pregnancy has the added benefit of allowing the most effective interventions to prevent MTCT of HIV to be initiated, including ARV prophylaxis, planning an appropriate mode of delivery (elective cesarean delivery or vaginal delivery, depending on maternal viral load near delivery), and avoidance of breastfeeding. HIV antibody testing later in pregnancy, or even after delivery of the newborn infant, still allows initiation of effective ARV interventions that can reduce the risk of MTCT of HIV.

Benefits of HIV Testing Early in Pregnancy

Single-Drug ARV Prophylaxis and MTCT of HIV

The 3-part 1994 Pediatric AIDS Clinical Trials Group study 076 (PACTG 076) regimen is the starting point for understanding ARV prophylaxis and the prevention of MTCT of HIV. Among nonbreastfeeding pregnant women with HIV infection and a $CD4^+$ T-lymphocyte count of greater than 200 cells per mm^3, oral zidovudine (ZDV) prophylaxis initiated after the first trimester, followed by administration of intravenous ZDV beginning at the onset of labor and continued until the cord is clamped, combined with 6 weeks of oral ZDV administered to the infant (2 mg/kg per dose every 6 hours), reduces the rate of MTCT of HIV from 25% to 8%.[18] Among nonbreastfeeding pregnant women with HIV infection, initiation of ZDV prophylaxis before the 28th week of pregnancy is associated with a lower risk of in utero transmission of HIV than is prophylaxis initiated at 35 weeks of pregnancy.[19]

Combination ARV Regimens and MTCT of HIV

Regimens that include combinations of 3 ARV drugs are more effective for prevention of MTCT of HIV than is

ZDV alone.[20,21] For nonbreastfeeding pregnant women with HIV infection, successful combination therapy with 3 ARV drugs and resultant reduction of maternal plasma virus load to below the limits of detection on sensitive assays (the goal of standard ARV therapy) is associated with rates of MTCT of HIV of less than 1%.[22–24] Current US Public Health Service (USPHS) guidelines for prevention of MTCT of HIV recommend use of combination ARV regimens including at least 3 ARV drugs during pregnancy and labor for all pregnant women with HIV infection. ARV drugs are discontinued after delivery unless the mother requires ARV therapy for her own health, in which case ARV therapy would be continued following guidelines for nonpregnant HIV-infected adults.[25,26] Intravenous ZDV should be administered to the pregnant woman during labor until the cord is clamped, with the other ARV drugs in the regimen continued orally during labor, and all infants should receive 6 weeks of ZDV prophylaxis.[25]

The full 6-week course of infant ARV prophylaxis, and careful instructions for its administration, should be provided to the family before discharge from the hospital. A prescription and recommendations to purchase ZDV for use by the infant are not adequate to ensure appropriate prophylaxis. In some states, infants may not be registered for insurance for a few weeks after birth, so even if the family has insurance, coverage may not be immediately available to pay for health care costs for the infant. Some families have health insurance that covers inpatient costs but not prescription medications. Outpatient pharmacies may not stock the infant-dosage form of ZDV. At hospital discharge, the family should be supplied with the medication itself, along with careful instructions for its administration, not just a prescription.

Mode of Delivery and MTCT of HIV

Elective cesarean delivery (performed before onset of labor and before rupture of membranes) can prevent MTCT of HIV[27] and is associated with at least a 50% decrease in the risk of MTCT among HIV-infected women either not receiving ARV drugs or receiving ZDV alone.[28] Although several studies have suggested that elective cesarean delivery performed before labor onset and before rupture of membranes may remain effective among HIV-infected women with low virus load (low either intrinsically off ARV therapy or low because of administration of combination ARV regimens during pregnancy), further research is required to definitively demonstrate whether elective cesarean delivery can further reduce the risk of MTCT of HIV for women being successfully treated with combinations of 3 or more ARV drugs (eg, virus load undetectable on sensitive assays while on a combination 3-drug ARV regimen).[29] Current American College of Obstetricians and Gynecologists (ACOG)[30] and USPHS guidelines for prevention of MTCT recommend elective cesarean delivery at 38 weeks' gestation for all HIV-infected pregnant women with HIV RNA levels greater than 1000 copies per mL near the time of delivery (or who have unknown viral load), regardless of the type of maternal ARV prophylaxis being received.[14,25]

Breastfeeding

Breastfeeding confers approximately 9% to 15% excess risk of MTCT of HIV. In the United States, because safe infant feeding alternatives exist, women with HIV infection should not breastfeed regardless of maternal ARV use.[31,32]

Benefits of HIV Testing in the Peripartum and Newborn Periods

When HIV antibody testing is performed before or during pregnancy, if a woman is found to be infected with HIV, it is possible to use all 3 known efficacious interventions for prevention of MTCT of HIV (prepartum and intrapartum maternal and postpartum infant ARV prophylaxis, elective cesarean delivery, and avoidance of breastfeeding). However, if HIV diagnostic testing is not performed until the peripartum or postpartum periods, then only 2 of the 3 interventions can be implemented (intrapartum maternal and postpartum infant ARV prophylaxis and avoidance of breastfeeding). Although ARV prophylaxis initiated during pregnancy is most effective at reducing MTCT of HIV, prophylaxis initiated for the pregnant woman at the time of labor and continued to the infant after birth, or even prophylaxis only administered to the infant after birth, can reduce the risk of MTCT of HIV compared with no prophylaxis.[6,7,10] Moreover, identification of HIV exposure allows the pediatrician to offer advice on appropriate alternatives to breastfeeding, follow-up testing, and prophylaxis against opportunistic infections for the infant as well as referral of the mother for care of her HIV infection.[12]

For the woman with HIV infection identified at the time of labor, maternal prophylaxis with intravenous ZDV, together with infant prophylaxis with 6 weeks of ZDV, is associated with an approximately 60% lower risk of MTCT of HIV[7] compared with no prophylaxis. For infants whose mothers received no ARV therapy during pregnancy or labor, prompt (optimally as soon as possible after birth but certainly within 12 hours after birth) prophylaxis of the infant with ZDV alone for 6 weeks is associated with a 50% reduction in the risk of MTCT of HIV compared with no prophylaxis.[7]

In certain situations, some experts combine the 6-week infant ZDV prophylaxis regimen with additional ARV drugs. Such situations might include infants born to mothers who received prenatal ARV drugs but had suboptimal viral suppression at delivery, particularly if the infant was delivered vaginally; infants born to mothers who have received only intrapartum ARV drugs; infants born to mothers who have received no prepartum or intrapartum ARV drugs; and infants born to mothers with known drug-resistant virus. Whether combining ZDV with other ARV drugs provides additional efficacy for prevention of MTCT of HIV has not been proven in clinical trials. In addition, appropriate ARV drug formulations and dosing regimens for neonates are incompletely defined for many drugs, and there are minimal data about the safety of combination ARV drugs in the neonate. Therefore, use of combination infant ARV prophylaxis involves complex balancing of potential benefits in terms of prevention of MTCT of HIV and risks in

terms of toxicity to the infant. The USPHS guidelines for prevention of MTCT of HIV include extensive discussion of considerations for infant ARV prophylaxis regimens for different clinical scenarios and should be reviewed for specific recommendations.[25] If infant prophylaxis with ARV drugs in addition to ZDV is being considered, decisions and choice of ARV drugs should be determined in consultation with a practitioner who is experienced in care of infants with HIV infection.

Other Considerations

Early identification of HIV-exposed infants allows (1) appropriate testing to identify HIV-infection status of the infant, (2) counseling of the mother regarding the risk of HIV transmission through breastfeeding and institution of appropriate infant feeding, and (3) prophylaxis with trimethoprim-sulfamethoxazole to prevent *Pneumocystis jiroveci* infection for infants whose HIV-infection status has not been determined or are identified as being HIV infected.[12]

SUMMARY: PROPHYLAXIS AND TREATMENT OF PREGNANT WOMEN WITH HIV INFECTION AND THEIR INFANTS

Guidelines for initiation of ARV therapy for pregnant women are the same as for nonpregnant HIV-infected adults and follow the USPHS "Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents"[26] except that the choice of ARV drugs includes special considerations related to pregnancy and fetal drug exposure as described in the "Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-Infected Women for Maternal Health and Interventions to Reduce Perinatal HIV Transmission in the United States."[25] For women who need immediate initiation of ARV therapy for their own health, treatment should be initiated as soon as possible, including in the first trimester. For women who do not require treatment for their own health, the effectiveness of ARV prophylaxis depends on the timing of institution of such prophylaxis. For women identified as being HIV infected early in pregnancy, generally 3 ARV drugs are recommended for prophylaxis during their pregnancy and should be continued until the time of delivery. Delaying initiation of prophylaxis until after the first trimester can be considered if treatment of HIV infection is not needed for the woman's own health, intravenous ZDV is administered to the pregnant woman at the time of labor and continued until the cord is clamped, and the other ARV components of the regimen are continued orally during labor. Oral ZDV is administered to the infant for the first 6 weeks of life.[25] For women identified as being HIV infected during labor, intravenous ZDV is recommended together with infant ARV prophylaxis. For infants born to women who have not received prepartum or intrapartum ARV therapy, prophylaxis of the infant with 6 weeks of ZDV is recommended. In the latter 2 situations, some experts may administer additional ARV drugs to the mother and/or infant. The USPHS guidelines for prevention of MTCT of HIV should be consulted for detailed discussion of these more complex situations, and decisions for maternal and infant prophylaxis and therapy in such situations should be made in consultation with a practitioner who is experienced in care of infants with HIV infection.[25]

RISKS OF HIV TESTING IN THE PRENATAL AND NEWBORN PERIODS

A positive HIV antibody test result for an infant identifies HIV infection in the mother and HIV exposure (with possible infection) of the infant. Therefore, even if testing is only performed on the infant after birth, if the infant is found to be HIV-seropositive, the infant's mother will be identified as having HIV infection, which can be associated with personal psychological trauma and societal stigma if the mother does not know that she is infected. Linkage of the newly identified HIV-infected mother to appropriate psychosocial supports and to HIV care programs is important. If the test result is found to be a false-positive, this psychological harm will have occurred needlessly. Thus, the fact that confirmatory testing is required to definitively diagnose HIV infection of the mother, and the need for rapid presumptive treatment of the infant to prevent MTCT should she be HIV infected, should be explained to the mother when performing rapid testing during labor or after delivery. ARV administration to the mother and/or infant may be associated with infant drug toxicity,[33–35] and if the rapid test result is not confirmed to be positive, the benefit/risk ratio may not favor prophylaxis. However, the infant should have received only 1 to 2 days of ARV prophylaxis in such a situation, and short-term toxicity of ARV drugs is limited. Expedited confirmatory testing should be performed to ensure that results are reported quickly so that the duration of infant exposure to ARV drugs is minimized.

CONSENT FOR HIV TESTING

Opt-out consent (documented patient notification, with testing to take place unless rejected by the patient) is associated with higher testing percentages than opt-in consent,[36–38] and universal HIV screening of pregnant women with opt-out consent is recommended by the CDC,[11] the ACOG,[14] and the AAP.[39] As part of its recommendation, the CDC states that HIV screening should be included in the routine panel of prenatal screening tests for all pregnant women and that separate written consent for HIV testing should not be required. The CDC also states that general consent for medical care should be considered sufficient to encompass consent for HIV care.[11] In states where laws or regulations require written informed maternal consent for testing ("opt-in" consent), practitioners should obtain appropriate consent as required. A compendium of state HIV-testing laws can be found at www.ucsf.edu/hivcntr.

In states where laws and regulations require written informed maternal consent for testing, practitioners should work to modify the laws or regulations to permit opt-out consent. Such an advocacy effort is best undertaken with a broad coalition of interested parties throughout the state, including state and local health departments, the state AAP chapter, representatives of the ACOG and the American Academy of Family Physi-

cians, nursing groups, community groups interested in maternal health, and AIDS activist organizations.

Mandatory HIV testing of the newborn infant whose mother has not been tested during pregnancy or in the immediate postpartum period has been associated with high rates of prenatal testing in New York state[7] and may act as a safety net for identifying infants who would not have been tested otherwise. There has not been a study to compare the percentage of women tested before delivery in programs with mandatory newborn testing compared with those with opt-out consent policies. Therefore, an evidence-based recommendation for or against mandatory newborn testing cannot be made. A few states have passed laws that require HIV testing of newborn infants without maternal consent when the HIV-infection status of the mother is unknown. In states where legislation aimed at mandating testing of newborn infants has been proposed, issues have been raised regarding the ethics and legality of this approach, because it diagnoses HIV infection in the mother without her consent for testing. In addition, concerns have been raised about the costs of such screening programs, given the already high numbers of mothers and newborn infants tested in voluntary (opt-out) programs. Regardless of the form of consent used in testing programs, it is important that the results of infant testing be returned as rapidly as possible so that ARV prophylaxis for the infant can be started promptly if needed. Infant ARV prophylaxis is likely to be less effective in the prevention of MTCT of HIV when started later than 12 hours after birth. Optimal prevention of MTCT of HIV requires identification of the mother's HIV status during pregnancy.

TIMING OF TESTING IN PREGNANCY

As noted, testing of the pregnant woman early in pregnancy is recommended to allow informed and timely therapeutic decisions concerning health care for her and for prevention of MTCT of HIV.[11] A second HIV test during the third trimester has been shown to be cost-effective under certain conditions,[40] and the CDC recommends that a second test be performed late in pregnancy but at <36 weeks' gestation for women who are in areas of high incidence, for women delivering in hospitals with HIV prevalence in pregnant women of at least 1 in 1000, and for women at high risk of acquiring HIV (women with a sexually transmitted infection diagnosed during pregnancy, injection drug users and their partners, women who exchange sex or money for drugs, women who are sex partners of HIV-infected persons, women who have had a new or more than 1 sex partner during pregnancy, or women with signs/symptoms of acute HIV infection).[11] However, because risk-based and prevalence-based testing programs may be difficult to implement, some practitioners and hospitals choose to test all pregnant women a second time late in pregnancy, even in the absence of specific prevalence or risk data. Because of the high levels of viral replication observed with acute HIV infection, women who become infected with HIV during pregnancy have a particularly high risk of transmitting HIV to their infants. For women whose HIV status is unknown at the time of presentation in labor, testing should be timed so that results are available to allow predelivery administration of prophylaxis if indicated. For a newborn infant whose mother's HIV status is unknown, testing should be performed quickly enough so that results can be available for infant ARV prophylaxis to begin within 12 hours of birth, as stated previously.[11]

CONCLUSIONS

Universal HIV testing of pregnant women is standard care in the United States. Identification of HIV infection early in pregnancy allows the greatest ability to treat the pregnant woman for her HIV infection for her own health and to prevent MTCT of HIV. Rapid HIV antibody testing allows for timely identification of HIV infection in women even late in pregnancy, during labor, or in the immediate postpartum period as well as HIV exposure in their newborn infants. The results can be available quickly enough to implement successful ARV interventions that can reduce MTCT of HIV when administered to the mother started later in pregnancy or in labor or to the infant when administered within the first few hours of life.

RECOMMENDATIONS

1. Information about HIV infection, prevention of MTCT of HIV, and HIV antibody testing should be provided routinely as part of a comprehensive program of health care for pregnant women.
2. Documented, routine HIV antibody testing should be performed for all pregnant women in the United States after notifying the patient that testing will be performed, unless the patient declines HIV testing (opt-out consent or right of refusal). All HIV antibody testing should be performed in a manner consistent with state and local laws.
3. In states where laws and regulations require written informed maternal consent for testing, health care professionals should work to modify the laws or regulations to permit opt-out consent.
4. All programs for the detection of HIV infection in pregnant women and their infants should periodically evaluate the proportion of women who are not tested. Programs in which an unacceptably high proportion of women do not receive HIV antibody testing should examine the reasons and make appropriate program modifications as needed.
5. Repeat HIV antibody testing is recommended in the third trimester, preferably before 36 weeks' gestation, for women in states with high HIV prevalence in women 15 to 45 years of age, for women delivering in hospitals with HIV prevalence of 1 or more in 1000 pregnant women screened, or for women at increased risk of acquiring HIV (women with a sexually transmitted infection diagnosed during pregnancy, injection drug users and their partners, women who exchange sex or money for drugs, women who are sex partners of HIV-infected per-

sons, women who have had a new or more than 1 sex partner during pregnancy, or women with signs/symptoms of acute HIV infection). Because prevalence-based testing may be difficult to implement and individual risk assessment is unreliable and the risk of MTCT of HIV is high in women who first acquire HIV infection during pregnancy, some experts recommend that repeat HIV screening be considered for all pregnant women in the third trimester.

6. For women in labor with undocumented HIV-infection status during the current pregnancy, maternal HIV antibody testing with opt-out consent, using a rapid HIV antibody test, is recommended. For women with a positive HIV rapid antibody test result, ARV prophylaxis should be administered to the mother and newborn infant on the basis of the positive rapid antibody test result without waiting for results of confirmatory HIV testing, and breastfeeding should not occur. Assistance with the immediate initiation of hand and pump expression to stimulate milk production should be offered to the mother, given the possibility that the confirmatory test results may be negative. If confirmatory test results are negative, prophylaxis should be stopped and breastfeeding may be initiated.
7. Rapid HIV antibody testing should be available on a 24-hour basis at all facilities with an obstetric unit and/or newborn nursery of any level.
8. The health care professional for the newborn infant needs to be informed promptly of maternal HIV serostatus so that appropriate care and testing of the newborn infant can be accomplished and so that ARV prophylaxis can be administered to HIV-exposed infants. The infant medical chart needs to contain documentation of the maternal HIV-infection status. Presence of maternal HIV-infection status on the maternal and infant record should be a standard measure of the adequacy of hospital care for the mother and infant.
9. For newborn infants whose mother's HIV serostatus is unknown, the newborn infant's health care professional should order rapid HIV antibody testing to be performed for the mother or the newborn, with appropriate consent as required by state or local law. Results should be reported to health care professionals quickly enough to allow effective ARV prophylaxis to be administered, if indicated, to the infant as soon as possible after birth but certainly by 12 hours after birth. ARV prophylaxis for the newborn infant should be administered promptly on the basis of a positive rapid antibody test result without waiting for results of confirmatory HIV testing. Breastfeeding should be avoided. Confirmatory testing should be performed, and assistance with hand and pump expression to stimulate milk production should be offered to the mother, given the possibility that the confirmatory test results may be negative. If confirmatory test results are negative (indicating that the infant was not truly exposed to HIV), then ARV prophylaxis should be stopped and breastfeeding may be initiated. If the confirmatory test result is positive, infants should receive ARV prophylaxis for 6 weeks after birth, and they should not breastfeed. Prophylaxis is most effective if administered within 12 hours of birth but may still be effective when administered as late as at 48 hours of life.
10. The full 6-week course of infant ARV prophylaxis, and careful instructions for its administration, should be provided to the family before discharge from the hospital. Payment for this should be covered by all third-party payers.
11. If the mother or infant has a positive test result for HIV antibody, the infant should not breastfeed.
12. In the absence of parental availability for consent to test the newborn infant for HIV antibody, the newborn infant should be tested, ideally within the first 12 hours of life. State and local jurisdictions need to develop procedures to facilitate the rapid evaluation and testing of the infant.
13. For infants of unknown HIV exposure status at the first health supervision visit, HIV antibody testing with appropriate consent should be performed to guide appropriate care and follow-up testing if needed.
14. Care of the mother, fetus, newborn, and child with perinatal exposure to HIV should be performed in consultation with specialists in obstetric and pediatric HIV infection.

AMERICAN ACADEMY OF PEDIATRICS

Committee on School Health

Home, Hospital, and Other Non–School-based Instruction for Children and Adolescents Who Are Medically Unable to Attend School

ABSTRACT. The American Academy of Pediatrics recommends that school-aged children and adolescents obtain their education in school in the least restrictive setting, that is, the setting most conducive to learning for the particular student. However, at times, acute illness or injury and chronic medical conditions preclude school attendance. This statement is meant to assist evaluation and planning for children to receive non–school-based instruction and to return to school at the earliest possible date.

ABBREVIATIONS. IDEA, Individuals with Disabilities Education Act of 1997; AAP, American Academy of Pediatrics; IEP, individual education plan.

All school-aged children are entitled to obtain their education in a school setting. This recommendation exists not only because of legal mandates, but also because of the social and developmental advantages the school setting provides all children, including those with special needs.[1–3] Federal and state legislation clearly dictate that the most appropriate setting for education is the school; this setting should provide the least restrictive environment possible so children can achieve their maximum potential.[3–5]

Homebound instruction is governed by federal and state laws, but implementation may vary not only from state to state, but also from one school district to another. It must be clear that homebound instruction is meant for acute or catastrophic health problems that confine a child or adolescent to home or hospital for a prolonged but defined period of time and is not intended to relieve the school or parent of the responsibility for providing education for the child in the least restrictive environment. This is defined by the Individuals with Disabilities Education Act (IDEA) of 1997 and Section 504 of the Rehabilitation Act of 1973.[5,6] The responsibility of public schools is further defined by the 1999 Supreme Court ruling in *Cedar Rapids Community School District v Garrett F.*[7] Individual pediatricians and state chapters of the American Academy of Pediatrics (AAP) should make themselves aware of how these laws are being implemented in their local communities and states and use them when indicated to keep children in school.

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

Some children, by virtue of acute or chronic medical problems, are unable to attend school on a regular basis. The problems include a diverse set of maladies, such as recovery from surgery, trauma, prolonged recuperation from medical illness, chronic disease, and mental health conditions. Documentation of the student's inability to attend school should be provided by the primary care physician, who should serve as the student's medical home, providing comprehensive care in a setting of continuity in a culturally sensitive environment. This may require the assistance of the appropriate subspecialist, and, in the case of mental health issues, input from the psychiatrist, psychologist, or mental health counselor. The primary care physician must, in collaboration with the school district homebound education team, specify the anticipated duration of the homebound instruction. The need for homebound instruction should be reviewed at the end of that period.

When referral is made because of a mental health diagnosis, this referral should be made for a reasonable period, and psychiatric confirmation should be obtained. There should be evidence that counseling and/or medication is being provided. The rationale is that mental health issues may be less well-defined and more difficult to document. In cases in which there is a difficult diagnosis, such as chronic fatigue syndrome or fibromyalgia, without objective evidence of medical illness, an independent consult should be obtained before acceptance for homebound instruction.

Clearly defined school policies for non–school-based instruction should be established. Absence from school for any period will disrupt the educational process and should prompt the school administrator, school nurse, child's primary care physician, or child's parent to request non–school-based instruction. This non–school-based instruction should be considered as soon as possible for a child who may be absent for a prolonged period (eg, cystic fibrosis) or for a child repeatedly absent for brief periods (eg, hospitalization for acute asthma).[4,8] Information should be exchanged among the school, parents, and primary care physician to select the most appropriate type of non–school-based instruction for the child. For the hospitalized child, educational goals should be addressed in the discharge plan.

The following parameters should be considered during planning for a program of non–school-based instruction. First, non–school-based instruction should attempt, at a minimum, to mirror the progress the

child would make in the classroom. Second, the pediatrician should assess whether the child and teacher place each other at medical risk (eg, contagious disease). Third, a parent or other responsible adult should be available during instruction. Finally, instruction hours and contacts should be based on the health status of the student and on available resources.

The school should identify a team to review the pertinent data for the child with the family and appropriate school administrators. This team could be linked to the IEP (individual education plan) team required by IDEA. Discussions should include review of relevant medical data, consideration of all educational options, a specific duration for services, and a plan for returning the child to the classroom. The decision for non–school-based instruction must be reviewed yearly by the school team with the goal of maintaining academic progress and returning the child to school as soon as possible.

Frequent or intermittent absences attributable to recurring illnesses, such as recurrent asthma or sickle cell vaso-occlusive crises, present a situation requiring frequent communication among parents, school administrators, and the primary care physician. This situation needs to be anticipated, and plans should be made, because there is often a delay between requests for and implementation of non–school-based instruction.

Other important issues include the following: the need to assess community resources to support return to school (transportation), the option of part-time school attendance, and in-school resources needed to allow an early return to school.

CONCLUSION

For children who are unable to attend school, education should be available in an alternative setting, such as a rehabilitation center, hospital, or the home. However, if special services, such as transportation, are provided, most children with medically fragile conditions or who require technological support can attend school. For these children, placement in the least restrictive environment that is medically feasible is the best way to normalize the learning environment.

Alternative educational settings are not intended to replace regular school-based instruction or relieve the school of the responsibility of providing meaningful program adaptations for children with special needs or medically fragile conditions. Pediatricians acting as child advocates by serving as school health advisors or as primary care physicians in the community must ensure that appropriate non–school-based instruction is initiated when necessary and that the child is returned to the regular school setting as soon as possible.

It is beyond the scope of this statement to discuss the complex range of federal, state, and local laws and systems for special education and related services for children and adolescents in public schools. Readers are referred to previous AAP statements for additional background material.[9,10]

abstract

Increasingly, children and adolescents with complex chronic conditions are living in the community. Federal legislation and regulations facilitate their participation in school. Some of these children and adolescents and their families may wish to forego life-sustaining medical treatment, including cardiopulmonary resuscitation, because they would be ineffective or because the risks outweigh the benefits. Honoring these requests in the school environment is complex because of the limited availability of school nurses and the frequent lack of supporting state legislation and regulations. Understanding and collaboration on the part of all parties is essential. Pediatricians have an important role in helping school nurses incorporate a specific action plan into the student's individualized health care plan. The action plan should include both communication and comfort-care plans. Pediatricians who work directly with schools can also help implement policies, and professional organizations can advocate for regulations and legislation that enable students and their families to effectuate their preferences. *Pediatrics* 2010;125:1073–1077

INTRODUCTION

In a groundbreaking statement in 1974, the American Heart Association declared that cardiopulmonary resuscitation (CPR) is not indicated for all patients. Cases of terminal, irreversible illness in which death is an expected outcome do not necessarily merit CPR.[1] Do-not-resuscitate (DNR) orders developed out of efforts to identify patients who do not wish to receive CPR. The terminology eventually changed to "do not attempt resuscitation" (DNAR), acknowledging that resuscitation is not always successful. Some contemporary authors have proposed replacing the term "DNAR" with "allow natural death" (AND) to indicate the positive goal. DNAR orders are physician orders, in contrast to patient directives. In 1994, the American Academy of Pediatrics (AAP) issued guidelines on foregoing life-sustaining medical treatment, including CPR, for children and adolescents.[2] The AAP believes it is ethically acceptable to forego CPR when it is unlikely to be effective or when the risks outweigh the benefits, including the parents' and child's assessment of the child's quality of life.

DNAR orders are not orders to "do nothing," nor do they represent a decrease in the quality or intensity of care. DNAR orders should be implemented in the context of palliative care, including plans for managing pain and other symptoms, as well as addressing emotional and spiritual needs. Components may include disease-directed treatment

but should always include anticipatory and aggressive symptom control. Spiritual, psychological, and social needs are addressed through delineation of the preferred site for dying, the desired conditions of care, who will provide such care, and even who may be in attendance.[3,4]

Although DNAR orders have become accepted within inpatient health care facilities, such as hospitals and nursing homes, there have been challenges to coordinating end-of-life care in other settings, particularly in situations in which the use of CPR is an established standard of care, such as for emergency medical services (EMS). In the late 1980s, states developed mechanisms, such as bracelets and standardized order forms, to alert EMS personnel to patients who did not wish to receive CPR.[5] These mechanisms have various names including prehospital, out-of-hospital, portable, or durable DNAR policies. A task force in Oregon, for example, developed an order form that they referred to as "physician orders for life-sustaining treatment," which specified patients' preferences regarding 4 separate types of medical treatment: antibiotics, nutrition, hydration, and CPR.[6] To encourage compliance, policies may provide immunity from criminal and civil liability and disciplinary action to particular categories of individuals if they act in good faith. Although common, such laws and regulations are not universal and frequently do not apply to children and teenagers.[7]

Increasingly, children and adolescents with life-limiting conditions are living in the community and attending school. Some may wish to forego CPR. It is estimated that on any given day, 2500 adolescents and 1400 preadolescent children are within 6 months of dying from a complex chronic condition (CCC). Although in the United States, deaths attributable to CCCs have decreased over time across all pediatric age groups, those who are dying from a CCC are increasingly likely to do so away from a medical facility. In Washington State, the percentage of older children and young adults with a CCC who died at home increased from 21% in 1980 to 43% in 1998.[8] Concern about the potential ineffectiveness of CPR applied out-of-hospital is justified. The authors of a recent review summarized representative studies by stating that "[s]urvival to hospital discharge typically occurs for $<$10% of these children, and many have severe neurologic sequelae."[9] Some individuals with a CCC and their families may, therefore, wish to forego CPR.

HONORING DNAR REQUESTS IN THE SCHOOL SETTING

Recent health care and societal trends have made it possible for children with CCCs to attend school, which in turn has raised the issue of accommodating students' and families' preferences regarding health care in this context. The Individuals with Disabilities Education Act of 1997 (IDEA) and section 504 of the Rehabilitation Act of 1973 ensured that children with health care needs will be accommodated in school. As a result, more students with CCCs have been able to attend school, despite inherent medical risks and requirements that accompany them. Attending school may be particularly important for children and adolescents with life-limiting conditions. For example, it may permit them to accomplish crucial developmental tasks such as socializing with their peer group. In 2000, the AAP issued a statement advocating that pediatricians assist parents who desire a DNAR order to develop a consensual agreement with school officials about goals and procedures for in-school medical treatment.[10]

Although the law mandates that the school district accommodate students with CCCs by providing supplementary aid and health care services, fulfilling the spirit of the law under all circumstances can prove challenging. The Individuals with Disabilities Education regulations exempt schools from providing "medical services" while stipulating that the provision of intermittent care necessary for the student's participation cannot be used as grounds for exclusion. To fully integrate students with educational, health, or mental health challenges, schools use an individualized education plan (IEP) and/or a 504 plan. These plans, developed collaboratively by the student, family, and school district, articulate the services to be provided to accommodate the child. Within this process, health care needs can be addressed by an individualized health care plan (IHCP), which also may include an emergency care plan. These plans represent an important framework for extending health care into the school environment, because they are integrated with the student's educational IEP or 504 plan. The essential role of the licensed school nurse in the development and implementation of a student's IHCP is supported by the AAP.[11] The IHCP is a crucial factor for the participation of children and adolescents with CCCs in school, and it offers them the opportunity to remain in school.[12]

Although DNAR requests in schools are becoming more accepted, a minority of school districts have adopted policies on this topic. The percentage of schools in which health services staff were reported to follow DNAR orders increased from 29.7% in 2000 to 46.2% in 2006 according to a Centers for Disease Control and Prevention survey.[13] Another study revealed that 80% of the nation's 50 largest school districts and districts in 31 additional state capitals did not have a policy, regulation, or

protocol supporting a student's DNAR order in 2005.[7] For a DNAR order to be applied within the school setting requires more than just the cooperation of the school district. Without an overarching local or state regulatory or legal framework, honoring the request and not performing CPR potentially represents a liability for the staff members who honor them.

After the AAP policy statement on DNAR orders in schools was published in 2000, articles and commentaries from physicians, lawyers, school nurses, and school administrators raised several concerns.[14,15] Some argued that schools are not medical facilities. Without education, their staff members have a limited understanding of a child's medical condition, care requirements, or expected course. In a cardiac or respiratory arrest situation, school staff members lack the training and perspective regarding when to effectuate a DNAR request. Faced with developing symptoms that may culminate in cardiac or respiratory arrest in a child, they may be uncertain how to proceed. A student's arrest may not be the result of the underlying disease process but rather caused by another, reversible cause. Some individuals also may voice an unwillingness to "stand around and do nothing" for legal or moral reasons. In addition, an arrest is a startling event to witness and potentially traumatic for bystanders when CPR is withheld.

It is important for the pediatrician to understand, acknowledge, and address these concerns openly and sympathetically. The DNAR order directs laypeople trained in CPR to forego using their resuscitation skills in the case of an arrest, irrespective of its etiology. The student's IHCP should direct the staff to provide specified comfort-care measures such as holding him or her, providing supplemental oxygen, or keeping the student warm. Notification of the school nurse and/or activation of EMS may both provide staff much-needed support and the student a broader range of interventions, if warranted. Parents and adolescents need to acknowledge these realities as part of their permission and assent. Pediatricians and school nurses should collaborate to develop plans that can be successfully implemented in the school environment.

Several commentators have expressed concern regarding the effect of withholding CPR on the other students. The implementation of DNAR requests in schools is not, however, the only situation that may engender distress for bystanders. Witnessing unsuccessful CPR may also be traumatic.[16] Action plans should specify a location to which staff can move the student in case of an arrest. In addition, many schools have developed counseling resources for a wide variety of potentially traumatic events.

The legal context in which such planning occurs is complex, and pediatricians and school staff members who honor a DNAR request may not be explicitly protected by the law.[7,14] (Similar issues related to EMS personnel are beyond the scope of this statement.) The ability to honor DNAR requests in schools may be influenced by a variety of factors including state statutes or regulation, judicial decisions, state attorney general's or local prosecutor's actions, and local school district policy or procedures. Although most states permit physicians to write out-of-hospital DNAR orders, few states provide legal authority for advance health care directives by minors. Even fewer states provide explicit legal protection against liability for school personnel who honor a student's DNAR request. Because of the complexity and fluidity of state laws and regulations, pediatricians should contact the AAP Division of State Government Affairs for current information. They should also contact local school districts for information about related policies and procedures.

Pediatricians, therefore, need to respect the school staff's concerns when approaching them on behalf of a family who desires to forego CPR. Still, as results of a study by Kimberly et al[7] illustrated, 1 of 5 school districts that reported having a DNAR policy are in states that do not offer explicit legal indemnification, a finding corroborated by the School Health Policies and Programs Study of the Centers for Disease Control and Prevention.[13] Creating a legal framework in which schools and their personnel are immune from liability when complying with a DNAR request in good faith is a crucial step toward furthering acceptance of DNAR requests in schools.

Even when medical justification and legal indemnification exist at the local and state levels, the schools still need support in adopting policies on DNAR orders. The pediatrician's best ally when approaching the school staff is the school nurse. Although school nurses typically are the health authorities within schools, staffing restrictions may limit their availability during an arrest. Thus, individuals without formal clinical training may be the first personnel at the scene and, therefore, need guidance. To ensure the effectiveness of the DNAR plan within the child's IHCP, the pediatrician may need to help school and local EMS staff to understand its implementation.[17] One means of promoting an informed and prepared population for the circumstances surrounding a DNAR order is to incorporate teaching about DNAR orders within training on CPR.

THE PEDIATRICIAN'S ROLES

Pediatricians and their professional organizations have a variety of potential roles in supporting patients and

their families in their efforts to achieve school integration, especially in the face of life-limiting conditions. Primary care providers and subspecialists who serve as a medical home frequently participate in the development of IEP and/or 504 plans. When appropriate, they can help the school nurse to integrate a DNAR request into the student's IHCP. The pediatrician can assist the family to educate the relevant parties about the child or adolescent's condition, potential complications, and health care goals. It is crucial that physicians be open and sympathetic when listening to the concerns of others about dealing with a potential arrest situation. The most effective tool a physician can offer school staff members is a specific action plan (see Table 1). Presentation of the order to the EMS team, along with the child's use of a medical identification bracelet indicating the DNAR status, will ensure recognition of the child's and family's wishes for end-of-life care. In the unusual event that a student with a standing DNAR order does experience cardiac or respiratory arrest at school, the communication plan and physician's clearly written comfort-care plan will be critical for directing staff actions in lieu of starting CPR. The AAP supports adequate physician reimbursement for these important services,[18] which may be reported as part of the care plan oversight codes (*Current Procedural Terminology*[19] [CPT] codes 99339–99340).

Pediatricians who work directly with schools as school physicians or consultants can help school nurses, administrators and staff, the school board, the district's legal counsel, and EMS personnel understand these issues and participate in developing appropriate school policies (see Table 2). Pediatricians who create CPR-training resources should consider including information regarding requests to withhold interventions. Pediatricians and their professional organizations can assist these efforts by advocating for regulations and laws to support families and their children's wishes by protecting all individuals who act in accord with a DNAR request.

TABLE 1 Components of a DNAR Order

The DNAR order within the IHCP should outline the child's needs and provide specific directives for the staff to follow in the event of a cardiac or respiratory arrest. The elements of the plan should include:
Identification of staff members who should be informed of and educated about the IHCP and the DNAR order
The location to which the child will be moved if serious distress or sudden death should occur at school or plans to remove onlookers from the area if the child cannot be moved
Which comfort measures should be offered to the child
Protocols for notification of the prearranged EMS provider
Protocols for notification of the family and primary care physician
Protocols that define steps to take should the child die in school
Designation of the clinician who will pronounce the child's death (physician, nurse practitioner, or physician assistant)
A specific plan for removing the body from the school to a local health care facility or designated funeral home, including such details as the type of vehicle to be used, where it will park at the school, who will clear the corridors, and what kind of transport equipment will be required to move the body to the waiting vehicle

TABLE 2 Factors Shared by School Districts That Honor DNAR Orders

Presence of a district policy on the approach to the child with a DNAR order
Special consideration to meeting the needs both of the child and family and the other students and staff
A process for ensuring privacy during the event, such that students and staff other than those designated in the IHCP are removed from the scene
Involvement of the child's primary care clinician, the district's legal counselor, and the local EMS provider to reach an agreement on the care that EMS is able to provide
Reconciliation of all state statutes, including those on pronouncement, involvement of the medical examiner, and the procedure for limiting EMS actions at the scene
A process for conveying the plan to the school's staff with the assistance of the school nurse
Postevent planning for assisting the school's community to deal with the death of a student

RECOMMENDATIONS

1. Whether in a medical facility or in the community, the family of a child or adolescent with a CCC should be able to direct their caregivers to withhold CPR when its application is unlikely to be effective or when the risks outweigh the benefits.
2. Pediatricians should work with school nurses to incorporate the student's and family's preferences within the student's IHCP, including not only the decision to forego CPR but also a clearly written, specific approach for providing him or her comfort care. Physicians should receive adequate reimbursement for providing these important services.
3. Pediatricians, particularly those contracted by school districts, can support patients and their families by encouraging school administrators and staff members to implement a policy that accommodates health care preferences, including DNAR orders, at the school-district and school-building levels.
4. Organizations that develop training materials on CPR are encouraged to include information about the possible outcomes of CPR and about the option of withholding resuscitation as part of their curriculum.
5. For decisions to forego CPR to be respected outside the hospital environment, pediatricians, pediatric medical subspecialists and surgical specialists, AAP chapters, and

local leaders will need to advocate for regulations and laws that respect the rights of families and, when appropriate, children and adolescents to direct end-of-life care. Such laws should protect the school, school staff members, and EMS staff members who act in accordance with a decision by the family of a student with a CCC to forego CPR.

American Academy of Pediatrics
DEDICATED TO THE HEALTH OF ALL CHILDREN™

POLICY STATEMENT

Hospital Discharge of the High-Risk Neonate

Organizational Principles to Guide and Define the Child Health Care System and/or Improve the Health of All Children

Committee on Fetus and Newborn

ABSTRACT

This policy statement updates the guidelines on discharge of the high-risk neonate first published by the American Academy of Pediatrics in 1998. As with the earlier document, this statement is based, insofar as possible, on published, scientifically derived information. This updated statement incorporates new knowledge about risks and medical care of the high-risk neonate, the timing of discharge, and planning for care after discharge. It also refers to other American Academy of Pediatrics publications that are relevant to these issues. This statement draws on the previous classification of high-risk infants into 4 categories: (1) the preterm infant; (2) the infant with special health care needs or dependence on technology; (3) the infant at risk because of family issues; and (4) the infant with anticipated early death. The issues of deciding when discharge is appropriate, defining the specific needs for follow-up care, and the process of detailed discharge planning are addressed as they apply in general to all 4 categories; in addition, special attention is directed to the particular issues presented by the 4 individual categories. Recommendations are given to aid in deciding when discharge is appropriate and to ensure that all necessary care will be available and well coordinated after discharge. The need for individualized planning and physician judgment is emphasized. *Pediatrics* 2008;122:1119–1126

INTRODUCTION

The decision of when to discharge an infant from the hospital after a stay in the NICU is complex.[1] This decision is made primarily on the basis of the infant's medical status but is complicated by several factors. These factors include the readiness of families for discharge, differing opinions about what forms of care can be provided at home, and pressures to contain hospital costs by shortening the length of stay. Insofar as possible, determination of the readiness for discharge should be based on peer-reviewed scientific evidence. Shortening the length of a hospital stay may benefit the infant and family by decreasing the period of separation of infant and parents; moreover, the infant may benefit from shortening its exposure to the risks of hospital-acquired morbidity. However, the overriding concern is that infants may be placed at risk of increased mortality and morbidity by discharge before physiologic stability is established. Infants born preterm with low birth weight who require neonatal intensive care experience a much higher rate of hospital readmission and death during the first year after birth compared with healthy term infants.[2–5] Careful preparation for discharge and good follow-up after discharge may reduce these risks. It takes time for the family of a high-risk infant to prepare to care for their infant in a home setting and to obtain the necessary support services and mobilize community resources. With increased survival of very preterm and very ill infants, many infants are discharged with unresolved medical issues that complicate their subsequent care. Infants are often discharged requiring more care and closer follow-up than was typical in the past. In addition, societal and economic forces have come to bear on the timing and process of discharge and follow-up care. As a result, health care professionals need guidance in assessing readiness for discharge and planning for subsequent care. This policy statement, therefore, addresses 4 broad categories of high-risk infants: (1) the preterm infant; (2) the infant with special health care needs or dependence on technology; (3) the infant at risk because of family issues; and (4) the infant with anticipated early death. This policy statement updates a previous guideline published by the American Academy of Pediatrics in 1998.[1]

SIDS—sudden infant death syndrome

CATEGORIES OF HIGH-RISK INFANTS

The Preterm Infant

Historically, preterm infants were discharged only when they achieved a certain weight, typically 2000 g (5 lb). However, randomized clinical trials[6–8] have shown that earlier discharge is possible without adverse health effects

when preterm infants are discharged on the basis of physiologic criteria rather than body weight. Although the population characteristics, the nature and results of the outcome measures, and the content of the early discharge programs in these studies varied, the common elements included:

- physiologic stability;
- an active program of parental involvement and preparation for care of the infant at home;
- arrangements for health care after discharge by a physician or other health care professional who is experienced in the care of high-risk infants; and
- an organized program of tracking and surveillance to monitor growth and development.

The 3 physiologic competencies that are generally recognized as essential before hospital discharge of the preterm infant are oral feeding sufficient to support appropriate growth, the ability to maintain normal body temperature in a home environment, and sufficiently mature respiratory control. These competencies are achieved by most preterm infants between 36 and 37 weeks' postmenstrual age,[7,9] but maturation of respiratory control to a point that allows safe discharge may take longer, occasionally up to 44 weeks' postmenstrual age.[10,11] Although interrelated, not all competencies are achieved by the same postnatal age in a given infant. The pace of maturation is influenced by the birth weight, the gestational age at birth, and the degree and chronicity of neonatal illnesses. Infants born earlier in gestation and with more complicated medical courses tend to take longer to achieve these physiologic competencies.

Home monitors are rarely indicated for detection of apnea solely because of immature respiratory control, in part because infants with immature respiratory control, in general, are still hospitalized until they are no longer at risk of apnea of prematurity. Use of a home monitor does not preclude the need for demonstrated maturity of respiratory control before discharge and should not be used to justify discharge of infants who are still at risk of apnea. Home monitors are not indicated for prevention of sudden infant death syndrome (SIDS) in preterm infants,[12] although preterm infants are at increased risk of SIDS.[13] Formal laboratory analyses of breathing patterns (ie, "pneumograms") are of no value in predicting SIDS[12] and are not helpful in identifying patients who should be discharged with home monitors.

Preterm infants should be placed supine for sleeping,[14–17] just as term infants should, and the parents of preterm infants should be counseled about the importance of supine sleeping in preventing SIDS. Hospitalized preterm infants should be kept predominantly in the supine position, at least from the postmenstrual age of 32 weeks onward, so that they become acclimated to supine sleeping before discharge. Supine positioning for sleep has led to an increase in positional skull deformity, especially in preterm infants but also in term infants[16,18,19]; although only cosmetic, these deformities can be quite disturbing to parents. Ways of safely preventing and treating deformation of the skull have been identified and are the subject of further investigation.[15,18,20]

Late-preterm infants, those born between 34 and 37 weeks' gestation, are at increased risk of having feeding problems and hyperbilirubinemia after discharge. These problems can be minimized but not wholly prevented by careful discharge planning and close follow-up after discharge.[21]

The Infant With Special Health Care Needs or Dependence on Technology

In recent years, increasing numbers of children with unresolved medical problems or special health care needs have been discharged requiring some form of supportive technology.[22] For newborn infants, the main types of technological support needed are nutritional support and respiratory support, including supplemental oxygen. This discussion will focus on nutritional and respiratory support, although other forms of home technological support are sometimes needed, including intravenous medications, bladder catheterization, and renal replacement therapy.

For most preterm infants and those with complex medical problems, oral feeding is best learned in the hospital under the care of expert physicians, nurses, and feeding therapists. Gavage feeding has been used safely in the home setting for infants who are not able to feed well enough by breast or bottle.[23–25] This practice has a limited role and should be considered only when feeding is the last issue requiring continued hospitalization. Not all parents are capable of safely managing home gavage feedings. When little or no progress is being made with oral feeding skills and long-term tube feeding seems inevitable, placement of a feeding gastrostomy tube provides another alternative method of feeding.[26] Unless precluded by neurologic deficits that threaten airway defense, oral feeding should be continued along with tube feeding so that oral feeding skills can continue to develop. Ordinarily, gavage or gastrostomy tube feedings are used to complement what is eaten orally to ensure adequate total intake. Home intravenous nutritional support is sometimes needed when enteral feeding is not possible or is limited by short-bowel syndrome or poor gastrointestinal function. Parenteral nutrition in the home requires careful assessment of the caregivers and home environment, thorough education of caregivers, and the support of a well-qualified home-care company.[27]

Home oxygen therapy for infants with bronchopulmonary dysplasia has been used as a means of achieving earlier hospital discharge while avoiding the risks of growth failure and cor pulmonale resulting from marginal oxygenation.[28–33] Sufficient oxygen should be delivered to maintain oxygen saturation at an acceptable level during a range of activities.[34–36] Infants who are discharged on supplemental oxygen are often also discharged on a cardiorespiratory monitor or pulse oximeter in case the oxygen should become dislodged or the supply depleted. Reducing or stopping supplemental oxygen should be supervised by the physician or other

health care professional and attempted only when the infant demonstrates normal oxygen saturation, good growth velocity, and sufficient stamina for a full range of activity.[36] Tracheostomy is sometimes required for neonates with upper airway abnormalities or occasionally for infants who cannot be weaned from assisted ventilation.[37–40] Good parental teaching and coordinated multidisciplinary follow-up care are essential for these infants. Infants who require home ventilation should also be on a cardiorespiratory monitor in case the airway should become obstructed, but the home ventilator should also have a disconnect alarm to alert caregivers to ventilator disconnection. Home ventilation requires qualified personnel to provide bedside care; in most cases, home-nursing support will be needed for at least part of the day.

The Infant at Risk Because of Family Issues

Preterm birth and prolonged hospitalization are known family stressors and risk factors for subsequent family dysfunction and child abuse.[41–43] In addition to preterm birth and prolonged hospital stay, birth defects and disabling conditions are also risk factors.[44] Maternal factors include lower educational level, lack of social support, marital instability, and fewer prenatal care visits.[41,42] In 1 study, significantly fewer family visits during the stay in the NICU had occurred for infants in whom subsequent maltreatment was documented.[41] Parental substance abuse is another factor that places the infant at risk, both because of adverse effects on the developing fetus in utero and because of possible postnatal exposure to drugs through breastfeeding or by inhalation. Moreover, the drug-seeking behaviors of parents may compromise the safety of the child's environment. Sequelae such as attachment disturbances, behavioral and developmental disorders, and child maltreatment have been observed frequently among children born to substance abusers.

Identifying effective strategies to help protect the infant who is at increased risk because of family reasons has been elusive. Most interventions have focused on multidisciplinary teams that provide follow-up monitoring, including home visits.[45] However, the efficacy of these interventions has been difficult to demonstrate. At the very least, it is hoped that an organized approach to planning for discharge can identify infants who require extra support or whose home environments present unacceptable risks.

The Infant With Anticipated Early Death

For many infants with incurable, terminal disorders, the best place to spend the last days or weeks of life is at home.[46] In these situations, the family provides most of the care, often with support by staff from a community hospice organization. In rare instances, withdrawal of assisted ventilation can occur in the home.[47] In preparing to discharge an infant for home hospice care, several aspects must be considered in addition to the usual factors.[48] These preparations include arrangements for medical follow-up and home-nursing visits; management of pain and other distressing symptoms; arrangements for home oxygen or other equipment and supplies; providing the family with information on bereavement support for the parents, siblings, and others; discussion of possible resources for respite of caregivers; and assistance in addressing financial issues. If appropriate, a letter should be provided for the family to show to other caregivers or emergency medical workers indicating that the child should not be resuscitated. The focus of planning efforts should be to enhance the quality of the infant's remaining life for the benefit of both the infant and his or her family.

TIMING OF DISCHARGE

The appropriate time for discharge is when the infant demonstrates the necessary physiologic maturity (in the case of the preterm infant), discharge planning and arrangements for follow-up and any home care have been completed, and the parents have received the necessary teaching and have demonstrated their mastery of the essential knowledge and skills. In selected cases, an infant may be discharged before one of the infant's physiologic competencies has been met, provided the health care team and the parents agree that this is appropriate and suitable plans have been made to provide additional support needed to ensure safe care at home, such as tube feeding, cardiorespiratory monitoring, or home oxygen. The standard, default criterion remains that the infant should be sufficiently mature to need no such assistance at home. The decision to facilitate earlier discharge by providing such additional support should be made only as a mutual decision by the health care team and the parents.

Before discharge, the eyes of qualifying infants should be examined at specified times by an ophthalmologist with expertise in the diagnosis of retinopathy of prematurity.[49] The infant's hearing should be evaluated[50,51]; the results of the newborn metabolic screen should be reviewed[52]; appropriate immunizations should be given, if not given previously; and palivizumab should be given to qualifying infants during respiratory syncytial virus season.[53,54]

Sometimes infants are transferred to a hospital closer to home so that the family may visit more easily. This is appropriate provided appropriate medical care is available in the receiving hospital, including capabilities for ophthalmologic examinations to screen for retinopathy of prematurity and the experience and resources for planning discharge and follow-up care.

DISCHARGE PLANNING

High-risk infants should receive primary medical care from a physician with expertise in the care of patients who have spent time in the NICU, often in partnership with 1 or more specialized clinics in the discharging medical center. To ensure continuity of care after discharge, infants with unresolved medical issues that persist after their hospital stay, such as bronchopulmonary dysplasia or feeding dysfunction, should be comanaged by a neonatologist or other medical subspecialist from the hospital at which most of the care was provided. The

subspecialist provides consultation to the primary physician about issues such as the weaning and discontinuation of supplemental oxygen. Most high-risk infants should also be enrolled in a follow-up clinic that specializes in the neurodevelopmental assessment of high-risk infants. This neurodevelopmental follow-up is sometimes integrated with the child's visits to the neonatologist. Standardized assessments should be performed in the follow-up clinic at specific ages through early childhood.[55–57]

The care of each high-risk neonate after discharge must be coordinated carefully to provide ongoing multidisciplinary support of the family. The discharge-planning team should include parents, the neonatologist, neonatal nurses and nurse practitioners, and the social worker. Other professionals, such as surgical specialists and pediatric medical subspecialists, respiratory, physical, occupational, and speech therapists, infant educators, nutritionists, home-health care company staff, and others may be included as needed.

Discharge planning should begin early in the hospital course. The goal of the discharge plan is to ensure successful transition to home care. Essential discharge criteria are a physiologically stable infant, a family who can provide the necessary care with appropriate support services in the community, and a primary care physician who is prepared to assume the responsibility with appropriate backup from specialist physicians and other professionals as needed.[55,56] Six critical components must be included in discharge planning.

1. Parental Education

Parental contact and involvement in the care of the infant should be encouraged from the time of admission. The participation of the parents in whatever way possible from the beginning has a positive effect on their confidence in handling the infant and readiness to assume full responsibility for the infant's care at home.

The development of an individualized teaching plan helps parents to acquire the skills and judgment needed to care for their infant. A written checklist or outline of the specific areas and tasks to be mastered increases the likelihood that parents and other caregivers will receive complete instructions and experience. Caregivers and parents must understand that the infant's immaturity and medical status will require increased care and vigilance at home beyond that of the usual parental role. Thus, ample time for teaching the parents and caregivers the techniques and the rationale for each item in the care plan is essential. Requesting return demonstrations by the parents of their new knowledge, parent rooming-in, and telephone follow-up by hospital staff all facilitate parental education and adaptation to their infant's care. Although it is important for the parents to understand that their child may need extra care and surveillance, the infant's fragility should not be overstated. If this occurs, the parents may become excessively protective, which can restrict the child's social development and lead to behavior problems.[58] Parents should be coached in communicating about the infant with any older siblings, who may not fully understand the infant's condition and may even imagine themselves to be responsible for the vulnerable state of their younger brother or sister.

Insofar as possible, at least 2 responsible caregivers should be identified and learn the necessary care for each infant. The demands of home care can be physically and emotionally draining, especially at first, for infants who require frequent feeding. Young mothers who do not live with a parent or the father of the infant have been shown to be especially vulnerable to the strains of home care. Even in a 2-parent family, the primary caregiver may become ill and need relief.

2. Completion of Appropriate Elements of Primary Care in the Hospital

Preparing the infant for transition to primary care begins early in the hospitalization with administration of immunizations at the recommended postnatal ages, regardless of prematurity or medical condition,[59] completion of metabolic screening,[52] assessment of hearing by an acceptable electronic measurement,[50,51] and baseline neurodevelopmental and neurobehavioral assessment. For infants at risk, appropriate funduscopic examination for retinopathy of prematurity should be performed by an ophthalmologist who is skilled in the evaluation of the retina of the preterm infant.[49] Assessment of hematologic status is recommended for all infants because of the high prevalence of anemia after neonatal intensive care. Very preterm infants and those who have received parenteral nutrition for prolonged periods may be at risk of hypoproteinemia, vitamin deficiencies, and bone mineralization abnormalities; therefore, evaluation for nutritional or metabolic deficiencies may be indicated. When discharge is near, the high-risk infant should be evaluated to ensure physiologic stability in an appropriate car seat or car bed.[60–62]

3. Development of Management Plan for Unresolved Medical Problems

Review of the hospital course and the active problem list of each infant and careful physical assessment will reveal any unresolved medical issues and areas of physiologic function that have not reached full maturation. From such a review, the diagnostic studies required to document the current clinical status of the infant can be identified and management can be continued or adjusted as appropriate. The intent should be to ensure implementation of appropriate home-care and follow-up plans.

4. Development of the Comprehensive Home-Care Plan

Although the content of the home-care plan may vary with the infant's diagnoses and medical status, the common elements include (1) identification and preparation of the in-home caregivers, (2) formulation of a plan for nutritional care and administration of any required medications, (3) development of a list of required equipment and supplies and accessible sources, (4) identification and mobilization of the primary care physician, the necessary and qualified home-care personnel and community support services, (5) assessment of the adequacy of the physical facilities within the home, (6) development

of an emergency care and transport plan, and (7) assessment of available financial resources to ensure the capability to finance home-care costs. The input of the primary care physician in formulating the home-care plan of the technology-dependent infant is essential. Many infants, particularly extremely preterm and technology-dependent infants, require continued care by multiple specialists and subspecialists, who should be included in the predischarge assessment and discharge planning.

5. Identification and Involvement of Support Services

The infant's optimal outcome ultimately depends on the capacity and effort of the family. The psychological, social, economic, and educational condition and needs of the family should be addressed from the beginning of the infant's hospitalization, noting strengths that can support the infant's continued adaptation, growth, and development and any risk factors that may contribute to an adverse infant outcome. The availability of social support is essential for the success of every parent's adaptation to the home care of a high-risk infant. Before discharge and periodically thereafter, a review of the family's needs, coping skills, use of available resources, financial problems, and progress toward goals in the home care of their infant should be evaluated. After the social support needs of the family have been identified, an appropriate, individualized intervention plan using available community programs, surveillance, or alternative care placement of the child may be implemented.

6. Determination and Designation of Follow-Up Care

In general, the attending neonatologist or other discharging physician has the responsibility for coordination of follow-up care, although in some institutions this responsibility may be delegated to another professional. A primary care physician (or "medical home") should be identified well before discharge to facilitate the coordination of follow-up care planning between the staff responsible for planning the discharge and the primary health care professionals. Pertinent information about the nursery course, including a discharge summary, and the home-care plan should be given to the primary care physician before the infant's discharge. In specialty center units, the primary care attending physician should work with the neonatologist in coordinating the discharge planning.

Arrangements for an initial appointment with the primary care physician should be made before discharge. Specific follow-up appointments with each involved surgical specialist and pediatric medical subspecialist should be made, giving attention to grouping the appointments as much as possible for the convenience of the family. A plan should be developed and discussed for emergency care and transportation to a hospital, should it be necessary.

Periodic evaluation of the developmental progress of every infant is essential for identifying deviations in neurodevelopmental progress at the earliest possible point, thereby facilitating entry into early intervention programs. The primary care physician with appropriate skills, the pediatric medical subspecialist, or clinic personnel may provide longitudinal developmental follow-up. When need for input from multiple disciplines is identified before discharge, a clinic that provides multidisciplinary care, usually in an academic or tertiary center, may be the least cumbersome option for the family.

SPECIAL CONSIDERATIONS

Many infants are transported to hospitals nearer to their family homes for convalescent care. In these hospitals, the discharge-planning process should follow the same principles as those outlined previously in this statement for an infant being discharged from a subspecialty center. It is especially important that periodic examination by a qualified ophthalmologist be available for infants who still require evaluation for retinopathy of prematurity.

In caring for the discharged high-risk infant, use of community resources, both public and private, should be encouraged. The goal should be to provide coordinated care and family support. Efficient teamwork by health care professionals is imperative. Home-nursing visits are often indicated. When this is so, it is important to use experienced nurses who are qualified to perform the required assessments. When choosing a home-care company or agency for technology-dependent infants, it is essential that previous performance and existing quality-control programs be considered.

RECOMMENDATIONS

The following recommendations are offered as a framework for guiding decisions about the timing of discharge. It is prudent for each institution to establish guidelines that ensure a consistent approach yet allow some flexibility on the basis of physician and family judgment. It is of foremost importance that the infant, family, and community be prepared for the infant to be safely cared for outside the hospital.

Infant Readiness for Hospital Discharge

The infant is considered ready for discharge if, in the judgment of the responsible physician, the following have been accomplished:

- A sustained pattern of weight gain of sufficient duration has been demonstrated.
- The infant has demonstrated adequate maintenance of normal body temperature fully clothed in an open bed with normal ambient temperature (20–25°C).
- The infant has established competent feeding by breast or bottle without cardiorespiratory compromise.
- Physiologically mature and stable cardiorespiratory function has been documented for a sufficient duration.
- Appropriate immunizations have been administered.
- Appropriate metabolic screening has been performed.

- Hematologic status has been assessed and appropriate therapy has been instituted, if indicated.
- Nutritional risks have been assessed and therapy and dietary modification has been instituted, if indicated.
- Hearing evaluation has been completed.
- Funduscopic examinations have been completed, as indicated.
- Neurodevelopmental and neurobehavioral status has been assessed and demonstrated to the parents.
- Car seat evaluation has been completed.
- Review of the hospital course has been completed, unresolved medical problems have been identified, and plans for follow-up monitoring and treatment have been instituted.
- An individualized home-care plan has been developed with input from all appropriate disciplines.

Family and Home Environmental Readiness

Assessment of the family's caregiving capabilities, resource availability, and home physical facilities has been completed as follows:

- identification of at least 2 family caregivers and assessment of their ability, availability, and commitment;
- psychosocial assessment for parenting strengths and risks;
- a home environmental assessment that may include on-site evaluation; and
- review of available financial resources and identification of adequate financial support.

In preparation for home care of the technology-dependent infant, it is essential to complete an assessment documenting availability of 24-hour telephone access, electricity, safe in-house water supply, and adequate heating. Detailed financial assessment and planning are also essential. Parents and caregivers should have demonstrated the necessary capabilities to provide all components of care, including:

- feeding, whether by breast, bottle, or an alternative technique, including formula preparation, if required;
- basic infant care, including bathing; skin, cord, and genital care; temperature measurement; dressing; and comforting;
- infant cardiopulmonary resuscitation and emergency intervention;
- assessment of clinical status, including understanding and detection of the general early signs and symptoms of illness as well as the signs and symptoms specific to the infant's condition;
- infant safety precautions, including proper infant positioning during sleep and proper use of car seats or car bed;
- specific safety precautions for the artificial airway, if any; feeding tube; intestinal stoma; infusion pump; and other mechanical and prosthetic devices, as indicated;
- administration of medications, specifically proper storage, dosage, timing, and administration and recognition of potential signs of toxicity;
- equipment operation, maintenance, and problem solving for each mechanical support device required; and
- the appropriate technique for each special care procedure required, including special dressings for infusion entry site, intestinal stoma, or healing wounds; maintenance of an artificial airway; oropharyngeal and tracheal suctioning; and physical therapy, as indicated.

Specific modification of home facilities must have been completed if needed to accommodate home-care systems. Plans must be in place for responding to loss of electrical power, heat, or water and for emergency relocation mandated by natural disaster.

Community and Health Care System Readiness

An emergency intervention and transportation plan have been developed and emergency medical services providers have been identified and notified, if indicated.

Follow-up care needs have been determined, appropriate providers have been identified, and appropriate information has been exchanged, including the following:

- A primary care physician has been identified and has accepted responsibility for care of the infant.
- Surgical specialty and pediatric medical subspecialty follow-up care requirements have been identified and appropriate arrangements have been made.
- Neurodevelopmental follow-up requirements have been identified and appropriate referrals have been made.
- Home-nursing visits for assessment and parent support have been arranged, as indicated by the complexity of the infant's clinical status and family capability, and the home-care plan has been transmitted to the home health agency.
- For breastfeeding mothers, information on breastfeeding support and availability of lactation counselors has been provided.

The determination of readiness for care at home of an infant after neonatal intensive care is complex. Careful balancing of infant safety and well-being with family needs and capabilities is required while giving consideration to the availability and adequacy of community resources and support services. The final decision for discharge, which is the responsibility of the attending physician, must be tailored to the unique constellation of issues posed by each infant's situation.

Committee on Injury and Poison Prevention

The Hospital Record of the Injured Child and the Need for External Cause-of-Injury Codes

ABSTRACT. Proper record-keeping of emergency department visits and hospitalizations of injured children is vital for appropriate patient management. Determination and documentation of the circumstances surrounding the injury event are essential. This information not only is the basis for preventive counseling, but also provides clues about how similar injuries in other youth can be avoided. The hospital records have an important secondary purpose; namely, if sufficient information about the cause and mechanism of injury is documented, it can be subsequently coded, electronically compiled, and retrieved later to provide an epidemiologic profile of the injury, the first step in prevention at the population level. To be of greatest use, hospital records should indicate the "who, what, when, where, why, and how" of the injury occurrence and whether protective equipment (eg, a seat belt) was used. The pediatrician has two important roles in this area: to document fully the injury event and to advocate the use of standardized external cause-of-injury codes, which allow such data to be compiled and analyzed.

OVERVIEW

In 1996, injuries accounted for 64% of deaths in children and teenagers 1 to 19 years of age.[1] The National Center for Health Statistics estimates that for every injury death occurring in the United States, about 18 hospitalizations and 250 emergency department visits occur for people of all ages.[2] Information about the external cause of injury fatalities, in general, is more accurate and precise than is information about the external cause of nonfatal injuries.

Several problems exist with nonfatal injury data. First, national morbidity estimates are based on a representative statistical sample of the US population. The data cannot be disaggregated to the state or local level. Second, national estimates of morbidity data are not always reported in a timely manner. Third, not all states have statewide hospital discharge data systems that actively gather information concerning the specific external cause of injury. In communities without ready access to local cause-specific injury data that are coded, hospital administrators, public health officials, and safety advocates are impeded in their attempts to prioritize and plan appropriate services for their communities, such as emergency medical services, acute and rehabilitative inpatient and outpatient services, and primary prevention activities. Lack of local data makes it difficult to identify high-risk groups and environmental hazards that are specific to a given community. This in turn impedes efforts to develop and implement targeted, population-specific prevention programs.

The first logical step for local injury programs should be a review of local morbidity data. Ideally these data should be available in a readily accessible and electronic form. Data must be of high quality, with ascertainment of all cases or a statistically representative sample of all cases.

INJURY SURVEILLANCE SYSTEMS

Three types of ongoing injury surveillance systems are 1) the national vital statistics registry, 2) hospital discharge data systems, and 3) local emergency department data systems. The national mortality reporting system (vital statistics) serves as a model because data collection, coding, compilation, and reporting have been in use longer and are more refined than are morbidity-based systems. Vital records are collected by each county and state health department by compiling data from death certificates. The underlying and contributing causes of death, as certified by the physician, are coded (as of January 1, 1999) using the *International Classification of Diseases*, 10th revision (*ICD*-10).[3] Under this system (and its predecessor, *ICD*-9),[4] fatal injuries can receive two types of codes: an external cause-of-injury code and one or more diagnosis codes. The external cause-of-injury code specifies both the mechanism (eg, motor vehicle, fire, fall) and the intent (unintentional, suicide, homicide, or undetermined). The diagnosis code specifies the anatomic site and nature of the injury; for example, a skull fracture or an open wound of the chest.

In *ICD*-9 (effective 1979–1998), the codes for external causes of injury are referred to as E-codes. The nature of injury codes were often referred to as "N-codes." With *ICD*-10, however, the use of the term "E-code" should be replaced with "external cause-of-injury" code because the referent chapters now are prefaced with the letters "V," "W," "X," and "Y" and the codes range from V01 to Y89. Similarly in *ICD*-10, the nature of injury codes are prefaced with the letters "S" and "T" and codes range from S00 to T98.

A comparable classification system exists for coding nonfatal injuries, known as the *Clinical Modification of the ICD* (*ICD CM*).[5] Currently, the 9th revision is in effect. *ICD*-10 *CM* will most likely become effective after October 1, 2001. *ICD*-10 *CM* will likely have twice the number of external cause-of-injury

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

PEDIATRICS (ISSN 0031 4005).

codes as the *ICD-9 CM*, allowing for more precise and specific codes.

The combined use of diagnosis and external cause-of-injury codes is a highly specific way to classify injuries. For example, a facial fracture resulting from a bicycle injury can be distinguished from a similar fracture resulting from a fight. Information about the diagnosis, cause, and place of occurrence is needed to plan effective injury-prevention programs.

PROBLEMS WITH CURRENT MORBIDITY-REPORTING SYSTEMS

Two major problems exist with current morbidity-reporting systems. First, documentation of the injury event in the hospital record often is incomplete or even absent. For example, physicians and nurses treating a patient in the emergency department or hospital may note that a playground injury occurred but neglect to define the particular circumstances of the injury, eg, whether the injury was sustained because the child fell from a height, the distance of the fall, the type of equipment involved, the surface on to which the child fell, whether anyone else was present or involved in the occurrence, and whether the playground was in a schoolyard, at a private residence, or in a public recreation area. The record does not indicate the "who, what, when, where, why, and how" of the injury occurrence, probably because the caregivers focus their efforts on the immediate treatment of the injury. The hospital record should document key patient identification data such as the child's name, date of birth, sex, race, ethnicity, address, and telephone number. To maximize the use of hospital records, physicians, nurses, and other health care professionals should record the time, place, nature, and mechanism of injury; whether the injury was inflicted intentionally; contributing risk factors (eg, the use of alcohol or other drugs); whether protective equipment was used; whether any other persons were injured in the event; and whether the injury was work-related. If the primary (intake) record does not include such information, reconstructing the event later is difficult, even by direct interview.

The second problem is that medical records department personnel may not assign the hospital record an external cause-of-injury code. As of October 1997, 42 states had statewide hospital discharge data systems, but only 23 had mandatory external cause-of-injury code reporting for injury-related hospital discharges.[6] Based on a 1996 national survey of emergency department visits by patients of all ages, it is estimated that >34 million injury-related visits were made that year.[7] However, only nine states currently have mandates that require the reporting of external cause-of-injury codes for injury-related emergency department visits.[6] Voluntary reporting by external cause-of-injury code is incomplete and possibly biased by the number of diagnostic codes assigned; patient characteristics (eg, age, sex, or race); the nature and severity of the injury; and the type of hospital (eg, size, location).[8] As a result, compilations based on voluntary external cause-of-injury coding may not reflect all injuries accurately. Mandatory reporting of external cause-of-injury codes would improve the quality of the estimates of external causes of injury morbidity in the United States.

BENEFITS TO BE GAINED

Administrators of hospitals and managed care organizations can expect to gain several direct benefits from universal reporting of injuries by external cause-of-injury code. The improvement in population-based case ascertainment and accuracy if reporting is implemented by *all* hospitals would allow for planning, implementation, and evaluation of acute care and rehabilitation services (eg, bed, staffing, and emergency department needs) and would provide data needed to assess the financial effect of different types of injuries. Public health officials would have the necessary data to identify risk factors and high-risk populations to target primary prevention programs and to provide improved prehospital care. Pediatricians and other advocates would learn which injury issues warrant the most attention in their community. For example, the Indian Health Service, which has included external cause-of-injury codes in its hospital discharge data for >20 years, combined such information with police reports to identify a narrow stretch of roadway in Cherokee, NC, where motor vehicle–pedestrian collisions were occurring at a high rate. The roadway was modified, thereby virtually eliminating the problem.[9] Improved external cause-of-injury code data would help state and federal injury experts track national and state objectives for injury prevention according to goals established by *Healthy People 2000*.[10] Policy-makers could study more readily the effects of local and state injury-prevention legislation, such as laws mandating the installation of residential smoke detectors, use of safety belts and motorcycle helmets, and the recision of the 55-mph speed limit. Mandatory reporting of external cause-of-injury codes for hospital discharge data has been endorsed by the Council of State and Territorial Epidemiologists, the American Public Health Association, the American College of Emergency Medicine, the National Center for Health Statistics, the National Center for Injury Prevention and Control of the Centers for Disease Control and Prevention,[11] and the American Academy of Pediatrics,[12] as well as many state and local health departments.

The administrative costs associated with the external cause-of-injury coding of inpatient hospital records are relatively small.[13] It takes ≤3 minutes to assign an external cause-of-injury code to each injury record and, because only 9% of hospital discharges are injury-related,[14] most inpatient records would not require external cause-of-injury coding. Also, because many large hospitals already assign external cause-of-injury codes (by mandate or voluntarily) to the hospital admission records, the additional cost of external cause-of-injury coding all hospital discharge records may not be excessive.

RECOMMENDATIONS

Proper coding of injuries is critical for establishing priorities for child and adolescent injury-prevention programs. Pediatricians can serve their patients and communities well by documenting the injury event

thoroughly in the hospital record and by encouraging the expanded reporting of external cause-of-injury codes. The American Academy of Pediatrics recommends the following specific steps:

1. Pediatricians and other health care professionals who treat injured children and adolescents should obtain a thorough history of the cause of injury and document it in the hospital record. Appropriate documentation should include the who, what, when, where, why, and how of each injury event. Medical school and residency training should teach these history-taking skills, as well as the importance of standardized classification systems for injuries and diseases.
2. External cause-of-injury codes should be recorded in the hospital record for each hospital admission and emergency department visit in which an injury is the principal diagnosis or is related directly to the principal diagnosis.
3. Pediatricians should support state legislation or regulation to mandate the use of external cause-of-injury codes (as well as diagnostic codes) in hospital discharge data systems. External cause-of-injury codes should not replace other required data and should have designated separate fields in discharge databases.
4. Pediatricians should work with other medical and public health professionals to expand efforts to improve documentation, coding, collection, monitoring, and dissemination of injury data. Managed care organizations and other health insurance companies also may be interested in cost-of-injury data.
5. Pediatricians, other health care professionals, and injury-control researchers should work with hospital records personnel to become familiar with standardized uniform coding procedures, definitions, and guidelines for external cause-of-injury coding.

abstract

The hospital stay of the mother and her healthy term newborn infant should be long enough to allow identification of early problems and to ensure that the family is able and prepared to care for the infant at home. The length of stay should also accommodate the unique characteristics of each mother-infant dyad, including the health of the mother, the health and stability of the infant, the ability and confidence of the mother to care for her infant, the adequacy of support systems at home, and access to appropriate follow-up care. Input from the mother and her obstetrician should be considered before a decision to discharge a newborn is made, and all efforts should be made to keep mothers and infants together to promote simultaneous discharge. *Pediatrics* 2010;125:405–409

BACKGROUND

The hospital stay of the mother and her healthy term newborn infant (mother-infant dyad) should be long enough to allow identification of early problems and to ensure that the family is able and prepared to care for the infant at home. Many cardiopulmonary problems related to the transition from an intrauterine to an extrauterine environment usually become apparent during the first 12 hours after birth.[1] However, detection of significant jaundice,[2] ductal-dependant cardiac lesions,[3,4] gastrointestinal obstruction,[5] and other problems may require a longer period of observation by skilled and experienced health care professionals.[6] The average length of stay of the mother-infant dyad after delivery declined steadily from 1970 until the mid-1990s.[7] Early newborn discharge was implemented in the 1990s, but in response to the ensuing debate on the care and safety of mothers and their infants, most states and the US Congress enacted legislation that ensured hospital stay for up to 48 hours for a vaginal delivery and up to 96 hours after birth by cesarean delivery. Several subsequent studies have reported that the postpartum-length-of-stay legislation has led to an increase in postpartum length of stay, but the impact of this increase in length of stay on the rate of neonatal readmissions has been inconsistent.[7–10]

Risk of Readmission

Criteria for newborn discharge include physiologic stability, family preparedness and competence to provide newborn care at home, availability of social support, and access to the health care system and resources. An inadequate assessment by health care providers

in any of these areas before discharge can place an infant at risk and may result in readmission. In several large epidemiologic studies, readmission rates were used to assess the adequacy of the newborn hospital length of stay. In these reports, readmissions after an early discharge varied from no increase to a significant increase.[7,11–14] However, the differences in the definition of early discharge, postdischarge follow-up and support, and the timing of readmissions make it difficult to compare the results. In some of these studies the risk factors for readmission to identify infants who may benefit from either a longer hospital stay or close postdischarge follow-up were also evaluated. These studies identified jaundice, dehydration, and feeding difficulties as the most common reasons for readmission.[14,15] Other frequently reported risk factors for readmission were Asian race, primiparity, associated maternal morbidities, shorter gestation or lower birth weight, instrumented vaginal delivery, male gender, and small size for gestational age.[11,13–16] Close follow-up and better coordination of postdischarge care were important factors in decreasing the readmission rates.[11,15]

Readiness for Discharge

Readiness for discharge of a healthy term infant is traditionally determined by pediatricians after a review of the mother's and family members' ability to provide care to a newborn infant at home. However, perceptions of readiness or unreadiness at the time of discharge often differ among pediatricians, obstetricians, and mothers.[17] Factors associated with perceptions of unreadiness for newborn discharge include first live birth, maternal history of chronic disease or illness after birth, in-hospital neonatal illness, intent to breastfeed, mothers with inadequate prenatal care and poor social support, and black non-Hispanic maternal race.[12,17] Although no specific clinical tool is currently available to evaluate mothers' or families' perception of readiness for discharge after delivery, the American Academy of Pediatrics Safe and Healthy Beginnings toolkit contains a discharge-readiness checklist that can aid clinicians with preparation of a newborn for discharge. This tool was tested by 22 clinical practice teams during the Safe and Healthy Beginnings improvement project and focuses on risk for severe hyperbilirubinemia, breastfeeding support, and coordination of care to improve care for newborns.[18] Nonetheless, all efforts should be made to keep mothers and infants together to promote simultaneous discharge. To accomplish this, a pediatrician's decision to discharge a newborn should be made jointly with input from the mother, her obstetrician, and other health care providers such as nursing staff and social workers who are involved in the care of mother and her infant.

RECOMMENDATIONS

The length of stay of a healthy term newborn should be based on the unique characteristics of each mother-infant dyad, including the health of the mother, the health and stability of the infant, the ability and confidence of the mother to care for her infant, the adequacy of support systems at home, and access to appropriate follow-up care. Input from the mother and her obstetrician and nursing staff should be considered before a decision to discharge a newborn is made, and all efforts should be made to keep mothers and infants together to promote simultaneous discharge. It is recommended that the following minimum criteria be met before discharge of a term newborn, defined as an infant born between 37 and 41 completed weeks of gestation.

1. Clinical course and physical examination at discharge have not revealed abnormalities that require continued hospitalization.
2. The infant's vital signs are documented as being within normal ranges, with appropriate variations based on physiologic state, and stable for the 12 hours preceding discharge. These ranges include a respiratory rate below 60 per minute and no other signs of respiratory distress, a heart rate of 100 to 160 beats per minute, and axillary temperature of 36.5°C to 37.4°C (97.7–99.3°F) measured properly in an open crib with appropriate clothing.[19–21]
3. The infant has urinated regularly and passed at least 1 stool spontaneously.
4. The infant has completed at least 2 successful consecutive feedings, with assessment to verify that the infant is able to coordinate sucking, swallowing, and breathing while feeding.
5. There is no significant bleeding at the circumcision site.
6. The clinical risk of development of subsequent hyperbilirubinemia has been assessed, and appropriate management and/or follow-up plans have been instituted as recommended in American Academy of Pediatrics clinical practice guidelines for management of hyperbilirubinemia.[2]
7. The infant has been adequately evaluated and monitored for sepsis on the basis of maternal risk factors and in accordance with current guidelines for prevention of perinatal group B streptococcal disease.[22]
8. Maternal blood test and screening results are available and have been reviewed, including:

- maternal syphilis and hepatitis B surface antigen status; and
- screening tests, including a test for HIV, performed in accordance with state regulations.

9. Infant blood tests are available and have been reviewed such as cord or infant blood type and direct Coombs test results, as clinically indicated.[2]
10. Initial hepatitis B vaccine has been administered according to the current immunization schedule.[23]
11. Newborn metabolic and hearing screenings have been completed per hospital protocol and state regulations.
12. The mother's knowledge, ability, and confidence to provide adequate care for her infant have been assessed for competency regarding:
    - breastfeeding or bottle feeding (the breastfeeding mother and infant should be assessed by trained staff regarding breastfeeding position, latch-on, and adequacy of swallowing)[24];
    - the importance and benefits of breastfeeding for both mother and infant;
    - appropriate urination and defecation frequency for the infant;
    - cord, skin, and genital care, including circumcision care, for the infant;
    - the ability to recognize signs of illness and common infant problems, particularly jaundice; and
    - infant safety (such as use of an appropriate car safety seat, supine positioning for sleeping, maintaining a smoke-free environment, and room sharing).[24–26]
13. Family, environmental, and social risk factors have been assessed, and the mother and her other family members have been educated about safe home environment. If risk factors are identified, discharge should be delayed until they are resolved or a plan to safeguard the infant is in place. This plan may involve discussions with social services and/or state agencies such as child protective services. These risk factors include but are not limited to:
    - untreated parental substance abuse or positive urine toxicology results in the mother or newborn;
    - history of child abuse or neglect;
    - mental illness in a parent who is in the home;
    - lack of social support, particularly for single, first-time mothers;
    - mothers who live in a shelter, a rehabilitation home, or on the street;
    - history of domestic violence, particularly during this pregnancy;
    - communicable illness in a parent or other members of the household[27]; and
    - adolescent mother, particularly if other above-listed conditions apply.
14. A medical home for continuing medical care for the infant has been identified and a plan for timely communication of pertinent clinical information to the medical home is in place. For newborns discharged less than 48 hours after delivery, an appointment should be made for the infant to be examined by a licensed health care professional, preferably within 48 hours of discharge based on risk factors but no later than 72 hours in most cases.[10,11,15,28,29] If this cannot be ensured, discharge should be deferred until a mechanism for follow-up evaluation is identified. The follow-up visit can take place in a home or clinic setting as long as the health care professional who examines the infant is competent in newborn assessment and the results of the follow-up visit are reported to the infant's physician or his or her designee on the day of the visit.
15. Barriers to adequate follow-up care for the newborn, such as lack of transportation to medical care services, lack of easy access to telephone communication, and non–English-speaking parents, have been assessed and, whenever possible, assistance has been given to the family to make suitable arrangements to address them. The purpose of the follow-up visit is to:
    - weigh the infant; assess the infant's general health, hydration, and extent of jaundice; identify any new problems; review feeding pattern and technique; and obtain historical evidence of adequate urination and defecation patterns for the infant;
    - assess quality of mother-infant attachment and details of infant behavior;
    - reinforce maternal or family education in infant care, particularly regarding infant feeding and safety such as breastfeeding, back to sleep, and child safety seats;
    - review the results of outstanding laboratory tests, such as newborn metabolic screens, performed before discharge;
    - perform screening tests in accordance with state regulations

and other tests that are clinically indicated, such as bilirubin measurement;

- verify the plan for health care maintenance, including a method for obtaining emergency services, preventive care and immunizations, periodic evaluations and physical examinations, and necessary screenings; and
- assess for parental well-being including postpartum depression in the mother.

16. Obstetrical care, newborn nursery care, and follow-up care should be considered independent services to be reimbursed as separate packages and not as part of a global fee for maternity-newborn labor and delivery services.

CONCLUSIONS

Each mother-infant dyad should be evaluated individually to determine the optimal time of discharge. The timing of discharge should be the decision of the physician caring for the infant and based on these guidelines. Local implementation of these guidelines is best accomplished through the collaborative efforts of all parties concerned. Institutions should develop guidelines in collaboration with appropriate community agencies, and third-party payers, to establish hospital-stay and follow-up programs for healthy term infants that implement these recommendations.

Human Immunodeficiency Virus and Other Blood–borne Viral Pathogens in the Athletic Setting

ABSTRACT. Because athletes and the staff of athletic programs can be exposed to blood during athletic activity, they have a very small risk of becoming infected with human immunodeficiency virus, hepatitis B virus, or hepatitis C virus. This statement, which updates a previous position statement of the American Academy of Pediatrics,[1] discusses sports participation for athletes infected with these pathogens and the precautions needed to reduce the risk of infection to others in the athletic setting. Each of the recommendations in this statement is dependent upon and intended to be considered with reference to the other recommendations in this statement and not in isolation.

ABBREVIATIONS. HIV, human immunodeficiency virus; HBV, hepatitis B virus; HCV, hepatitis C virus; CI, 95% confidence interval; AAP, American Academy of Pediatrics; OSHA, Occupational Safety and Health Administration.

During sports participation, the blood of an athlete who is infected with human immunodeficiency virus (HIV), hepatitis B virus (HBV), or hepatitis C virus (HCV) may occasionally contaminate the skin or mucous membranes of other athletes or the staff of athletic programs. Common sense suggests that this likelihood is greatest in contact sports, but transmission can potentially occur indirectly or in noncontact sports. Even in contact sports, the very limited available data indicate that bleeding wounds are not necessarily common.[2]

HIV INFECTION

The risk of HIV infection via skin or mucous membrane exposure to blood or other infectious bodily fluids during sports participation is very low. The most relevant research has been conducted with health care workers, for whom the risk from skin or mucous membrane exposure is less than the risk from parenteral exposure, which is .2% to .3% per exposure (95% confidence interval [CI], .1%–.5%).[3] The risk from exposure to mucous membranes or damaged skin determined from pooling 6 prospective studies was 1 infection in 1007 exposures, or .1% (95% CI, .01%–.5%). Such transmission appears to require, in addition to a portal of entry, prolonged exposure to large quantities of blood.[3] Transmission through intact skin has not been documented: no HIV infections occurred after 2712 such exposures in 1 large prospective study (95% CI, 0%–.1%).[3] Transmission of HIV in sports has not been documented. One unsubstantiated report describes possible transmission during a collision between professional soccer players.[4]

HBV INFECTION

The HBV is more easily transmitted via exposure to infected blood than is HIV.[3] In 2 studies of health care professionals who had percutaneous exposure to HBV-infected blood, the risk of infection was 27% and 45%; approximately 25% of cases were symptomatic. The risk of infection was greater if the blood was positive for HBV e antigen. The health care workers received immune serum globulin, and so some of them were protected from infection.[5,6] Transmission of infection by contamination of mucous membranes or broken skin with infected blood has been documented, but the magnitude of risk has not been quantified.[3]

Although transmission of HBV is apparently rare in sports, 2 reports document such transmission. An asymptomatic high school sumo wrestler who had a chronic infection transmitted HBV to other members of his team.[7] An epidemic of HBV infection occurred through unknown means among Swedish athletes participating in track finding (orienteering).[8] The epidemiologists concluded that the most likely route of infection was the use of water contaminated with infected blood to clean wounds caused by branches and thorns.

An effective way of preventing HBV transmission in the athletic setting is through immunization of athletes. The American Academy of Pediatrics (AAP) recommends that all children and adolescents be immunized.[9] Clinicians and the staff of athletic programs should aggressively promote immunization.

HCV INFECTION

Although the transmission risks of HCV infection are not completely understood, the risk of infection from percutaneous exposure to infected blood is estimated to be 10 times greater than that of HIV but lower than that of HBV.[3] Transmission via contamination of mucous membranes or broken skin also probably has a risk intermediate between that for blood infected with HIV and HBV.[3]

The recommendations in this statement are based upon present available knowledge. They do not indicate an exclusive course of treatment or serve as a standard of medical care. Laws vary from state to state and state law may dictate a different course of action for the physician or those in charge of an athletic program. Variations, taking into account individual circumstances, may also be appropriate.

PEDIATRICS (ISSN 0031 4005).

SUMMARY

Because of the very low probability of transmission of their infection to other athletes, athletes infected with HIV, HBV, or HCV should be allowed to participate in all sports.

CONFIDENTIALITY AND OTHER LEGAL ISSUES

Confidentiality about an athlete's infection with a blood–borne pathogen is necessary to prevent exclusion of the athlete from sports because of inappropriate fear among others in the program. Except for the reporting required by law, the patient (and parent or guardian if the patient is a minor) must give informed consent for clinicians to share information about these medical conditions with a school or sports organization. Testing of athletes for these viral infections is not indicated. Infected athletes should be told that they have a very small risk of infecting other competitors. This risk, although unknown for any sport, is probably greatest in wrestling and boxing. Infected athletes can be encouraged not to participate in these activities or in others in which contamination of skin or mucous membranes with blood is relatively likely. This may also be protective for infected athletes themselves, reducing their possible exposure to blood–borne pathogens other than the one(s) with which they are infected.

The AAP opposes boxing as a sport for youth. Pediatricians should counsel athletes not to participate in this sport, whatever their infection status.

Athletic programs should inform athletes and parents that athletes have a very small but finite risk of contracting a blood–borne infection from another athlete. This is part of the duty to warn about risks of participation that is the responsibility of all athletic programs.

Pediatricians can avoid reporting the presence of infections with blood–borne pathogens by making it clear on the preparticipation form or elsewhere that they support the AAP policy, "Human Immunodeficiency Virus and Other Blood–borne Pathogens in the Athletic Setting," and that the AAP policy acknowledges that the physician should respect the right of infected athletes to confidentiality.

The US Supreme Court has not ruled specifically on the legality of excluding from competition an athlete who has a chronic infection with a blood–borne viral pathogen but has held that a person infected with a contagious disease may be handicapped and therefore entitled to protection from unlawful discrimination. On the basis of this authority, when considering whether an athlete infected with a blood–borne viral pathogen can be excluded from competition, an inquiry would have to be made "based on reasonable medical judgements given the state of medical knowledge" into whether the athlete poses a significant risk of communicating the disease to others in the competition that cannot be eliminated by reasonable accommodation.[10,11]

PREVENTION OF INFECTION

Strict safety precautions are particularly important for those persons in athletic programs who provide first aid and have repeated exposure to blood or other bodily fluids visibly contaminated with blood. Specific precautions are discussed in Recommendation 10 below. Other discussions of safety precautions appropriate for sports programs, with some additional information, are available elsewhere.[10,12–14]

EDUCATION OF ATHLETES

Coaches, athletic trainers, and health care professionals can expand discussions about the risks of transmission of blood–borne viral pathogens during sports participation to teach athletes about how these pathogens are transmitted and how to prevent infection.

RECOMMENDATIONS

1. Athletes infected with HIV, HBV, or HCV should be allowed to participate in all competitive sports.
2. The physician should respect the right of infected athletes to confidentiality. This includes not disclosing the patient's infection status to other participants or the staff of athletic programs.
3. Athletes should not be tested for blood–borne pathogens because they are sports participants.
4. Pediatricians are encouraged to counsel athletes who are infected with HIV, HBV, or HCV that they have a very small risk of infecting other competitors. Infected athletes can consider choosing a sport in which this risk is apparently relatively low. This may be protective for other participants and for infected athletes themselves, reducing their possible exposure to blood–borne pathogens other than the one(s) with which they are infected. Wrestling and boxing, a sport opposed by the AAP, probably have the greatest potential for contamination of injured skin by blood.
5. Athletic programs should inform athletes and their parents that the program is operating under the policies in Recommendations 1 through 3 and that the athletes have a very small risk of becoming infected with a blood–borne pathogen.
6. Clinicians and the staff of athletic programs should aggressively promote HBV immunization among athletes and among coaches, athletic trainers, equipment handlers, laundry personnel, and any other persons at risk of exposure to athletes' blood as an occupational hazard. All athletes should, if possible, receive HBV immunization; >95% of those who receive this immunization will be protected against infection.[9]
7. Each coach and athletic trainer must receive training in first aid and emergency care and in the prevention of transmission of blood–borne pathogens in the athletic setting. These staff members can then help to implement recommendations made here.
8. Coaches and members of the health care team should educate athletes about the precautions described in these recommendations and about the greater risks of transmission of HIV and other blood–borne pathogens through sexual ac-

tivity and needle sharing during the use of illicit drugs, including anabolic steroids. Athletes should be told not to share personal items, such as razors, toothbrushes, and nail clippers that might be contaminated with blood.

9. In some states, depending on state law, schools may need to comply with Occupational Safety and Health Administration (OSHA) regulations[13] for the prevention of transmission of blood–borne pathogens. The athletic program must determine what rules apply. Compliance with OSHA regulations is a reasonable and recommended precaution even if this is not specifically required by the state.
10. The following precautions should be adopted in sports with direct body contact and other sports in which an athlete's blood or other bodily fluids visibly tinged with blood may contaminate the skin or mucous membranes of other participants or staff members of the athletic program. Even if these precautions are adopted, the risk that a participant or staff member may become infected with a blood–borne pathogen in the athletic setting will not be entirely eliminated.
    - Athletes must cover existing cuts, abrasions, wounds, or other areas of broken skin with an occlusive dressing before and during participation. Caregivers should cover their own damaged skin to prevent transmission of infection to or from an injured athlete.
    - Disposable, water-impervious vinyl or latex gloves should be worn to avoid contact with blood or other bodily fluids visibly tinged with blood and any object such as equipment, bandages, or uniforms contaminated with these fluids. Hands should be cleaned with soap and water or an alcohol-based antiseptic handwash as soon as possible after gloves are removed.
    - Athletes with active bleeding should be removed from competition as soon as possible and the bleeding stopped. Wounds should be cleaned with soap and water. Skin antiseptics may be used if soap and water are not available. Wounds must be covered with an occlusive dressing that remains intact during further play before athletes return to competition.
    - Athletes should be advised to report injuries and wounds in a timely fashion before or during competition.
    - Minor cuts or abrasions that are not bleeding do not require interruption of play but can be cleaned and covered during scheduled breaks. During these breaks, if an athlete's equipment or uniform fabric is wet with blood, the equipment should be cleaned and disinfected (see below), or the uniform should be replaced.
    - Equipment and playing areas contaminated with blood must be cleaned until all visible blood is gone and then disinfected with an appropriate germicide such as a freshly-made bleach solution containing 1 part bleach in 10 parts of water. The decontaminated equipment or area should be in contact with the bleach solution for at least 30 seconds. The area may be wiped with a disposable cloth after the minimum contact time or be allowed to air dry.[9]
    - Emergency care must not be delayed because gloves or other protective equipment is not available. If the caregiver does not have the appropriate protective equipment, a towel may be used to cover the wound until an off-the-field location is reached where gloves can be used during more definitive treatment.
    - Breathing (Ambu) bags and oral airways should be available for giving resuscitation. Mouth-to-mouth resuscitation is recommended only if this equipment is not available.[12]
    - Equipment handlers, laundry personnel, and janitorial staff must be trained in proper procedures for handling washable or disposable materials contaminated with blood.[9, 12]

AMERICAN ACADEMY OF PEDIATRICS

AMERICAN COLLEGE OF OBSTETRICIANS AND GYNECOLOGISTS

Human Immunodeficiency Virus Screening

JOINT STATEMENT OF THE AMERICAN ACADEMY OF PEDIATRICS AND THE AMERICAN COLLEGE OF OBSTETRICIANS AND GYNECOLOGISTS

ABBREVIATIONS. HIV, human immunodeficiency virus; IOM, Institute of Medicine; AIDS, acquired immunodeficiency syndrome; AAP, American Academy of Pediatrics; ACOG, American College of Obstetricians and Gynecologists.

The problem of perinatal transmission of human immunodeficiency virus (HIV) infection was first appreciated in 1982. In 1991, the Institute of Medicine (IOM) recommended a policy of routine counseling and offering testing (with specific informed consent) for HIV infection to all pregnant women. Since 1991, there have been major advances in the treatment of HIV infection, including demonstration in 1994 of the efficacy of zidovudine to reduce perinatal transmission. The US Public Health Service subsequently issued guidelines for use of zidovudine to reduce perinatal transmission and for counseling and voluntary testing for pregnant women. Dramatic declines in reported pediatric acquired immunodeficiency syndrome (AIDS) cases have been observed as a consequence of implementation of these guidelines. However, for a variety of reasons, screening pregnant women in the United States has been far from universal and infected infants continue to be born to undiagnosed infected women. Further reduction in the rate of perinatal HIV infection will require wider application of both screening to identify infected women, and treatments that have demonstrated efficacy in reducing vertical transmission.

The IOM recently completed a study of interventions that would be helpful to further reduce the rate of perinatal HIV infection in the United States (*Reducing the Odds*). They have recommended that "the United States adopt a national policy of universal HIV testing, with patient notification, as a routine component of prenatal care." Early diagnosis of HIV infection in pregnant women allows them to institute effective antiretroviral therapy for their own health and to reduce the risk of HIV transmission to their infants. The use of "patient notification" provides women the opportunity to decline to be tested but eliminates the obligation to provide extensive pretest counseling, which has been a barrier to testing in many settings. Care providers would be charged with responsibility for the details of how the notification would take place. The IOM has recommended universal testing for two reasons. First, attempts to identify those "at risk" for infection inevitably fail to identify some infected individuals. Second, universal testing of all pregnant women avoids stereotyping and stigmatizing any social or ethnic group. The IOM recognizes in its report that many states now have laws requiring a formal, and in many cases written, informed consent process before testing. They recommend that the federal government adopt policies that will encourage these states to change their laws.

The American Academy of Pediatrics (AAP) and the American College of Obstetricians and Gynecologists (ACOG) strongly support efforts to further reduce the rate of perinatal transmission of HIV in the United States. We therefore support the recommendation of the IOM for universal HIV testing with patient notification as a routine component of prenatal care. If a patient declines testing, this should be noted in the medical record. We recognize that current laws in some states may prevent implementation of this recommendation at this time. We encourage our members and Fellows to include counseling as a routine part of care, but not as a prerequisite for and barrier to prenatal HIV testing.

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

Human Milk, Breastfeeding, and Transmission of Human Immunodeficiency Virus in the United States

Committee on Pediatric AIDS

ABBREVIATIONS. HIV, human immunodeficiency virus; AAP, American Academy of Pediatrics; OSHA, Occupational Safety and Health Administration.

THE PROBLEM

Physicians caring for infants born to women infected with human immunodeficiency virus (HIV) or at risk for HIV infection are likely to be involved in making recommendations concerning the appropriateness of breastfeeding or the use of expressed human milk. Because the number of women with HIV infection in the reproductive age range is increasing rapidly, the importance of understanding the potential risk of HIV transmission to infants via human milk is critical.

BACKGROUND

Breastfeeding provides numerous health benefits to infants. Besides being an excellent source of nutrition, human milk protects against morbidity and mortality from infectious diseases of bacterial, viral, and parasitic origin, and the act of breastfeeding establishes a bond between mother and infant. Human milk also has a low likelihood of contamination by environmental pathogens. The American Academy of Pediatrics (AAP) strongly supports the promotion of breastfeeding of infants.[1]

It is well-known that HIV, the virus that causes acquired immunodeficiency syndrome, can be transmitted from mother to infant during pregnancy as well as during the peripartum period. In addition, recent reports from throughout the world have documented the transmission of HIV through human milk.[2–4] Despite the multiple anti-infectious, protective substances that have been identified in human milk, HIV may be recovered from human milk and has been shown to be the source of HIV infection in some infants.[3]

Research studies are presently investigating factors associated with infectivity as well as the potential protective elements of breast milk. Such factors include potential differences in the virus content of colostrum and early human milk compared with later milk, the relationship of the duration of breastfeeding to transmission, the role of the immature gastrointestinal tract of the young infant in viral transmission, and the potential protective effect of HIV-specific immune globulins in human milk[4] and of human milk glycosaminoglycans, which appear to inhibit HIV binding to the CD4 molecule.[5]

Currently no randomized clinical trials are available that accurately document the incremental risk of HIV transmission through breastfeeding over that occurring during the intrauterine and intrapartum periods. Evaluation of populations that vary only by method of infant feeding have been limited to date, due to the homogeneity of feeding practices in current cohorts, with breastfeeding the norm in developing countries and formula feeding the norm in industrialized countries.

Although some studies do not indicate an increased risk of transmission of HIV by human milk,[6] a recent meta-analysis of data from cohort studies in which some infants were breastfed and others were exclusively bottlefed indicated an increased risk of transmission attributable to breastfeeding.[7] Mothers who develop primary HIV infection while nursing may pose an especially high risk for transmitting the infection via human milk because the infant potentially is exposed to secretions or cells containing a higher virus burden.[8] In the meta-analysis, the risk of transmission by breastfeeding from mothers who developed primary infection during the postpartum period was 29% (95% confidence interval, 16% to 42%).[7]

The interpretation of the results from the meta-analysis has caused a great deal of controversy. This approach to data analysis indicates that the incremental risk of transmission by breastfeeding from mothers with established infection before pregnancy is 14% (95% confidence interval, 7% to 22%).[7] Recent reports note the incremental risk of transmitting HIV infection to the breastfeeding infant to range from 3% to 12% in various African populations.[9,10]

The use of expressed human milk for nutrition of sick, premature, and recuperating neonates in intensive care units has become commonplace, and some mothers may express milk for their infants in a child care setting. Breast milk is not included in the Occupational Safety and Health Administration (OSHA) standards definition of "other potentially infectious materials."[11] Although human milk has been implicated in perinatal transmission of HIV and the hepatitis B surface antigen has been found in the milk of mothers infected with HBV,[12] contact with breast milk does not constitute occupational exposure as defined by the OSHA standards. The determination

The recommendations in this statement do not indicate an exclusive course of treatment or procedure to be followed. Variations, taking into account individual circumstances, may be appropriate.

that human breast milk has not been implicated in the transmission of HIV[13] or the hepatitis B virus to workers, was based on separate findings of the Centers for Disease Control and Prevention, and the World Health Organization.[13] Gloves are not recommended for the routine handling of expressed human milk; but should be worn by health care workers in situations where exposures to breast milk might be frequent or prolonged, for example, in milk banking.[13]

Whatever the actual risk of HIV transmission through breastfeeding is in the United States, the potential for infection through human milk exists and must be examined in the context of the prevalence of HIV in women of childbearing age, the low incidence of breastfeeding in populations with the highest incidence of HIV infection, and the known general benefits of human milk.

CONCLUSIONS

When making recommendations concerning feeding options for infants, health care providers in the United States must balance the potential for transmission of HIV through human milk with the known benefits of breastfeeding. Additional epidemiologic studies are needed to assess accurately the actual risk of HIV transmission to infants from human milk in the United States. However, because HIV transmission via human milk is possible, knowledge of the HIV serostatus of pregnant women is important to determine whether breastfeeding is appropriate.

RECOMMENDATIONS

The World Health Organization has developed recommendations for breastfeeding in the developing world.[13] The following recommendations are made by the AAP for the United States, where infectious diseases and malnutrition are not major causes of infant mortality and where safe alternatives to breastfeeding are available.

1. Women and their health care providers need to be aware of the potential risk of transmission of HIV infection to infants during pregnancy and in the peripartum period, as well as through human milk.
2. The AAP recommends documented, routine HIV education, and routine testing with consent of all women seeking prenatal care so that each woman will know her HIV status and the methods available both to prevent the acquisition and transmission of HIV and to determine whether it is appropriate to breastfeed.
3. At the time of delivery, provision of education about HIV and testing with consent of all women whose HIV status during this pregnancy is unknown are recommended. Knowledge of the woman's HIV status assists in counseling on breastfeeding and helps each woman understand the benefits to herself and her infant of knowing her serostatus and the behaviors that would decrease the likelihood of acquisition and transmission of HIV.
4. Women who are known to be HIV-infected must be counseled not to breastfeed or provide their milk for the nutrition of their own or other infants.
5. In general, women who are known to be HIV-seronegative should be encouraged to breastfeed. However, women who are HIV-seronegative but at particularly high risk of seroconversion (injection drug users and sexual partners of known HIV-positive persons or active drug users) should be provided education about HIV with an individualized recommendation concerning the appropriateness of breastfeeding. In addition, during the perinatal period, information should be provided on the potential risk of transmitting HIV through human milk and about methods to reduce the risk of acquiring HIV infection.
6. Each woman whose HIV status is unknown should be informed of the potential for HIV-infected women to transmit HIV during the peripartum period and through human milk and the potential benefits to her and her infant of knowing her HIV status and how HIV is acquired and transmitted. The health care provider needs to make an individualized recommendation to assist the woman in deciding whether to breastfeed.
7. Neonatal intensive care units should develop policies that are consistent with the above recommendations for the use of expressed human milk for the nutrition of neonates. Current OSHA standards do not require gloves for the routine handling of expressed human milk.[11] However, gloves should be worn by health care workers in situations where exposure to breast milk might be frequent or prolonged, for example, in milk banking.[13]
8. Human milk banks should follow the guidelines developed by the United States Public Health Service, which includes screening all donors for HIV infection and assessing risk factors that predispose to infection, as well as pasteurization of all milk specimens.
