1. Across all age groups, pitchers, catchers, and fielders have a relative frequency of injury in a season comparable to batters and base runners, with one exception: as age increases, the proportion of injuries to catchers increases, whereas the proportion of injuries to fielders decreases.
2. The younger the age group, the more frequently injuries occur during practice sessions, not games. Also, in younger age groups, relatively higher frequencies of injuries came from "before/after" baseball play, such as warm-ups or postgame horseplay.
3. Pitcher injuries are also age-related, with noncontact overuse injuries increasing in each older age group. Younger pitchers are more likely to be hit by a batted or thrown ball.
4. Catchers principally are injured in catching a pitch, getting hit by a foul tip, or tagging a base runner. Younger catchers are more frequently injured trying to catch the pitched ball, whereas older catchers are more likely to be injured by foul tips. Although home-plate collisions during a tag play generate a modest but constant pattern of injury for catchers of all ages, these collisions produce a greater injury risk to the older catcher.
5. Batters are most frequently injured by a pitched ball (and by a foul ball as they get older). The younger the batter, the more likely they are to be injured by a swung bat of another player while getting into position. Approximately 10% of batting injuries among older batters are of a noncontact nature, indicating some form of overswinging resulting in an injury to the muscles, bones, or connective tissues of the rib cage.
6. Injuries to base runners occurred almost equally at all bases, with slightly more injuries at home plate than at first base. Two-thirds of these injuries occurred from sliding, and one-third occurred from base running. Base running injuries are not related to age, occurring almost equally from collisions, being hit by a thrown ball, or simply running (such as falling, stepping wrong on the base, or straining a muscle).
7. Fielder injuries occur at the base (33%), in foul territory (10%), and in the field (57%). Younger fielders are more likely to be hit by a batted ball, whereas older fielders are more likely to be injured by colliding with a sliding opponent.

Catastrophic Injuries

Research from the National Amateur Baseball Catastrophic Injury Surveillance Program places the rate of catastrophic injury very low, at approximately 1 injury per 1 million participants annually. Such injuries may be caused by trauma related to participating in the skills of the sport, such as contact with a bat, baseball, or softball (direct catastrophic injury), by a body system failure resulting from exertion while participating in a sport or activity (eg, cardiac collapse or heat stroke) or by a complication that resulted from a nonfatal injury (indirect catastrophic injury). Catastrophic injuries are further classified according to outcome as fatal (athlete died), nonfatal (athlete left with permanent disability), and serious (athlete experienced severe injury but recovered, to be left with no permanent functional disability).[12] The National Amateur Baseball Catastrophic Injury Surveillance Program data revealed an annual fatality rate of 0.05 per 100 000 participants, 0.03 for nonfatal catastrophic injuries and 0.04 for serious catastrophic injuries.[18] Between 1996 and 2006, deaths in youth baseball averaged just over 2 per year.[18] These deaths occurred from impact to the head resulting in intracranial bleeding and from blunt chest impact, likely prompting ventricular fibrillation or asystole (commotio cordis).[11,12]

Another study based on statistics compiled by the CPSC[11] indicated that there were 88 baseball-related deaths (approximately 4 per year) to children 5 to 18 years old between 1973 and 1995.[11,19] The injury causing death in 38 cases (43%) was direct-ball impact with the chest (commotio cordis); in 21 cases (24%), the injury causing death was direct-ball contact with the head; in 13 cases (15%), the injury causing death was from impact from bat contact; in 9 cases (10%), the injury causing death was from direct contact with a ball impacting the neck, ears, or throat; and in 7 (8%), the injury causing death was unknown.[11,19]

Among high school baseball athletes (with approximately 475 000 participating annually), there have been 10 "direct" deaths, 14 "indirect" deaths, 17 nonfatal catastrophic injuries, and 22 serious catastrophic injuries between 1982 and 2008.[12] Direct injury rates are between 2 and 5 times greater in high school than in youth baseball (5–14 years of age) and 4 times greater in college than high school baseball (but still less than 1/100 000 participants annually in any of the 3 categories).

Among high school softball athletes (371 000 annual participants), there has been 1 direct death, no indirect deaths, 2 nonfatal catastrophic injuries, and 1 serious catastrophic injury in the 15 seasons from 1993 and 2008; these rates are approximately one-tenth of those for high school baseball.[12]

Commotio Cordis

Young baseball and softball players who receive direct ball impact to the anterior chest wall over the cardiac silhouette may develop cardiac arrest. Commotio cordis is the second highest cause of death in athletes younger than 14 years and is considered to be only a pediatric problem because of its unique occurrence in children, usually younger than 16 years.[20–22] Children 5 to 14 years of age may be uniquely vulnerable to this blunt chest impact, because their chest walls are more elastic and more easily compressed.[20–24]

Although protective gear can be a key preventive measure, it is not always effective. Research has shown that even with protective gear, the fatality rate for commotio cordis is alarmingly high at 90%.[19–24,25,26] Proper coaching and execution can augment protective equipment. Batters who learn to avoid the ball and turn away from an inside pitch can greatly reduce their risk. This is particularly difficult, however, while bunting and, thus, requires special attention and instruction. The risk to pitchers can also be reduced by teaching proper fielding position after ball release as well as ball avoidance when necessary.[19] The capacity to recognize that a batted ball is coming at you quickly and the ability to react to that event before the ball arrives are crucial traits for protecting these athletes. Speed of processing and reaction time are commonly measured during the computer-based neuropsychological tests given to high school athletes as a baseline in concussion management programs. Presumably, these are skills that can be improved marginally with proper training and sufficient repetitions. It is estimated that 400 milliseconds is required for a pitcher to complete a protective movement, such as lifting a hand to the chest or face; this corresponds to a batted ball speed of 42 m/second.[27] Because balls hit from some metal bats may exceed 42 m/second, performance standards for composite metal bats were developed in 2003 to limit their capacity to transfer force (velocity) to the batted ball.

It is noteworthy that cardiac death caused by commotio cordis is potentially preventable. If cardiac arrest occurs, an immediate and appropriate response may, in many cases, save a young player's life. AEDs are becoming more prevalent in the sports world at athletic complexes and certainly in patrol cars and emergency medical vehicles. The use of these devices, along with cardiopulmonary resuscitation, has become a standard first step in treating cardiac arrest.[6,28] If no AED is available near the affected child, the emergency medical care system should be activated by using 911 to get an AED to the athlete's side as soon as possible (ideally within 3 minutes). Baseball coaches should be routinely reminded to have a local cellular phone and emergency medical numbers at every youth baseball and softball game and practice in the event of a medical emergency.

Concussion

Concussion in sports continues to garner ever-increasing public attention and concern. Data on high school concussion rates in baseball and softball were generated through the Reporting Information Online system, developed from the National High School Sports-Related Injury Surveillance Study, over the 5-year period from the 2005–2006 to 2009–2010 school years. The rate of concussions for baseball was 0.2 per 1000 athletic exposures, and for softball the rate of concussions was 0.5 per 1000 athletic exposures. Of the 9 sports surveyed (including football, wrestling, soccer, and basketball), baseball had the lowest rate, and softball was seventh. The top 2 activities associated with concussion in high school boys playing baseball were batting (36.7%) and running the bases (21.5%), whereas for girls playing softball, the top 2 activities were catching (33.3%) and fielding (25.0%).[29] The most recent concussion recommendations, including the AAP Clinical Report published in 2010, stress removing an athlete suspected of sustaining a concussion from play immediately with no return to play on the day of injury. Resting the brain is the key to the most rapid resolution of the concussion; such rest includes no physical activity, with minimal cognitive and social activity. The concussed athlete should seek prompt medical attention from an appropriate health professional. Once the athlete is fully free of symptoms and cleared by a physician knowledgeable in the treatment and management of concussion, the athlete should enter a graduated return-to-play protocol to ensure a safe return to sporting activity.[30]

Summary of Acute Injuries

Although the rates of injury for baseball and softball are low in comparison with other sports, the combination of relatively high severity of injuries that do occur and the very large number of participants in these sports produces a substantial number of individuals with significant injuries each year. Focused media attention on these cases often produces a groundswell for action, even when the scientific evidence for change is lacking.

OVERLOAD CAUSING OVERUSE INJURY OF THE SHOULDER AND ELBOW IN BASEBALL

Overuse arm injuries in youth baseball primarily affect pitchers. The repetitive stress of throwing can lead to muscle fatigue and then to muscle, tendon, and ligament damage. To control the number of these injuries, it is critical that pediatricians, coaches, athletes, and parents understand the anatomy, biomechanics, and kinetics of throwing a baseball pitch.[31–33]

In throwing, especially pitching, the arm force and speed generated during the full windup motion is astonishingly high (7200 degrees, or 20 revolutions of a circle, per second for professional pitchers). At ball release, the rotator cuff muscles and long head of the biceps contract to decelerate arm motion and prevent the arm from following the ball ("throwing one's arm out").[34]

The shoulder girdle (including the clavicle [collarbone], scapula [shoulder blade], glenohumeral joint, humerus, and all of the various muscular attachments to the thorax and scapula) permits the arm to enjoy remarkable freedom of movement. Greater joint range of motion sacrifices the inherent joint stability that is usually provided by bony articulation or ligamentous limitation. Unlike other joints, such as the knee and ankle, the glenohumeral joint of the shoulder acquires nearly all of its stability during activity from the muscles of the shoulder with little or no assistance from bones or ligaments. Therefore, when the muscles become fatigued (and cannot do their job properly), the shoulder becomes an unstable joint. Pitchers who continue to throw when the arm is fatigued risk serious and possibly permanent injury to their muscles, ligaments, capsules, labra, and bones.[35]

The scapula plays a critical role in the functioning kinetic chain of the upper extremity. The scapula is attached to the distal end of the clavicle by the broad acromioclavicular ligament and the 2 coracoclavicular ligaments that arise from the hooklike coracoid. The clavicle attaches proximally to the sternum at the sternoclavicular joint; the sternoclavicular joint is the only joint connection of the entire upper extremity to the main skeleton of the body. The scapula rests on the thorax (chest wall) and is connected through numerous muscles (scapulothoracic joint) that permit the shoulder blade to rise (shrugging shoulders), to glide around the body (protraction), and to glide back toward the spinal column (retraction). Strength and endurance of these extrinsic shoulder girdle muscles, especially the serratus anterior, are essential to ensure safe pitching. These muscles must move the scapula to its appropriate position and stabilize its base before the acceleration phase of the throwing motion can proceed. With excellent scapular muscular control, the athlete can then use the long lever of the upper extremity to throw with power, speed, and accuracy.[36]

It also has long been recognized, however, that the source of power (velocity) in throwing is part of a larger kinetic chain, which begins in the legs, travels through the pelvis into the torso ("the core"), and finally comes out through the scapula into the upper extremity. Strong legs and especially a strong core help generate a majority of the force behind a pitched ball.[37]

Relative weakness of the serratus anterior muscle is often responsible for injuries to the rotator cuff muscles, biceps, and elbow (farther down the kinetic chain). Scapular winging (being able to slide one's hand under the medial or inferior edge of the scapula when relaxed), scapular depression (inferior pole sits lower than the other side or below T-7), and protraction (sits farther away from the vertebral spines than the opposite side) are noted on inspection. Observing an athlete (from behind) performing the arm component of a "jumping jack" approximately a dozen times will demonstrate poor movement patterns, or scapulothoracic dyskinesis. A second test entails forward flexing the arm to the fully overhead position and slowly lowering the arm 180 degrees to its natural position. Scapulothoracic dyskinesis consists of unsmooth or uncontrolled scapular motion while bringing the arms up or down, including marked scapular winging during descent. Although the athlete may perform the first few repetitions well, scapulothoracic dyskinesis may become evident toward the end of the set, when fatigue sets in.[36,38]

The scapula also forms part of the glenohumeral joint (true shoulder joint). The scapula's glenoid is a shallow socket surrounded by a cuplike rim called the labrum, which provides additional stability. The 2 main ligaments of the glenohumeral joint perform most of their stabilizing function when the shoulder is not being used dynamically. During sporting activity and especially during throwing, the 4 rotator cuff muscles and the long head of the biceps are responsible for keeping the humeral head in the glenoid socket. The larger muscles (deltoids, trapezius, pectorals, latissimus dorsi, short head of the biceps, and triceps) provide the powerful dynamic forces to move the arm and generate ball velocity.

The term "Little League shoulder" refers to the widening of the proximal humeral physis resulting from chronic recurrent traction stress across the growth plate. This lesion is felt to be primarily the result of throwing a large number of pitches or maximum-effort throws or insufficient rest between pitching assignments, but can also be related to improper mechanics or premature attempts with certain pitch

types. When unrecognized, or when recognized in an advanced stage of overuse, Little League shoulder can lead to chronic pain with throwing, early shoulder instability, or degenerative arthritis.[39]

The term "Little League elbow" refers to medial elbow pain in skeletally immature athletes resulting from throwing issues similar to those mentioned in the description of "Little League shoulder." Pitchers are most likely to be affected by this condition, but it can also occur in other players at positions requiring frequent and forceful throwing. Traction forces occur on the medial elbow and compression forces laterally. The medial traction forces can cause separation or avulsion of the humeral medial epicondyle apophysis and overuse injury to the common flexor tendon. The compression forces laterally can cause collapse and deformity of the distal humerus (capitulum), also known as osteochondritis dissecans in adolescents and Panner disease in children younger than 10 years. Early recognition of symptoms is important to avoid chronic elbow pain, instability, and arthritis.[35] The inability to fully straighten the elbow is usually an indication of an overuse elbow injury. Complete tears of the ulnar collateral ligament (UCL) are repaired by "Tommy John" surgery, which is followed by nearly a year of rehabilitation before return to pitching is allowed. UCL tears have risen to nearly epidemic proportions in the past 5 years among youth and high school pitchers, increasing almost 20-fold from the previous decade.[35,40] When the pitch velocity exceeds 80 miles per hour, the forces experienced at the UCL are near the point of failure (32 Newton meters).[35,41]

Prevention of Shoulder and Elbow Overuse Injuries in Baseball

In 2006, the Medical and Safety Advisory Committee of USA Baseball set pitching limits for a season and a calendar year, based on age.[42] In 2007 and 2008, on the basis of extensive research, Little League Baseball released its pitch count regulation guide in an attempt to reduce the risk of overuse injuries to elbows and shoulders.[43,44] This guide for parents, coaches, and league officials sets a maximum number of pitches to be thrown in a day on the basis of age as well as the number of rest days between pitching assignments on the basis of number of pitches thrown and age. It replaces the previous regulations, which set a maximum number of innings pitched in a calendar week. Beginning in 2010, Little League tournament pitching regulations became the same as for regular season play, as shown in Tables 1 and 2.[44,45] It is the responsibility of the coach to know when an athlete has reached his or her pitch count limit. When pitchers exceed recommended pitch count maximums for age for an entire season or a full year, the injury rates for shoulders and elbows increase dramatically.[41]

Young pitchers should avoid pitching on multiple teams with overlapping seasons; the guidelines for rest requirements must be enforced across all teams. Youth pitchers should not pitch competitively in more than 8 months in any 12-month period; 3 consecutive months of complete rest from pitching each year is recommended. A pitcher should also not be a catcher for his or her team. Catchers throw even more frequently than pitchers, and although the return throws are only moderately stressful, catchers also make many hard throws to the bases during a game. Thus, playing both positions greatly increases the repetitive stress to the arm.[35,46]

A preseason conditioning program that includes strengthening the core, the rotator cuff, and the shoulder-stabilizing muscles (scapular stabilizers) also may help reduce throwing injuries. A prospective epidemiological research study among asymptomatic adolescent and preadolescent tennis athletes found those with decreased scapula stabilizing muscular strength (noted by scapula winging, protraction, and depression) demonstrated a higher rate of shoulder injury during the subsequent season.[47]

Teaching proper pitching mechanics may also prevent serious overuse injuries.[35,42,43,48] Allowing sufficient time during the early part of the season to gradually increase the amount and intensity of throwing may provide young arms an opportunity to adapt to the stresses of throwing. During the off-season and preseason, after allowing for a period of several months of complete rest from throwing, daily throwing of a strictly limited number of pitches may enhance strength development (as regular strength training does for other muscle regions) with little risk of overuse injury or fatigue.[35,49] A core-stabilizing exercise program will improve strength and should also be adopted for pitchers and hitters.[35,37,47]

Four keys to successful pitching within the 5- to 14-year age group are (1) the development of a fastball; (2) accuracy of locating pitches (control); (3) development of an off-speed pitch (change-up); and (4) changing pitch speeds and plate locations to keep batters guessing. Conventional wisdom has long considered the curve ball and slider to be stressful to the young elbow, and recommendations to delay their introduction until later years (when the skeletal maturity is more significantly advanced) were common.[43] Recent studies challenge those theories and indicate that, when properly thrown, the curve ball may not overly stress the elbow.[35,50,51] Nevertheless, on the basis of those

TABLE 1 Little League Baseball 2010 Pitching Guidelines: Maximum Pitches per Game

10 y and younger	75 pitches per d
11–12 y	85 pitcher per d
13–16 y	95 pitches per d
17–18 y	105 pitches per d

Source: Little League (http://www.littleleague.org/media/newsarchive/2009/Sep-Dec/LLTournamentRegularSeasonPitchingRulesMadeSame.htm).

studies that show increased injury among those who throw curve balls and sliders at early ages, researchers currently continue to recommend delaying introduction of the curve ball until after age 14 or when pubertal development has advanced to the stage when the athlete has started to shave (sliders should be delayed until age 16).[41] The American Academy of Pediatrics endorses this recommendation. Finally, on the basis of the increasing number of elbow ligament surgeries in younger and younger pitchers, it is clear that players, parents, and coaches require more respect for the limits of the developing child's arm to withstand the forces incurred while pitching and should understand that the consequence of overload causing overuse injuries which can permanently damage anatomic structures.[35]

OVERUSE INJURY FROM SOFTBALL PITCHING

Data on softball injuries were included in the previous sections; in general, these demonstrate injury patterns similar to baseball with several minor variations. One unique feature of softball, however, is the nature of pitching; pitchers throw underhand from a flat mound. Although the softball windmill pitching motion may be less stressful to the pitcher's shoulder and elbow than throwing a hardball overhand, there are still significant forces placed on various body structures to cause overuse injury.

The same concerns exist for arm safety: do not throw when fatigued. As of 2011, inning limitations and rest days for softball windmill pitchers in the various age divisions of Little League apply to tournament play only. Many softball teams rely on fewer pitchers per team than baseball. Before such inning limitations, some pitchers pitched in multiple games during weekend tournaments, running up pitch counts between 1500 and 2000 pitches in a 3-day period.[52]

The driving force of the windmill softball pitch is in the lower body[53]; 1 study reported more than 50% of the total kinetic energy of upper extremity during overhead movements is supplied by the trunk and legs.[54] The softball pitcher engages the gluteal muscles to achieve stabilization of the pelvis, which in turn helps the scapula achieve adequate control.

The lower extremity supports the mechanics of the upper body during the softball windmill pitch, especially during the single-leg support component; however, the site of failure (injury) may not be located where the problem originates, but at a more remote site (the weakest link). This kinetic chain theory produces "culprits" and "victims" in describing injuries. For example, although 70% of 131 injuries to collegiate softball pitchers were from overuse, only 13% were reported in the lower extremity.[55] The majority occurred in the shoulder or elbow. Thus, although the "culprit" may be weak gluteal muscles and lack of pelvic stabilization, the athlete may present with shoulder pain, because the "victim" shoulder is inherently "the weakest link."

The pelvis and torso work to accelerate the segments of the upper extremity in a sequential manner. Scapular retraction is stimulated by ipsilateral hip extension and trunk extension. A stable scapula is vital for optimal rotator cuff function that helps to keep the humerus in the glenoid fossa (thus avoiding impingement).

Accordingly, examination and treatment of shoulder pain in softball windmill pitchers should include an assessment of and rehabilitation for pelvic stability and gluteal strength. Scapular stabilization must also be evaluated and treated as well as the affected shoulder or elbow. Off-season and preseason conditioning programs for softball windmill pitchers should include gluteal strengthening and pelvic stabilization exercises.

TABLE 2 Little League Baseball 2010 Pitching Guidelines: Rest Requirements for Pitchers

Pitchers 14 y and younger	
66 or more pitches in a day	Four (4) calendar days
51–65 pitches in a day	Three (3) calendar days
36–50 pitches in a day	Two (2) calendar days of rest must be observed
21–35 pitches in a day	One (1) calendar day of rest must be observed
1–20 pitches in a day	NO (0) calendar day of rest must be observed
Pitchers 15–18 y	
76 or more pitches in a day	Four (4) calendar days
61–75 pitches in a day	Three (3) calendar days
46–60 pitches in a day	Two (2) calendar days of rest must be observed
31–45 pitches in a day	One (1) calendar day of rest must be observed
1–30 pitches in a day	NO (0) calendar day of rest must be observed

ROLE OF EQUIPMENT IN INJURY RISK AND PREVENTION

Playing Equipment

The game of baseball requires playing equipment (ball, bat, gloves, bases), as well as equipment to dress and protect the athlete. Although there are overarching concerns about equipment

performance and safety that apply to every athlete who plays baseball, some concerns typically apply to only a small segment of players depending on age, developmental level, and skill.[56,57]

The ball is the cause of most baseball injuries, through being hit by a pitched ball, being struck while attempting to field a batted ball, trying to catch a thrown ball, or being hit by a thrown or batted ball while running the bases. Accordingly, modifications in the hardness and compressibility of baseballs (and softballs) were developed by equipment manufacturers several decades ago for use by children of different ages with the intent of reducing the force of impact by the ball while maintaining adequate performance characteristics; they were known as reduction-in-force balls. These softer balls, however, are alleged to possess a more "lively" bounce than traditional baseballs.[56–58] The National Operating Committee on Standard for Athletic Equipment (NOCSAE) has developed standards for these softer baseballs (levels 1, 2, and 3),[59,60] and an expert review panel and other researchers have indicated that softer balls meeting the NOCSAE standard are less likely to cause injury, specifically serious head injury or commotio cordis by impact.[22–24,60,61] Children with the lowest skill level (in general, those younger than 10 years) should use the lowest-impact NOCSAE-approved balls (level 1). Level 2 low-impact balls are designed for children 10 to 12 years of age with moderate skill levels. Children younger than 10 years of age with moderate skills may use either level 1 or level 2 balls. Level 3 balls are designated for youths older than 12 years and those 10 to 12 years of age with advanced skills.[61]

Baseball has the highest number of sports-related eye injuries in children, with the highest incidence in 5- to 14-year-olds (T.J. Schroeder, MS, personal communication, 2009).[11,13] Approximately one-third of baseball-related eye injuries result from being struck by a pitched ball; other common causes of eye injuries are attempting to field a batted ball or catch a thrown ball.

The composition of the bat has provoked much discussion in recent years, especially for baseball players older than 15 years. Composite (metal) bats have largely replaced wooden bats.[62] Initially, the introduction of metal bats led to an increased velocity of the batted ball, putting fielders at greater risk of injury, especially pitchers and third basemen.[62] Considerable research has been conducted comparing both types of bats, but no consensus exists regarding safety of composite metal bats compared with wooden bats in youth baseball.[62,63] All bats, wooden or metal, are momentarily deformed upon contact with the baseball; the recoil or restitution characteristics of the bat to its usual shape result in imparting additional velocity to the batted ball. Industry performance standards for composite metal bats were developed in 2003 through the leadership of the National Collegiate Athletic Association and National Federation of State High School Associations. These standards limit the dimensions of the bat and its capacity to transfer force (velocity) to the batted ball (ball exit speed ratio). Bat composition for National Collegiate Athletic Association baseball was required to meet the Batted Ball Coefficient of Restitution guidelines in 2011, and high school baseball will follow suit in 2012.[64] For Little League Baseball, the maximum bat length is 33 inches and maximum barrel diameter may not exceed 2 1/4 inches. Since 2009, all Little League bats must be labeled with a bat performance factor of 1.15 or lower.[65,66] Bat performance factor is a measure of a nonwood bat's performance relative to wood bats. For 2011, Little League International has imposed a moratorium on the use of composite bats for all baseball divisions citing research that found that "composite bats, while they meet the standard when new, can exceed that standard after a break-in process."[67] Although the media continue to report anecdotal stories of significant head and facial injuries associated with metal bats, epidemiological injury surveillance studies do not show an increase in the rate of such injuries since metal bats were introduced.[62]

Equipment-related injuries also include those caused by bases and cleats. Foot and ankle injuries occur regularly in baseball and softball, especially during sliding. Early studies showed that at least 35% of all injuries in softball occurred while sliding feet first into a base, and, in one study, 82% of those injuries resulted in ankle fractures or dislocations.[68,69] Subsequently, a 2-year study comparing traditional stationary bases and bases capable of disengaging noted a greater than 95% reduction in foot and ankle injuries with breakaway bases.[70–74] In 2008, Little League baseball and softball mandated the use of breakaway bases.[74] Youth softball leagues have also incorporated the use of a separate "runner's base" at first base to avoid collisions; the orange "runner's base" sits adjacent to the white regular base, but in foul territory, providing the runner and fielder separate, equal-size bases. Metal spikes are dangerous to basemen covering bases; rubber spikes are preferred for youth baseball.

Protective Equipment

Protective equipment should always be properly fitted, well maintained, and clean; equipment hygiene is important to prevent infections, such as methicillin-resistant *Staphylococcus aureus*. Although not all equipment adaptations have been tested scientifically for

efficacy, experts believe those mentioned in this article will help reduce injuries in softball and baseball players.[24]

Padded sliding pants worn underneath the baseball pants provide good protection against contusions and abrasions to the hips and thigh when athletes slide feet first into a base. For athletes who slide head and hands first, wearing gloves can reduce hand abrasions; similarly, use of batting gloves improves the grip on the bat and reduces the risk of blisters. Head-first sliding creates the risk of head injuries from collisions with the fielder or from being hit by a thrown ball; upper-extremity injuries can occur from the contact and deceleration forces that occur when the hands of the diving body encounter the stationary base. According to current Little League Baseball rules, a runner may not slide head-first except when retreating to a previously held base.[75]

Chest protectors for batters were introduced in the 1990s to protect the heart from ball impact, which can cause commotio cordis.[19] However, this protective barrier has not been shown to be reliable in either the human experience or in animal laboratory studies.[22–25,28,63] More study is required to develop and target equipment that will better prevent commotio cordis.[24] Recent design modifications indicate that progress is being made, but these advances have not been validated in evidence-based peer-reviewed scientific journal articles or abstracts presented at professional meetings.[76] Even the chest protectors for catchers, which are effective for blunting the usual forces encountered from pitches, foul tips, throws, and collisions do not reliably prevent commotio cordis.[24,77]

Hard plastic shell batting helmets have long been an integral part of protecting baseball and softball players from head injuries while batting and running the bases. The NOCSAE developed standards for helmets and their testing decades ago.[59] Their design and characteristics have been modified over the years to better protect the eyes, ears, face, mouth, and nose.[78] In 2009, a new batting helmet was introduced with the capacity to withstand the impact of a 100-mph fastball; it has a layer of expanded polypropylene, the hard, foamlike material used in bicycle helmets.[79,80]

Face and eye protection can be achieved by securing additional protection to the batting helmet, such as a polycarbonate plastic face guard, metal cage, or a polycarbonate full-face shield. Although full plastic face shields have been demonstrated to reduce injury risk significantly, their acceptance by players and league officials has been mixed, primarily because of compromised visibility through the shield over time.[56] More recent epidemiological research among high school baseball athletes has led to a call for infielders and pitchers to wear face shields.[14]

Eye protection may be worn to reduce the risk for eye injury.[81–84] This protection may be particularly important for young athletes who have undergone eye surgery or experienced a previous serious eye injury.[85] Polycarbonate face guards and shields must meet the F910 standard of the American Society of Testing and Materials.[84,86] Face guards cover the lower part of the face from the tip of the nose to below the chin, directly protecting the teeth and facial bones; the space between the top of the guard and the brim of the helmet is less than the diameter of a baseball, thereby indirectly protecting the eyes without impairing vision. Functionally one-eyed athletes (best corrected vision in the worse eye of less than 20/50) must use one of these protectors when batting and also must protect their good eye when fielding the ball by using polycarbonate sports goggles that meet American Society of Testing and Materials standard F803.[86] Some parents may also prefer the use of a face guard or eye goggles when their children are in the field. All athletes who wear glasses or sunglasses while playing baseball or softball should make sure that the lenses and frames meet appropriate safety standards, thus minimizing the risk of breaking or shattering on contact with a baseball or softball.[86]

An essential piece of equipment for all boys playing baseball or softball is use of a hard plastic athletic cup to protect the testicles. Although catchers, pitchers, and infielders are at the greatest risk, testicular injuries can occur to any player while in the field, batting, or running the bases.

The development of triangular-shaped foam pads ("knee savers") for catchers is another advance in safety equipment that has enjoyed widespread use since its introduction.[87] These pads fit into the popliteal fossa behind the knee and are designed to minimize the strain on the knee joint while the catcher is in the crouched position. Some batters opt for shin guards to protect their medial distal tibia; another innovation gaining notice is the elbow protective pad for batters.

ENVIRONMENTAL RISKS

Environmental risks include weather-related concerns and field conditions and boundaries (perimeters).

Baseball and softball players are at risk for injury from weather-related factors, including lightning, sun, and heat. Recreational facilities managers, coaches, and umpires need to be well-versed in lightning safety guidelines[5,88] and prepare an emergency action prevention plan in advance. In particular, lightning presents a unique challenge because of the difficulty in

predicting and appreciating the presence of electrical storms. More and more facilities are installing automatic lightning detectors and alarm systems to ensure that everyone responds appropriately to the presence of lightning. In the absence of an automated warning system, estimating the distance of the storm from the fields can be accomplished by counting the number of seconds between seeing lightning and hearing thunder. Divide the number of seconds by 5 to estimate the distance in miles. A "flash-to-bang" of 30 seconds or less is an indication to move athletes and spectators to a safe area. A preassigned individual should be responsible for the decision to evacuate. In general, a period of 30 minutes should elapse from the last sound of thunder and from the last visible lightning flash before play should be resumed.

Hot and/or humid weather conditions pose significant risk for heat-related illness in children and adolescents. Ambient temperature, relative humidity, wind speed, and solar radiant heat all affect risk for heat illness.[89,90] The ability to dissipate body heat into the surrounding environment decreases as the ambient temperature rises closer to body temperature. Similarly, as the humidity rises and the air becomes more saturated with water, the ability to cool oneself through evaporation decreases. Wind and sun exposure can damage the skin and eyes. Being acclimatized to the environment, ensuring adequate hydration, wearing a baseball cap, and having a covered dugout are important features of minimizing the risk of sun- and heat-related illness. Recommendations regarding sunscreen, sunglasses, and proper uniforms for practice and games are appropriate for players of all ages. Similarly, in cold weather, athletes need to be properly dressed. When necessary, games should be postponed or game times altered when weather conditions are extreme.

Fields need to be inspected regularly for hazards, including problems with sprinkler heads, gopher holes in the outfield, or rocky infields. A warning track (usually 15 feet wide) should surround the entire grass or artificial turf playing surface and should meet all recommended specifications; the change in surface texture serves to alert fielders that they are nearing the perimeter barriers, such as when outfielders are going back on long hits to the fence. All fences should be in good repair, especially the backstop and the fence along both foul lines. If a chain-link fence is curled up and the grass becomes high, an athlete may receive a laceration when reaching down to pick up the ball (not noticing the hazard produced by the defective fencing).

Elimination of the on-deck circle, placing dugouts behind a fence, and the wearing of batting helmets by the first-base and third-base coaches have further reduced the risk of injury on the playing field.

DEVELOPMENTAL CONSIDERATIONS

The pediatrician needs to have an understanding of developmental considerations as they apply to baseball and softball participation at various ages. This will allow the pediatrician to offer appropriate counseling and guidance to the many boys and girls, their parents, and members of the sporting community who participate in baseball and softball each year.

Compared with older players, children between 5 and 10 years often have less coordination, slower reaction times, a reduced ability to pitch accurately, and a greater fear of being struck by the ball.[91,92] Some developmentally appropriate rule modifications, therefore, are advisable for this age group, including the use of batting tee, a pitching machine, or an adult pitcher. The avoidance of head-first sliding for children younger than 10 years is especially important, because there have been anecdotal reports of rare but serious cervical spine injuries occurring when a young player slides head-first, hitting an opponent with the top of the helmet. This injury is similar to that caused by "spearing" (using the head as the lead object) in football. Feet-first sliding should be taught consistently (as players become developmentally ready) so that all players become comfortable with this key technique of the game. The use of softer balls, as described in a previous section of this statement, is also recommended in this age group to reduce serious impact injury.

Youth baseball has long recognized that the game must be modified to meet the developmental level and skills of its players. The distance between bases begins at 45 feet for Tee Ball, moves to 60 feet for Minor League and Little League (Majors) for ages 10 to 12 years, goes to 70 to 75 feet for ages 13 to 15 years, and eventually advances to 90 feet for boys 16 to 18 years of age; similarly, the pitcher's mound increases from 46 feet, to 50 feet, to 60.5 feet from home plate, respectively. The distances of the outfield fences also grow as the field enlarges. The length and weight of bats is another variable that changes as the youth grow in size, strength, and ability.

Some children are able to track ball movement at early ages and can accurately move to and catch a fly ball or hit live pitching as early as 5 years old; most children, however, do not achieve these capabilities until ages 8 or 9.[91] Therefore, it is appropriate to begin introduction to baseball batting for 5- to 7-year-olds using a ball that is not moving but placed on a tee. For

children who are capable of hitting a thrown pitched ball, however, being forced to hit the tee ball may not enhance their skill development.

Coaches who are not knowledgeable in child development may become frustrated trying to teach basic skills to young boys and girls who are simply not ready to acquire these skills, no matter how many balls are pitched to them or how many fly balls they are asked to catch during practice. For these reasons, Little League baseball tracks its athletes into the minors and the majors for boys 10 through 12, separating those children who are developmentally advanced from those who are developing at the typical rate. It must be remembered, however, that "late bloomers" may ultimately turn out to be the finest athletes of all, despite their slower beginning. Proper instruction and persistent repetition in the fundamentals of baseball are essential for youth to develop the talent and skills required to perform proficiently at a high level during late adolescence and adulthood.

RECOMMENDATIONS

The American Academy of Pediatrics recommends the following:

1. Because baseball and softball for children 5 through 18 years of age are relatively safe sports, participation should be encouraged by pediatricians.
2. Preventive measures should be used to protect young baseball pitchers from throwing injuries. Adequate core strength and scapular muscle strength provide a critical foundation; proper instruction in throwing mechanics, conditioning, and training is another essential component. Delay introduction of the curve ball until after age 14 and the slider until age 16. Three key elements in preventing overuse injuries in pitchers include: (a) age guidelines regarding the number of pitches thrown daily; (b) rest requirements between pitching assignments; and (c) season and yearly total pitch limits.[38,42,44] Young pitchers should avoid pitching on multiple teams with overlapping seasons; the guidelines for rest requirements must be enforced across all teams. Youth pitchers should not pitch competitively in more than 8 months in any 12-month period; 3 months of rest from pitching are recommended each year. A pitcher should also not be a catcher for his or her team.
3. Parents, coaches, and players should be educated about the early warning signs of elbow and shoulder overuse injuries as well as the importance of parascapular muscle strength. Athletes should cease pitching immediately when signs of arm fatigue or pain occur; they should be encouraged to seek timely and appropriate treatment of significant or persistent pain.[35]
4. Serious and potentially catastrophic baseball injuries can be minimized by the proper use of available safety equipment. This safety equipment includes: (a) for hitters, approved batting helmets with face protection; (b) for catchers, helmets, masks with throat guards, chest protectors, and shin guards; (c) for all male players, hard plastic athletic cup; and (d) for all baseball and softball players, rubber-spiked soles. In light of the relatively high percentage and severity of head, face, and mouth injuries in baseball, strong consideration should be given to head and facial protection for pitchers and infielders, especially in younger age groups and for less-skilled players. Protective equipment should always be properly fitted, well maintained, and clean.
5. Current data show that chest barriers or protection are not sufficiently effective in preventing commotio cordis; thus, the routine use of these heart protectors is not recommended for baseball players at this time. Catchers must continue to wear approved chest protectors.
6. Coaches and officials must be prepared to activate the emergency response system (call 911) and to obtain rapid access to an AED, ideally in less than 3 minutes, to assist young baseball or softball players who are experiencing cardiac arrest or another medical emergency. Coaches should have a local cellular phone and emergency medical phone numbers available for use at all times.
7. Coaches, parents, umpires, and league officials need to be knowledgeable regarding the cause, prevention, recognition, and response to concussion. New policies exist with excellent free educational and prevention materials, especially from the Centers for Disease Control and Prevention. Furthermore, free on-line trainings are available through the Centers for Disease Control and Prevention (http://www.cdc.gov/concussion/) and the National Federation of State High School Associations (www.nfhs.org).
8. Youth baseball and softball players should wear polycarbonate eye protection guards or shields or metal cages on their batting helmets to reduce the risk of eye injury. For functionally one-eyed athletes (best corrected vision in the worse eye of less than 20/50) and those who have undergone eye surgery or experienced previous severe eye injuries, eye protection (one of the 3 types of

face shields or polycarbonate sports goggles) should be required at all times while the athlete is batting or fielding.

9. Children with the lowest skill level (in general, those younger than 10 years of age) should use the lowest-impact NOCSAE-approved balls (level 1). Level 2 low-impact balls are recommended for children 10 to 12 years of age with moderate skill levels. Children younger than 10 years with moderate skills may use either level 1 or level 2 balls. Level 3 balls are designated for youths older than 12 years and those 10 to 12 years of age with advanced skills.
10. Continued research into the relative safety of composite metal versus wooden bats is appropriate and necessary.
11. Awareness of heat and lightning safety is essential for all coaches and officials of Little League baseball and softball. The Web site http://www.lightningsafety.noaa.gov/outdoors.htm[88] and weather forecasts are critical resources for prevention of lightning injuries. When necessary, games or practices should be postponed or game times altered when weather conditions are extreme.
12. Protective fencing of dugouts and benches and the elimination of the on-deck circle are recommended during games and practices in organized and informal participation. Proper field maintenance is required to minimize injury risks.
13. New developmentally appropriate rule modifications should continue to be implemented when indicated.
14. Surveillance of baseball and softball injuries should be continued. Continual strong support of research is essential to develop other new, improved, and efficacious safety equipment and rule modifications.

abstract

FREE

Breastfeeding and human milk are the normative standards for infant feeding and nutrition. Given the documented short- and long-term medical and neurodevelopmental advantages of breastfeeding, infant nutrition should be considered a public health issue and not only a lifestyle choice. The American Academy of Pediatrics reaffirms its recommendation of exclusive breastfeeding for about 6 months, followed by continued breastfeeding as complementary foods are introduced, with continuation of breastfeeding for 1 year or longer as mutually desired by mother and infant. Medical contraindications to breastfeeding are rare. Infant growth should be monitored with the World Health Organization (WHO) Growth Curve Standards to avoid mislabeling infants as underweight or failing to thrive. Hospital routines to encourage and support the initiation and sustaining of exclusive breastfeeding should be based on the American Academy of Pediatrics-endorsed WHO/UNICEF "Ten Steps to Successful Breastfeeding." National strategies supported by the US Surgeon General's Call to Action, the Centers for Disease Control and Prevention, and The Joint Commission are involved to facilitate breastfeeding practices in US hospitals and communities. Pediatricians play a critical role in their practices and communities as advocates of breastfeeding and thus should be knowledgeable about the health risks of not breastfeeding, the economic benefits to society of breastfeeding, and the techniques for managing and supporting the breastfeeding dyad. The "Business Case for Breastfeeding" details how mothers can maintain lactation in the workplace and the benefits to employers who facilitate this practice. *Pediatrics* 2012;129:e827–e841

INTRODUCTION

Six years have transpired since publication of the last policy statement of the American Academy of Pediatrics (AAP) regarding breastfeeding.[1] Recently published research and systematic reviews have reinforced the conclusion that breastfeeding and human milk are the reference normative standards for infant feeding and nutrition. The current statement updates the evidence for this conclusion and serves as a basis for AAP publications that detail breastfeeding management and infant nutrition, including the *AAP Breastfeeding Handbook for Physicians*,[2] *AAP Sample Hospital Breastfeeding Policy for Newborns*,[3] *AAP Breastfeeding Residency Curriculum*,[4] and the *AAP Safe and Healthy Beginnings Toolkit*.[5] The AAP reaffirms its recommendation of exclusive breastfeeding for about 6 months, followed by continued breastfeeding as complementary foods are introduced, with continuation

of breastfeeding for 1 year or longer as mutually desired by mother and infant.

EPIDEMIOLOGY

Information regarding breastfeeding rates and practices in the United States is available from a variety of government data sets, including the Centers for Disease Control and Prevention (CDC) National Immunization Survey,[6] the NHANES,[7] and Maternity Practices and Infant Nutrition and Care.[8] Drawing on these data and others, the CDC has published the "Breastfeeding Report Card," which highlights the degree of progress in achieving the breastfeeding goals of the Healthy People 2010 targets as well as the 2020 targets (Table 1).[9–11]

The rate of initiation of breastfeeding for the total US population based on the latest National Immunization Survey data are 75%.[11] This overall rate, however, obscures clinically significant sociodemographic and cultural differences. For example, the breastfeeding initiation rate for the Hispanic or Latino population was 80.6%, but for the non-Hispanic black or African American population, it was 58.1%. Among low-income mothers (participants in the Special Supplemental Nutrition Program for Women, Infants, and Children [WIC]), the breastfeeding initiation rate was 67.5%, but in those with a higher income ineligible for WIC, it was 84.6%.[12] Breastfeeding initiation rate was 37% for low-income non-Hispanic black mothers.[7] Similar disparities are age-related; mothers younger than 20 years initiated breastfeeding at a rate of 59.7% compared with the rate of 79.3% in mothers older than 30 years. The lowest rates of initiation were seen among non-Hispanic black mothers younger than 20 years, in whom the breastfeeding initiation rate was 30%.[7]

Although over the past decade, there has been a modest increase in the rate of "any breastfeeding" at 3 and 6 months, in none of the subgroups have the Healthy People 2010 targets been reached. For example, the 6-month "any breastfeeding" rate for the total US population was 43%, the rate for the Hispanic or Latino subgroup was 46%, and the rate for the non-Hispanic black or African American subgroup was only 27.5%. Rates of exclusive breastfeeding are further from Healthy People 2010 targets, with only 13% of the US population meeting the recommendation to breastfeed exclusively for 6 months. Thus, it appears that although the breastfeeding initiation rates have approached the 2010 Healthy People targets, the targets for duration of any breastfeeding and exclusive breastfeeding have not been met.

Furthermore, 24% of maternity services provide supplements of commercial infant formula as a general practice in the first 48 hours after birth. These observations have led to the conclusion that the disparities in breastfeeding rates are also associated with variations in hospital routines, independent of the populations served. As such, it is clear that greater emphasis needs to be placed on improving and standardizing hospital-based practices to realize the newer 2020 targets (Table 1).

TABLE 1 Healthy People Targets 2010 and 2020(%)

	2007[a]	2010 Target	2020 Target
Any breastfeeding			
Ever	75.0	75	81.9
6 mo	43.8	50	60.5
1 y	22.4	25	34.1
Exclusive breastfeeding			
To 3 mo	33.5	40	44.3
To 6 mo	13.8	17	23.7
Worksite lactation support	25	—	38.0
Formula use in first 2 d	25.6	—	15.6

INFANT OUTCOMES

Methodologic Issues

Breastfeeding results in improved infant and maternal health outcomes in both the industrialized and developing world. Major methodologic issues have been raised as to the quality of some of these studies, especially as to the size of the study populations, quality of the data set, inadequate adjustment for confounders, absence of distinguishing between "any" or "exclusive" breastfeeding, and lack of a defined causal relationship between breastfeeding and the specific outcome. In addition, there are inherent practical and ethical issues that have precluded prospective randomized interventional trials of different feeding regimens. As such, the majority of published reports are observational cohort studies and systematic reviews/meta-analyses.

To date, the most comprehensive publication that reviews and analyzes the published scientific literature that compares breastfeeding and commercial infant formula feeding as to health outcomes is the report prepared by the Evidence-based Practice Centers of the Agency for Healthcare Research and Quality (AHRQ) of the US Department of Health Human Services titled *Breastfeeding and Maternal and Infant Health Outcomes in Developed Countries*.[13] The following sections summarize and update the AHRQ meta-analyses and provide an expanded analysis regarding health outcomes. Table 2 summarizes the dose-response relationship between the duration of breastfeeding and its protective effect.

Respiratory Tract Infections and Otitis Media

The risk of hospitalization for lower respiratory tract infections in the first year is reduced 72% if infants breastfed exclusively for more than 4 months.[13,14] Infants who exclusively breastfed for 4

TABLE 2 Dose-Response Benefits of Breastfeeding[a]

Condition	% Lower Risk[b]	Breastfeeding	Comments	OR[c]	95% CI
Otitis media[13]	23	Any	—	0.77	0.64–0.91

ALL, acute lymphocytic leukemia; AML, acute myelogenous leukemia; BF, breastfeeding; HM, human milk; RSV, respiratory syncytial virus.

[a] Pooled data.

[b] % lower risk refers to lower risk while BF compared with feeding commercial infant formula or referent group specified.

[c] OR expressed as increase risk for commercial formula feeding.

[d] Referent group is exclusive BF ≥6 months.

to 6 months had a fourfold increase in the risk of pneumonia compared with infants who exclusively breastfed for more than 6 months.[15] The severity (duration of hospitalization and oxygen requirements) of respiratory syncytial virus bronchiolitis is reduced by 74% in infants who breastfed exclusively for 4 months compared with infants who never or only partially breastfed.[16]

Any breastfeeding compared with exclusive commercial infant formula feeding will reduce the incidence of otitis media (OM) by 23%.[13] Exclusive breastfeeding for more than 3 months reduces the risk of otitis media by 50%. Serious colds and ear and throat infections were reduced by 63% in infants who exclusively breastfed for 6 months.[17]

Gastrointestinal Tract Infections

Any breastfeeding is associated with a 64% reduction in the incidence of nonspecific gastrointestinal tract infections, and this effect lasts for 2 months after cessation of breastfeeding.[13,14,17,18]

Necrotizing Enterocolitis

Meta-analyses of 4 randomized clinical trials performed over the period 1983 to 2005 support the conclusion that feeding preterm infants human milk is associated with a significant reduction (58%) in the incidence of necrotizing enterocolitis (NEC).[13] A more recent study of preterm infants fed an exclusive human milk diet compared with those fed human milk supplemented with cow-milk-based infant formula products noted a 77% reduction in NEC.[19] One case of NEC could be prevented if 10 infants received an exclusive human milk diet, and 1 case of NEC requiring surgery or resulting in death could be prevented if 8 infants received an exclusive human milk diet.[19]

Sudden Infant Death Syndrome and Infant Mortality

Meta-analyses with a clear definition of degree of breastfeeding and adjusted for confounders and other known risks for sudden infant death syndrome (SIDS) note that breastfeeding is associated with a 36% reduced risk of SIDS.[13] Latest data comparing any versus exclusive breastfeeding reveal that for any breastfeeding, the multivariate odds ratio (OR) is 0.55 (95% confidence interval [CI], 0.44–0.69). When computed for exclusive breastfeeding, the OR is 0.27 (95% CI, 0.27–0.31).[20] A proportion (21%) of the US infant mortality has been attributed, in part, to the increased rate of SIDS in infants who were never breastfed.[21] That the positive effect of breastfeeding on SIDS rates is independent of sleep position was confirmed in a large case-control study of supine-sleeping infants.[22,23]

It has been calculated that more than 900 infant lives per year may be saved in the United States if 90% of mothers exclusively breastfed for 6 months.[24] In the 42 developing countries in which 90% of the world's childhood deaths occur, exclusive breastfeeding for 6 months and weaning after 1 year is the most effective intervention, with the potential of preventing more than 1 million infant deaths per year, equal to preventing 13% of the world's childhood mortality.[25]

Allergic Disease

There is a protective effect of exclusive breastfeeding for 3 to 4 months in

reducing the incidence of clinical asthma, atopic dermatitis, and eczema by 27% in a low-risk population and up to 42% in infants with positive family history.[13,26] There are conflicting studies that examine the timing of adding complementary foods after 4 months and the risk of allergy, including food allergies, atopic dermatitis, and asthma, in either the allergy-prone or nonatopic individual.[26] Similarly, there are no convincing data that delaying introduction of potentially allergenic foods after 6 months has any protective effect.[27–30] One problem in analyzing this research is the low prevalence of exclusive breastfeeding at 6 months in the study populations. Thus, research outcomes in studies that examine the development of atopy and the timing of introducing solid foods in partially breastfed infants may not be applicable to exclusively breastfed infants.

Celiac Disease

There is a reduction of 52% in the risk of developing celiac disease in infants who were breastfed at the time of gluten exposure.[31] Overall, there is an association between increased duration of breastfeeding and reduced risk of celiac disease when measured as the presence of celiac antibodies. The critical protective factor appears to be not the timing of the gluten exposure but the overlap of breastfeeding at the time of the initial gluten ingestion. Thus, gluten-containing foods should be introduced while the infant is receiving only breast milk and not infant formula or other bovine milk products.

Inflammatory Bowel Disease

Breastfeeding is associated with a 31% reduction in the risk of childhood inflammatory bowel disease.[32] The protective effect is hypothesized to result from the interaction of the immunomodulating effect of human milk and the underlying genetic susceptibility of the infant. Different patterns of intestinal colonization in breastfed versus commercial infant formula–fed infants may add to the preventive effect of human milk.[33]

Obesity

Because rates of obesity are significantly lower in breastfed infants, national campaigns to prevent obesity begin with breastfeeding support.[34,35] Although complex factors confound studies of obesity, there is a 15% to 30% reduction in adolescent and adult obesity rates if any breastfeeding occurred in infancy compared with no breastfeeding.[13,36] The Framingham Offspring study noted a relationship of breastfeeding and a lower BMI and higher high-density lipoprotein concentration in adults.[37] A sibling difference model study noted that the breastfed sibling weighed 14 pounds less than the sibling fed commercial infant formula and was less likely to reach BMI obesity threshold.[38] The duration of breastfeeding also is inversely related to the risk of overweight; each month of breastfeeding being associated with a 4% reduction in risk.[14]

The interpretation of these data is confounded by the lack of a definition in many studies of whether human milk was given by breastfeeding or by bottle. This is of particular importance, because breastfed infants self-regulate intake volume irrespective of maneuvers that increase available milk volume, and the early programming of self-regulation, in turn, affects adult weight gain.[39] This concept is further supported by the observations that infants who are fed by bottle, formula, or expressed breast milk will have increased bottle emptying, poorer self-regulation, and excessive weight gain in late infancy (older than 6 months) compared with infants who only nurse from the breast.[40,41]

Diabetes

Up to a 30% reduction in the incidence of type 1 diabetes mellitus is reported for infants who exclusively breastfed for at least 3 months, thus avoiding exposure to cow milk protein.[13,42] It has been postulated that the putative mechanism in the development of type 1 diabetes mellitus is the infant's exposure to cow milk β-lactoglobulin, which stimulates an immune-mediated process cross-reacting with pancreatic β cells. A reduction of 40% in the incidence of type 2 diabetes mellitus is reported, possibly reflecting the long-term positive effect of breastfeeding on weight control and feeding self-regulation.[43]

Childhood Leukemia and Lymphoma

There is a reduction in leukemia that is correlated with the duration of breastfeeding.[14,44] A reduction of 20% in the risk of acute lymphocytic leukemia and 15% in the risk of acute myeloid leukemia in infants breastfed for 6 months or longer.[45,46] Breastfeeding for less than 6 months is protective but of less magnitude (approximately 12% and 10%, respectively). The question of whether the protective effect of breastfeeding is a direct mechanism of human milk on malignancies or secondarily mediated by its reduction of early childhood infections has yet to be answered.

Neurodevelopmental Outcomes

Consistent differences in neurodevelopmental outcome between breastfed and commercial infant formula–fed infants have been reported, but the outcomes are confounded by differences in parental education, intelligence, home environment, and socioeconomic status.[13,47] The large, randomized Promotion of Breastfeeding Intervention Trial provided evidence that adjusted outcomes of intelligence scores and teacher's ratings are significantly greater in breastfed infants.[48–50] In

addition, higher intelligence scores are noted in infants who exclusively breastfed for 3 months or longer, and higher teacher ratings were observed if exclusive breastfeeding was practiced for 3 months or longer. Significantly positive effects of human milk feeding on long-term neurodevelopment are observed in preterm infants, the population more at risk for these adverse neurodevelopmental outcomes.[51–54]

PRETERM INFANTS

There are several significant short- and long-term beneficial effects of feeding preterm infants human milk. Lower rates of sepsis and NEC indicate that human milk contributes to the development of the preterm infant's immature host defense.[19,55–59] The benefits of feeding human milk to preterm infants are realized not only in the NICU but also in the fewer hospital readmissions for illness in the year after NICU discharge.[51,52] Furthermore, the implications for a reduction in incidence of NEC include not only lower mortality rates but also lower long-term growth failure and neurodevelopmental disabilities.[60,61] Clinical feeding tolerance is improved, and the attainment of full enteral feeding is hastened by a diet of human milk.[51,52,59]

Neurodevelopmental outcomes are improved by the feeding of human milk. Long-term studies at 8 years of age through adolescence suggest that intelligence test results and white matter and total brain volumes are greater in subjects who had received human milk as infants in the NICU.[53,54] Extremely preterm infants receiving the greatest proportion of human milk in the NICU had significantly greater scores for mental, motor, and behavior ratings at ages 18 months and 30 months.[51,52] These data remain significant after adjustment for confounding factors, such as maternal age, education, marital status, race, and infant morbidities. These neurodevelopmental outcomes are associated with predominant and not necessarily exclusive human milk feeding. Human milk feeding in the NICU also is associated with lower rates of severe retinopathy of prematurity.[62,63] Long-term studies of preterm infants also suggest that human milk feeding is associated with lower rates of metabolic syndrome, and in adolescents, it is associated with lower blood pressures and low-density lipoprotein concentrations and improved leptin and insulin metabolism.[64,65]

The potent benefits of human milk are such that all preterm infants should receive human milk (Table 3). Mother's own milk, fresh or frozen, should be the primary diet, and it should be fortified appropriately for the infant born weighing less than 1.5 kg. If mother's own milk is unavailable despite significant lactation support, pasteurized donor milk should be used.[19,66] Quality control of pasteurized donor milk is important and should be monitored. New data suggest that mother's own milk can be stored at refrigerator temperature (4°C) in the NICU for as long as 96 hours.[67] Data on thawing, warming, and prolonged storage need updating. Practices should involve protocols that prevent misadministration of milk.

TABLE 3 Recommendations on Breastfeeding Management for Preterm Infants

1. All preterm infants should receive human milk.
   - Human milk should be fortified, with protein, minerals, and vitamins to ensure optimal nutrient intake for infants weighing <1500 g at birth.
   - Pasteurized donor human milk, appropriately fortified, should be used if mother's own milk is unavailable or its use is contraindicated.
2. Methods and training protocols for manual and mechanical milk expression must be available to mothers.
3. Neonatal intensive care units should possess evidence-based protocols for collection, storage, and labeling of human milk.[150]
4. Neonatal intensive care units should prevent the misadministration of human milk (http://www.cdc.gov/breastfeeding/recommendations/other_mothers_milk.htm).
5. There are no data to support routinely culturing human milk for bacterial or other organisms.[151]

MATERNAL OUTCOMES

Both short- and long-term health benefits accrue to mothers who breastfeed. Such mothers have decreased postpartum blood loss and more rapid involution of the uterus. Continued breastfeeding leads to increased child spacing secondary to lactational amenorrhea. Prospective cohort studies have noted an increase in postpartum depression in mothers who do not breastfeed or who wean early.[68] A large prospective study on child abuse and neglect perpetuated by mothers found, after correcting for potential confounders, that the rate of abuse/neglect was significantly increased for mothers who did not breastfeed as opposed to those who did (OR: 2.6; 95% CI: 1.7–3.9).[69]

Studies of the overall effect of breastfeeding on the return of the mothers to their pre-pregnancy weight are inconclusive, given the large numbers of confounding factors on weight loss (diet, activity, baseline BMI, ethnicity).[13] In a covariate-adjusted study of more than 14 000 women postpartum, mothers who exclusively breastfed for longer than 6 months weighed 1.38 kg less than those who did not breastfeed.[70] In mothers without a history of gestational diabetes, breastfeeding duration was associated with a decreased risk of type 2 diabetes mellitus; for each year of breastfeeding, there was a decreased risk of 4% to 12%.[71,72] No beneficial effect for breastfeeding was noted in mothers who were diagnosed with gestational diabetes.

The longitudinal Nurses Health Study noted an inverse relationship between the cumulative lifetime duration of breastfeeding and the development of rheumatoid arthritis.[73] If cumulative duration of breastfeeding exceeded 12

months, the relative risk of rheumatoid arthritis was 0.8 (95% CI: 0.8–1.0), and if the cumulative duration of breastfeeding was longer than 24 months, the relative risk of rheumatoid arthritis was 0.5 (95% CI: 0.3–0.8).[73] An association between cumulative lactation experience and the incidence of adult cardiovascular disease was reported by the Women's Health Initiative in a longitudinal study of more than 139 000 postmenopausal women.[74] Women with a cumulative lactation history of 12 to 23 months had a significant reduction in hypertension (OR: 0.89; 95% CI: 0.84–0.93), hyperlipidemia (OR: 0.81; 95% CI: 0.76–0.87), cardiovascular disease (OR: 0.90; 95% CI: 0.85–0.96), and diabetes (OR: 0.74; 95% CI: 0.65–0.84).

Cumulative lactation experience also correlates with a reduction in both breast (primarily premenopausal) and ovarian cancer.[13,14,75] Cumulative duration of breastfeeding of longer than 12 months is associated with a 28% decrease in breast cancer (OR: 0.72; 95% CI: 0.65–0.8) and ovarian cancer (OR: 0.72; 95% CI: 0.54–0.97).[76] Each year of breastfeeding has been calculated to result in a 4.3% reduction in breast cancer.[76,77]

ECONOMIC BENEFITS

A detailed pediatric cost analysis based on the AHRQ report concluded that if 90% of US mothers would comply with the recommendation to breastfeed exclusively for 6 months, there would be a savings of $13 billion per year.[24] The savings do not include those related to a reduction in parental absenteeism from work or adult deaths from diseases acquired in childhood, such as asthma, type 1 diabetes mellitus, or obesity-related conditions. Strategies that increase the number of mothers who breastfeed exclusively for about 6 months would be of great economic benefit on a national level.

DURATION OF EXCLUSIVE BREASTFEEDING

The AAP recommends exclusive breastfeeding for about 6 months, with continuation of breastfeeding for 1 year or longer as mutually desired by mother and infant, a recommendation concurred to by the WHO[78] and the Institute of Medicine.[79]

Support for this recommendation of exclusive breastfeeding is found in the differences in health outcomes of infants breastfed exclusively for 4 vs 6 months, for gastrointestinal disease, otitis media, respiratory illnesses, and atopic disease, as well as differences in maternal outcomes of delayed menses and postpartum weight loss.[15,18,80]

Compared with infants who never breastfed, infants who were exclusively breastfed for 4 months had significantly greater incidence of lower respiratory tract illnesses, otitis media, and diarrheal disease than infants exclusively breastfed for 6 months or longer.[15,18] When compared with infants who exclusively breastfed for longer than 6 months, those exclusively breastfed for 4 to 6 months had a fourfold increase in the risk of pneumonia.[15] Furthermore, exclusively breastfeeding for 6 months extends the period of lactational amenorrhea and thus improves child spacing, which reduces the risk of birth of a preterm infant.[81]

The AAP is cognizant that for some infants, because of family and medical history, individual developmental status, and/or social and cultural dynamics, complementary feeding, including gluten-containing grains, begins earlier than 6 months of age.[82,83] Because breastfeeding is immunoprotective, when such complementary foods are introduced, it is advised that this be done while the infant is feeding only breastmilk.[82] Mothers should be encouraged to continue breastfeeding through the first year and beyond as more and varied complementary foods are introduced.

CONTRAINDICATIONS TO BREASTFEEDING

There are a limited number of medical conditions in which breastfeeding is contraindicated, including an infant with the metabolic disorder of classic galactosemia. Alternating breastfeeding with special protein-free or modified formulas can be used in feeding infants with other metabolic diseases (such as phenylketonuria), provided that appropriate blood monitoring is available. Mothers who are positive for human T-cell lymphotrophic virus type I or II[84] or untreated brucellosis[85] should not breastfeed nor provide expressed milk to their infants Breastfeeding should not occur if the mother has active (infectious) untreated tuberculosis or has active herpes simplex lesions on her breast; however, expressed milk can be used because there is no concern about these infectious organisms passing through the milk. Breastfeeding can be resumed when a mother with tuberculosis is treated for a minimum of 2 weeks and is documented that she is no longer infectious.[86] Mothers who develop varicella 5 days before through 2 days after delivery should be separated from their infants, but their expressed milk can be used for feeding.[87] In 2009, the CDC recommended that mothers acutely infected with H1N1 influenza should temporarily be isolated from their infants until they are afebrile, but they can provide expressed milk for feeding.[88]

In the industrialized world, it is not recommended that HIV-positive mothers breastfeed. However, in the developing world, where mortality is increased in non-breastfeeding infants from a combination of malnutrition and infectious diseases, breastfeeding may outweigh the risk of the acquiring HIV infection

from human milk. Infants in areas with endemic HIV who are exclusively breastfed for the first 3 months are at a lower risk of acquiring HIV infection than are those who received a mixed diet of human milk and other foods and/or commercial infant formula.[89] Recent studies document that combining exclusive breastfeeding for 6 months with 6 months of antiretroviral therapy significantly decreases the postnatal acquisition of HIV-1.[90,91]

There is no contraindication to breastfeeding for a full-term infant whose mother is seropositive for cytomegalovirus (CMV). There is a possibility that CMV acquired from mother's milk may be associated with a late-onset sepsis-like syndrome in the extremely low birth weight (birth weight <1500 g) preterm infant. Although not associated with long-term abnormalities, such a syndrome may warrant antiviral therapy.[92] The value of routinely feeding human milk from seropositive mothers to preterm infants outweighs the risks of clinical disease, especially because no long-term neurodevelopmental abnormalities have been reported.[93] Freezing of milk reduces but does not eliminate CMV.[94] Heating, either as Holder pasteurization (heating at 62.5°C for 30 minutes) or high-temperature short pasteurization (72°C for 5–10 seconds) eliminates the viral load from the milk but also affects bioactive factors and nutrients.[95] Thus, fresh mother's own milk is preferable for routinely feeding all preterm infants.

Maternal substance abuse is not a categorical contraindication to breastfeeding. Adequately nourished narcotic-dependent mothers can be encouraged to breastfeed if they are enrolled in a supervised methadone maintenance program and have negative screening for HIV and illicit drugs.[96] Street drugs such as PCP (phencyclidine), cocaine, and cannabis can be detected in human milk, and their use by breastfeeding mothers is of concern, particularly with regard to the infant's long-term neurobehavioral development and thus are contraindicated.[97] Alcohol is not a galactogogue; it may blunt prolactin response to suckling and negatively affects infant motor development.[98,99] Thus, ingestion of alcoholic beverages should be minimized and limited to an occasional intake but no more than 0.5 g alcohol per kg body weight, which for a 60 kg mother is approximately 2 oz liquor, 8 oz wine, or 2 beers.[100] Nursing should take place 2 hours or longer after the alcohol intake to minimize its concentration in the ingested milk.[101] Maternal smoking is not an absolute contraindication to breastfeeding but should be strongly discouraged, because it is associated with an increased incidence in infant respiratory allergy[102] and SIDS.[103] Smoking should not occur in the presence of the infant so as to minimize the negative effect of secondary passive smoke inhalation.[104] Smoking is also a risk factor for low milk supply and poor weight gain.[105,106]

MATERNAL DIET

Well-nourished lactating mothers have an increased daily energy need of 450 to 500 kcal/day that can be met by a modest increase in a normally balanced varied diet.[107–109] Although dietary reference intakes for breastfeeding mothers are similar to or greater than those during pregnancy, there is no routine recommendation for maternal supplements during lactation.[108,109,110] Many clinicians recommend the continued use of prenatal vitamin supplements during lactation.[109]

The mother's diet should include an average daily intake of 200 to 300 mg of the ω-3 long-chain polyunsaturated fatty acids (docosahexaenoic acid [DHA]) to guarantee a sufficient concentration of preformed DHA in the milk.[111,112] Consumption of 1 to 2 portions of fish (eg, herring, canned light tuna, salmon) per week will meet this need. The concern regarding the possible risk from intake of excessive mercury or other contaminants is offset by the neurobehavioral benefits of an adequate DHA intake and can be minimized by avoiding the intake of predatory fish (eg, pike, marlin, mackerel, tile fish, swordfish).[113] Poorly nourished mothers or those on selective vegan diets may require a supplement of DHA as well as multivitamins.

MATERNAL MEDICATIONS

Recommendations regarding breastfeeding in situations in which the mother is undergoing either diagnostic procedures or pharmacologic therapy must balance the benefits to the infant and the mother against the potential risk of drug exposure to the infant. There are only a limited number of agents that are contraindicated, and an appropriate substitute usually can be found. The most comprehensive, up-to-date source of information regarding the safety of maternal medications when the mother is breastfeeding is LactMed, an Internet-accessed source published by the National Library of Medicine/National Institutes of Health.[114] A forthcoming AAP policy statement on the transfer of drugs and other chemicals into human milk will provide additional recommendations, with particular focus on psychotropic drugs, herbal products, galactagogues, narcotics, and pain medications.[115] In general, breastfeeding is not recommended when mothers are receiving medication from the following classes of drugs: amphetamines, chemotherapy agents, ergotamines, and statins.

There are a wide variety of maternally administered psychotropic agents for which there are inadequate pharmacologic data with regard to human milk and/or nursing infant's blood

concentrations. In addition, data regarding the long-term neurobehavioral effects from exposure to these agents during the critical developmental period of early infancy are lacking. A recent comprehensive review noted that of the 96 psychotropic drugs available, pharmacologic and clinical information was only available for 62 (65%) of the drugs.[116] In only 19 was there adequate information to allow for defining a safety protocol and thus qualifying to be compatible for use by lactating mothers. Among the agents considered to be least problematic were the tricyclic antidepressants amitriptyline and clomipramine and the selective serotonin-reuptake inhibitors paroxetine and sertraline.

Detailed guidelines regarding the necessity for and duration of temporary cessation of breastfeeding after maternal exposure to diagnostic radioactive compounds are provided by the US Nuclear Regulatory Commission and in medical reviews.[117–119] Special precaution should be followed in the situation of breastfeeding infants with glucose-6-phosphate-dehydrogenase deficiency. Fava beans, nitrofurantoin, primaquine, and phenazopyridine should be avoided by the mother to minimize the risk of hemolysis in the infant.[120]

HOSPITAL ROUTINES

The Sections on Breastfeeding and Perinatal Pediatrics have published the Sample Hospital Breastfeeding Policy that is available from the AAP Safe and Healthy Beginnings Web site.[3,5] This sample hospital policy is based on the detailed recommendations of the previous AAP policy statement "Breastfeeding and the Use of Human Milk"[1] as well as the principles of the 1991 WHO/UNICEF publication "Tens Steps to Successful Breastfeeding" (Table 4)[121] and provides a template for developing a uniform hospital policy for support of breastfeeding.[122] In particular, emphasis is placed on the need to revise or discontinue disruptive hospital policies that interfere with early skin-to-skin contact, that provide water, glucose water, or commercial infant formula without a medical indication, that restrict the amount of time the infant can be with the mother, that limit feeding duration, or that provide unlimited pacifier use.

In 2009, the AAP endorsed the Ten Steps program (see Table 4). Adherence to these 10 steps has been demonstrated to increase rates of breastfeeding initiation, duration, and exclusivity.[122,123] Implementation of the following 5 postpartum hospital practices has been demonstrated to increase breastfeeding duration, irrespective of socioeconomic status: breastfeeding in the first hour after birth, exclusive breastfeeding, rooming-in, avoidance of pacifiers, and receipt of telephone number for support after discharge from the hospital.[124]

The CDC National Survey of Maternity Practices in Infant Nutrition and Care has assessed the lactation practices in more than 80% of US hospitals and noted that the mean score for implementation of the Ten Steps was only 65%.[34,125] Fifty-eight percent of hospitals erroneously advised mothers to limit suckling at the breast to a specified length of time, and 41% of the hospitals gave pacifiers to more than some of their newborns—both practices that have been documented to lower breastfeeding rates and duration.[126] The survey noted that in 30% of all birth centers, more than half of all newborns received supplementation commercial infant formula, a practice associated with shorter duration of breastfeeding and less exclusivity.[34,125] As indicated in the benefits section, this early supplementation may affect morbidity outcomes in this population. The survey also reported that 66% of hospitals reported that they distributed to breastfeeding mothers discharge packs that contained commercial infant formula, a practice that has been documented to negatively affect exclusivity and duration of breastfeeding.[127] Few birth centers have model hospital policies (14%) and support breastfeeding mothers after hospital discharge (27%). Only 37% of centers practice more than 5 of the 10 Steps and only 3.5% practice 9 to 10 Steps.[34]

There is, thus, a need for a major conceptual change in the organization of the hospital services for the mother and infant dyad (Table 5). This requires that medical and nursing routines and practices adjust to the principle that breastfeeding should begin within the first hour after birth (even for Cesarean deliveries) and that infants must be continuously accessible to the mother by rooming-in

TABLE 4 WHO/UNICEF Ten Steps to Successful Breastfeeding

1. Have a written breastfeeding policy that is routinely communicated to all health care staff.
2. Train all health care staff in the skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help mothers initiate breastfeeding within the first hour of birth.
5. Show mothers how to breastfeed and how to maintain lactation even if they are separated from their infants.
6. Give newborn infants no food or drink other than breast milk, unless medically indicated.
7. Practice rooming-in (allow mothers and infants to remain together) 24 h a day.
8. Encourage breastfeeding on demand.
9. Give no artificial nipples or pacifiers to breastfeeding infants.[a]
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from hospital.

[a] The AAP does not support a categorical ban on pacifiers because of their role in SIDS risk reduction and their analgesic benefit during painful procedures when breastfeeding cannot provide the analgesia. Pacifier use in the hospital in the neonatal period should be limited to specific medical indications such as pain reduction and calming in a drug-exposed infant, for example. Mothers of healthy term breastfed infants should be instructed to delay pacifier use until breastfeeding is well-established, usually about 3 to 4 wk after birth.

arrangements that facilitate around-the-clock, on-demand feeding for the healthy infant. Formal staff training should not only focus on updating knowledge and techniques for breastfeeding support but also should acknowledge the need to change attitudes and eradicate unsubstantiated beliefs about the supposed equivalency of breastfeeding and commercial infant formula feeding. Emphasis should be placed on the numerous benefits of exclusive breastfeeding. The importance of addressing the issue of the impact of hospital practices and policies on breastfeeding outcomes is highlighted by the decision of The Joint Commission to adopt the rate of exclusive breast milk feeding as a Perinatal Care Core Measure.[127] As such, the rate of exclusive breastfeeding during the hospital stay has been confirmed as a critical variable when measuring the quality of care provided by a medical facility.

Pacifier Use

Given the documentation that early use of pacifiers may be associated with less successful breastfeeding, pacifier use in the neonatal period should be limited to specific medical situations.[128] These include uses for pain relief, as a calming agent, or as part of structured program for enhancing oral motor function. Because pacifier use has been associated with a reduction in SIDS incidence, mothers of healthy term infants should be instructed to use pacifiers at infant nap or sleep time after breastfeeding is well established, at approximately 3 to 4 weeks of age.[129–131]

Vitamins and Mineral Supplements

Intramuscular vitamin K_1 (phytonadione) at a dose of 0.5 to 1.0 mg should routinely be administered to all infants on the first day to reduce the risk of hemorrhagic disease of the newborn.[132] A delay of administration until after the first feeding at the breast but not later than 6 hours of age is recommended. A single oral dose of vitamin K should not be used, because the oral dose is variably absorbed and does not provide adequate concentrations or stores for the breastfed infant.[132]

Vitamin D deficiency/insufficiency and rickets has increased in all infants as a result of decreased sunlight exposure secondary to changes in lifestyle, dress habits, and use of topical sunscreen preparations. To maintain an adequate serum vitamin D concentration, all breastfed infants routinely should receive an oral supplement of vitamin D, 400 U per day, beginning at hospital discharge.[133]

Supplementary fluoride should not be provided during the first 6 months. From age 6 months to 3 years, fluoride supplementation should be limited to infants residing in communities where the fluoride concentration in the water is <0.3 ppm.[134] Complementary food rich in iron and zinc should be introduced at about 6 months of age. Supplementation of oral iron drops before 6 months may be needed to support iron stores.

Premature infants should receive both a multivitamin preparation and an oral iron supplement until they are ingesting a completely mixed diet and their growth and hematologic status are normalized.

GROWTH

The growth pattern of healthy term breastfed infants differs from the existing CDC "reference" growth curves, which are primarily based on data from few breastfeeding infants. The WHO multicenter curves are based on combined longitudinal data from healthy breastfed infants from birth to 24 months and cross-sectional data from 2 to 5 years of the same children from 6 diverse geographical areas

TABLE 5 Recommendations on Breastfeeding Management for Healthy Term Infants

1. Exclusive breastfeeding for about 6 mo
   - Breastfeeding preferred; alternatively expressed mother's milk, or donor milk
   - To continue for at least the first year and beyond for as long as mutually desired by mother and child
   - Complementary foods rich in iron and other micronutrients should be introduced at about 6 mo of age
2. Peripartum policies and practices that optimize breastfeeding initiation and maintenance should be compatible with the AAP and Academy of Breastfeeding Medicine Model Hospital Policy and include the following:
   - Direct skin-to-skin contact with mothers immediately after delivery until the first feeding is accomplished and encouraged throughout the postpartum period
   - Delay in routine procedures (weighing, measuring, bathing, blood tests, vaccines, and eye prophylaxis) until after the first feeding is completed
   - Delay in administration of intramuscular vitamin K until after the first feeding is completed but within 6 h of birth
   - Ensure 8 to 12 feedings at the breast every 24 h
   - Ensure formal evaluation and documentation of breastfeeding by trained caregivers (including position, latch, milk transfer, examination) at least for each nursing shift
   - Give no supplements (water, glucose water, commercial infant formula, or other fluids) to breastfeeding newborn infants unless medically indicated using standard evidence-based guidelines for the management of hyperbilirubinemia and hypoglycemia
   - Avoid routine pacifier use in the postpartum period
   - Begin daily oral vitamin D drops (400 IU) at hospital discharge
3. All breastfeeding newborn infants should be seen by a pediatrician at 3 to 5 d of age, which is within 48 to 72 h after discharge from the hospital
   - Evaluate hydration (elimination patterns)
   - Evaluate body wt gain (body wt loss no more than 7%
   from birth and no further wt loss by day 5: assess feeding and consider more frequent follow-up)
   - Discuss maternal/infant issues
   - Observe feeding
4. Mother and infant should sleep in proximity to each other to facilitate breastfeeding
5. Pacifier should be offered, while placing infant in back-to-sleep-position, no earlier than 3 to 4 wk of age and after breastfeeding has been established

(Brazil, Ghana, India, Norway, Oman, and the United States).[135] As such, the WHO curves are "standards" and are the normative model for growth and development irrespective of infant ethnicity or geography reflecting the optimal growth of the breastfed infant.[136] Use of the WHO curves for the first 2 years allows for more accurate monitoring of weight and height for age and, in comparison with use of the CDC reference curves, results in more accurate (lower) rates of undernutrition and short stature and (higher) rates of overweight. Furthermore, birth to 6-month growth charts are available where the curves are magnified to permit monitoring of weight trajectories. As such, the WHO curves serve as the best guide for assessing lactation performance because they minimize mislabeling clinical situations as inadequate breastfeeding and identify more accurately and promptly overweight and obese infants. As of September 2010, the CDC, with the concurrence of the AAP, recommended the use of the WHO curves for all children younger than 24 months.[137,138]

ROLE OF THE PEDIATRICIAN

Pediatricians have a critical role in their individual practices, communities, and society at large to serve as advocates and supporters of successful breastfeeding (Table 6).[139] Despite this critical role, studies have demonstrated lack of preparation and knowledge and declining attitudes regarding the feasibility of breastfeeding.[140] The AAP Web site[141] provides a wealth of breastfeeding-related material and resources to assist and support pediatricians in their critical role as advocates of infant well-being. This includes the Safe and Healthy Beginnings toolkit,[5] which includes resources for physician's office for promotion of breastfeeding in a busy pediatric practice setting, a pocket guide for coding to facilitate appropriate payment, suggested guidelines for telephone triage of maternal breastfeeding concerns, and information regarding employer support for breastfeeding in the workplace. Evidence-based protocols from organizations such as the Academy of Breastfeeding Medicine provide detailed clinical guidance for management of specific issues, including the recommendations for frequent and unrestricted time for breastfeeding so as to minimize hyperbilirubinemia and hypoglycemia.[4,142,143] The critical role that pediatricians play is highlighted by the recommended health supervision visit at 3 to 5 days of age, which is within 48 to 72 hours after discharge from the hospital, as well as pediatricians support of practices that avoid non–medically indicated supplementation with commercial infant formula.[144]

Pediatricians also should serve as breastfeeding advocates and educators and not solely delegate this role to staff or nonmedical/lay volunteers. Communicating with families that breastfeeding is a medical priority that is enthusiastically recommended by their personal pediatrician will build support for mothers in the early weeks postpartum. To assist in the education of future physicians, the AAP recommends using the evidence-based Breastfeeding Residency Curriculum,[4] which has been demonstrated to improve knowledge, confidence, practice patterns, and breastfeeding rates. The pediatrician's own office-based practice should serve as a model for how to support breastfeeding in the workplace. The pediatrician should also take the lead in encouraging the hospitals with which he or she is affiliated to provide proper support and facilities for their employees who choose to continue to breastfeed.

TABLE 6 Role of the Pediatrician

1. Promote breastfeeding as the norm for infant feeding.
2. Become knowledgeable in the principles and management of lactation and breastfeeding.
3. Develop skills necessary for assessing the adequacy of breastfeeding.
4. Support training and education for medical students, residents and postgraduate physicians in breastfeeding and lactation.
5. Promote hospital policies that are compatible with the AAP and Academy of Breastfeeding Medicine Model Hospital Policy and the WHO/UNICEF "Ten Steps to Successful Breastfeeding."
6. Collaborate with the obstetric community to develop optimal breastfeeding support programs.
7. Coordinate with community-based health care professionals and certified breastfeeding counselors to ensure uniform and comprehensive breastfeeding support.

BUSINESS CASE FOR BREASTFEEDING

A mother/baby-friendly worksite provides benefits to employers, including a reduction in company health care costs, lower employee absenteeism, reduction in employee turnover, and increased employee morale and productivity.[145,146] The return on investment has been calculated that for every $1 invested in creating and supporting a lactation support program (including a designated pump site that guarantees privacy, availability of refrigeration and a handwashing facility, and appropriate mother break time) there is a $2 to $3 dollar return.[147] The Maternal and Child Health Bureau of the US Department of Health and Human Services, with support from the Office of Women's Health, has created a program, "The Business Case for Breastfeeding," that provides details of economic benefits to the employer and toolkits for the creation of such programs.[148] The Patient Protection and Affordable Care Act passed by Congress in March 2010 mandates that employers provide "reasonable break time" for nursing mothers and private non-bathroom areas to express

breast milk during their workday.[149] The establishment of these initiatives as the standard workplace environment will support mothers in their goal of supplying only breast milk to their infants beyond the immediate postpartum period.

CONCLUSIONS

Research and practice in the 5 years since publication of the last AAP policy statement have reinforced the conclusion that breastfeeding and the use of human milk confer unique nutritional and nonnutritional benefits to the infant and the mother and, in turn, optimize infant, child, and adult health as well as child growth and development. Recently, published evidence-based studies have confirmed and quantitated the risks of not breastfeeding. Thus, infant feeding should not be considered as a lifestyle choice but rather as a basic health issue. As such, the pediatrician's role in advocating and supporting proper breastfeeding practices is essential and vital for the achievement of this preferred public health goal.[35]

abstract

FREE

Teen pregnancy and parenting remain an important public health issue in the United States and the world, and many children live with their adolescent parents alone or as part of an extended family. A significant proportion of teen parents reside with their family of origin, significantly affecting the multigenerational family structure. Repeated births to teen parents are also common. This clinical report updates a previous policy statement on care of the adolescent parent and their children and addresses medical and psychosocial risks specific to this population. Challenges unique to teen parents and their children are reviewed, along with suggestions for the pediatrician on models for intervention and care. *Pediatrics* 2012;130:e1743–e1756

INTRODUCTION

Adolescent parents and their children represent populations at increased risk for medical, psychological, developmental, and social problems. This clinical report updates an American Academy of Pediatrics policy statement published in 2001.[1] Although the most recent birth rate data from 2009 indicate historic low birth rates for infants of 15- to 19-year-old females in the United States, the rate remains higher than a number of other developed countries.[2] Further, between 2005 and 2007, there was an interruption in a 15-year decline that occurred from 1991 through 2005, emphasizing the need to continue to address prevention of unplanned pregnancy in this age group.[2–5] Additionally, factors that improve outcomes for parenting adolescents and their offspring must be identified as the numbers of younger adolescents at risk for becoming teen parents is increasing.[6]

ADOLESCENT PREGNANCY AND THE CHANGING LANDSCAPE DURING THE PAST DECADE

After a 15-year decline between 1991 and 2005, there was a 5% increase in rates of births to 15- to 19-year-olds in the United States from 2005 to 2007. However, the rate has consistently declined since 2007, such that in 2009, the teen birth rates in the United States reached a low of 37.9 births per 1000 females 15 through 19 years of age accounting for 409 802 births. It decreased further in 2010 to 34.3 births per 1000 females, or 367 752 births.[7] Birth rates fell for other age groups as well.[7] The rate for 10- to 14-year-olds declined from 0.5 per 1000 (5029 births) in 2009 to 0.4 per 1000 (4500 births) in 2010. The birth rate for teenagers 15 to 17 years old was 17.3 per 1000 in 2010 (109 193 births), down from 19.6 in 2009

(124 247 births), which represents a 12% decline from 2009. A similar decrease in birth rates was seen for older teenagers, aged 18 to 19 years. In 2010, birth rates were 58.3 per 1000 (258 559 births) in 2010 compared with 64.0 (285 555 births) in 2009.

With regard to ethnic background, American Indian/Alaska Native teenagers' birth rates increased 7% during 2006–2007, to 59.0 per 1000 in females 15 through 19 years of age but declined to 43.8 per 1000 in 2009, with a continued downward trend in preliminary 2010 data reaching a low of 38.7.[3–7] Birth rates in the same age group for non-Hispanic white and black teenagers and Asian or Pacific Islander teenagers have steadily decreased to a low of 23.5 and 51.5 per 1000, respectively, in 2010.[3,7] Birth rates for Hispanic teenagers decreased to 75.3 per 1000 in 2007, with an additional decrease to 63.6 per 1000 in 2009 and preliminary rates of 55.7 per 1000 in 2010 in the same age group.[3,7]

Although it is encouraging to see a downward trend in teen birth rates, there continues to be important issues to consider. Health care providers should not assume that the teenager has made an autonomous decision whether to engage in sexual activity.[8] Older age of the teenager's partner is a risk factor for initiation of sexual behavior.[8–10] Young adolescent girls, particularly those aged 13 or younger with a partner at least 4 years older, are much more likely than their peers to have sex with their partner, which exposes them to the risks of pregnancy and other health problems. The power dynamic between the adolescent and her partner may be coercive in nature and needs to be addressed. Also, it is especially important to ensure that the pregnant adolescent is not a victim of nonconsensual sex, particularly in younger children. The pediatrician needs to explore these issues and should be familiar with the legal nuances of their specific state. If needed, teenagers should be connected to the appropriate source for additional services.

MEDICAL AND PSYCHOSOCIAL RISKS TO THE ADOLESCENT MOTHER

Medical complications associated with adolescent pregnancy include poor maternal weight gain, anemia, and pregnancy-induced hypertension. These complications seem to be the greatest for the youngest adolescents. Poverty, lower educational level, and inadequate family support seem to contribute to a lack of adequate prenatal care, which may account for the majority of negative health outcomes for both the adolescent mother and her child.[11] The long-term socioeconomic consequences of adolescent childbearing were evaluated longitudinally in Sweden from 1941 to 1970, but no such data are available for the United States. On the basis of this homogeneous sample of 140 000 teen mothers, the Swedish study is one of the largest to date and showed increased likelihood of low educational attainment (odds ratio [OR], 1.7–1.9), single living arrangements (OR, 1.5–2.3), and welfare dependency (OR, 1.9–2.6), supporting the view that childbearing during adolescence is a risk factor for poverty in later life.[12]

Violence during pregnancy is recognized as a serious public health concern, particularly for those of younger age (12–24 years). Intimate partner violence (IPV), which can include verbal abuse, assault by a partner or family member, being in a fight or being hurt, or witnessing violence, may be increased during pregnancy, with 3% to 19% of women identified as victims of IPV.[13] It is more common among pregnant adolescents than among nonpregnant adolescents. Reported rates of domestic violence to pregnant teenagers have ranged from 20% to 31.6%.[14] One study reported a rate of abuse during pregnancy of 20.6% in a diverse population of women in Texas and Maryland of lower socioeconomic status. Of the 1203 pregnant women enrolled in the study, 29.6% (356) were teenagers between 13 and 19 years of age. Abused teenagers were at greater risk of poor weight gain, first- or second-trimester bleeding, and substance use. Other studies have indicated that 1 in 5 teenagers experience abuse during pregnancy, which was also associated with late entry into prenatal care (third trimester) and low birth weight.[15,16] Harrykissoon et al[17] examined the prevalence of IPV prospectively during a 24-month period in adolescent mothers and found that 41% of young mothers reported being victims of abuse. Similarly, Mylant and Mann[18] reported in 2008 that 61% of the subjects in their study cohort experienced IPV, with 37.5% reporting having experienced it during pregnancy and 22.5% reporting current sexual trauma at the time of the study.

An extremely concerning statistic relates to the cause of death for all women of childbearing age and 1 year postpartum. Consistent with other maternal mortality studies conducted in urban areas, homicide was shown to be the leading cause of death for women of reproductive age. Risk of death by homicide was 2.63 times greater for teenagers 15 to 19 years of age who had recently given birth compared with teenagers who were not pregnant or had not recently given birth in the same age group, stratified by age, race, and urban/rural residence (95% confidence interval [CI], 1.17–5.95), but the reason for this increased risk is not known.[19–21] In 1987, the Division of Reproductive Health of the National Center for Chronic Disease

Prevention and Health Promotion at the Centers for Disease Control and Prevention, the American College of Obstetricians and Gynecologists, and state health departments established the Pregnancy Mortality Surveillance System to collect data on all reported deaths during pregnancy and within 1 year of pregnancy. The pregnancy-associated homicide rate reported was 1.7 per 100 000 live births; risk factors included being younger than 20 years, being black, and having later or no prenatal care.[22–24] To date, younger age during pregnancy remains a risk factor of dying by homicide, particularly for the 15- to 19-year-old group.[25,26]

In terms of psychosocial risk factors for early motherhood, a number of studies have suggested that being a teen mother may be related to poorer mental health outcomes, such as mood disorders. Birkeland et al in 2005[27] studied 149 adolescent mothers with a mean age of 17 years (range, 15–19 years) in 2 school systems (Tampa Bay, FL, and Twin Cities, MN). The participants took part in a school-based teen parent program and completed mental health assessments, which included symptoms of depression. Overall, the results suggested that the first year postpartum is difficult for adolescent mothers, regardless of ethnic background, with 29% of the sample reporting symptoms consistent with clinical depression. More recently and on the basis of longitudinal primary care data from 87 000 dyads of parents in the United Kingdom, a higher incidence of depression of mothers compared with fathers was shown. Younger parental age (15–24 years) at the time of the birth of the child was associated with a higher risk of maternal depression; similarly, depression affected fathers with no history of mood disorders.[28] These 2 studies support efforts to detect depression in parents, particularly younger ones, because parental depression is associated with adverse outcomes for children.

Other studies have suggested that early motherhood may also be related to poorer educational outcomes and future economic difficulties. Boden and colleagues[29] studied a birth cohort of New Zealand children over a 25-year span and found that 16.8% of the children were born to mothers who were younger than 21 years, with 86% reporting that their pregnancy was unplanned. The authors concluded that younger mothers are less likely to finish high school and have poorer future economic circumstances. In the United States, on the basis of longitudinal data from almost 2000 adolescents who took part in the National Longitudinal Study of Adolescent Health (1995–2001), the study showed that, for black and American Indian adolescents, pregnancy carried a significant risk (4.2 and 19 times, respectively) of the teenager being more likely to have received public assistance. In addition, American Indian and non-Hispanic black young women, respectively, were 2.6 and 2.7 times more likely if ever pregnant than white young women to have received public assistance.[30]

Although pregnant adolescents have been shown to decrease or limit their use of alcohol, cigarettes, marijuana, and other substances during gestation, the use of cigarettes and alcohol, in particular, has been shown to increase steadily during the first 6 months postpartum.[31–33] Daily smoking of cigarettes and alcohol and drug problems are known to be associated with adolescent parenthood. The tendency of the adolescent mother to reduce substance use during pregnancy provides a window of opportunity in the immediate postpartum period for the pediatrician to emphasize and encourage healthy choices by the mother.[34]

RISK OF REPEAT ADOLESCENT PREGNANCY

Repeat births in adolescents have been linked to decreased educational achievement, increased dependence on governmental support by the adolescent mother, increased infant mortality, and low birth weight.[35] These negative outcomes result in increased societal expense and contribute to the continuation of the adolescent pregnancy cycle. In contrast to adult women experiencing a second pregnancy, adolescents with a repeat pregnancy tend to delay prenatal care.[36] A second adolescent birth may be more deleterious to the teen mother and her offspring by compounding negative socioeconomic impact and the influence of a short interpregnancy interval. A study by Partington et al[37] conducted with Milwaukee teen mothers examined rates of pregnancy and childbearing from 1993 to 2002. The authors found that the second births tended to be preterm in 15% of the cases, particularly if the mother smoked during pregnancy, had inadequate prenatal weight gain, or had an interpregnancy interval of less than 18 months; also, teenagers younger than 16 years had increased odds of having an infant with low birth weight with their second pregnancy. Data from the National Youth Risk Behavior Survey from 1999 to 2003 revealed that multiple pregnancies during adolescence were associated with risk behaviors. A dose-response relationship was evident between multiple adolescent pregnancies and earlier sexual initiation and more lifetime sexual partners. Even though causation cannot be determined because of the cross-sectional nature of the survey, multiple adolescent pregnancies may be part of a broad profile of risk behaviors.[38]

An extensive review of the literature in 2005 revealed that a repeat or second

pregnancy occurs in 19% of adolescent mothers within 1 year after delivery and in 38% within 2 years of the first birth, with the highest rates documented for non-Hispanic black teenagers with reported lower socioeconomic status.[39] Raneri and Wiemann[40] conducted a 48-month follow-up study in a diverse population of adolescent mothers in Texas and found that 42% of mothers were pregnant within 2 years after delivery, with 73% of those going on to deliver a second child.

Several factors are associated with repeat adolescent pregnancy occurring in less than 2 years: not returning to school within 6 months after delivery, being married or living with a male partner, receiving major child care assistance from the adolescent's mother, not using a long-acting contraceptive within 3 months of delivery, experiencing IPV,[41] and having peers who were adolescent parents.[40]

Another significant factor that influences rapid subsequent pregnancies in adolescent mothers is mood disorders. In a study of 269 non-Hispanic black teenagers attending 5 prenatal clinics in Maryland, Barnet and colleagues[42] determined that depressive symptoms may be an independent risk factor for subsequent pregnancy. The authors found that of the 49% of the teenagers experiencing a second pregnancy within 2 years postpartum within their study, 46% had reported symptoms of depression at baseline.

An adolescent who drops out of school may choose to remain at home in a parenting role, reflecting a conscious decision not to return to school in the near future, if at all.[43] A study by Brosh et al[44] with 54 female students who were either pregnant or had 1 child showed that the majority of students wanted to obtain a high school diploma or a general equivalency diploma. Teenagers found relatives to be the most helpful source of support; in contrast, government assistance programs were rated the least helpful.

Because adolescents themselves often report that their second pregnancies are intentional, repeat pregnancy-prevention programs need to focus on defining and supporting an adolescent's educational goals and on providing motivations for delaying a second pregnancy. Knowledge and access to contraceptive services alone will not decrease repeat pregnancy rates. The use of long-acting contraceptive methods, such as subdermal progestin implants or injectable progestins or intrauterine devices, is associated with significantly lower rates of pregnancy than is the use of oral contraceptives.[1,4] Programs that help adolescent mothers return to school combined with intensive psychosocial postpartum care tend to successfully prevent early repeat pregnancies.[45] Cultural norms for extended family roles in child-rearing or for early parenting may vary. Not all ethnic or cultural subpopulations in the United States share the dominant cultural assumptions about adolescent childbearing, thus increasing the need for cultural sensitivity when dealing with diverse populations.

FACTORS ASSOCIATED WITH IMPROVED OUTCOMES FOR ADOLESCENT MOTHERS

Several studies in the literature address outcomes of adolescent parenting. A 20-year follow-up study of pregnant adolescents from the late 1960s defined "long-term success" as high school completion and employment or support by a spouse at the time of follow-up. The study population ranged from 32 to 38 years of age, with 68% of the women being unmarried. Factors positively associated with this definition of long-term success included having completed school before becoming pregnant, actively participating in a program for pregnant adolescents, remaining in school with no subsequent pregnancy at 26 months postpartum, having a sense of control over one's life, experiencing little social isolation, and having only 1 or 2 subsequent lifetime children after the first adolescent pregnancy.[46]

Another study involving a 17-year follow-up of black adolescent mothers documented that the universally negative outcomes described for teen parents previously suggested in the literature were not substantiated.[47] More than two-thirds of the women in that study had completed high school, had regular employment, and were not dependent on the government for income. In contrast, however, their offspring displayed greater rates of difficulties at school and behavioral problems at home than did the offspring of adult mothers.[47]

Family factors associated with improved outcomes for the adolescent mothers and their children include early child care for the infant of the young adolescent mother provided by the infant's family of origin, support that also allows the adolescent to finish school, playful interaction between infant and father, and stability of marital status for the teen mothers.[48] Unfortunately, common problems encountered in this type of research include small sample size, lack of control groups, attrition, and outcome measurement heterogeneity; furthermore, no research studies have addressed how best to enhance the typical sources of support to adolescent parents (family, parents, peer support) that positively affect the adolescent's own psychosocial growth as both a teenager and a parent while meeting the developmental needs of the infant.[49]

FATHERS OF INFANTS BORN TO ADOLESCENT MOTHERS

The literature defines paternal involvement in terms of a father's engagement, accessibility to the child,

and responsibility to the child—in other words, the amount of support from the father to his partner and offspring. A number of factors play a role in this dynamic, including the type of romantic involvement the couple had during the pregnancy and after birth; paternal ability to provide and support their family; father's level of education and socioeconomic status; father's relationship with his family of origin; and father's ethnic background, cultural values, and beliefs, including moral values and spirituality. Evidence supports the concept that fathers who are romantically involved with their partner and cohabitate are more involved with their children.[50] Most of the literature on adolescent pregnancy and parenting includes only mothers; furthermore, adolescent pregnancy-prevention programs are targeted at young females, and the positive contributions of adolescent fathers have not been well studied. A long-standing gender bias as it relates to adolescent males' perspectives on and attitudes toward pregnancy and pregnancy outcomes exists.[51] Of all pregnancies to adolescent mothers, estimates include that 18% to 35% of the pregnancies involve fathers younger than 20 years at the time of the children's births.[52] Adult men who father a child with an adolescent girl tend to be more socioeconomically and psychologically similar to adolescent fathers than to other adult fathers.[53] In evaluating the cost and consequences for young fathers, Brien et al[54] used data from the National Longitudinal Survey of Youth in which participants were 14 to 21 years of age in 1979. The authors reported that 8 of 10 young fathers do not marry the mother of their first child; furthermore, these fathers pay less than $800 annually for child support—probably related to being poor themselves.

Adolescent fathers are more likely to live in poverty, with adolescent fatherhood, like adolescent motherhood, often repeated from 1 generation to the next.[55] Young adult men who father children with adolescent mothers are also more likely to be impoverished. One study found that 64% of unwed fathers 19 to 26 years of age lived with a parent or close relative, most likely reflecting low socioeconomic status.[1,56] Although more than 80% of unwed fathers in their late teens and early 20s live away from their children, one-third to one-half of these fathers visit their children weekly.[56] Some fathers may be incarcerated and, therefore, unavailable or unable to be involved. One study found that at least 30% of fathers of children born to adolescent mothers were in prison.[20] Although social support, in general, correlates positively with improved outcomes for adolescent mothers, support by the father has been linked with increased maternal risk of not completing school.[57] However, partner support has been related to decreased distress and depression in the adolescent mother, along with improved self-esteem.[58] Marital status may transiently improve socioeconomic status for adolescent mothers, but a paucity of long-term marriages exists in this population, because most marriages precipitated by pregnancy in the adolescent age group end in divorce. Single status for the mother at 5 years postpartum has been associated with a threefold increased risk of receiving governmental assistance, at least in the short-term.[57]

The father's role in family functioning may also play an important role in the initiation, continuation, and ultimate success of breastfeeding. Although the positive benefits of breastfeeding have been well documented, few teenage mothers even initiate breastfeeding, and of those, few sustain the practice for at least 6 months. Harner and McCarter-Spaulding[59] studied the impact of paternal age on infant feeding method initiated by teen mothers during their hospital stay after giving birth by interviewing 86 teen mothers younger than 18 years in Philadelphia. The authors found that 30% of the teen mothers had an adult partner (defined as being 4 years older than the mother), and 24% (21) reported breastfeeding while in the hospital. Of the total sample, 40% of teen mothers reported that the father of the baby had an influence on their decision to breastfeed or not, regardless of the age of the father.

As the child matures, fathers are important for teaching life-survival skills, in general, and in the school setting for helping with homework, coaching, and social skills and encouraging a healthy lifestyle. Moore et al[60] studied a convenience sample of 104 English-speaking, urban fathers looking at the support to their families in attending well-child visits, and concluded that all health care providers should encourage early involvement of fathers, particularly for those younger than 25 years. Strengthening the father-child bond will benefit family functioning and ultimately may improve the child's health and well-being.[61,62] In a study to evaluate the interaction between adolescent fathers and health care professionals, Dallas[63] interviewed 111 participants. The sample included 25 sets of unmarried, low-income, black adolescent fathers and mothers and 50 grandmothers and 11 grandfathers; the interviews were conducted in their place of residence at 1, 6, 12, 18, and 24 months after birth. The authors concluded that treating adolescent fathers as if peripheral in their parenting role risks "marginalizing" an already alienated group and negatively affects the ability of the

father to seek future advice and education.

Children of adolescent mothers who continue to have close ties with the child's biological father have better outcomes in employment and education, are less depressed, and are at less risk of adolescent parenting themselves. However, children of adolescent parents in general, with or without paternal involvement, remain a group at risk, with a 33% rate of school dropout, 31% incidence of depression, 16% incidence of incarceration, and 25% risk of adolescent parenthood.[47] Fathers' engagement positively affects the psychosocial, cognitive, and behavioral outcomes of children, with evidence that cohabitation of the mother and father is associated with less externalizing behavioral problems in their children.[64]

Adolescent or adult fathers who maintain active participation in the prenatal, neonatal, and immediate postpartum processes with an adolescent mother have a greater likelihood of ongoing involvement with their children.[65] Such interactions include playing with their children, giving them gifts, or feeding them but are less likely to involve diapering, bathing, and caring for the child alone. Parenting interventions can help teach such skills to adolescent fathers as well as to adolescent mothers. Several successful father programs exist, and all adolescent parenting programs should make a more concerted effort to engage the fathers.[66–68]

MEDICAL AND PSYCHOSOCIAL RISKS TO THE INFANT

Infants of adolescent mothers have an increased risk of adverse health outcomes, including higher incidences of perinatal mortality, low birth weight, preterm birth, developmental disabilities, and poorer developmental outcomes compared with offspring of older mothers.[69] Markovitz and associates investigated the relationships between infant mortality, socioeconomic status, and maternal age in a large, retrospective study.[70] The researchers compared the risk of neonatal and infant mortality in a cohort of adolescent mothers 12 to 19 years of age in Missouri compared with those 20 to 35 years of age. After adjusting for socioeconomic factors, they concluded that the risk of postnatal mortality (OR, 1.73; 95% CI, 1.14–2.64) but not neonatal mortality (OR, 1.43; 95% CI, 0.98–2.08) was significantly higher in infants born to adolescent mothers 17 years or younger, compared with infants born to mothers between 18 and 25 years of age. This study corroborated the findings of Phipps et al, who evaluated the risk of infant mortality (defined as death within the first year after live birth) in a US birth cohort from the National Center for Health Statistics from 1995 to 1996.[71] The analysis included more than 700 000 single births. Of these births to women 12 through 19 years of age, there were 4631 infant deaths. The risk of infant mortality was 1.6 (95% CI, 1.4–1.7) times greater for those with teen mothers younger than 15 years than for those with mothers 18 through 19 years old—a 56% greater risk.[71]

Another study by Gilbert and associates[74] reported an increased risk of negative health outcomes for infants and adolescent parents. They examined birth and death certificates by using maternal and neonatal hospital discharge records of primiparous women (11–29 years of age) in California who delivered between January 1, 1992, and December 31, 1997. Pregnancy outcomes of early (11- to 15-year-old) and late (16- to 19-year-old) adolescents were compared with those of a control group of women 20 to 29 years of age. When compared with older women, all teen pregnancies were associated with higher rates of poor obstetric outcomes, including infant and neonatal deaths, preterm birth, and low birth weight. Even more striking, non-Hispanic black mothers and infants of all ages had worse outcomes than did white mothers and infants.[72]

Not all adverse health outcomes of children are directly associated with maternal age. Maternal age alone has not been shown to be a risk factor in sudden infant death syndrome, injuries, child abuse, or infections; factors such as substance abuse and socioeconomic status do appear to have a role. However, 1 study found that the rare occurrence of infant homicide, which tends to occur during the first 4 months of life, was associated with having an adolescent parent, especially one who had given birth previously.[73]

NEURODEVELOPMENTAL PERSPECTIVE

Longitudinal neuroimaging studies on subjects from 3 through 30 years of age conducted by the child psychiatry branch of the National Institute of Mental Health have shown significant changes in brain development throughout the adolescent developmental period. The dorsolateral frontal cortex is one of the latest regions to mature and is the one associated with "executive brain functions," such as planning, foresight, evaluating risk and reward ratios, and the capacity to balance decision-making with emotional demands. Substantial neurobiological, behavioral, and emotional changes take place in the adolescent and young adult brain, making it a time of risk but also a time of significant opportunity.[74] Therefore, any interventions put into place need to take into account the adolescent's

developing brain function to enhance these executive brain functions.

Studies have shown that children born to adolescent mothers are at risk for deficits in cognitive and social development. These deficits may persist into adolescence.[69,75] During the first 3 to 4 years of life, the anatomic brain structures and physiologic response patterns that determine a child's learning processes, coping skills, and personality traits become established, encoded, and strengthened.[76,77] These neuronal structures have the potential to atrophy if unused.[78] Negative environmental conditions, including lack of stimulation or close and affectionate interaction with primary caregivers, child abuse, violence within the family, or even repeated threats of physical and verbal abuse during these critical years can have a profound influence on these nerve connections and neurotransmitter networks, potentially resulting in impaired brain development.[79] Childhood negative life experiences may have long-term consequences in the developing brain of children; toxic stress has been defined as "an excessive or prolonged activation of the physiological stress response system in the absence of the buffering protection afforded by stable, responsive relationships." The American Academy of Pediatrics is committed to mitigate the negative effects of toxic stress in children; therefore, identifying children at risk for toxic stress must be a priority for pediatricians.[80] Maternal substance use before and after delivery may further affect infant development as a result of physiologic or anatomic changes in the infant's brain or the parents' ability to nurture appropriately.[72]

A study by the National Institute of Child Health and Human Development found that one of the most important predictors of child development was the quality of the parent-child interaction.[81] An adolescent mother's attitude toward parenting influences her parenting style; mothers who place inappropriate expectations on the child are likely to use harsh and rejecting discipline strategies.[82] Such strategies are linked with child anger, low self-esteem, and social withdrawal. Furthermore, mothers with intense feelings of inadequacy and failure in the parenting role tend to withdraw emotionally and physically from the infant. This withdrawal has been linked to angry and resistant infant behaviors and troubled mother-child relationships.[19]

Compared with older mothers of similar parity and socioeconomic status, adolescent mothers may vocalize, touch, and smile at their infants less and may be less sensitive to and accepting of their infants' behavior.[83] Teen mothers tend to hold less realistic developmental expectations of their children. They may underestimate or not be knowledgeable about the importance of simple interactions within the home. Parent-child relationship focused interventions have been shown to moderate maternal behaviors and child developmental outcomes. Educating mothers on interaction styles may improve maternal responsiveness and lead to less directive parenting styles and more engaging interactions, which promote child development.[83] Also, adolescent mothers who have more social support exhibit less anger and use less punitive methods of parenting than do adolescent mothers with fewer social supports.[84]

Another factor that contributes to child development is the home literacy environment. Research has shown that teen mothers provide fewer literacy experiences than do older mothers.[85] The consequences of an impoverished literacy environment on early brain development and later child development may manifest as a delay in oral language skills and later have a negative effect on early reading skills.[85] Teen mothers need instruction on how to incorporate literacy activities in the home and why it is important for their child's development. Because adolescent mothers may not be trained in appropriate stimulation techniques and may be coping with stress in their own lives, ongoing education and support by the pediatrician and other nurturing adults are imperative to help prevent negative sequelae in them and in their offspring.

MODELS OF INTERVENTION FOR ADOLESCENT PARENTS

A number of models of intervention and support for adolescent parents exist. These programs, which may be individual and/or group based, predominantly have focused on adolescent mothers and their children. Not all programs have been evaluated rigorously. These types of interventions are aimed to improve parenting knowledge, practices, attitudes, and skills for the adolescents and may be part of prenatal or postpartum care. Coren and Barlow reviewed 23 studies of parenting programs for teen parenting. Positive outcomes were shown in maternal-child interaction, communication at mealtimes, and offspring cognition; methodological limitations included the small number of studies reviewed, with a small number of outcome measures. Despite these limitations, the findings suggested that parenting programs may be effective in improved outcomes for teen parents and their children.[86] Similar conclusions were reached in a recent Cochrane update of parenting programs.[87] Successful teen programs were highlighted in a study from New Mexico, a state with

one of the highest teen birth rates in the United States. These parenting programs of predominantly Latino-Hispanic youth resulted in lower rates of late entry into prenatal care and decreased birth rates. Participants in the program were more likely to have higher rates of education attainment and employment postpartum. One of the specific program recommendations was the inclusion of teen fathers within the program.[88] Another important model has been the nurse-family partnership —in particular, the home-visit model focusing on high-risk, first-time single mothers.[89] Programs like Health Access Nurturing Development Services in Kentucky have been successful in achieving goals related to infant health and well-being, subsequent child health and development, risk reduction and home safety, and maternal well-being.[90] The Nurse–Family Partnership, a program of prenatal and postpartum home visitation by nurses for low-income mothers and their first child across the United States, currently serves more than 20 000 families. A focus on family planning for the mother has decreased the rapid-succession second pregnancy effectively within the 2-year postpartum period, with encouraging results in rural locations and younger mothers.[91]

School-Based Programs

Specialized school-based programs can provide a means of providing multidisciplinary services to pregnant and parenting adolescents while keeping them in school. A student's prepregnancy academic achievement affects the outcome of such interventions; low-achieving students require longer and more intensive interventions than do students who are doing well academically before pregnancy.[9] For the marginally achieving student, specialized educational programs with a small student-to-teacher ratio can foster a sense of achievement and help the adolescent feel capable of completing school. The concept of a "school-within-a-school," or consistent peer group placement within a larger school, has been useful for academically challenged pregnant and nonpregnant adolescents.[92] Quality school-based child care programs facilitate the participation of the adolescent in school, provide support and parenting education to the parent, and can assist in improved health and development in their children.

Positive results for a school-based "children of teen parents" program were shown in a study by Crean et al[93] in Rochester, New York. Eighty-one teen mothers and their children received free on-site child care, the service most frequently requested by adolescent mothers; 89 wait-listed teen mothers served as a control group. The study included those mothers born between 1969 and 1976 and included those whose children were born in the 1986–1987 academic year. Participant mothers were found to have better school attendance, with 70% graduating from high school. Letourneau et al[49] conducted a review of studies published between 1982 and 2003 that evaluated resources and support or education interventions for teen mothers and found that small sample size, significant attrition, lack of suitable comparison groups, and inconsistency among measures used were significant limitations in validity and reliability for the data.

Multidisciplinary and Non–School-Based Programs

Multidisciplinary programs provide medical care, psychological support, and a comprehensive life-skills approach to adolescent parents. These programs have shown that participating female adolescents are more likely to be employed, work more hours, earn more money, and report a better home environment 5 years after the intervention began than are socioeconomically matched adolescents in cities without this comprehensive approach.[94] Adolescents receiving these interventions were also less likely to be receiving Aid to Families With Dependent Children (now relabeled as Temporary Assistance to Needy Families).

Teen Tot programs (in which adolescent parents and their children receive care simultaneously) have been developed in many medical centers and ambulatory clinic settings to provide structured medical visits and support. Such use of time and space creates access to multidisciplinary services. When all visits are scheduled in a clinic on a consistent day each week, teaching sessions specifically addressing adolescent parenting issues can be timed with clinic visits. This model for care often provides the adolescent with a peer support group; however, these social support and parenting interventions appear to improve maternal-child interactions but do not seem to reduce low birth weight or neonatal deaths.[95] One such model program at Children's Hospital in Boston evaluated 142 young mothers (average age, 17.3 $\pm$ 1.2 years) and their offspring (average age, 8.3 $\pm$ 5 months); the sample was racially diverse and had 91 young mothers in the intervention group and 54 controls. The program included 12 sessions of a once-a-week parenting group with a comprehensive curriculum geared toward improving teen parenting skills and reducing life stress, with pregroup and postgroup measures. The authors reported positive effects with this type of intervention, but no longer-term follow-

up data were available to evaluate sustainability of the changes.[96] Although the arrangement of a joint visit has its advantages, the pediatrician needs to focus the visits on each of the individuals separately to ensure that the adolescent's concerns of her own health and her infant's health are not overlooked.

Peer Group and Role Model Programs

Using adolescent parents as role models may enhance self-efficacy in the adolescents serving as instructors as well as in the adolescents being instructed about parenting. Innovative approaches using technology and the media have shown promise in enhancing parenting skills of adolescent mothers.[97] From a developmental perspective, use of peer groups makes sense in getting a message across. Unfortunately, there is no evidence that peer group and role model programs effectively reduce adolescent pregnancy or improve adolescent parenting skills. Many programs still use this technique. In the future, positive outcome data may become available.

When possible, all caregivers involved in the care of the infant should be given practical, evidenced based information that support early brain development for the infant. The pediatrician should provide encouragement and support to the adolescent parent to make decisions for her infant even when other adults are involved in the child's care. When the adolescent needs more support, the pediatrician can facilitate a co-decision model that ensures the optimal welfare of the infant.

Programs such as Head Start and Early Head Start are designed to address the needs of both parents and children. Prenatal and early childhood home visitation has been associated with reduction in the number of subsequent pregnancies, use of governmental assistance, child abuse and neglect, and criminal behavior in adolescent mothers. These visitations also have been associated with reduced risk of serious antisocial behavior and substance abuse by adolescent offspring followed up during the first 15 years of life.[98–101] Multidimensional family and peer support with positive role models and concrete examples of how to overcome challenges has also been shown to help teenagers initiate and continue breastfeeding.[102]

Special Education Initiatives

Female adolescents in some special education programs become pregnant in disproportionate numbers and drop out of school at earlier ages than do adolescents in regular education.[103] School-based care for these adolescents should include sexuality education[8] and discussions on safety for the adolescent mother and her child. These discussions should focus on self-efficacy and should help the mother acquire decision-making and concrete, task-oriented skills. This task-centered approach also can be used to strengthen the adolescent's ability to access external support systems and to develop supportive family relationships, which directly and indirectly can improve the adolescent's self-esteem.

GUIDANCE FOR THE PEDIATRICIAN

1. Continuity of care and a "medical home" for adolescent parents, as well as for their children, is important in caring for this population. Specific attention needs to be directed toward anticipatory guidance, the critical importance of nurturing relationships and positive parenting on their young child's development, and the teaching of basic caregiving skills involving the adolescent mother and the infant's father, when possible. Pediatricians and other health care providers can build on their established relationship with adolescent parents and their children to provide developmentally appropriate care to both.
2. A multidisciplinary and comprehensive approach to caring for parenting adolescents is encouraged, by using community resources with the needed funding for programs, such as social services, nurse visitations programs, and the Special Supplemental Nutrition Program for Women, Infants, and Children. Early and Periodic Screening, Diagnosis, and Treatment and Title XXI should be used to include medical and developmental services to low-income adolescent parents and their children. Pediatricians and their staff are ideal for facilitating coordination of these services.
3. The pediatrician can help promote breastfeeding to all adolescent mothers, realizing the importance of educating the teen father when available. Opportunities to discuss the benefits and management of breastfeeding may be available for the pediatrician and staff in the school setting where pregnant teenagers attend. Continued support is necessary for adolescents who choose to breastfeed so that they may overcome barriers typically encountered in their environment. Pediatricians can help by working with schools to dedicate an area for breastfeeding and/or milk expression that provides privacy and access to a hand-washing sink and a refrigerator.

4. A good time to initiate contraceptive counseling is during pregnancy; such discussion should include an emphasis on long-acting methods, such as DMPA, Nexplanon, and the IUD, coupled with condom use during every visit for the teenager and may be part of the anticipatory guidance offered at visits for the teen parent's infant. Pediatricians should not assume that all adolescent parents are open to discussing their needs while having their infant visit; when appropriate, the pediatrician can negotiate the use of this time for the adolescent's needs. The 2- or 4-week infant visit follow-up visit is a good time to remind the adolescent to have a visit with her gynecologist or adolescent specialist and initiate contraception.
5. Pediatricians can be important advocates for youth development programs that have proven, evidence-based strategies to prevent unwanted, or to delay, teen pregnancies.
6. Pediatricians can play an important role to the adolescent parent in emphasizing the importance of completing high school, pursuing higher education or vocational training, and being knowledgeable about community resources and programs that may better support adolescents and their infants.
7. Pediatricians can encourage the continuation of healthy lifestyles that may have been initiated during pregnancy. Information on the effect of maternal substance use and cigarette smoking on infant and child health and development is important to provide at mother and infant visits.
8. Assessment by the pediatrician for risk of domestic violence and mental health issues, particularly depression, is encouraged both during and after pregnancy. IPV is a significant problem among young mothers and is not restricted to a particular sociocultural group. Screening to assess IPV can include asking the adolescent if she has been hit, kicked, or punched by a partner or ex-partner. Pediatricians and health care providers caring for pregnant adolescents are in a unique position to identify and help prevent violence in adolescents' lives.
9. In the preadolescent and young adolescent age group, it is of particular importance to ensure that the pregnant adolescent is not a victim of sexual abuse and/or exploitation. Pediatricians and other health care providers should not assume that sexual activity during adolescence, particularly for younger adolescents, is voluntary. Pediatricians should advocate and help develop protocols that elicit information from adolescents about whether their sexual activity was voluntary; this can be accomplished with the help of social workers or psychologists.
10. Pediatricians are encouraged to stress the importance of the adolescent parent caring for the child even if other adults are involved in the caregiving (eg, grandparents and great-grandparents). These other caregivers need support and education to allow optimal infant development while helping the adolescent to achieve her own developmental milestones. From the ethical point of view, pediatricians should question whether the adolescent parent is capable of making decisions on behalf of her offspring; when in doubt, consideration should be given to a co-decision maker in support of the adolescent parent and the best interest of the child. Pediatricians can provide positive reinforcement for success by praising adolescents who are successful (eg, graduating from high school or college; abstaining from use of drugs, alcohol, and nicotine; continuing breastfeeding; keeping the child's immunizations current; and attending all well-child visits).
11. Counseling by pediatricians includes adapting their counseling approach to the developmental level of the adolescent, by using office-based and school-based interventions that incorporate intensive instruction on infant care and development, positive parenting techniques, and coping with the stress associated with parenting. Use of support groups in the office, clinic, or school setting; home visits; and creative use of videos and media can improve parenting skills.
12. A heightened sense of awareness by pediatricians to attend to the developmental needs of both the infant and the adolescent parent is important. The pediatrician can advocate for quality community resources, such as competent, culturally sensitive, effective preterm and infant classes, postpartum home visits, nurse home visitations, quality child care programs, and well-managed programs supported by Head Start and Individuals with Disabilities Education Act–Part C (for children ages 0–3 years with disabilities or at risk), and encourage adolescent parents to use these resources when available and appropriate.
13. In the nursery and early on, efforts should be made that

target young fathers, supporting their involvement in their children's care. Pediatricians and other professionals working with children and their families can actively encourage fathers' involvement with their offspring from an early age.

14. Further studies are needed on outcomes of teen parents and their infants when interventions specifically involve fathers of infants born to adolescents and on the involvement of grandparents assisting in child-rearing or as primary caregivers. Short- and long-term outcome evaluations on adolescent parenting programs are vitally needed to better understand the effects that teen pregnancy has within heterogeneous groups within the United States.
15. Although rates of teen pregnancy are declining, the pediatrician can continue to advocate for longitudinal, comprehensive solutions, including advocacy, which focuses on primary prevention strategies to continue this downward trend.

POLICY STATEMENT

Cheerleading Injuries: Epidemiology and Recommendations for Prevention

abstract

FREE

Over the last 30 years, cheerleading has increased dramatically in popularity and has evolved from leading the crowd in cheers at sporting events into a competitive, year-round sport involving complex acrobatic stunts and tumbling. Consequently, cheerleading injuries have steadily increased over the years in both number and severity. Sprains and strains to the lower extremities are the most common injuries. Although the overall injury rate remains relatively low, cheerleading has accounted for approximately 66% of all catastrophic injuries in high school girl athletes over the past 25 years. Risk factors for injuries in cheerleading include higher BMI, previous injury, cheering on harder surfaces, performing stunts, and supervision by a coach with low level of training and experience. This policy statement describes the epidemiology of cheerleading injuries and provides recommendations for injury prevention. *Pediatrics* 2012;130:966–971

INTRODUCTION

When cheerleading originated in the late 1800s,[1] the primary purpose was to lead the crowd in cheering on sports teams through the use of pompoms, toe-touch jumps, splits, and clapping. However, over the last century, cheerleading has evolved dramatically into a competitive, physically demanding, year-round activity consisting of fast-paced floor routines with leaps and jumps, gymnastics-style tumbling, and complex stunts, such as pyramid building and tossing athletes in the air (see Appendix for definitions of cheerleading terminology). Cheerleading has also become much more popular. From 1990 to 2003, the number of US cheerleaders 6 years and older increased by approximately 600 000 from 3.0 to 3.6 million.[2] This number includes traditional school-based cheerleading squads as well as "all-star" cheerleading squads, which are not associated with a school or sports league and whose main objective is competition. In 2009, the National Federation of State High School Associations (NFHS) reported that there were approximately 400 000 participants in high school cheerleading, with approximately 123 000 on competitive cheer teams.[3,4] Girls represent the majority (96%) of participants.[5] With this growth in participation and the more physically demanding routines comes a greater number of injuries and, subsequently, an increase in the number of cheerleaders presenting to the pediatrician for treatment and advice about prevention.

EPIDEMIOLOGY OF INJURIES

Although most high schools and colleges have cheerleaders, only 29 state high school athletic associations recognize cheerleading as a sport,[3] and the National Collegiate Athletic Association (NCAA) does not include competitive cheerleading in its list of sponsored sports. This has important implications on injury rates and prevention, because being classified as a sport affords valuable safety resources and regulations, such as qualified coaches, adequate and well-maintained practice facilities, preseason conditioning, access to certified athletic trainers and team physicians, and mandated preparticipation physical examinations. It also means injury data for cheerleaders are not uniformly captured in the sports injury surveillance systems of state high school athletic associations, the NFHS, and the NCAA. Fortunately, a few epidemiologic studies completed in recent years have provided some data on cheerleading injuries. The data presented here do not include dance teams, baton, or color guard.

Cheerleading injuries in the United States have been increasing steadily over the past few decades. The US Consumer Product Safety Commission reported 4954 hospital emergency department visits for cheerleading injuries in 1980.[6] By 2007, the Consumer Product Safety Commission reported this number had climbed more than 400% to 26 786. Although 98% of injured cheerleaders were treated and released, 221 were hospitalized.

The number of catastrophic injuries related to cheerleading has increased from 1.5 per year from 1982 to 1992 to 4.8 per year from 2003 to 2009.[7] This rising incidence of injury is likely attributable to a combination of (1) larger numbers of children, as young as 3 years of age, participating in cheerleading classes and teams; (2) incorporation of more complex skills, including tumbling, pyramids of 15 ft or higher, and partner stunts with athletes lifting, tossing, and catching each other; and (3) better reporting of cheerleading injuries through a few recent epidemiologic studies and a case report.

The overall injury rate in cheerleading across all age groups is 1.0 per 1000 athletic exposures. An athletic exposure is defined as 1 athlete participating in 1 practice or competition session. College cheerleaders have the highest injury rate (2.4), followed by elementary school (1.5), high school (0.9), all-star (0.8), middle school (0.5), and recreational (0.5) cheerleaders. The overall injury rate in high school cheerleading is lower than in other girls' high school sports (Table 1).[5,8]

As in other sports, cheerleading injury rates increase with age and competitive level.[5,9] Middle and high school cheerleaders have lower overall rates of injury than do collegiate cheerleaders (0.5 and 0.9 vs 2.4 per 1000 athletic exposures, respectively).[5] This is probably because older, better-skilled cheerleaders perform more complex gymnastics and height-based stunts. Rates of stunt-related injuries are higher for collegiate versus high school and middle school cheerleaders (1.59 vs 0.59 and 0.23 per 1000 athlete exposures, respectively).[10]

TABLE 1 Overall Injury Rates in Girls' High School Sports[5,7,8]

Sport	Overall Injury Rate (per 1000 Exposures)	Catastrophic Injury Rate (per 100 000 Exposures)
Cheerleading	0.9	0.50–1.62[a]
Gymnastics	8.5	0.44
Soccer	5.3	0.03
Basketball	4.4	0.03
Field hockey	3.7	0.00
Softball	3.5	0.02
Volleyball	1.7	0.00

[a] Injury rate is 1.62 when based on 123 644 actual exposures reported by the NFHS for competitive cheer squads. Injury rate is 0.50 when based on 400 000 exposures estimated by the NFHS for all types of cheer teams (competitive and noncompetitive).

INJURY MECHANISMS

The most common mechanisms of injury are basing/spotting (23%), tumbling (14%–26%), and falls from heights (14%–25%).[5,11] Stunting accounts for 42% to 60% of all cheerleading injuries and 96% of concussions and closed-head injuries.[10,12,13] Pyramid stunts are responsible for the majority of head/neck injuries (50%–66%).[14,15]

TYPES OF INJURIES

When all age groups are considered together, lower-extremity injuries are most common (30%–37% of all cheerleading injuries), followed by injuries to the upper extremities (21%–26%), head/neck (16%–19%), and trunk (7%–17%).[5,7,9,15] Younger cheerleaders are more likely to experience upper-extremity injuries (41% vs 25% of all injuries for 6- to 11-year-olds vs 12- to 17-year-olds, respectively), and older cheerleaders are more likely to have lower-extremity injuries (38% vs 29% of all injuries for 12- to 17-year-olds vs 6- to 11-year-olds).[9]

Overall, sprains and strains are the most common types of injuries (53% of all cheerleading injuries), followed by abrasions/contusions/hematomas (13%–18%), fractures/dislocations (10%–16%), lacerations/punctures (4%), and concussion/head injuries (3.5%–4%).[5,9] A single case report reveals a cheerleader with a splenic rupture after being thrown in the air and caught by a fellow cheerleader in a cradle.[16]

Younger cheerleaders (5- to 11-year-olds) are 1.6 times more likely to suffer a fracture or dislocation compared with older cheerleaders (12- to 18-year-olds), and older cheerleaders are 1.2 times more likely to suffer

a sprain or strain than are younger cheerleaders.[9]

Head Injuries

Concussions and other closed-head injuries account for 4% to 6% of all cheerleading injuries,[5,9,11] and head and neck injuries account for approximately 15% of all cheerleading injuries seen in US emergency departments.[6] Concussion rates in cheerleading (0.06 per 1000 exposures) are relatively low compared with other girls' high school sports, such as soccer (0.36), basketball (0.16–0.21), lacrosse (0.20), softball (0.07–0.11), and field hockey (0.10).[17,18] However, from 1998 to 2008, concussion rates in cheerleading increased by 26% each year, a rate greater than any of the other girls' sports studied.[18] Concussion rates increase with age and competitive level, likely because of the increasing difficulty of stunts.[5]

Catastrophic Injuries

Catastrophic injuries are classified as direct (trauma related to participating in the skills of the sport) or indirect (body system failure resulting from exertion while participating in a sport [eg, cardiac collapse or heat stroke] or a complication from a nonfatal injury). Direct catastrophic injuries include closed-head injury, skull fractures, and cervical spine injuries resulting in permanent brain injury, paralysis, or death. From 1982 to 2009, the National Center for Catastrophic Sports Injury Research recorded 76 direct catastrophic injuries in high school cheerleaders and 34 in collegiate cheerleaders.[7] However, because of the much larger number of high school cheerleaders, the rate of catastrophic injuries was 5 times higher for collegiate versus high school cheerleaders (2.0 vs 0.4 per 100 000 participants, respectively).[1] Although the overall risk of injury is lower in cheerleading than in most other sports, the risk of direct catastrophic injury is considerably higher for cheerleading. From 1982 to 2009, cheerleading accounted for 65.0% of all direct catastrophic injuries to girl athletes at the high school level and 70.8% at the college level.[7]

RISK FACTORS FOR INJURY

Risk factors for cheerleading injuries include higher BMI,[11] previous injury,[11] cheering on harder surfaces,[19] performing stunts, and supervision by a coach with low level of training and experience.[11] Critical height is defined as the approximate fall height below which a life-threatening injury would not be expected to occur. Critical height is much higher for a landing mat on a foam floor (11 ft) and for a spring floor (10.5 ft) than for concrete or vinyl tile floor (0.5 ft).[19] Critical heights for natural grass, artificial turf, and wood gym floor are 3.5 ft, 4 ft, and 4.5 ft, respectively (Fig 1). The most serious cheerleading injuries occur at or above the critical height for the surface on which the cheerleader is performing at the time of injury.[20] Some data[11] indicate that bases and flyers are at similar risk for injury during stunts, but others suggest that bases are at higher risk.[10]

INJURY PREVENTION

To increase safety, the American Association of Cheerleading Coaches and Advisors (AACCA)[21] and the NFHS[22] have enacted rules and recommendations, including requiring coach training and certification, proper strength and conditioning for all cheerleaders, avoiding stunts and tumbling on hard surfaces, and specific rules for execution of technical skills. Examples include the following: (1) pyramid height limited to no more than 2 persons; (2) top cheerleader must be supported by 1 or more bases in direct weight-bearing contact with performing surface; (3) bases must be stationary and maintain constant contact with suspended cheerleaders; (4) basket toss should be limited to 4 throwers, the toss should start from ground level, and 1 thrower must be behind the flyer during the toss; (5) spotters must be present for every

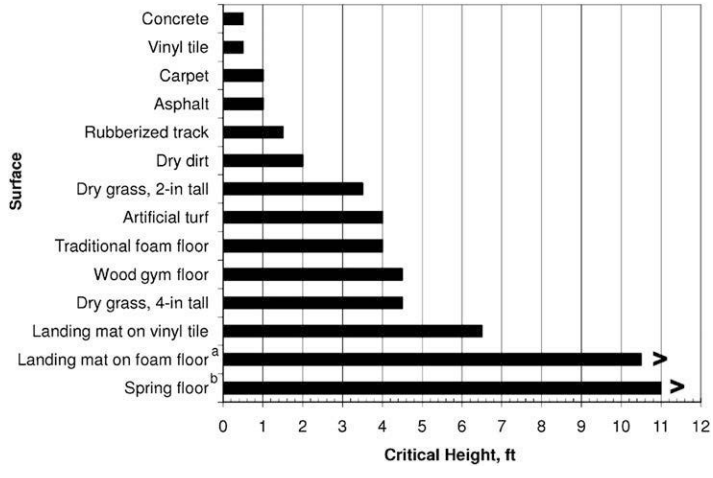

FIGURE 1

Critical height for cheerleading surfaces. [a]Landing mat on traditional foam floor. Limits of Triax 2000 were reached before critical height was attained. The potential for brain injury on selected surfaces used by cheerleaders. *J Athl Train.* 2009;44(6):573.

person extended above shoulder level; and (6) suspended persons are not to be inverted or rotated on dismount.

Although spotters are commonly used during more difficult skills, active spotting of a maneuver does not significantly decrease the number of serious injuries sustained.[20] This could be because spotters may not have had appropriate training or lack sufficient core and upper body strength and balance to spot effectively.

One study revealed cheerleaders supervised by coaches with the most education, qualifications, and training had a nearly 50% reduction in injury risk compared with cheerleaders supervised by coaches with the lowest amount of education, qualifications, and training.[11] However, another study revealed that injury rates were not associated with the number of cheerleading safety training or certification programs completed by the coach or years of coaching experience.[5] Still, most agree that requiring coaches to obtain certification in a standardized training program that focuses on safe practices is a logical step in decreasing risk of injury among cheerleaders.

RECOMMENDATIONS

The American Academy of Pediatrics recommends that its chapters and individual pediatricians, especially those serving as school physicians, advisors, or consultants, work with their interscholastic athletic associations and other state and local cheerleading regulating bodies to ensure that the following guidelines are followed to reduce cheerleading injuries.

1. Cheerleading should be designated a sport so that it is subject to rules and regulations set forth by sports governing bodies (eg, NCAA, NFHS) and school athletic departments. Designation of cheerleading as a sport will afford it the same benefits as other sports, such as availability of athletic trainers, improved access to medical care, limits on practice time, better facilities, certified/qualified coaches, and inclusion in injury surveillance data.
2. Cheerleaders should have a preparticipation physical examination before participating in a cheerleading program and should have access to appropriate strength and conditioning programs.
3. Cheerleaders should be supervised by qualified coaches who have been trained and certified in proper spotting for gymnastics and partner stunts, safety measures, and basic injury management.
4. Cheerleaders should be trained in proper spotting techniques and should only attempt stunts after they have demonstrated appropriate skill progression and proficiency required to complete the stunt. Spotters and bases should have adequate upper body and core strength and balance to support flyers.
5. Technical skills, such as pyramids, mounts, tosses, and tumbling, should not be performed on hard (eg, concrete, asphalt), wet, or uneven surfaces or surfaces with obstructions. No cheer events should take place on dirt, vinyl floors, concrete, or asphalt.
6. Pyramids and partner stunts should only be performed on a spring floor or with a landing mat on either a traditional foam floor or grass/turf.
7. Pyramids should not be more than 2 people high and should only be performed with spotters.
8. Coaches should follow rules for execution of technical skills set forth in the most recent version of the NFHS *Spirit Rules Handbook* (http://www.nfhs.com/c-229-spirit.aspx) and the AACCA *Cheerleading Safety Manual* (http://aacca.org/content.aspx?item=Safety/2011-12SchoolCheerleadingRules.xml).
9. Coaches, parents, and athletes should have access to a written emergency plan, designed by school administrators in conjunction with the team physician and/or certified athletic trainer. Whenever possible, a certified athletic trainer or physician should be present at practices and competitions.
10. Cheer competitions should be held in venues that are compliant with guidelines of the National Cheer Safety Foundation and the AACCA.
11. Any cheerleader showing signs of a head injury should be removed from practice or competition and not allowed to return until he or she has received written clearance from a physician or qualified health care provider. Coaches, parents, and officials should be knowledgeable regarding the cause, prevention, recognition, and response to concussion. Free online educational materials are available through the Centers for Disease Control and Prevention (http://www.cdc.gov/concussion/) and the NFHS (http://www.nfhs.org).
12. Surveillance of cheerleading injuries should continue. All catastrophic injuries should be reported to the National Center for Catastrophic Sports Injury Research at Mueller@e-mail.unc.edu or National Cheer Safety Foundation at http://nationalcheersafety.com or by calling their Injury Reporting Hotline at 1-800-596-7860 ext 201. Research regarding injury epidemiology, mechanisms, and effectiveness of safety measures is necessary to guide new rules

and recommendations for improving safety.

APPENDIX: CHEERLEADING TERMINOLOGY

Tumbling

Any gymnastic or acrobatic skill executed on the performing surface. Examples include the following:

Round-off

A skill similar to a cartwheel but with both feet landing at the same time. It is almost always the beginning skill for all back tumbling passes.

Handspring/Flip-Flop

A front or back tumbling skill that takes off from the feet onto the hands and back onto the feet. It is commonly a set-up for a front or back tuck (flip).

Somersault/Salto/Flip/Somie

An acrobatic movement where the body makes a complete aerial turn (360 degrees) in the transverse axis. Can be performed forward, backward, or sideways.

Base

Person with at least 1 foot on the floor who is in direct, weight-bearing contact with the performing surface and who provides primary support for another person (flyer).

Flyer

Person who is elevated and/or tossed in the air by a base and may perform twists and/or flips before being caught by 1 or more bases.

Spotter

Person who remains in contact with the performing surface, is responsible for watching for hazards, and must be prepared to catch the flyer if he or she falls.

Stunts

Maneuvers in which 1 or more bases supports 1 or more flyers off the ground, such as the following:

Basket Toss

A stunt in which a flyer is tossed by bases whose hands are interlocked.

Cradle

A dismount from a stunt in which the flyer is caught in a face-up, piked position in the arms of 1 or more bases.

Pyramid

A stunt in which 2 or more bases support 1 or more flyers off the ground.

FREE

Male circumcision is a common procedure, generally performed during the newborn period in the United States. In 2007, the American Academy of Pediatrics (AAP) formed a multidisciplinary task force of AAP members and other stakeholders to evaluate the recent evidence on male circumcision and update the Academy's 1999 recommendations in this area. Evaluation of current evidence indicates that the health benefits of newborn male circumcision outweigh the risks and that the procedure's benefits justify access to this procedure for families who choose it. Specific benefits identified included prevention of urinary tract infections, penile cancer, and transmission of some sexually transmitted infections, including HIV. The American College of Obstetricians and Gynecologists has endorsed this statement. *Pediatrics* 2012;130:585–586

POLICY STATEMENT

Systematic evaluation of English-language peer-reviewed literature from 1995 through 2010 indicates that preventive health benefits of elective circumcision of male newborns outweigh the risks of the procedure. Benefits include significant reductions in the risk of urinary tract infection in the first year of life and, subsequently, in the risk of heterosexual acquisition of HIV and the transmission of other sexually transmitted infections.

The procedure is well tolerated when performed by trained professionals under sterile conditions with appropriate pain management. Complications are infrequent; most are minor, and severe complications are rare. Male circumcision performed during the newborn period has considerably lower complication rates than when performed later in life.

Although health benefits are not great enough to recommend routine circumcision for all male newborns, the benefits of circumcision are sufficient to justify access to this procedure for families choosing it and to warrant third-party payment for circumcision of male newborns. It is important that clinicians routinely inform parents of the health benefits and risks of male newborn circumcision in an unbiased and accurate manner.

Parents ultimately should decide whether circumcision is in the best interests of their male child. They will need to weigh medical information in the context of their own religious, ethical, and

cultural beliefs and practices. The medical benefits alone may not outweigh these other considerations for individual families.

Findings from the systematic evaluation are available in the accompanying technical report. The American College of Obstetricians and Gynecologists has endorsed this statement.

INTRODUCTION

Clostridium difficile is a spore-forming, obligate anaerobic, Gram-positive bacillus and is acquired from the environment or by the fecal-oral route. Toxins A and B are responsible for intestinal disease. *C difficile* is the most common cause of antimicrobial-associated diarrhea and is a common health care-associated pathogen. Clinical symptoms vary widely, from asymptomatic colonization to pseudomembranous colitis with bloody diarrhea, fever, and severe abdominal pain.

The incidence of *C difficile* infections (CDIs) among hospitalized children has been increasing across the United States since 1997.[1–3] Kim et al evaluated the annual incidence of *C difficile*–associated disease from 2001 to 2006 at 22 freestanding children's hospitals and found increases in the number of admissions (2.4 to 4.0/1000 admissions; $P = .04$) as well as the number of cases per patient-days in the hospital (4.4 to 6.5 cases/10 000 patient-days; $P = .06$).[1] Nylund et al evaluated data from 1997, 2000, 2003, and 2006 and demonstrated an increase in the number of CDIs, from 3565 cases in 1997 to 7779 cases in 2006 (total cases, 21 274; $P < .01$).[2] Zilberberg et al also demonstrated an increase of hospitalizations attributable to *C difficile*, from 7.24 to 12.80/10 000 hospitalizations.[3] The emergence of the epidemic strain of toxin-producing *C difficile* (North American pulsed field type 1 [NAP1]) in recent years may have changed the epidemiology in children. Published guidelines for managing CDI in adults affirm that there are gaps in the knowledge surrounding CDIs in infants and children.[4]

Disease in the Neonate/Infant/Young Child 0 to 3 Years of Age

Although testing of infants is not recommended, recent data have shown that 26% of children hospitalized with CDIs were infants younger than 1 year, and 5% were neonates.[1] What cannot be determined from these data are whether the rates of hospitalization for CDIs represent true disease or asymptomatic carriage.

The intestine of the newborn infant is sterile, but by 12 months of age, an infant's intestine has flora similar to that of an adult.[5] *C difficile* carriage rates average 37% for infants 0 to 1 month of age and 30% between 1 and 6 months of age.[5] Vaginal delivery, premature rupture of membranes, and previous administration of antimicrobial agents have little effect on carriage rates, but exposure to environments where *C difficile* is present (eg, ICUs) is important.[6–8] The organism has been recovered from the hands of hospital personnel, baby baths, oximeters, electronic thermometers, and hospital floors. Breastfed infants have lower carriage rates than do formula-fed infants (14% vs 30%, respectively).[9] At 6 to 12 months of age, approximately 14% of children are colonized with *C difficile*, and by 3 years of age, the rate is similar to that of nonhospitalized adults (0% to 3%).[5] Recognized risk factors for older children acquiring CDI included antimicrobial therapy, use of proton pump inhibitors, repeated enemas, use of diapers, prolonged nasogastric tube insertion, gastrostomy and jejunostomy tubes, underlying bowel disease, gastrointestinal tract surgery, renal insufficiency, and impaired humoral immunity. Carriage rates in hospitalized children and adults approximate 20%.[4] Many of these risk factors are common among hospitalized children; the presence of risk factors does not necessarily prove causation of CDI in an individual patient.

Clinical illness is rarely reported before 12 to 24 months of age. It is possible that neonates/infants may lack the cellular machinery to bind and process the toxins of *Clostridium* species.[10] There have been relatively few studies of *C difficile* with diarrhea that include control groups. In an emergency department treating children, 7% of patients with diarrhea and 15% of controls were colonized with *C difficile*.[11] In 2 studies of inpatients 0 to 2 years of age, 11% to 59% of patients with diarrhea and 24% to 33% of controls were colonized with *C difficile*.[12,13] Among inpatients 0 to 34 months of age, 21% of those with diarrhea and 33% of controls carried *C difficile*.[14] Among patients 0 to 12 years of age, 2.9% of outpatients, 4.6% of inpatients, and 6.6% of controls were colonized with *C difficile*.[15] In the setting of a high prevalence of asymptomatic carriage, detection of *C difficile* toxin cannot be assumed to be the causative agent for diarrhea in children before adolescence, particularly young children.[16]

The NAP1 Isolate of *C difficile*

The NAP1 strain of *C difficile* has been described as causing severe disease, including an increased incidence of symptomatic infection relative to colonization, recurrent disease, sepsis, toxic megacolon, bowel perforation, and mortality.[17] The NAP1 strain has entered the pediatric population at lower rates (10%–19% of *C difficile* isolates) than reported for adults (>50%).[18,19] NAP1-associated CDIs occur in children without exposure to health care facilities and/or to antimicrobial agents.[20,21] Whether the NAP1 strain is truly responsible for more severe disease in children requires further investigation. Newer strains of *C difficile* have also been isolated (eg, NAP7, NAP8), and their role in human disease has yet to be elucidated completely.[22] Detection of the NAP1 strain of *C difficile* is not possible in most laboratories and, in most situations, would not influence the clinical care of an individual patient.

DIAGNOSTIC TESTING

The diagnosis of *C difficile* disease is based on the presence of diarrhea and of *C difficile* toxins in a diarrheal stool specimen. Diarrhea is often defined as 3 or more stools that take the shape of their container in a 24-hour period. Because of a slow turnaround time, isolation of the organism from stool is not a clinically useful diagnostic test, nor is testing of stool from asymptomatic patients. The cell culture cytotoxicity assay (CCCA) has been replaced by more sensitive diagnostics. The most common testing method used today for *C difficile* toxins is the commercially available enzyme immunoassay (EIA), which detects toxins A and/or B. Mean test sensitivities range from 72% to 82%, with mean specificities of 97% to 98%, compared with the CCCA.[23] With low prevalence rates of disease in children, sensitivities and specificities such as these lead to an unacceptably low positive predictive value, thus limiting the usefulness of such testing.[11–15] Testing for glutamine dehydrogenase produced by *C difficile* should only be used as part of a 2-step algorithm with a confirmation of positive results by using either a toxin assay A/B EIA or a CCCA.[4]

Molecular assays using nucleic acid amplification tests (NAATs) are approved by the US Food and Drug Administration (FDA) and are now preferred by many laboratories. NAATs combine good sensitivity and specificity, have turnaround times comparable to EIAs, and are not required to be part of a 2- or 3-step algorithm.[24] In a recent study, the sensitivities of the real-time polymerase chain reaction (PCR) assay for toxin A/B compared with EIA for toxin A/B were superior (95% vs 35%, respectively), and the specificity was equal (100%).[25] With the use of the PCR, the positivity rates for stool samples doubled, from 7.9% to 8.3% with EIA to 14.9% to 18.1% with PCR, and the numbers of repeated samples decreased. Many children's hospitals are converting to NAAT technology to diagnose CDIs, but more data are needed before NAATs can be used routinely.[4]

Because carriage is so common, it is prudent to avoid routine testing for *C difficile* in children younger than 1 year. Testing for *C difficile* can be considered in children 1 to 3 years of age with diarrhea, but testing for other causes of diarrhea, particularly viral, is recommended first.[19] For children older than 3 years, testing can be performed in the same manner as for older children and adults. Endoscopic findings of pseudomembranes and hyperemic, friable rectal mucosa suggest pseudomembranous colitis and are sufficient to diagnose a CDI at any age.

A common mistake is to use EIAs and NAATs as tests of cure after treatment of CDIs. *C difficile*, its toxins, and genome are shed for long periods after resolution of diarrheal symptoms. None of the assays are licensed or recommended for tests of cure. Excretion of toxin approximates 13% to 24% at 2 weeks and 6% at 4 weeks after therapy.[26,27] Given that NAAT testing is more sensitive than toxin assays, an interval greater than 4 weeks since last testing should be used for testing with a recurrence.

TREATMENT

Discontinuation of antimicrobial agents is the first step in treating CDI and may suffice in most instances. For patients with moderate or severe disease, proper empirical antibiotic treatment should be started as soon as the diagnosis is suspected. Antiperistaltic medications should be avoided because they may obscure symptoms and precipitate complications, such as toxic megacolon. Although orally administered vancomycin is still the only agent approved by the US FDA for the treatment of CDI in children, it was replaced as the drug of choice in the 1990s in response to concerns over the emergence of vancomycin-resistant enterococcus. Metronidazole is currently the drug of choice for the initial treatment of children and adolescents with mild to moderate disease on the basis of efficacy, cost, and antimicrobial stewardship. Oral vancomycin or vancomycin administered by enema with or without intravenous metronidazole is indicated as initial therapy for patients with severe disease and for patients who do not respond to oral metronidazole.[4] Severe or fatal disease is more likely to occur in neutropenic children with leukemia, in children with intestinal stasis (eg, Hirschsprung disease), and in patients with inflammatory bowel disease. Prospective trials for therapy longer than 10 days have not been performed for either drug. Historically, metronidazole resistance in *C difficile* was rare, and there is no evidence that the new epidemic isolates, NAP1, is more resistant to metronidazole compared with the nonepidemic isolates. A recent randomized controlled trial evaluating a subgroup of patients with severe disease suggested that vancomycin treatment was superior to metronidazole even in patients infected with the NAP1 isolate.[28] Extrapolating these data to treatment with infants and children is difficult, and more data are required.

Up to 30% of patients treated for CDIs experience a recurrence after discontinuing therapy. Recurrences represent either relapse with the original isolate or reinfection with a new isolate. In clinical practice, the distinction cannot be made. Patients with a recurrence will usually respond to a second course of the same treatment. Metronidazole should not be used for the treatment of the second recurrence (third episode) or for chronic therapy (because of possible neurotoxicity[4]), and tapered or pulsed regimens of vancomycin are recommended for this situation. Vancomycin therapy is recommended in adults with the first recurrence if the patient has a white blood cell count of 15 000/μL or higher or has an increasing serum creatinine concentration, because they are at a higher risk of developing complications from CDI. No data exist for children. Other antimicrobial agents with activity against *C difficile* include nitazoxanide, fidaxomicin (FDA approved for treatment of CDI in adults in 2011), and rifaximin; criteria for optimal use of these drugs in children are unknown. Because there is a lack of controlled studies in children, probiotics are not recommended for either the prevention or the treatment of CDI. In rare instances, severely ill patients may require cecostomy for irrigation or a colectomy. Fecal transplantation (enteric administration of donor stool flora) is used anecdotally.[29]

CONTROL

Transmission is via the fecal-oral route, and CDI is transmitted to others by contact with the patient or the patients' contaminated environment. Control of *C difficile* in the environment is essential to the control of CDIs in health care facilities. People with *C difficile*–associated diarrhea should be placed in standard plus contact precautions for the duration of their diarrhea. Test of cure is not recommended; the patient may be removed from isolation once the diarrhea has resolved. Use of gloves is the best proven method for preventing patient-to-patient transmission via the hands of health care personnel. Hand-washing with soap and water is more effective for the removal of spores than is alcohol-based hand sanitizer. Germicidal wipes with 10% sodium hypochlorite are good adjuncts for cleaning the environment, especially in an outbreak situation.

RECOMMENDATIONS

1. Testing for *C difficile* colonization or toxin should only be performed in

children with diarrhea who meet the clinical and age-related conditions listed in the following recommendations.

2. Testing in infants (younger than 12 months of age) is complicated by a high rate of asymptomatic colonization. Testing of these infants should be limited to those with Hirschsprung disease or other severe motility disorders or in an outbreak situation. Alternative etiologies should be sought even in those with a positive test result for *C difficile*.
3. Testing in the second and third year of life is difficult to interpret; alternative etiologies should be sought. A positive test result indicates possible CDI.
4. A positive test result after the third year of life indicates probable CDI. Risk factors increasing the probability of CDI include antimicrobial therapy, use of proton pump inhibitors, underlying bowel disease, renal insufficiency, or impaired humoral immunity.
5. Endoscopic or histologic test results positive for pseudomembranous colitis indicate definite CDI.
6. Test of cure is not recommended. Testing for recurrences less than 4 weeks after initial testing is only useful when the results of repeat testing are negative.
7. Discontinuation of antimicrobial agents is the first step in treating CDI and may suffice in most instances. Antiperistaltic medications should be avoided.
8. When antimicrobial treatment is indicated for moderate disease, metronidazole (30 mg/kg/day in 4 divided doses, orally; maximum, 2 g/day) is the drug of choice for initial treatment of first episode of CDI and for first recurrence.
9. Oral vancomycin (40 mg/kg/day in 4 divided doses; maximum, 2 g/day), with or without metronidazole, is recommended for severe disease and second recurrence.
10. Use of gloves with symptomatic patients, washing of hands with soap and water, and environmental decontamination using chlorine products are key control measures. Contact isolation may be removed once the diarrhea has resolved.

abstract

FREE

Despite the complexity of diagnosis and management, pediatricians have an important collaborative role in referring and partnering in the management of adolescents with bipolar disorder. This report presents the classification of bipolar disorder as well as interviewing and diagnostic guidelines. Treatment options are described, particularly focusing on medication management and rationale for the common practice of multiple, simultaneous medications. Medication adverse effects may be problematic and better managed with collaboration between mental health professionals and pediatricians. Case examples illustrate a number of common diagnostic and management issues. *Pediatrics* 2012;130:e1725–e1742

Pediatricians are faced with increasing numbers of patients diagnosed with bipolar disorder and taking multiple psychotropic medications. In addition, pediatricians may be seeing these patients long before they are diagnosed and treated by a child and adolescent psychiatrist or other mental health professional. Pediatric bipolar disorder, once thought to be rare in adolescents and nearly nonexistent in younger children, has been diagnosed increasingly over the past decade.[1–3] In 2004, bipolar disorder accounted for 26% of primary discharge diagnoses among psychiatrically hospitalized adolescents in the United States.[3] Bipolar spectrum disorders,[4] encompassing the several types of bipolar disorder, have an estimated prevalence of 4% of children and adolescents in the general population.[5] The diagnosis remains controversial, and there has been a shift in how the diagnosis has been defined in youth.[1]

Associated impairments may include severe depression, high risk of suicide, psychosis, impulsive and dangerous behaviors, social and cognitive deficits, and frequent comorbidity with other psychiatric disorders, including substance use disorders, attention-deficit/hyperactivity disorder (ADHD), anxiety disorders, oppositional defiant disorder, and conduct disorder. Insight is frequently diminished, with youth vehemently blaming others for their difficulties and having little recognition of their own disruptive symptoms.[1] Management of these youth is additionally complicated by medication limitations, including troublesome adverse effects, lack of full response and the resultant common prescription of multiple medications, and incomplete prevention of relapse.[1] Not surprisingly, poor adherence to prescribed dosing is common.[6]

This report is not expected to give general pediatricians the tools necessary to diagnose and manage these complex cases independently. Some specific techniques are described with the intent of facilitating partnerships between pediatricians and child and adolescent psychiatrists and other mental health professionals. Additional goals include improved understanding of diagnosis and treatment; earlier referral of new, suspected cases, and patients with symptom relapse or worsening; and assistance in recognizing and managing medication adverse effects.

The focus of this report is diagnosis and management of adolescents with bipolar disorder. Children are mentioned as well when the subject matter applies to them.

CLASSIFICATION

The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)[7] describes 4 types of bipolar disorders, all without age limitations: bipolar I disorder, bipolar II disorder, cyclothymic disorder, and bipolar disorder not otherwise specified. Manic symptoms are the key feature of these diagnoses; Tables 1, 2, and 3 provide criteria for mania, hypomania, and mixed episodes.[7] A key criterion is duration: the minimum duration for mania and mixed episodes is 7 days and for hypomania is 4 days.

Bipolar I Disorder

Bipolar I disorder is the "classic" form of the disorder and requires a current or past manic or mixed episode. At any given time, the patient may be in a manic, hypomanic, mixed, or major depressive episode or may have fully or partially recovered from the last mood episode. Notably, this is a historical diagnosis because the patient may be in any current mood state and still meet this criterion. History of a depressive episode is common but not required. Other criteria are that the mood symptoms cause significant distress or impaired functioning; are not better accounted for by schizoaffective disorder or superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified; and are not the effect of a substance (including medications) or general medical condition.

TABLE 1 Diagnostic Criteria for a Manic Episode

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood, lasting at least 1 wk (or for any duration if hospitalization is necessary)
B. During the period of mood disturbance, 3 (or more) of the following symptoms have persisted (4 if the mood is only irritable) and have been present to a significant degree
   1. Inflated self-esteem or grandiosity
   2. Decreased need for sleep (eg, feels rested after only 3 h)
   3. More talkative than usual or pressure to keep talking
   4. Flight of ideas or subjective experience that thoughts are racing
   5. Distractibility (ie, attention too easily drawn to unimportant or irrelevant external stimuli)
   6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
   7. Excessive involvement in pleasurable activities that have a high potential for painful consequences (eg, engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments)
C. The symptoms do not meet criteria for a mixed episode
D. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features
E. The symptoms are not due to the direct physiologic effects of a substance (eg, a drug of abuse, a medication, or other treatment) or a general medical condition (eg, hyperthyroidism)

Reprinted with permission from American Psychiatric Association. *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)*. Washington, DC: American Psychiatric Association; 2000.

TABLE 2 Diagnostic Criteria for a Hypomanic Episode

A. A distinct period of persistently elevated, expansive, or irritable mood, lasting throughout at least 4 d, that is clearly different from the usual nondepressed mood
B. Same as manic episode "B" (Table 1)
C. The episode is associated with an unequivocal change in functioning that is uncharacteristic of the person when not symptomatic
D. The disturbance in mood and the change in functioning are observable by others
E. The episode is not severe enough to cause marked impairment in social or occupational functioning or to necessitate hospitalization, and there are no psychotic features
F. Same as manic episode "E" (Table 1)

DSM-IV-TR asks for specification of certain patterns, including longitudinal course as with or without full interepisode recovery and/or rapid cycling. Rapid cycling is defined as more than 4 mood changes in a year. Researchers have defined patterns that commonly apply to pediatric bipolar disorder, including ultrarapid cycling, episodes lasting a few days to a few weeks, and ultradian cycling, variation occurring within a 24-hour period.[8,9]

Bipolar II Disorder

Depression typically is the major problem in bipolar II disorder. A current or at least 1 past major depressive episode is required, and the patient must have a current or past episode of hypomania with no manic or mixed episodes at any time. That is, currently or historically, a patient with bipolar I disorder has big "ups" (mania) and may or may not have "downs" (depression). A patient with bipolar II disorder has little "ups" (hypomania) plus big "downs" (major depression).

Cyclothymic Disorder

Cyclothymic disorder is characterized by relatively mild but chronic symptoms (hypomanic and depressive symptoms) that last at least 2 years (1 year with children and adolescents) before any full manic, mixed, or major depressive

TABLE 3 Diagnostic Criteria for a Mixed Episode

A. The criteria are met for both a manic episode and a major depressive episode (except for duration) nearly every day during at least a 1-wk period
B. Same as manic episode "D" (Table 1)
C. Same as manic episode "E" (Table 1)

episodes. These patients have little "ups" (hypomania) and little "downs" (dysthymia), but the disorder is chronic.

Bipolar Disorder Not Otherwise Specified

DSM-IV-TR describes the category of bipolar disorder not otherwise specified as including, "disorders with bipolar features that do not meet criteria for any specific bipolar disorder."[7] The American Academy of Child and Adolescent Psychiatry recommends using this diagnosis for youth with manic symptoms lasting hours to days or for those with chronic manic-like symptoms.[1] These youth may be significantly impaired and constitute the majority of those referred to mental health professionals.[10] Emerging evidence suggests that this disorder is on a continuum with bipolar I disorder,[11,12] and 45% of patients converted to bipolar I or bipolar II disorder at follow-up an average of 5 years later, particularly patients with a family history of bipolar disorder.[13]

Beyond DSM-IV-TR

Akiskal and Pinto described a bipolar spectrum in adults, ranging from bipolar I disorder to hyperthymic temperament.[4] The disorders and conditions on the spectrum share symptom characteristics that generally responded better to mood-stabilizing medication than to antidepressant medication.

Leibenluft et al suggested research diagnostic criteria for 3 clinical phenotypes of pediatric bipolar disorder: narrow, intermediate, and broad[14] (Tables 4, 5, and 6). These criteria are included in this report to illustrate important features of diagnosis that are not present in DSM-IV-TR; they should not be construed as generally accepted by physicians or researchers. Narrow phenotype refers to a disorder in which, for at least 1 episode, full DSM-IV-TR criteria are met, including duration criteria, and elation and/or grandiosity also is present. Elation and grandiosity were argued by Geller et al[9] to be core bipolar features. Intermediate phenotype refers to patients with episodes that met full DSM-IV-TR criteria but lacked duration criteria (episodes too short) or had mania/hypomania that was irritable rather than euphoric. This phenotype still includes mood cycling as a required feature. Broad phenotype refers to a disorder characterized by chronic irritability and hyperarousal and does not include mood cycling. Compared with their peers, children and adolescents who have the broad phenotype show markedly increased reactivity to negative emotional stimuli. The broad phenotype has been referred to as severe mood dysregulation (SMD).

TABLE 4 Research Criteria for the Narrow Phenotype of Juvenile Mania

A. Modification to the DSM-IV-TR criteria for manic episode
a. The child must exhibit either elevated/expansive mood or grandiosity while also meeting the other DSM-IV-TR criteria for a (hypo)manic episode
B. Guidelines for applying the DSM-IV-TR criteria
a. Episodes must meet the full duration criteria (ie, at least 7 d for mania and at least 4 d for hypomania) and be demarcated by switches from other mood states (depression, mixed state, euthymic).
b. Episodes are characterized by a change from baseline in the patient's mood and, simultaneously, by the presence of the associated symptoms.
c. Decreased need for sleep should be distinguished from insomnia.
d. Poor judgment is not a diagnostic criterion unless it is in the context of "increased goal-directed activity" or "excessive involvement in pleasurable activities that have a high potential for painful consequences."

TABLE 5 Research Criteria for the Intermediate Phenotypes of Juvenile Mania

A. The child meets the criteria for the narrow phenotype except:
a. (Hypo)manic episodes are 1to 3 d in duration OR
b. The (hypo)manic episodes include exclusively irritable, not elevated or expansive, mood, and DSM-IV-TR duration criteria are met

SMD among children 9 to 19 years of age has a lifetime prevalence of 3.3%, with most affected children having comorbid psychiatric disorders, most frequently disruptive behavior disorders (ADHD, conduct disorder, and oppositional defiant disorder).[15] Children with SMD were 7 times more likely to develop depression as young adults compared with those without SMD. Compared with children with narrow phenotype bipolar disorder, subjects with SMD had different psychopathological measures and were less likely to have parents with bipolar disorder,[16] suggesting that SMD is a disorder distinct from narrow phenotype bipolar disorder.

Mood diagnoses continue to evolve. The development web site for the forthcoming *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition,* lists an additional proposed mood diagnosis of "disruptive mood dysregulation disorder,"[17] characterized by severe recurrent temper outbursts in response to common stressors and similar to the broad phenotype. Characteristics for this diagnosis as well as others on the development Web site have been changing in response to public feedback. The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, is expected to be published in May 2013. Because the final version may be fairly different, this report

TABLE 6 Research Criteria for Broad Phenotype of Juvenile Mania: Severe Mood and Behavioral Dysregulation

A. Inclusion criteria
  a. Age 7–17 y, with onset of symptoms before age 12
  b. Abnormal mood present at least half of the day most days and of sufficient severity to be noticeable by people in the child's environment
  c. Hyperarousal, as defined by at least 3 of the following symptoms: insomnia, agitation, distractibility, racing thoughts or flight of ideas, pressured speech, intrusiveness
  d. Compared with his/her peers, the child exhibits markedly increased reactivity to negative emotional stimuli that is manifest verbally or behaviorally
  e. The symptoms noted in the previous 3 items are currently present and have been present for at least 12 mo without any symptom-free periods exceeding 2 mo in duration
  f. The symptoms are severe in at least 1 setting and at least mild symptoms in a second setting
B. Exclusion criteria
  a. The individual exhibits any of the cardinal bipolar symptoms: elevated or expansive mood, grandiosity or inflated self-esteem, episodically decreased need for sleep
  b. The symptoms occur in distinct periods lasting more than 4 d
  c. The individual meets criteria for schizophrenia, schizoaffective illness, pervasive developmental disorder, or posttraumatic stress disorder
  d. The individual has met the criteria for substance abuse disorder in the past 3 mo
  e. IQ <80
  f. The symptoms are attributable to the direct physiologic effects of a drug of abuse or to a general medical or neurologic condition

does not include additional mention of diagnoses listed on the development web site.

The balance of this report refers to *DSM-IV-TR* as well as proposed research diagnoses. Pediatricians should be aware, however, of the changing classification of bipolar and related disorders.

INTERVIEWING FOR MANIA

The presence or history of mania of some sort is the determining factor for a diagnosis of bipolar disorder. Typically, depressive symptoms are also present at some point in the illness and may be the major concern, but depression is not required to be present either currently or historically for a bipolar diagnosis. Depressed patients with bipolar disorder, particularly those with the narrow or intermediate phenotype, may require different medication from those with depression alone, so it is important for the pediatrician or mental health professional to attempt to make this differentiation before initiating pharmacotherapy.

Challenges in Diagnosing Mania

At a minimum, a full psychiatric evaluation should be performed to determine diagnosis.[1] A significant problem is that the diagnosis of mania typically is historical. Even with a patient who demonstrates manic symptoms during the interview, the interviewer still needs to determine that the symptoms represent a change, interfere with functioning, and are associated with less evident manic symptoms. Much more often, however, the patient presents as depressed or euthymic, leaving it for the interviewer to tease out groups of symptoms that occur together in episodes and are different from "normal adolescence." Adolescents and parents may tend to minimize these symptoms, wanting the trouble to be something less serious or, conversely, may tend to exaggerate, grasping at a bipolar diagnosis as a means of explaining a range of difficulties. Much of the public now has some education about bipolar disorder, often just enough to produce misconceptions about the diagnosis and associated symptoms, thus complicating the job of the interviewer.

Simplifications

Without specific training in this area, the general pediatrician should not attempt initiation of treatment in newly diagnosed cases. The goal for the pediatrician in identification, therefore, should be reasonable suspicion rather than diagnosis, followed by referral or seeking an appropriate mental health professional as partner. The balance of this section discusses several historical symptoms that may be considered red flags for the diagnosis. The clear presence of any of these should be considered sufficient for reasonable suspicion.

Red Flag Symptoms

Rage Outbursts or Verbal or Physical Aggression

Rage is not a bipolar symptom per se but is common with adolescents experiencing episodic irritable mania or chronic severe mood dysregulation. In both cases, the adolescent is edgy and easily frustrated and provoked. Questions the interviewer may ask include, "Do you lose your temper?" If so, the adolescent should be asked about frequency, duration, what happens, and what the triggers are (see Table 7 for a summary of examples of interview questions).

Episodes of Requiring Little Sleep

Requiring little sleep needs to be distinguished from going to bed late and getting up late and from receiving less sleep and consequently being tired the next day. Staying up late for 1 night during a sleepover or for a concert also does not count. Adolescents with this symptom have the experience of having high energy, receiving at least 2 hours less sleep per night, and remaining full of energy often after several nights of this.[18] Questions include, "Do you ever have nights when you have lots of energy, do not need to sleep much, and do lots of things?" If so, "Are you tired the next day?"

TABLE 7 Examples of Interview Questions

Symptom	Question examples
Rage outbursts	"Do you lose your temper?" If so, ask about frequency, duration, what happens, what the triggers are.
Episodes of requiring little sleep	"Do you ever have nights when you have lots of energy, do not need to sleep much, and do lots of things?" If so, "Are you tired the next day?"
Spontaneous mood shifts	"Do you find yourself suddenly angry or extremely happy for no apparent reason?" If so, ask about frequency and duration of the moods.
Running away, sneaking out at night, spending money, hypersexuality	"Have you even run away or snuck out of the house at night?" "Do you have time when you spend a lot of money or when you feel that you cannot control your sexual urges?"
Grandiosity	"Do you have times when you feel that nothing can happen to you?" "Do you have times when you greatly overestimate your talents or abilities?"
Agitation or mania with antidepressant	"Have you ever taken medication for depression?" If so, "Did you have any side effects?" "Did you ever become very edgy or much more happy or angry than is typical for you?"

Spontaneous Mood Shifts

The adolescent experiences sudden mood shifts between euthymic, giddy, depressed, or angry, with no evident circumstantial trigger. The giddy, depressed, or angry mood state should significantly interfere with functioning, such as making concentration in school or appropriate behavior with friends much more difficult. A mood shift may happen multiple times per day. Questions include, "Do you find yourself suddenly angry or extremely happy for no apparent reason?" If so, ask about frequency and duration of the moods.

Running Away, Sneaking Out at Night, Spending Money, Hypersexuality

These activities may be categorized as "excessive involvement in pleasurable activities that have a high potential for painful consequences" (Table 1).[7] Running away also may be an example of an impulsive activity related to severe irritability. Questions include, "Have you ever run away or snuck out of the house at night?" "Do you have times when you spend a lot of money or when you feel that you cannot control your sexual urges?"

Grandiosity

Grandiosity is a grossly inflated belief in oneself having special talents or abilities, such as never being in danger regardless of the activity or being the best at a certain sport, or endless talk about a real talent. This must be a change from baseline and does not include a consistent picture of boastfulness or failure to appreciate consequences. Questions include, "Do you have times when you feel that nothing can happen to you?" "Do you have times when you greatly overestimate your talents or abilities?"

Agitation or Mania With Antidepressant

Adverse effects for a patient under the influence of antidepressant medication may be edginess, agitation, or less commonly, frank mania. By definition, a cluster of manic symptoms resulting from a medication or substance is not mania. It is, however, a risk factor for mania either continuing once the medication is withdrawn or mania at another time. Questions include, "Have you ever taken medication for depression?" If so, "Did you have any side effects?" "Did you ever become very edgy or much more happy or angry than is typical for you?"

Any or all of these symptoms may be present currently, recently, or in the more distant past.

TREATMENT

Psychotherapy

Psychotherapeutic interventions are an important component of an overall treatment plan.[1] Interventions should be targeted to the following areas.

Psychoeducation

Information is provided to patient and family on the illness, treatment options, impact on functioning, and heritability. Relapse prevention typically is an important issue. Education is provided regarding importance of treatment adherence, avoidance of precipitating factors, and early recognition of symptoms. The illness may result in a dramatic tendency to blame others and minimize one's own symptoms and limitations, making engagement in the treatment plan difficult. For some individuals and families, education regarding relapse prevention is the key intervention.

Individual Psychotherapy

Cognitive-behavioral psychotherapy and interpersonal therapy support emotional and cognitive development, coping, and symptom monitoring.

Social and Family Functioning

Interventions aimed at communication and problem solving are needed to address disruptions in family and social relationships.

Academic and Occupational Functioning

Educational planning, specialized educational programs, and occupational training and support may be needed to address disruption of functioning in

school or work from ongoing or intermittent symptoms.

Treatment of Comorbidities

Psychosocial interventions should be aimed at treatment of pre- or coexisting substance abuse disorders, behavioral disorders, anxiety disorders, learning problems, and confounding social issues.

Inpatient Psychiatric Hospitalization

Inpatient care typically is aimed at preventing imminent harm to self and others as well as allowing for treatment that could not be accomplished in a less restrictive setting.[19] A common reason for admission is suicidality, including suicidal ideation or a recent attempt. To be at high risk of suicide, the patient need not be thinking of suicide at the time of admission. Mood and behavior may have considerable day-to-day or even minute-to-minute variation; therefore, judgment as to safety should be based on recent thoughts, moods, and behaviors rather than just the current ones and on near-future projection on the basis of possible and sudden occurrence of common adolescent stressors. For example, in an adolescent with recent suicidal behavior and a history of grossly overreacting to negative circumstances, a romantic breakup could be lethal.

Other common reasons for psychiatric hospitalization for harm prevention are recent episodes of severe rage, agitation, or aggression attributable to mood symptoms or manic symptoms accompanied by severe impulsivity in areas that could inadvertently result in self-harm, such as running away or sexual activity with multiple partners. Patients with florid mania or acute psychosis typically require hospitalization even in the absence of overtly dangerous behaviors or ideation because of the high unpredictability of the behavior of afflicted individuals as well as difficulty with treatment adherence at a time when vigorous treatment is indicated.

Partial hospitalization[20] or hospital day treatment is used as a less restrictive, step-down treatment from inpatient care or as step-up treatment from mental health office services. Partial hospitalization does not afford the 24-hour monitoring and harm prevention provided with inpatient services but is less disruptive to the patient's life, less expensive, and gives the patient and family more responsibility for the patient's care while still providing intensive psychotherapeutic and medical management.

Residential treatment[21] is longer-term, 24-hour-a-day care in a less intensive, typically nonhospital setting, and may be a month to a year or more in duration. Residential care is designed for patients who cannot be safely managed otherwise despite adequate treatment or who have symptoms that require long-term behavioral intervention to effect improvement.

Psychopharmacology

Medication management is an important component of treatment of youth with bipolar disorder and is the primary treatment in cases of well-defined mania.[1,5] The primary medications used to treat patients with bipolar disorder are mood stabilizers, such as lithium; certain anticonvulsant medications, including divalproex, lamotrigine, carbamazepine, oxcarbazepine, gabapentin, and topiramate; and atypical antipsychotics, including aripiprazole, olanzapine, quetiapine, risperidone, ziprasidone, paliperidone, clozapine, asenapine, and iloperidone. Adjunctive medications include antidepressant medications and "typical" antipsychotics, as well as medications for ADHD, anxiety, and insomnia; more information is available from the American Academy of Child and Adolescent practice parameters.[1,22–25]

The American Academy of Child and Adolescent Psychiatry[1] recommends basing the medication choice on the following: evidence of efficacy, phase of illness, type of presentation (eg, with psychotic symptoms), safety and adverse effect profile, history of medication response, and patient or family preference. Medication combinations are common, with some patients on 5 or more drugs. See Kowatch et al[5] for a suggested prescribing algorithm.

Efficacy Studies

Currently, lithium, aripiprazole, risperidone, olanzapine, and quetiapine are approved by the US Food and Drug Administration (FDA) for use in adolescents with bipolar disorder (Table 8).[26] In addition, divalproex, lamotrigine, carbamazepine, oxcarbazepine, gabapentin, and topiramate have nonmental health pediatric indications, and divalproex, lamotrigine, ziprasidone, and asenapine have indications for treatment of adults with bipolar disorder. Published studies have had mixed results (Tables 9, 10, and 11). Not all studies are available, because pharmaceutical companies are not required to publish their studies even when submitted to the FDA as part of an application for an indication. Lithium, aripiprazole, and olanzapine showed efficacy in published, double-blind, placebo-controlled studies, with open-label, chart review, and comparison studies giving support for use of divalproex, lamotrigine, clozapine, risperidone, quetiapine, and carbamazepine. Notably, divalproex and oxcarbazepine each failed to show efficacy in a double-blind, placebo-controlled study, but given the heterogeneity of this disorder, 1 negative study is not conclusive. Divalproex, lamotrigine, lithium, aripiprazole,

TABLE 8 FDA Indications for Oral Formulations of Mood Stabilizers and Atypical Antipsychotics

Medication	Bipolar disorder	Schizophrenia	Irritability associated with autism	Nonmental health	All adult mental health
Mood stabilizer					
Lithium (Eskalith)	Mania, ages 12–17				Mania
Divalproex (Depakote)				Seizures, ages 0–17	Mania
Lamotrigine (Lamictal)				Seizures, ages 2–17	Bipolar maintenance
Carbamazepine (Tegretol)				Seizures, ages 0–17; trigeminal neuralgia	
Oxcarbazepine (Trileptal)				Seizures, ages 2–17	
Gabapentin (Neurontin)				Seizures, ages 3–17	
Topiramate (Topamax)				Seizures, ages 2–17	
Atypical antipsychotics					
Aripiprazole (Abilify)	Manic and mixed episodes, ages 10–17	Ages 13–17	Ages 6–17		Bipolar mania, schizophrenia, adjunctive for major depression
Risperidone (Risperdal)	Manic and mixed episodes, ages 10–17	Ages 13–17	Ages 5–16		Schizophrenia, bipolar manic and mixed episodes
Olanzapine (Zyprexa)	Manic and mixed episodes, ages 13–17	Ages 13–17			Schizophrenia, bipolar manic and mixed episodes, bipolar and resistant depression (in combination with fluoxetine)
Quetiapine (Seroquel)	Manic episodes, ages 10–17	Ages 13–17			Schizophrenia, bipolar mania, bipolar depression
Ziprasidone (Geodon)					Schizophrenia, bipolar manic and mixed episodes, bipolar maintenance
Paliperidone (Invega)					Schizophrenia, schizoaffective disorder
Clozapine (Clozaril)					Schizophrenia, schizoaffective disorder
Asenapine (Saphris)					Schizophrenia, bipolar manic and mixed episodes
Iloperidone (Fanapt)					Schizophrenia
Lurasidone (Latuda)					Schizophrenia

quetiapine, risperidone, and topiramate have shown efficacy in medication combination studies. Kowatch et al[27] found a medication combination response rate of 80% among patients who did not respond to monotherapy with a mood stabilizer.

Adverse Effects

Mood stabilizer (Table 12)[5] and atypical antipsychotic (Table 13)[28,29] medications have a variety of adverse effects, interactions, and safety concerns. Pediatricians probably need to be most aware of weight gain and metabolic effects common with the atypical antipsychotics, although weight gain is also commonly associated with valproate and, to a lesser extent, lithium. Prescription of atypical antipsychotics in youth for bipolar disorder as well as for psychosis, disruptive behavior disorders, and other mood disorders has increased drastically in recent years.[30] Children and adolescents may be more vulnerable than adults to weight gain from these medications and, thus, likely to be at higher risk of glucose and lipid abnormalities.[31] Weight management potentially can be addressed with suggestions of diet and exercise as well as changing the dose and/or type of medication. Use of metformin may be of some help.[32,33] Stable patients should be seen by their pediatrician every 4 to 6 months, with more frequent visits when there are active adverse effects, interactions, or safety issues.

The American Diabetes Association[34] published a protocol for use in monitoring for weight gain and metabolic changes in adults treated with atypical antipsychotics, including obtaining personal and family history of related disorders, determining weight and height, determining waist circumference, taking blood pressure, and measuring fasting plasma glucose and fasting lipid profile. Weight should

TABLE 9 Published Studies of Efficacy of Mood Stabilizers With Pediatric Bipolar Disorder[a]

Medication	Study	Ages	Type	Results	Comments
Divalproex	Wagner et al (2002)[41]	7–19; *n* = 40	Open-label trial	Response rate 61% with manic symptoms	Manic, mixed, or hypomanic
Divalproex	Henry et al (2003)[42]	4–18; *n* = 15	Records review	Response rate 53% after 1 y	Divalproex alone and as add-on
Divalproex	Wagner et al (2009)[43]	10–17; *n* = 150	Double-blind	No significant difference from placebo	Manic or mixed
Lamotrigine	Chang et al (2006)[44]	12–17; *n* = 20	Open-label trial	Significant decreases in depression, mania, and aggression	Lamotrigine alone and in combination with other medication
Lamotrigine	Pavuluri et al (2009)[45]	8–18; *n* = 46	Open-label trial	Response rate 72% with manic symptoms and 82% with depressive symptoms	Monotherapy
Lithium	Strober et al (1990)[46]	13–17, *n* = 37	Naturalistic prospective follow-up	Relapse rate 3 times higher when lithium discontinued	Lithium alone and in combination with other medication
Lithium	Geller et al (1998)[47]	12–18; *n* = 25	Double-blind	Significant response rate difference, 46% versus 8% of placebo group	Bipolar disorder with secondary substance dependence
Lithium	Kafantaris et al (2003)[48]	12–18; *n* = 100	Open-label trial	Response rate 63% with manic symptoms	Acute mania
Lithium	Kafantaris, et al (2004)[49]	12–18; *n* = 40	Double-blind discontinuation	No significant difference from placebo	Mania with or without psychosis or aggression
Lithium	Patel et al (2006)[50]	12–18; *n* = 27	Open-label trial	Response rate 48% with depressive symptoms	Acute bipolar depression
Oxcarbazepine	Wagner et al (2006)[51]	7–18; *n* = 116	Double-blind	No significant difference from placebo	Manic or mixed
Topiramate	Del Bello et al (2002)[52]	5–20; *n* = 26	Chart review	Response rate 73% for mania and 62% for overall illness	Outpatient with acute manic, mixed, or depressive episode; adjunctive or monotherapy
Topiramate	Barzman et al (2005)[53]	7–20; *n* = 25	Chart review	Response rate 64%	Hospitalized with acute manic, mixed, or depressive episode; adjunctive or monotherapy
Topiramate	DelBello, et al (2005)[54]	6–17; *n* = 56	Double-blind	Mixed results	Inconclusive; study stopped early when early adult studies failed to show efficacy

[a] Includes only the most recent studies of divalproex and lithium.

TABLE 10 Published Studies of Efficacy of Atypical Antipsychotics for Pediatric Bipolar Disorder

Medication	Study	Ages	Type	Results	Comments
Aripiprazole	Barzman et al (2004)[55]	5–19; *n* = 30	Chart review	Response rate 67%	Bipolar or schizoaffective; adjunctive or monotherapy
Aripiprazole	Biederman et al (2005)[56]	4–17; *n* = 41	Records review	71% improvement of manic symptoms	Aripiprazole alone and as add-on
Aripiprazole	Biederman et al (2007)[57]	6–17; *n* = 19	Open-label trial	Significant improvement	Mania
Aripiprazole	Tramontina et al (2007)[58]	8–17; *n* = 10	Open-label trial	Significant improvement	Comorbid bipolar and ADHD; improved both mania and ADHD symptoms
Aripiprazole	Findling et al (2009)[59]	10–17; *n* = 296	Double-blind	Significant response rate difference, 44% (10 mg), 64% (30 mg), 26% (placebo)	Manic or mixed
Aripiprazole	Tramontina et al (2009)[60]	8–17; *n* = 43	Double-blind	Significant response rate difference, 89% vs 52% of placebo group	Manic or mixed comorbid with ADHD
Clozapine	Masi et al (2002)[61]	12–17; *n* = 10	Open-label trial	Significant improvement	Severe treatment-resistant manic or mixed
Olanzapine	Frazier et al (2001)[62]	5–14; *n* = 23	Open-label trial	Response rate 61%	Acute mania
Olanzapine	Tohen et al (2007)[63]	13–17; *n* = 161	Double-blind	Significant response rate difference, 45% vs 19% of placebo group	Acute manic or mixed
Olanzapine	Joshi et al (2010)[64]	4–17; *n* = 52	Open-label trial; secondary analysis of 2 trials	Significantly less antimanic response with comorbid OCD	Bipolar disorder
Quetiapine	Del Bello et al (2007)[65]	12–18; *n* = 20	Single-blind, open label	Response rate 87% with mood symptoms	Patients at high risk for bipolar I
Quetiapine	Del Bello et al (2009)[66]	12–18; *n* = 32	Double-blind	No significant difference from placebo	Bipolar depression
Quetiapine	Scheffer et al (2010)[67]	6–16; *n* = 75	Open-label trial	94% much improved at 8 wk; rapid loading tolerated well	Bipolar disorder
Risperidone	Frazier et al (1999)[68]	4–17; *n* = 28	Records review	Response rate 82% with manic and aggressive symptoms	Mixed or hypomanic
Risperidone	Biederman et al (2005)[69]	6–17; *n* = 30	Open-label trial	Response rate 70% with manic symptoms	Manic, mixed, or hypomanic
Risperidone	Haas et al (2009)[70]	10–17; *n* = 169	Double-blind	Significant response rate difference, 59% (0.5–2.5 mg), 63% (3–6 mg), 26% (placebo)	Acute manic or mixed
Risperidone	Carlson et al (2010)[71]	5–12; *n* = 151	Chart review	Reduced duration or rages	Hospitalized children with possible bipolar disorder
Risperidone	Krieger et al (2011)[72]	7–17; *n* = 21	Open-label trial	Significant reduction of irritability, depression, ADHD symptoms, and global functioning	Severe mood dysregulation
Ziprasidone	Biederman et al (2007)[73]	6–17; *n* = 21	Open-label trial	Response rate 71% with manic symptoms	Mania

be reassessed monthly for 3 months and then quarterly. Lipids and fasting plasma glucose may be measured after 3 months and then every 6 months. There is no a protocol currently for children and adolescents.[28]

When medications are prescribed by a physician other than the pediatrician, the decision of which physician monitors the patient's weight and metabolic consequences of the medication may be a matter of practicality. Certain measurements, such as vital signs, height, weight, and waist size, are easily and routinely obtained in a pediatrician's office but much more difficult to obtain in a psychiatrist's office, because it typically is not set up with the proper equipment and usually does not have a nurse on staff. In addition, at times, the patients may perceive these measurements to be physically intrusive when obtained by the psychiatrist. The pediatrician should collaborate with the prescribing physician in monitoring for and managing these medication adverse effects.

Other Medication Caution

A number of medications should be used with care because they may increase mood cycling (Table 14).[18] In particular, antidepressant medications are commonly prescribed, because bipolar disorder usually includes depression, and depression is the most common reason for the initial referral for treatment. Antidepressant induction of mania may be less frequent than once thought,[35] but common practice is to start with a mood stabilizer or atypical antipsychotic (or combination) and add an antidepressant to the mix only if there is insufficient response.

Few studies have addressed the use of mood stabilizers and atypical antipsychotics with pediatric bipolar depression. Lithium and lamotrigine

TABLE 11 Published Comparison Studies of Efficacy of Mood Stabilizers and Atypical Antipsychotics With Pediatric Bipolar Disorder

Medication	Study	Ages	Type	Results	Comments
Lithium, Divalproex, Carbamazepine	Kowatch et al (2000)[74]	6–18; *n* = 42	Open-label trial	Large effect size for all 3 medications; response rate with manic symptoms of divalproex 53%, lithium 38%, and carbamazepine 38%	Manic or mixed
Quetiapine, Divalproex	Del Bello et al (2002)[75]	12–18; *n* = 30	Double-blind	Significant response rate difference, 87% vs 53% of placebo group	Manic or mixed; divalproex plus quetiapine versus divalproex plus placebo
Risperidone, Lithium, Divalproex	Pavuluri et al (2004)[76]	5–18; *n* = 37	Open-label trial	Response rate 80% for risperidone plus divalproex and 82% for risperidone plus lithium	Manic or mixed
Lithium, Divalproex	Findling et al (2005)[77]	5–17; *n* = 60	Double-blind; no placebo group	No significant difference between the groups	Stabilized on lithium plus divalproex and then compared maintenance monotherapy with one or the other
Quetiapine, Divalproex	Del Bello et al (2006)[78]	12–18; *n* = 50	Double-blind, no placebo group	Significant improvement in both groups; no significant difference in amount of improvement but significantly faster improvement in quetiapine group	Manic or mixed; compared quetiapine and divalproex
Risperidone, Divalproex	MacMillan et al (2008)[79]	5–14; *n* = 28	Records review	Risperidone group showed significantly faster decrease of symptoms than divalproex group	More wt gain with risperidone
Risperidone, Divalproex	Pavuluri et al (2010)[80]	8–18; *n* = 66	Double-blind, no placebo group	More rapid improvement in risperidone group but no difference in final scores	No significant wt gain in either group; better retention of subjects in risperidone group

have shown efficacy in open-label trials (Table 9) and quetiapine was not significantly better than placebo (Table 10).

Medication Combinations

Adolescents with bipolar disorder may have a range of symptoms within the disorder, including symptoms of mania or hypomania, depression, and psychosis, and commonly have comorbidities with a variety of other psychiatric disorders, including ADHD, generalized anxiety disorder, obsessive-compulsive disorder (OCD), posttraumatic stress disorder, and others.[5] These comorbidities can lead to a complexity of symptoms and often difficult choices for medication management. As a result, use of multiple medications is common in treating adolescents with bipolar disorder, who often are prescribed 2 to 5, or more, simultaneous medications. Even in a research setting using algorithms designed to limit the number of medications, only 28% of patients were able to remain on monotherapy for >6 months.[36]

Reasons for combining medications include the following:

- Partial response. A group of symptoms, such as expansive mood, grandiosity, and pleasure-seeking behaviors, may have improved with a particular medication (with adequate dose and time), but symptoms continue sufficiently to cause distress and/or impairment of functioning. A second (or sometimes third) medication is then added as an "augmentation agent" to improve response. Another type of partial response is when some symptoms improve and others do not (eg, symptoms of mania improve but the patient still suffers from intermittent or persistent depression).
- Target specific symptom. There may be a particular troublesome and/or easily treated symptom, such as

TABLE 12 Adverse Effects and Possible Monitoring of Mood Stabilizers

Medication	Summary of adverse effects	Suggested monitoring
Lithium	Reduced renal function, hypothyroidism, nausea, diarrhea, abdominal distress, sedation, tremor, polyuria, wt gain, acne, cardiac conduction problems, hypoparathyroidism	Baseline: serum electrolytes, creatinine, BUN, calcium, CBC count, TFTs, EKG, pregnancy test (sexually active female patients)
	Wt gain may be additive when combined with an atypical antipsychotic[28]	Ongoing: lithium level, renal function, thyroid function, calcium
	Toxic levels may produce confusion, ataxia, dysarthria, seizures, coma, death	
Divalproex	Polycystic ovaries, nausea, increased appetite, wt gain, sedation, thrombocytopenia, hair loss, tremor, vomiting, rare pancreatitis or liver failure	Baseline: height and wt, pregnancy test (sexually active female patients), liver function tests, CBC
	Wt gain may be additive when combined with an atypical antipsychotic[28]	Every 6 mo: divalproex level, liver function tests, CBC
Carbamazepine	Multiple medication interactions (decrease or increase the other medication levels including oral contraceptive failure), sedation, ataxia, dizziness, blurred vision, nausea, vomiting, aplastic anemia, hyponatremia, Stevens-Johnson	Baseline: CBC Every 6 mo: carbamazepine level, CBC
Lamotrigine	Severe cutaneous reactions (risk 3 times greater <16), dizziness, tremor, sedation, asthenia, headache, interactions with oral contraceptives; case reports of leucopenia, agranulocytosis, hepatic failure, multiorgan failure	Baseline: CBC and liver function tests
Oxcarbazepine	Hyponatremia, oral contraceptive failure, cutaneous reactions, cognitive symptoms, sedation, coordination difficulties, nausea, vomiting, asthenia, headache, dizziness[26]	Baseline and periodic: serum sodium
Gabapentin	Mostly benign; most common are sedation, dizziness, tremor, headache, ataxia, fatigue, wt gain	None
Topiramate	Oral contraceptive failure, sedation, fatigue, impaired concentration, psychomotor slowing, word-finding difficulties, nephrolithiasis	Baseline and periodic: serum bicarbonate

BUN, blood urea nitrogen; CBC, complete blood cell (count); EKG, electrocardiogram; TFT, thyroid function test.

insomnia, that is treated with a medication just for that symptom.

- Cross-taper. When a medication is thought to be working poorly or not at all, a decision may be to replace it with another medication. The cleanest way to do so is to taper down the dose of the first medication, wait for a period of time for medication "wash out," and then start the second medication at a low dose with subsequent appropriate increases. This approach may be problematic at times if, in retrospect, the first medication is discovered to have been more effective than previously thought, but regardless, the patient goes longer without an effective medication. The likelihood of a relapse is higher, and depending on the patient's history, relapse may be debilitating or life-threatening or may interfere with a planned transition, such as starting school or leaving the hospital. The way to decrease the likelihood of relapse and treat current symptoms more quickly is to "cross-taper," for example, starting the second medication with the full dose of the first medication, and then, if the second medication is tolerated and appears to be adding incremental benefit, the second medication gradually is increased while the first medication is decreased.
- Treat comorbid disorders. Additional medications may be used to treat symptoms of comorbid disorders, such as inattentiveness with ADHD or worrying with an anxiety disorder.

PRESCRIBING GUIDELINES

The process of medicating is stepwise, with few patients having a full, lasting response to all symptoms with the first dose of the first medication. Each step is the opportunity for the physician to make a change (add or stop a medication or change a dose) or continue the current regimen as is (eg, the patient is stable or improving or needs a longer amount of time for a medication to work or for an adverse effect to resolve). Each patient becomes an individual study, with the result sometimes being good efficacy with odd-appearing or counterintuitive medication combinations. A number of issues may guide the decision at each step:

- **One Change at a Time.** With multiple medications, knowing which medication is causing positive effects or adverse effects may be difficult. Making 1 change at a time and then observing the effect can help deal with this problem, although this guideline may be discontinued at times for the sake of urgency or when there is little expected overlap in effects and

TABLE 13 Adverse Effects and Possible Monitoring of Atypical Antipsychotics

Adverse effect	Time course	Suggested monitoring	Medications most likely to cause
Anticholinergic	Early		Clozapine, olanzapine
Acute parkinsonism	Early	During titration, at 3 mo and annually	Paliperidone, risperidone
Akathisia	Early/intermediate	During titration, at 3 mo and annually	Aripiprazole
Cardiovascular events	Not known	EKG at baseline if taking ziprasidone or clozapine and during titration if taking ziprasidone	
Diabetes	Late	Fasting blood glucose at 3 mo and then every 6 mo	Clozapine, olanzapine (but problem for all)
Increased lipids	Early?	Lipids at 3 mo and then every 6 mo	Clozapine, olanzapine (but problem for all)
Neutropenia	Most likely within first 6 mo	Clozapine registry recommended CBC monitoring	Clozapine
Orthostasis	Early	Orthostatic blood pressure and pulse if symptomatic; blood pressure and pulse at 3 mo and annually	Clozapine, olanzapine, quetiapine
Increased prolactin and sexual dysfunction	Early	Sexual history during titration and then every 3 mo; prolactin level only if symptomatic	Paliperidone, risperidone, olanzapine
Decreased prolactin	Early	Prolactin level only if symptomatic	Aripiprazole
Increased QTc interval	Not known	EKG at baseline if taking ziprasidone or clozapine and during titration if taking ziprasidone	Ziprasidone
Sedation	Early	Each visit	Clozapine, olanzapine, quetiapine (but problem for all)
Seizures	During titration		Clozapine
Tardive dyskinesia	Late	At 3 mo and annually (abnormal involuntary movement scale)	Lower risk compared with first generation antipsychotics
Withdrawal dyskinesia	Early during fast switch	During titration	Aripiprazole, paliperidone
Wt gain	First 3–6 mo	Height, wt, BMI percentile, BMI *z* score each visit	All, but clozapine and olanzapine highest and aripiprazole and ziprasidone least
Other laboratories		Electrolytes, CBC, renal function test annually, and liver function tests at 3 mo and annually	

TABLE 14 Medications That May Increase Mood Cycling in Children and Adolescents

Antidepressants
Tricyclic antidepressants
Selective serotonin reuptake inhibitors
Serotonin-norepinephrine reuptake inhibitors
Aminophylline
Oral or intravenous corticosteroids
Sympathomimetic amines (eg, pseudoephedrine)
Antibiotics (eg, clarithromycin, erythromycin, and amoxicillin)

adverse effects of medications in a particular combination.

- **Important Cluster of Symptoms.** When a group of symptoms is causing severe impairment and distress, such as full-fledged mania or acute psychosis, it must be addressed first.
- **Treat the Most Troublesome Symptoms First.** A more common situation is that there is no group of symptoms that is overwhelming. In that case, first treat the group of symptoms that is causing the most distress or impairment. For example, moderate depression is treated before mild to moderate inattentiveness.
- **Opportunity to Reduce the Number of Medications That Eventually Will Be Needed.** A medication may be used that may not be the best for any particular group of symptoms but has the potential to treat ≥2 groups of symptoms.
- **Manage an Adverse Effect.** Depending on the urgency of the need for clinical effect and the troublesomeness of the adverse effect, an adverse effect may temporarily halt the search for an effective regimen until it can be resolved or reduced to an acceptable level.
- **Treat a "Lynchpin" Symptom.** At times, a symptom seems to be the basis for other symptoms, for example, an anxious and inattentive adolescent who goes into a rage

attempting to complete homework. As an alternative to using a medication that works to reduce rage, using a medication to reduce anxiety or to increase attentiveness may be at least as effective (of course, the prescriber may choose to do both to potentially increase the effect).

- **Preference for a Medication That Works Quickly.** At times, a medication is chosen over another one for a particular effect because it works quickly. The thinking is that if it then does not work, less time is lost in pursuing the other medication, thus increasing the chance of finding an effective medication in a given period of time.

An example that illustrates the use of several of these guidelines is a patient with insomnia in the context of depression. Choices for the first medication(s) include (1) a mood agent to treat the depression (the more impairing symptom) while waiting for the insomnia to resolve as the depression improves, (2) a hypnotic to treat the insomnia because the response is likely to be quick and the patient's mood may improve once he or she no longer is sleep deprived, (3) combination of a hypnotic with an optimal mood agent for this patient, or (4) a sedating mood agent that may treat both the depression and the insomnia. For a particular patient, these may all be reasonable options, or there may be other factors, such as treatment history, that favor one option over others.

CONCURRENT MEDICAL CONDITIONS

Scheffer and Linden[37] divided medical conditions concurrent with pediatric bipolar disorder into 4 types: (1) conditions related to bipolar disorder or its treatment, (2) conditions that mimic mania, (3) conditions that occur more commonly in patients with bipolar disorder that appear unrelated to its treatment, and (4) conditions related to risk behaviors associated with bipolar disorder. The authors noted that little has been published specifically with regard to pediatric bipolar disorder and concurrent medical conditions, but a number of reports that focused on adults included pediatric subjects.

Tables 12 and 13 summarize medical adverse effects from medications commonly used to treat bipolar disorder. Pediatricians should familiarize themselves with these and monitor for them. Lithium treatment can result in hypothyroidism and, regardless of the cause, hypothyroidism can make bipolar disorder more difficult to treat.[37] Elevated prolactin levels, typically from certain atypical antipsychotics, are associated with low bone mass for chronologic age, sexual dysfunction, menstrual irregularities, gynecomastia, galactorrhea, and retrograde ejaculation. Cardiovascular disease[38] and type 2 diabetes mellitus[39] may be associated with the illness itself. Conditions that may mimic mania are listed in Table 15.[5,37] Unrelated conditions more common in patients with bipolar disorder[37] include migraine headaches, epilepsy, and at least in 1 large family, autosomal dominant medullary cystic kidney disease. Conditions associated with bipolar risk behaviors[37] include complications of substance use and abuse, sexually transmitted diseases, and traumatic brain injury.

CASE VIGNETTES

The following fictitious cases are conglomerates based on the authors' clinical experience and are designed to illustrate common diagnostic and treatment issues.

Case 1

Mary is a 16-year-old girl who presents for admission to psychiatry inpatient after sudden onset 1 week previously of euphoric and giddy mood, talking rapidly and jumping from topic to topic, and little sleep with almost none over the past 3 days. She has spent most of her time since then at her health club trying to "pick up" male patrons, a behavior very out of character for her. Before age 14, she was high achieving and well adjusted, earning mostly A's in school, socially active, and described by her parents as a "model daughter." At age 14, she broke up with a boyfriend and became severely depressed, responding after 2 months to a combination of sertraline and psychotherapy. She discontinued both treatments 4 months later because she had been doing well. She continued to do well until 1 year ago, when she developed an episode similar to the current one, but her behavior was controlled, and she was managed outside the hospital, responding after 2 weeks to a combination of lithium and psychotherapy. She had difficulty with moodiness and functioning in school for the next 6 months and again stopped the treatments. She then continued about the same until this current episode.

Mary is diagnosed with bipolar I disorder, current episode manic, severe, and without psychotic features. She has the narrow phenotype. She is restarted on lithium and also is started on quetiapine for sleeping, calming, and additional mood stabilization. Lithium is chosen because of her past response to this medication. Her psychiatrist decides to combine this with quetiapine immediately, despite treatment algorithms suggesting starting with monotherapy,[5,18] for 2 reasons: (1) previous treatment with lithium yielded a good acute response but only a partial response long-term, even before she stopped the medication and (2)

TABLE 15 Medical Conditions That May Mimic Mania

Hyperthyroidism
Closed or open head injury
Temporal lobe epilepsy
Multiple sclerosis
Systemic lupus erythematosus
Fetal alcohol spectrum disorder/alcohol-related neurodevelopmental disorder
Wilson disease
HIV
Lyme disease
Dementia
Fibromyalgia
Niemann-Pick disease
Familial leukoencephalopathy

lithium can easily take 1 week or more to be effective, and Mary needs something with more immediate effect for calming and sleeping.

Mary is in a relatively consistent (abnormal) mood state. The primary treatment goals are, therefore, to help her out of this state, return her to a euthymic mood, and prevent the next mood episode. If her current mood state were depression instead of mania, mood-stabilizing medication would still be the first choice, but often, antidepressant medication is cautiously added should the depression prove resistant to the mood stabilizing medication alone. The caution is related to the possibility that the antidepressant could make it easier for her to go into a manic episode, even when combined with the mood-stabilizing medication. In addition, during the time she is in a manic state, an antidepressant is generally not recommended.

Case 2

Charles is a 15-year-old boy who presents to the psychiatrist's office for his first mental health visit with the complaint of increasing, severe depression over the past month. He feels that the depression started 3 years ago when his parents divorced and he moved with his mother and siblings to a new city and new school. Additional questions reveal that depression probably existed on and off for quite some time before the divorce. Furthermore, the depression is not continuous. Even over the past week, he reports having 1 or 2 days at a time of feeling great and "energized," spending most of the night playing an online game with little fatigue the next day, talking more, having racing thoughts, and having a more difficult time focusing on school work. He has other times, up to 2 days at a time, of being easily angered, punching a wall at times, ruminating about slights from peers and parents, and generally feeling "edgy."

Charles is diagnosed with bipolar disorder not otherwise specified and the intermediate phenotype. He does not meet duration criteria for mania (7 days) or hypomania (4 days). Key features are the spontaneous and frequent changes of mood symptoms, unrelated or only very loosely related to environmental circumstances, and the lack of distinct, continuous manic or hypomanic states for even 4 days.

Medication management for Charles is similar to that for Mary in case 1; the primary initial objective is mood stabilization with $\geq$1 mood stabilizers and/or atypical antipsychotics. A difference is that Charles's mood symptoms are not stable. He only has to wait a few days or less to switch to a different group of symptoms. Despite depression being the primary concern, antidepressants may make his condition worse by increasing the frequency or intensity of mood changes or undermining the effects of the mood-stabilizing medication. Even for treating the depression symptoms, the preference is typically to find more effective mood stabilizing medication rather than add an antidepressant. Exceptions are common, however, with the treatment of bipolar illness.

Cases 1 and 2 illustrate the findings of a recent study showing that in 90% of cases the first mood episode in pediatric bipolar disorder is depression.[40]

Case 3

Dan is a 17-year-old boy who presents for psychiatric inpatient admission after damaging his father's car with a crow bar and threatening to kill his parents and then himself after parents took away his cell phone. The patient reports having had difficulty with temper outbursts for years. This is the worst such episode, but the patient commonly yells or leaves the house when upset and tends to overreact to his parents' attempts to set limits. Both patient and parents report that he does "fine" most of the time and just overreacts to frustration. He was diagnosed with ADHD in the third grade and has been on and off treatment for that (currently off). He has had mild to moderate depression at times but not recently. On interview, the patient reports that the incident with the car was "not a big deal" and says that he currently feels "fine," although he appears quite edgy and becomes frustrated with the interviewer for "asking too many questions."

The patient is diagnosed with mood disorder not otherwise specified and meets criteria for bipolar spectrum broad phenotype or severe mood dysregulation. He shows no evidence for mood cycling, except for the history of depression, but his mood changes quickly with minor provocation, and he is highly sensitive to frustrating circumstances.

Common practice is to treat the rage symptoms and edginess with mood stabilizers and/or atypical antipsychotics. Treatment of rage and edginess in this population has been poorly studied, but risperidone and aripiprazole are approved by the FDA for the treatment of irritability associated with autism (Table 8). With some patients, these symptoms may respond to $\geq$1

medications for depression, anxiety, or ADHD.

Case 4

Claire is a 13-year-old girl who presents to the psychiatrist's office because of daily episodes of rage, which have been present for years but increasing over the past year. She has the rage only at home and does well academically and socially. She denies any history of significant depression, although she does report a strong tendency to worry and has had this for most of her life. With further questioning, she reports multiple different ritualistic behaviors, such as needing to touch the doorframe in a certain way before going through it and needing to do household tasks in groups of 3. She becomes enraged when parents inadvertently interfere with her ability to complete a behavior.

Claire is diagnosed with OCD as well as generalized anxiety disorder. She does not have a mood disorder despite the rage outbursts. The rage would probably diminish with a mood stabilizer or atypical antipsychotic, but a better treatment is medication and psychotherapy for OCD and anxiety.

Case 5

George is a 14-year-old boy who presents to the pediatrician having recently moved from another state. According to his mother, he has been doing fairly well for the past 6 months and has been diagnosed with bipolar disorder and ADHD. He is currently taking lithium, methylphenidate, quetiapine, aripiprazole, sertraline, and clonazepam. He last saw his previous psychiatrist 2 months ago, and the mother requests a refill for his medications, because he does not have a psychiatrist currently. George's mother said that he has been in general good health but gained 40 pounds over the past year. George's mother attributes this to the medication. In addition to her routine for a new patient visit, the pediatrician does the following:

- Asks more questions to confirm clinical stability, such as potential adverse effects of the medications and clinical course, including depression, suicidality, and behavioral problems.
- Asks about medication dosing adherence.
- Contacts the previous psychiatrist to confirm medications and doses, obtain history, and obtain the psychiatrist's opinion on recent stability.
- Orders laboratory studies, including lithium concentration 12 hours after last dose, electrolytes, thyroid studies, calcium, lipids, and glucose (a fasting glucose may be ordered later if the random one is abnormal).
- Performs physical examination, including vital signs, height, and weight, and calculates BMI percentile.
- Refers George to a local child and adolescent psychiatrist for ongoing mental health care and arranges to partner with the out-of-state psychiatrist for care in the meantime.
- Renews the current medications unless there is a compelling reason otherwise. Given 6 months of stability, a slow medication taper may be safe, but this should be conducted under psychiatric supervision. Not renewing the medications is dangerous, because it may precipitate a major relapse as well as withdrawal symptoms.
- Refers George to a dietitian, recommends an exercise program, and plans to work with the psychiatrist on adjusting medications to reduce weight.

If it were determined that George may not be stable in some respect, resources include phone consultations with the out-of-state psychiatrist (and the out-of-state therapist, if there was one), urgent referral to a local child and adolescent psychiatrist, urgent referral to a local psychologist or other therapist for psychotherapy, and evaluation at a local hospital emergency department.

SUMMARY

Pediatricians have a collaborative role in diagnosis and management of adolescents with bipolar disorder, a common and often debilitating illness. Interviewing for current or past mania or hypomania, the defining feature of bipolar disorder, may be challenging but may be simplified by asking about red flag symptoms that, when present in the history, signal reasonable suspicion of bipolar disorder. In suspected or previously diagnosed cases of bipolar disorder, patients with current or recent symptoms or impairments should be referred for treatment. Pediatricians can actively monitor for and manage medication adverse effects, particularly weight gain, hyperlipidemia, and diabetes mellitus.

ADVICE FOR PEDIATRICIANS

1. Have some familiarity with diagnostic criteria and different types of bipolar disorder.
2. Maintain communication with child and adolescent psychiatrists and other mental health professionals.
3. Maintain familiarity with adverse effects and suggested monitoring protocols for mood-stabilizing and atypical antipsychotic medications.
4. Assist in monitoring for and managing medication adverse effects, particularly weight gain, hyperlipidemia, and diabetes mellitus.
5. Carefully and thoroughly document all recommendations, including referrals, medications prescribed, and instructions for observing and reporting adverse reactions.

Recess is at the heart of a vigorous debate over the role of schools in promoting the optimal development of the whole child. A growing trend toward reallocating time in school to accentuate the more academic subjects has put this important facet of a child's school day at risk. Recess serves as a necessary break from the rigors of concentrated, academic challenges in the classroom. But equally important is the fact that safe and well-supervised recess offers cognitive, social, emotional, and physical benefits that may not be fully appreciated when a decision is made to diminish it. Recess is unique from, and a complement to, physical education—not a substitute for it. The American Academy of Pediatrics believes that recess is a crucial and necessary component of a child's development and, as such, it should not be withheld for punitive or academic reasons. *Pediatrics* 2013;131:183–188

THE BENEFITS OF RECESS FOR THE WHOLE CHILD

The Centers for Disease Control and Prevention defines recess as "regularly scheduled periods within the elementary school day for unstructured physical activity and play."[1] The literature examining the global benefits of recess for a child's cognitive, emotional, physical, and social well-being has recently been reviewed.[2] Yet, recent surveys and studies have indicated a trend toward reducing recess to accommodate additional time for academic subjects in addition to its withdrawal for punitive or behavioral reasons.[3–6] Furthermore, the period allotted to recess decreases as the child ages and is less abundant among children of lower socioeconomic status and in the urban setting.[4,7]

Just as physical education and physical fitness have well-recognized benefits for personal and academic performance, recess offers its own, unique benefits. Recess represents an essential, planned respite from rigorous cognitive tasks. It affords a time to rest, play, imagine, think, move, and socialize.[8–11] After recess, for children or after a corresponding break time for adolescents, students are more attentive and better able to perform cognitively.[12–16] In addition, recess helps young children to develop social skills that are otherwise not acquired in the more structured classroom environment.[8,11,17]

COGNITIVE/ACADEMIC BENEFITS

Children develop intellectual constructs and cognitive understanding through interactive, manipulative experiences. This type of exploratory

experience is a feature of play in an unstructured social environment.[8,18] Optimal cognitive processing in a child necessitates a period of interruption after a period of concentrated instruction.[19,20] The benefits of these interruptions are best served by unstructured breaks rather than by merely shifting from 1 cognitive task to another to diminish stresses and distractions that interfere with cognitive processing.[9,11,15,20] Several studies demonstrated that recess, whether performed indoors or outdoors, made children more attentive and more productive in the classroom.[11–13,16,19,21] This finding was true even though, in many cases, the students spent much of their recess time socializing. In fact, a student's ability to refocus cognitively was shown to be stimulated more by the break from the classroom than by the mode of activity that occurred during that break; any type of activity at recess benefited cognitive performance afterward.[14] Although specified time afforded for recess diminishes with age, the benefits of periodic breaks in the academic day to optimize cognitive processing applies equally to adolescents and to younger children.

SOCIAL AND EMOTIONAL BENEFITS

Recess promotes social and emotional learning and development for children by offering them a time to engage in peer interactions in which they practice and role play essential social skills.[8,17,18,22,23] This type of activity, under adult supervision, extends teaching in the classroom to augment the school's social climate. Through play at recess, children learn valuable communication skills, including negotiation, cooperation, sharing, and problem solving as well as coping skills, such as perseverance and self-control.[8–11,15,17,22] These skills become fundamental, lifelong personal tools. Recess offers a child a necessary, socially structured means for managing stress. By adapting and adjusting to the complex school environment, children augment and extend their cognitive development in the classroom.[15,17]

PHYSICAL BENEFITS

There is a wealth of literature published on the need for and benefit of physical activity and fitness, not only for a child's physical well-being but also for academic and social maturation.[5,12,22–33] Although not all children play vigorously at recess, it does provide the opportunity for children to be active in the mode of their choosing and to practice movement and motor skills. Importantly, recess affords young children free activity for the sheer joy of it.[34] Even minor movement during recess counterbalances sedentary time at school and at home and helps the child achieve the recommended 60 minutes of moderate to vigorous activity per day, a standard strongly supported by the American Academy of Pediatrics (AAP) policy, which can help lower risk of obesity.[5,12,30–35]

SAFETY AND SUPERVISION

A child's safety during recess is a concern for many parents, teachers, and administrators. Some schools even have chosen to ban games or activities deemed unsafe and, in some cases, to discontinue recess altogether in light of the many issues connected with child safety.[10,36] Although schools should ban games and activities that are unsafe, they should not discontinue recess altogether just because of concerns connected with child safety. There are measures schools can take to address these concerns and protect children while still preserving play during recess.[5,11,24,28,34,37,38] Compliance with the Consumer Product Safety Commission's Playground Safety Handbook (http://www.cpsc.gov/CPSCPUB/PUBS/325.pdf) will help to ensure proper maintenance of playground equipment that meets all of the following applicable federal guidelines:

1. Provision of adequate safe spaces and facilities.
2. Maintenance of developmentally appropriate equipment with regular inspections.
3. Establishment and enforcement of safety rules.
4. Implementation of recess curriculum in physical education classes to teach games, rules, and conflict resolution.
5. Establishment of a school-wide, clear policy to prevent bullying or aggressive behavior.
6. Provision of adequate supervision by qualified adults who can intervene in the event a child's physical or emotional safety is in jeopardy.

Some playgrounds in areas with a high risk of violence may require additional protective measures to ensure the safety of children.

THE EMERGING ISSUE OF STRUCTURED RECESS

Structured recess is a recess based on structured play, during which games and physical activities are taught and led by a trained adult (teachers, school staff, or volunteers). Proponents for structured recess note that children often need help in developing games and require suggestions and encouragement to participate in physical activities. Recently, policy makers and funding organizations have called for more opportunities for daily activity as a means to address childhood obesity. These statements have strengthened the argument to maintain or reinstate recess as an integral component of the school day.[12,25,30,34] Although this new dimension to the recess debate has

increased attention on its role, it also has created tension. Some have promoted recess time as a solution for increasing children's physical activity and combating obesity. If recess assumes such a role, then, like physical education, it will need to be planned and directed to ensure that all children are participating in moderately vigorous physical activity.[4,7,12,31,33,38] Pediatric health care providers, parents, and school officials should be cognizant, however, that in designing a structured recess, they will sacrifice the notion of recess as an unstructured but supervised break that belongs to the child; that is, a time for the child to make a personal choice between sedentary, physical, creative, or social options.[2,8–10,18,22–24,30,34,37,39] However, there are many cited benefits of structured recess to consider, including[12]:

- Older elementary children may benefit from game instruction and encouragement for total class inclusion.
- Children can be coached to develop interpersonal skills for appropriate conflict resolution.
- More children can actively participate in regular activity, irrespective of skill level.
- Anecdotally, teachers have reported improved behavior and attention in the classroom after vigorous structured recess.

To be effective, structured recess requires that school personnel (or volunteers) receive adequate training so that they are able to address and encourage the diverse needs of all students.[12,38] One aspect of supervision should be to facilitate social relationships among children by encouraging inclusiveness in games. A problem arises when the structured activities of recess are promoted as a replacement for the child's physical education requirement. The replacement of physical education by recess threatens students' instruction in and acquisition of new motor skills, exploration of sports and rules, and a concept of lifelong physical fitness.[24,30,34]

There are ways to encourage a physically active recess without necessarily adding structured, planned, adult-led games, such as offering attractive, safe playground equipment to stimulate free play; establishing games/boundaries painted on the playground; or instructing children in games, such as four square or hopscotch.[37,38,40] These types of activities can range from fully structured (with the adult directing and requiring participation) to partly unstructured (with adults providing supervision and initial instruction) to fully unstructured (supervision and social guidance). In structured, partly structured, or unstructured environments, activity levels vary widely on the basis of school policy, equipment provided, encouragement, age group, gender, and race.[4,7,30,38,40] Consequently, the potential benefits of mandatory participation of all children in a purely structured recess must be weighed against the potential social and emotional trade-off of limiting acquisition of important developmental skills. Whichever style is chosen, recess should be viewed as a supplement to motor skill acquisition in physical education class.[5,23,24,33,34]

DURATION AND TIMING OF RECESS

In the United States, the duration and timing of recess periods vary by age, grade, school district, and sometimes by building.[4,7] The majority of elementary schools that offer lunch-time recess do so after the students eat lunch.[4,37,41–44] Many school wellness councils have adopted the "Recess Before Lunch" concept which stems from studies that examined food waste by students in relation to the timing of their recess.[42–44] When students have recess before lunch, more time is taken for lunch and less food is wasted. In addition, teachers and researchers noted an improvement in the student behavior at meal time, which carried into the classroom in the afternoon. The Centers for Disease Control and Prevention and the US Department of Agriculture support the concept of scheduling recess before lunch as part of a school's wellness policy.[2,45]

Peer-reviewed research has examined the timing and type of activity during recess and chronicled the many benefits of recess for children, without establishing an optimal required duration.[2,8,12,13,18,19,21] There is consensus about the need for regularly scheduled recess based on national guidelines, even though the length of the recess period has not been firmly established. In schools, the length specified for recess ranges widely, from 20 to 60 minutes per day.[24,30] In other countries, such as Japan, primary school-aged children have a 10- to 15-minute break every hour, and this is thought to reflect the fact that attention spans begin to wane after 40 to 50 minutes of intense instruction.[46] On the basis of this premise, to maximize cognitive benefits, recess should be scheduled at regular intervals, providing children sufficient time to regain their focus before instruction continues.

CONCLUSIONS

School attendance represents a unique opportunity to address nutrition and physical fitness. Each day, 55 million US students attend school, which constitutes nearly one-half of their waking hours.[47] In light of rising rates of overweight and obesity, schools have come under increased scrutiny. Within the school environment, there are competing calls for stricter standards and greater academic achievement as

well as calls for schools to provide greater opportunities for nonsedentary daily activity. Even with ample evidence of a whole-child benefit from recess, significant external pressures, such as standardized cognitive testing mandated by educational reforms, have led some to view recess as time that would be better spent on academics.[4] Time previously dedicated to daily activity in school, such as physical education and recess, is being reallocated to make way for additional academic instruction.

Ironically, minimizing or eliminating recess may be counterproductive to academic achievement, as a growing body of evidence suggests that recess promotes not only physical health and social development but also cognitive performance.[10,37] Although recess and physical education both promote activity and a healthy lifestyle, it is only supervised but unstructured recess that offers children the opportunity to actually play creatively. In this sense, then, pediatricians' support of recess is an extension of the AAP's policy statement supporting free play as a fundamental component of a child's normal growth and development.[16] On the basis of an abundance of scientific studies, withholding recess for punitive or academic reasons would seem to be counterproductive to the intended outcomes and may have unintended consequences in relation to a child's acquisition of important life skills.

RECOMMENDATIONS

In their role as child health experts, the pediatricians of the AAP stress the following perspective to parents, teachers, school administrators, and policy makers:

1. Recess is a necessary break in the day for optimizing a child's social, emotional, physical, and cognitive development. In essence, recess should be considered a child's personal time, and it should not be withheld for academic or punitive reasons.
2. Cognitive processing and academic performance depend on regular breaks from concentrated classroom work. This applies equally to adolescents and to younger children. To be effective, the frequency and duration of breaks should be sufficient to allow the student to mentally decompress.
3. Recess is a complement to, but not a replacement for, physical education. Physical education is an academic discipline. Whereas both have the potential to promote activity and a healthy lifestyle, only recess (particularly unstructured recess) provides the creative, social, and emotional benefits of play.
4. Recess can serve as a counterbalance to sedentary time and contribute to the recommended 60 minutes of moderate to vigorous activity per day, a standard strongly supported by AAP policy as a means to lessen risk of overweight.
5. Whether structured or unstructured, recess should be safe and well supervised. Although schools should ban games and activities that are unsafe, they should not discontinue recess altogether just because of concerns connected with child safety. Environmental conditions, well-maintained playground equipment, and well-trained supervisors are the critical components of safe recess.
6. Peer interactions during recess are a unique complement to the classroom. The lifelong skills acquired for communication, negotiation, cooperation, sharing, problem solving, and coping are not only foundations for healthy development but also fundamental measures of the school experience.

TECHNICAL REPORT

Dispensing Medications at the Hospital Upon Discharge From an Emergency Department

abstract

FREE

Although most health care services can and should be provided by their medical home, children will be referred or require visits to the emergency department (ED) for emergent clinical conditions or injuries. Continuation of medical care after discharge from an ED is dependent on parents or caregivers' understanding of and compliance with follow-up instructions and on adherence to medication recommendations. ED visits often occur at times when the majority of pharmacies are not open and caregivers are concerned with getting their ill or injured child directly home. Approximately one-third of patients fail to obtain priority medications from a pharmacy after discharge from an ED. The option of judiciously dispensing ED discharge medications from the ED's outpatient pharmacy within the facility is a major convenience that overcomes this obstacle, improving the likelihood of medication adherence. Emergency care encounters should be routinely followed up with primary care provider medical homes to ensure complete and comprehensive care. *Pediatrics* 2012;129:e562–e566

INTRODUCTION

The purpose of this report is provide information to support judicious dispensing of medications to improve compliance with discharge instructions and adherence to medication recommendations after a visit to the emergency department (ED). Unlike scheduled or sick visits to the medical home, most ED visits are unplanned and occur during "off hours." Families may be limited in their ability to get prescriptions filled immediately for treatment of these acute conditions. Although the primary site of health care should be in the medical home, the ED plays an important role as a safety net for children requiring emergent medical care.[1–4] Medical care provided in EDs often requires the treatment of acute clinical conditions, with a high priority placed on the timely administration of medications such as analgesics, antibiotics, bronchodilators, and corticosteroids. Prompt initiation and maintenance of therapy are important factors in achieving an optimal therapeutic effect. Relapses or exacerbations of chronic conditions (eg, epilepsy, diabetes) are often attributable to medication nonavailability or nonadherence. Because emergency care is provided around the clock, the lack of available pharmacy services to dispense outpatient medications can be a significant therapeutic barrier. Community-based pharmacies that are open 24 hours a day are valuable community resources in providing these medications at all hours. However, the nearest 24-hour pharmacy may be quite far

from the ED, and then the patient or parent must wait for the medication to be dispensed. Most patients and families have already spent a considerable amount of time in the ED receiving diagnostic tests and treatment, and some families do not have the resources to easily travel to an offsite pharmacy. These factors may impede adherence to essential discharge medications and instructions.

Several studies have demonstrated low medication adherence rates after ED visits.[5–14] In one of the more recent studies, one-third of insured pediatric patients who were prescribed "priority medications" (defined as new medications for an acute condition that excluded over-the-counter medications, refills, and continuation of therapy that was previously initiated) did not pick them up.[5] In examining the Medicaid subgroup separately, half did not pick up their "priority medications,"[5] despite the absence of financial barriers. The resources spent on emergency care will not result in optimal outcomes unless prompt medication adherence is achieved. Knowing that medication adherence rates are likely to be low, many emergency physicians choose to err on the side of caution and administer more medications (eg, corticosteroids, long-acting intramuscular antibiotics) before discharging patients from the ED, further increasing cost and lengthening ED stays, or they may choose to hospitalize the patient to avoid the risks associated with nonadherence, adding additional cost.

Although pharmacy access is not the only factor determining medication adherence, it has been demonstrated to be a significant one.[9] Most studies of medication adherence have been conducted in adult populations, but pediatric studies have demonstrated similar nonadherence rates.[5,11,12]

The short duration of action of some medications (eg, albuterol) makes it potentially risky not to provide additional doses on discharge from the ED for home use. Even families who adhere to medication regimens might have difficulty getting such prescriptions filled in time for the patient's next dose. During epidemics when there may be medication shortages, EDs can be prepared to dispense medication to those most a risk. Parents frequently request that medications be dispensed from the ED, because it is perceived to be faster, more convenient, and a logical patient expectation. Many families may be unfamiliar with the location of local pharmacies, especially a particular pharmacy providing late night service. Dispensing medications for the acute illness or injury from the ED is a means to both improve service to the patient and provide better care. The medical home should be notified of the ED visit and medications prescribed. Renewal of medications or refills of these medications after the acute illness or injury should be done by the primary physician in the medical home.

PRACTICES THAT HAVE BEEN PROPOSED AS POTENTIAL SOLUTIONS

Prescriptions May Be Called In, Faxed, or Submitted Electronically to the Community Pharmacy

Although this has the potential to save time, pharmacists will typically give priority to patients who are physically present and waiting over a patient who may or may not show up. Some antibiotic suspensions are expensive, and if the patient does not pick it up, the pharmacy might have to discard the medication. Thus, suspensions are frequently not reconstituted until the patient is physically present.

The First Antibiotic Dose Can Be Administered in the ED

This works well for patients who are able to take pills. For children, first-dose administration of antibiotic suspensions requires that unit doses be created. Pharmacies at larger hospitals can efficiently dispense multiple unit doses, but smaller hospitals are more likely to use fewer doses, resulting in more wastage of the remaining reconstituted antibiotic suspension. First-dose administration practice can at least guarantee that the first dose is given, and if the patient is observed briefly, it improves the likelihood that an immediate adverse reaction can be recognized and addressed. This practice can also reduce the need for initial parenteral antibiotic dosing, although long-duration parenteral antibiotics have some advantages over oral antibiotics. Administering a single oral dose in the ED does not necessarily ensure adherence, because the remainder of the medication course must be obtained from an outpatient pharmacy, but it does permit the patient's family to return home to get some rest so that they can obtain the remainder of the medication course at a more convenient time. Although administering the first antibiotic dose in the ED has significant advantages, dispensing the entire course from the ED is more convenient and is more in line with patient expectations. Factors that improve full adherence are less likely to result in complications from treatment failure and induction of antibiotic resistance.

A Few Days' Supply of Medication Can Be Dispensed to Allow the Patient Enough Time to Get to a Neighborhood Pharmacy

This solution also works better for medications in pill or capsule formulations but not as well for suspensions. A potential pitfall of this method is the failure of the caregiver to fill the remainder of the prescription because the child appears to be feeling better. This would also require a second prescription to be written for the

outpatient pharmacy and a second pharmacist to be involved in dispensing a single course of therapy. Both are potential sources of error. Electronic health record and order entry systems would need to generate 2 "prescriptions" with coordinated start and stop dates, making the process of ordering a single course of therapy twice as complicated and time-consuming.

Drug Company Samples Can Be Used

Samples dispensed in a private office setting are severely restricted in hospital-based EDs, essentially making them infeasible. All medications dispensed within a hospital (including samples) must be managed and regulated by the pharmacy. Additionally, samples are only available for a small proportion of medications used in children, and the appropriate formulation is often not available, making this option difficult to manage and unreliable. Electronic health records that maintain a patient's medication record would have difficulty keeping track of medication samples, because it is possible that no prescription would be generated, resulting in a lack of records in the patient's prescription history.

BARRIERS TO DISPENSING HOME MEDICATIONS FROM THE ED

Staffing of a 24-Hour Outpatient Pharmacy Is Not Likely to Be Cost-Effective

Transferring all the home prescriptions from the ED to the pharmacist(s) increases their workload substantially, such that it might compromise the other duties of the pharmacist(s) and create the potential for medication errors. Staffing of additional pharmacists may be difficult to achieve, because they are in short supply in many areas or the expense may not be supported by the revenue gained from filling home medication prescriptions. Many patient care improvements are not cost-neutral, but the overall systematic improvement in patient care may justify these expenses. Competing demands for pharmacist resources would need to be addressed in most health systems. Expecting that patient satisfaction improvements will be without cost is unreasonable. In this case, patient satisfaction and medication adherence can both potentially improve.

There Is Concern That This Prescribing Practice Might Be Illegal

Some states have regulations limiting outpatient dispensing by an inpatient facility. For example, the state of Massachusetts allows hospital inpatient pharmacies to dispense up to 14 days of medication, whereas the state of Washington only allows hospital inpatient pharmacies to dispense a 24-hour supply, except in extraordinary circumstances. Many hospital pharmacies have created programs to dispense to outpatients when confronted with extraordinary circumstances, such as free-care patients or medications that cannot be obtained in the community. Regulations cited typically apply to medications dispensed by the ED (not a pharmacy), medications dispensed by the hospital inpatient pharmacy, medications dispensed by the hospital, or a limited subset of medications (eg, controlled substances or "dangerous" medications). Note that these special regulations apply to hospital units or inpatient pharmacies but not to outpatient pharmacies, therefore the most efficient solution with the fewest regulatory obstacles is to have a 24-hour outpatient pharmacy available to service the needs of the ED.

Insurance Companies Might Choose to Deny Payment for Outpatient Medications Dispensed by an Inpatient Pharmacy

This is difficult to confirm or refute, because insurance company reimbursement practices may vary within a given state or region or health plan. In theory, there should be no reason why an insurance company would reimburse a community outpatient pharmacy but not a hospital pharmacy, as long as the costs and the regulatory requirements are the same. If this practice becomes more common, then insurance company reimbursement practices for this are likely to become more consistent. Having a 24-hour outpatient pharmacy available to service the needs of the ED would address this concern as well.

Hospitals Might Have an Economic Advantage (Because of Size and/or Nonprofit Status) Over Small Community Pharmacies, Because Hospitals Purchase Medications in Larger Bulk and Under Different Contract Agreements

This may be true relative to smaller community pharmacies; however, it is less common that a 24-hour pharmacy is a small community pharmacy. The current 24-hour pharmacies are generally part of larger pharmacy chains that have similar purchasing strength. Federal case law has been established in this issue, and the only restriction is that hospital-based pharmacies are limited in the total day supply that can be dispensed.[14]

POTENTIAL ADVERSE EFFECTS OF DISPENSING MEDICATIONS FROM THE ED OR HOSPITAL PHARMACY

Dispensing Home Medications From the ED or Hospital Pharmacy Simplifies and Increases the Convenience of Obtaining Medications, Which Might Further

Encourage the Inappropriate Use of the ED (Versus the Medical Home) for Minor Acute Care

The medical home is the preferred site of care for most common illnesses and minor injuries. Most EDs will triage patients with minor acute conditions to lower-priority categories, resulting in longer waiting times in most cases. It is a rare family that would wait hours in an ED just for the convenience of also getting their discharge medications. Perceived abuse of the emergency care system is more likely to be a symptom of community primary care availability rather than the desire to get a convenient medication. Not dispensing medications from the ED does not fix this problem. On the contrary, providing medications from the ED under these circumstances helps patients receive necessary treatment, providing the beneficial safety net of emergency care.

Obligating Hospital Pharmacies to Dispense Medications to Uninsured Patients Increases Financial Expenses

Community pharmacies are unlikely to dispense medications at no charge if the patient lacks financial resources to cover the expense of the medications. Dispensing the medications at no charge from a hospital pharmacy represents an expense, but this expense is often less than the overall health care costs of not treating the condition. Small rural hospital EDs should not be expected to have the same resources as larger hospitals; however, there should be an available option for patients to obtain their medications.

Both of These Potential Adverse Effects of Dispensing Medications on Discharge From the ED Can Be Reduced by Requiring the Physician to Confirm That the Need for the Medication Is a High Priority

For example, refilling a prescription that will run out in 1 week is not the role of an ED pharmacy. A standardized set of indications for dispensing discharge medications from the ED outpatient pharmacy (including a no-charge compassionate care provision) can be agreed on in advance to facilitate this process. Creation of such a system also permits physicians to appreciate cost and efficacy factors that are assessed to a lesser degree during conventional medication prescribing decisions. Special circumstances that cannot be anticipated in advance can be considered on a case-by-case basis with the ED physician and the pharmacist on duty.

Dispensing Medications May Further Slow ED Throughput

Turnaround time, or "throughput," is a critical focus in most EDs. By providing medications for discharge, a system must be set up so that dispensing of these medications does not impede patient flow. Such systems can be accomplished through a predetermined list of high-use medications that can be dispensed, which would facilitate the availability of templated paper orders or computerized order sets, preprinted labels, and appropriate stock and supplies. These preparations can significantly improve turnaround time for prescription dispensing in the ED environment.

SUMMARY

Clinical outcomes for many acute conditions are highly dependent on timely access to medications. Optimal care is compromised if it is accompanied by lack of ready access to such medications. Although most health care should be sought from the medical home, unanticipated and off-hour visits to an ED for an acute illness or injury occur. Access to quality emergency care should be available to all, including access to the essential components of "after care" following an ED visit.

Failing to provide access to appropriate medications to treat conditions identified by emergency care encounters compromises the emergency care safety net. Children and families with no insurance and no ability to pay for medications at a retail pharmacy are not likely to be given medications at no charge. Some parents will not disclose inability to pay at the time of the ED encounter. By dispensing medications at the site of service, inability to pay can be identified promptly so that less costly therapeutic options can be offered or a no-charge compassionate care provision can be used to dispense the medications under a predetermined protocol. Federal regulations require that that emergency care be provided regardless of ability to pay. The benefit of this first step is not fully realized until treatment is initiated and completed.

Providing important and necessary medications from the ED outpatient pharmacy in selected instances reduces the risk of nonadherence by providing the medications more conveniently, reliably, and in a manner more proximate to the encounter, giving providers additional opportunities to reinforce medication instructions and their importance. This results in a more optimal therapeutic approach in conjunction with primary care follow-up and communication to maximize the likelihood of a good outcome.

POLICY STATEMENT

Emergency Contraception

abstract

FREE

Despite significant declines over the past 2 decades, the United States continues to have teen birth rates that are significantly higher than other industrialized nations. Use of emergency contraception can reduce the risk of pregnancy if used up to 120 hours after unprotected intercourse or contraceptive failure and is most effective if used in the first 24 hours. Indications for the use of emergency contraception include sexual assault, unprotected intercourse, condom breakage or slippage, and missed or late doses of hormonal contraceptives, including the oral contraceptive pill, contraceptive patch, contraceptive ring (ie, improper placement or loss/expulsion), and injectable contraception. Adolescents younger than 17 years must obtain a prescription from a physician to access emergency contraception in most states. In all states, both males and females 17 years or older can obtain emergency contraception without a prescription. Adolescents are more likely to use emergency contraception if it has been prescribed in advance of need. The aim of this updated policy statement is to (1) educate pediatricians and other physicians on available emergency contraceptive methods; (2) provide current data on safety, efficacy, and use of emergency contraception in teenagers; and (3) encourage routine counseling and advance emergency-contraception prescription as 1 part of a public health strategy to reduce teen pregnancy. This policy focuses on pharmacologic methods of emergency contraception used within 120 hours of unprotected or underprotected coitus for the prevention of unintended pregnancy. Emergency contraceptive medications include products labeled and dedicated for use as emergency contraception by the US Food and Drug Administration (levonorgestrel and ulipristal) and the "off-label" use of combination oral contraceptives. *Pediatrics* 2012;130:1174–1182

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

BACKGROUND

Despite significant declines over the past 2 decades, the United States continues to have teen birth rates that are significantly higher than other industrialized nations.[1,2] The most recent birth data available indicate a birth rate of 34.3 per 1000 among 15- to 19-year-olds.[3] The most current pregnancy outcomes data indicate that 57% of teen pregnancies ended in live births, 27% ended in induced abortion, and 16% ended in miscarriage or stillbirth.[4,5] Pediatricians have an important role, through their interactions with adolescents, to address the major public health objective of continuing to reduce adolescent pregnancy in the United States.[6]

The current decrease in teen pregnancies since the 1990s has resulted from both increased abstinence and increased use of contraception,[7,8] but large numbers of teenagers continue to engage in unprotected sexual activity. The rate of "ever having intercourse" among 15- to 19-year-old females is 43%, and, among males of the same age range, this rate is 42%.[9] The rate increases between early and late adolescence, from 13% of 15-year-olds to 70% of 19-year-olds. Although most teenagers report first intercourse with a steady partner and consensual sex, approximately 10% report being forced to have sex. Rates of sexual assault among teenagers and young adults are higher than in any other group,[10] another factor increasing the risk of unintended pregnancy.[11]

Nearly 80% of pregnancies in adolescents are unintended[12] and result from contraceptive failure or nonuse. The most commonly used method of contraception reported by teenagers who have had intercourse is the condom, followed by withdrawal and the oral contraceptive pill.[9] Research has shown, however, that many teenagers use contraceptive methods inconsistently.[13] In addition to the risk of sexually transmitted infections (STIs), the pregnancy rate for withdrawal is particularly high (27% of women who use the withdrawal method will have an unintended pregnancy in the first year of using this method).[14] Although condoms are important for protection against STIs as well as pregnancy and the pill can be a very effective method for pregnancy prevention, both methods require strict adherence by the user to be maximally effective.

Emergency contraception can reduce the risk of pregnancy if used up to 120 hours after unprotected intercourse[15,16] or contraceptive failure and is most effective if used in the first 24 hours.[17,18]

In August 2007, the US Food and Drug Administration (FDA) authorized nonprescription access to Plan B (levonorgestrel, manufactured by Teva Women's Health, Woodcliff Lake, NJ) for women 18 years of age and older and then in 2009 changed the age limit to females 17 years of age and older. Prescription for emergency contraception is required for teenagers younger than 17 years in most states.[19] As of the date of publication, males 17 years or older can also access Plan B with or without a prescription.

Studies have shown that adolescents are more likely to use emergency contraception if it has been prescribed in advance of need.[20] However, a majority of practicing pediatricians and pediatric residents do not routinely counsel patients about emergency contraception and have not prescribed it.[21–24] This policy statement will focus on pharmacologic methods of emergency contraception used within 120 hours of unprotected or underprotected coitus for the prevention of unintended pregnancy (Table 1).

DEFINITION OF EMERGENCY CONTRACEPTION

Emergency contraception is the only contraceptive method designed to prevent pregnancy after intercourse. Indications for use of emergency contraception include sexual assault, unprotected vaginal sexual intercourse, and contraceptive failures, such as broken condoms and missed or late doses of other hormonal methods (ie, missing 3 consecutive doses of active birth control pills, patch off for more than 24 hours during 'patch-on' week, or vaginal ring out for more than 3 hours during 'ring-in' week). Emergency contraceptive medications include products labeled and approved for use as emergency contraception by the FDA (levonorgestrel and ulipristal acetate) and the "off-label" use of combination oral contraceptives—the Yuzpe method—described in the literature since 1974.[25] Pediatricians should also be aware that insertion of a copper intrauterine device within 5 days of unprotected intercourse is an additional method of emergency contraception available in the United States. This statement does not cover the intrauterine device method in more detail, because it is not an option available to most pediatricians in their offices.

EMERGENCY-CONTRACEPTION METHODS

Progestin-Only Regimens

Levonorgestrel emergency contraception was approved by the FDA in 1999 under the brand name Plan B and is currently marketed as Plan B, Plan B One Step (Teva Women's Health, Woodcliff Lake, NJ), and Next Choice (Watson Pharma Inc, Corona, CA). Plan B and Next Choice consist of 2 pills containing 0.75 mg of levonorgestrel each. Although prescribing directions indicate that patients should take each of the 2 pills 12 hours apart, recent data suggest that both pills taken together as a single dose (total treatment dose of 1.5 mg levonorgestrel) is equally effective and without increased adverse effect.[15] To this effect, the next generation of emergency contraception, Plan B One Step, is packaged as a single pill with 1.5 mg levonorgestrel to be taken 1 time.[26] Pharmacies may stock both 0.75-mg and 1.5-mg levonorgestrel versions. Package labeling indicates that all 3 brands of levonorgestrel emergency contraception should be taken within 72 hours of unprotected intercourse; however, data support that use up to 120 hours after intercourse may prevent pregnancy.[15,16]

TABLE 1 Selected Regimens for Emergency Contraception Available in the United States[14,72]

Brand	First Dose	Second Dose	Ethinyl Estradiol per Dose, μg	Levonorgestrel per Dose, mg
Progestin-only pills				
Next Choice or Plan B	2 pills	None	0	1.5
Plan B One-Step	1 pill	None	0	1.5
Ovrette	20 pills	20 pill	0	0.75
Other emergency contraception				
ella	30 mg of ulipristal acetate			
Combined estrogen and progestin pills				
Ovral	2 white pills	2 white pills	100	0.5
Levora	4 white pills	4 white pills	120	0.6
Nordette	4 light orange pills	4 light orange pills	120	0.6
Seasonale	4 pink pills	4 pink pills	120	0.6
Triphasil	4 yellow pills	4 yellow pills	120	0.5
Alesse	5 pink pills	5 pink pills	120	0.5

Additional combinations are available at: http://ec.princeton.edu.

The FDA-labeled levonorgestrel methods are currently the preferred emergency contraception for teenagers because of their improved adverse effect profile and increased effectiveness in comparison with combination oral contraceptive methods. Adolescents should be instructed to take 1.5 mg of levonorgestrel as soon as possible and up to 120 hours after unprotected intercourse. No physical examination or pregnancy testing is required before use. Adolescents are advised to have a pregnancy test done if they do not have a normal period within 3 weeks of emergency-contraception use.

Ulipristal Acetate Progesterone Agonist/Antagonist

In August 2010, the FDA approved a progesterone agonist/antagonist ulipristal acetate (ella, Watson Pharma Inc, Corona, CA) for use as an emergency contraceptive.[27] Ulipristal binds to the human progesterone receptor, thereby preventing the binding of progesterone. Ulipristal is a single pill containing 30 mg of ulipristal acetate and is indicated up to 120 hours after unprotected intercourse.[28] Unlike with hormonal emergency contraception, existing pregnancy must be excluded before prescribing ulipristal because of the risk of fetal loss if used in the first trimester of pregnancy.[28] Patients should be counseled that a pregnancy test is indicated if their period is more than 7 days later than expected after taking ulipristal. Patients should also be instructed to return for evaluation of the rare but possible occurrence of ectopic pregnancy if severe abdominal pain occurs 3 to 5 weeks after the dose. Ulipristal is available only by prescription regardless of age.

Combined Hormonal Regimens (Yuzpe Method)

The use of combination oral contraceptives for emergency contraception is commonly referred to as the "Yuzpe method."[25] Commonly used since 1974, its acceptability and efficacy was limited by adverse effects of nausea and vomiting. The Yuzpe method involves taking 2 doses of pills, each containing a minimum of 100 μg of ethinyl estradiol and a minimum of 500 μg of levonorgestrel. Levonorgestrel is the active isomer of norgestrel, so equivalent dosing of any pill containing norgestrel requires doubling the dose of progestin. Other pill formulations used for emergency contraception are included in Table 1. Similar information is available from the Office of Population Research at Princeton University, which maintains a comprehensive source of information on emergency contraception (http://ec.princeton.edu/). The availability of many combination oral contraceptives with norgestrel or levonorgestrel makes this alternative particularly helpful when there is no or limited access to an emergency-contraception product. Although combination oral contraceptives have not been labeled specifically for emergency contraception, the FDA Reproductive Health Advisory Committee and professional organizations such as the American College of Obstetricians and Gynecologists have declared the use of combination oral contraceptives safe and effective for emergency contraception.[29,30]

MECHANISM OF ACTION

Hormonal emergency contraception, including combined and progestin-only methods, inhibits ovulation, disrupts follicular development, and interferes with the maturation of the corpus luteum.[31–37] These are the same mechanisms by which other hormonal methods of contraception prevent pregnancy. Results of studies evaluating the effect of hormonal emergency contraception on the endometrium are conflicting. Some studies suggest that endometrial histologic or biochemical alterations occur after emergency contraception by which endometrial receptivity to the implantation of a fertilized egg is impaired.[31,38,39] Other studies demonstrate little to no effect on the endometrium.[32,33,35,37,40,41] Suggested mechanisms, including alteration of sperm or egg transport, interference with the fertilization process, and/or cervical mucus changes, have not been verified by clinical data.[42,43] Hormonal emergency

contraception does not interrupt established pregnancies and has not been linked to teratogenic effects.[44–47]

Ulipristal acetate inhibits follicular development and rupture, so its primary mechanism of action as an emergency contraceptive is considered to be inhibition or delay of ovulation.[28] It also decreases endometrial thickness and may have a direct effect on implantation. Ulipristal is in pregnancy category X, because data from animal studies suggest that fetal loss is a risk of use during the first trimester. Therefore, pregnancy should be excluded before a dose is given.

EFFICACY

The efficacy of combined hormonal or progestin-only emergency contraception depends on the timing of use within the menstrual cycle.[48,49] A randomized controlled trial has shown that the progestin-only method, Plan B, is more effective at preventing pregnancy than combination hormone methods. When the 2 regimens were started within 72 hours, the overall pregnancy rate was 1.1% in the levonorgestrel-only group in comparison with 3.2% in the combination oral contraceptive (Yuzpe method) group.[17] The proportion of pregnancies prevented in this study was 85% with levonorgestrel and 57% with the combination oral contraceptive (Yuzpe) method in comparison with the expected number when no treatment was given. The effectiveness of emergency contraception might be summarized as follows: if 100 female adolescents have unprotected coitus in the middle of their menstrual cycles, estimates suggest that approximately 8 will become pregnant. Appropriate use of emergency contraception would reduce this number to approximately 2 pregnancies.[14]

Compared with 1.5 mg of levonorgestrel, ulipristal acetate has been shown to be equally efficacious when taken within 72 hours of unprotected intercourse. Glasier and colleagues[50] observed no statistically significant difference in pregnancy rates between women taking 30 mg of ulipristal (1.8%) or 1.5 mg of levonorgestrel (2.6%) within 72 hours of unprotected intercourse (odds ratio, 0.69%; 95% confidence interval, 0.35–1.31). This finding was consistent with a previous study.[51] Between 72 and 120 hours, the Glasier study showed some evidence that ulipristal may be more effective at preventing pregnancy.

ADVERSE EFFECTS AND CONTRAINDICATIONS

Levonorgestrel-Only Methods (Plan B, Plan B One Step, and Next Choice)

The only contraindication to use of levonorgestrel emergency contraception is known pregnancy because of lack of utility, not concern for teratogenicity or fetal loss. Young women with contraindications to estrogen may use levonorgestrel. The rate of nausea and vomiting with levonorgestrel emergency contraception is approximately half that with the combination oral contraceptive (Yuzpe) method, and routine use of antiemetics is not indicated.[17] Package labeling for the newest levonorgestrel emergency-contraception product, Plan B One Step, indicates that the most common adverse effect reported after use was heavier menstrual bleeding.[26]

Repeated use of levonorgestrel emergency contraception is associated with the same adverse effects as 1-time use. A recent Cochrane review of the subject found no serious adverse effects in trials of repeated use.[52]

Ulipristal

The most common adverse effects reported by users of ulipristal include headache (18%), nausea (12%), and abdominal pain (12%).[28] As previously noted, animal studies suggest that fetal loss is a risk of use during the first trimester. No fetal malformations have been reported.[28] It is recommended to redose ulipristal if vomiting occurs within 3 hours of the initial dose.

Yuzpe/Estrogen-Containing Methods

The most common adverse effects that occur during the first 24 to 48 hours of using estrogen-containing emergency-contraception methods are nausea (approximately 50%) and vomiting (approximately 20%), which seem unaffected by food intake.[53–55] Other adverse effects might include fatigue, breast tenderness, headache, abdominal pain, and dizziness.[14] The severity and incidence of nausea and vomiting can be decreased significantly by using an antiemetic 1 hour before an estrogen-containing regimen.[55] Antiemetics are ineffective if taken after nausea is present.[55] Effective oral antiemetics include meclizine, 25 to 50 mg, and metoclopramide, 10 mg by mouth, taken once before combination-hormone methods.[55,56] Patients with contraindications to estrogen use such as history of thromboembolism should not use the combination oral contraceptive (Yuzpe) method.

OTHER CLINICAL CONSIDERATIONS

The discussion of emergency-contraception methods with patients must also include the fact that none of these methods will protect from STIs. Patients should be encouraged to contact their physician after use to schedule follow-up visits for STI testing or treatment, as indicated. In addition, these follow-up visits are an important time to discuss options for ongoing contraception, abstinence, and consensual intercourse. It should be emphasized to patients that emergency contraception is intended for emergency use and that routine use of

emergency contraception to prevent pregnancy is not as effective as the regular use of other forms of contraception. Although emergency contraception is exclusively for use by females, young men should be counseled on this method so that they may also suggest use to their female partners if needed.

ADOLESCENTS AND EMERGENCY CONTRACEPTION: AWARENESS AND ACCESS

The regulatory changes and public discourse surrounding emergency contraception have increased the public's awareness of the methods; however, large numbers of teenagers still do not have much knowledge about correct use. In 2002, Aiken and colleagues[57] reassessed the awareness and knowledge of emergency contraception among 13- to 21-year-old females recruited from the same Pittsburgh clinic and drug treatment center from which they recruited participants for a 1996 study of emergency-contraception knowledge. Their study showed that, in 2002, 73% of teenagers were aware of emergency contraception, an increase from 44% in 1996. Although 95% of teenagers who were aware also knew where to get emergency contraception in 2002, up from 78% in 1996, only 52% were aware of the correct time frame for use (up from only 20% in 1996). Recent studies conducted in New York City and Hawaii found the percentage of teenagers aware of emergency contraception was closer to 50%.[58,59]

Data from the most recent 2006–2008 National Survey of Family Growth indicate that 14% of sexually experienced adolescent girls have ever used emergency contraception,[9] up from 8% in the 2002 survey. Reasons for use of emergency contraception by teenagers were examined by Alford et al[60] in a retrospective cohort study published in 2010. The most common reason for use was condom failure. Importantly, 13% of adolescents' use of emergency contraception during the study period was for nonconsensual penetration. A qualitative study conducted in Philadelphia aimed to explore teenagers' attitudes about the use of emergency contraception in more detail. Themes that emerged as barriers to emergency contraception use among the teenagers included worries about confidentiality, ability to get emergency contraception depending on age, worries about adverse effects, and lack of transportation to obtain the medication.[61] In a recent study of college-aged students, fewer than 16% knew that emergency contraception was available in their college health center.[62]

One important strategy to increase timely access to emergency contraception for adolescent girls is advanced prescribing. Advanced prescription for emergency contraception means providing a teenager with a supply or a prescription for emergency contraception before it is needed. Advanced prescribing facilitates access for teenagers in states that require prescriptions and also reduces the cost of obtaining emergency contraception for adolescents of all ages whose insurance provides coverage for emergency contraception with a prescription. In a 2010 review of 7 randomized trials of emergency contraception that included teenagers, it was shown that advanced prescription increased the use of emergency contraception and decreased time to use.[20] None of the studies showed an increase in sexual activity or decrease in ongoing contraceptive use in adolescents given advanced access to emergency contraception.

Despite evidence that improved access to emergency contraception (through advanced prescribing and allowing nonprescription access) increases the likelihood of use, no studies have demonstrated that improved access to emergency contraception reduces the pregnancy rate in a population.[63,64] There may be statistical reasons for this related to sample size of the studies, but it also may be that pregnancy rates remain unchanged overall because unprotected intercourse remains more frequent than emergency contraceptive use, despite increased access. The lack of demonstrated population level impact does not negate the potential for the method to reduce the risk of unintended pregnancy for an individual woman, however.

ETHICAL DILEMMAS FOR PHYSICIANS AND PHARMACISTS

Despite multiple studies showing no increased risk behavior and evidence that hormonal emergency contraception will not disrupt an established pregnancy, public and medical discourse reflects that personal values of physicians and pharmacists continue to affect emergency-contraception access, particularly for adolescents.[65–70] Some physicians refuse to provide emergency contraception to teenagers, regardless of the circumstance, and others may provide emergency contraception only if nonconsensual penetration has occurred. Both of these choices by physicians have important adverse consequences for adolescents in their ability to access emergency contraception.

A study published in 2009 demonstrated that the decision to provide emergency contraception at a time of need but not in advance of need may be related to the physician's beliefs about whether it is okay for teenagers to have sex.[24] Often, physicians hold conflicting values when approaching reproductive health issues with teenagers. Physicians may object to

unprotected intercourse or intercourse outside of marriage, but they may also feel the need to prevent teen pregnancy. Pediatricians should strive to be aware of the ways in which the underlying beliefs they bring to their clinical practice affect the care that they provide.

The American Academy of Pediatrics has issued a policy statement on refusal to provide information or treatment on the basis of conscience.[71] According to the policy, pediatricians have a duty to inform their patients about relevant, legally available treatment options to which they object and have a moral obligation to refer patients to other physicians who will provide and educate about those services. Failure to inform/educate about availability and access to emergency-contraception services violates this duty to their adolescent and young adult patients.

SUMMARY AND RECOMMENDATIONS

1. Pediatricians should be aware that sexual behavior is prevalent among teenagers and that as many as 10% of sexually active teenagers may be the victims of sexual assault.
2. Effective contraceptive use with dual methods (condoms in addition to hormonal contraception/intrauterine device) or abstinence are the best ways for teenagers to avoid pregnancy. Many teenagers are at high risk of contraceptive failure, however, and emergency contraception is an important backup method for all teenagers. Emergency contraception is most effective in decreasing risk of pregnancy when used as soon as possible, but it may be used 120 hours after unprotected or underprotected intercourse.
3. Indications for use of emergency contraception include sexual assault, -unprotected intercourse, condom breakage or slippage, and missed or late doses of hormonal contraceptives, including the oral contraceptive pill, contraceptive patch, contraceptive ring, and injectable contraception.
4. Pediatricians should provide levonorgestrel 1.5 mg (Plan B, Plan B One Step, or Next Choice) for teenagers in immediate need of emergency contraception and provide prescriptions/supply for teenagers to have on hand in case of future need (ie, advanced provision). No pregnancy test is required before the use of levonorgestrel.
5. The levonorgestrel method has an improved adverse effect profile and increased effectiveness compared with combined hormonal emergency-contraception methods. The rate of nausea and vomiting with levonorgestrel emergency contraception is approximately half that with the combination oral contraceptive (Yuzpe) method, and routine use of antiemetics is not indicated. Advanced provision increases the likelihood that teenagers will use emergency contraception when needed, reduces the time to use, and does not decrease condom or other contraceptive use. Both males and females 17 years or older may obtain levonorgestrel without a prescription, but must show proof of age.
6. Other emergency-contraception methods include ulipristal (ella) and estrogen-containing (Yuzpe) emergency-contraception methods. Adverse effects of ulipristal include headache, nausea, and abdominal pain. Existing pregnancy must be excluded before prescribing ulipristal. The adverse effects of the estrogen-containing emergency contraception (Yuzpe) method include nausea, vomiting, and abdominal pain. Patients with contraindications to estrogen use, such as history of thromboembolism, should not use the combination oral contraceptive (Yuzpe) method.
7. All adolescents, males and females, and families of disabled adolescents should be counseled on emergency contraception as part of routine anticipatory guidance in the context of a discussion on sexual safety and family planning regardless of current intentions for sexual behavior. All contraceptive and STI counseling for adolescents should include education and counseling regarding the use and availability and advance prescription of emergency contraception wherever these visits occur, including emergency departments, clinics, and hospitals. Adolescents should be instructed to use emergency contraception as soon as possible after unprotected intercourse and to then schedule a follow-up appointment with their primary provider to address the need for STI testing and ongoing contraception.
8. At the policy level, pediatricians should advocate for increased nonprescription access to emergency contraception for teenagers regardless of age and for insurance coverage of emergency contraception to reduce cost barriers.

TECHNICAL REPORT

Epidemiology and Diagnosis of Health Care–Associated Infections in the NICU

abstract

FREE

Health care–associated infections in the NICU are a major clinical problem resulting in increased morbidity and mortality, prolonged length of hospital stays, and increased medical costs. Neonates are at high risk for health care–associated infections because of impaired host defense mechanisms, limited amounts of protective endogenous flora on skin and mucosal surfaces at time of birth, reduced barrier function of neonatal skin, the use of invasive procedures and devices, and frequent exposure to broad-spectrum antibiotics. This statement will review the epidemiology and diagnosis of health care–associated infections in newborn infants. *Pediatrics* 2012;129:e1104–e1109

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

INTRODUCTION

Health care–associated infections are infections acquired in the hospital while receiving treatment of other conditions. They are common occurrences in patients of all ages and are estimated to result in 2 million infections, 90 000 deaths, and $28 to $45 billion in excess health care costs annually.[1,2] In the Pediatric Prevention Network national point prevalence survey, 11.2% of NICU patients had a health care–associated infection on the day of the survey.[3] Although there are no recent estimates of the cost of health care–associated infections in the NICU, Payne et al[4] estimated that health care–associated bloodstream infections added almost $100 million to the cost of treating infants with birth weights from 500 to 1499 g in 1999 dollars. Because this finding represented the excess costs associated with only one type of infection in one gestational age cohort, it provides just a glimpse of the financial impact of health care–associated infections in the NICU. This financial estimate does not include the potential morbidity and mortality concerns for the infant and the effect that the prolonged hospital stay has on the family and resource utilization within the hospital. Reducing health care–associated infections in the NICU would have benefits to infants, families, and the health care delivery system. The purpose of this technical report was to review the epidemiology and diagnosis of health care–associated infections in the NICU. A companion policy statement addresses strategies for the prevention of health care–associated infections.

EPIDEMIOLOGY

Newborn infants hospitalized in a NICU have host factors that not only make them more vulnerable to acquisition of health care–associated

infections but also increase their risk of developing more serious illnesses. Whether an infant is born preterm or at term, many components of their innate and adaptive immune systems exhibit diminished function when compared with older children and adults. Infants with birth weights less than1500 g (very low birth weight) have rates of health care–associated infections 3 times higher than those who weigh greater than 1500 g at birth. However, the increased susceptibility to infection in infants of very low birth weight is multifactorial and related to both the developmental deficiencies in the innate and adaptive immune systems and a greater likelihood of a critical illness requiring invasive monitoring and procedures. Furthermore, the immunologic deficiencies can be exacerbated by the critical nature of many of the illnesses affecting newborn infants.[5]

Colonization of mucous membranes and the skin occurs rapidly after birth. Newborn infants delivered vaginally are colonized with maternal bacteria acquired from the birth canal. In most instances, those organisms do not cause invasive disease; however, in critically ill newborn infants, this colonization can potentially lead to systemic infection when skin or mucosal surfaces are compromised. The stratum corneum of the skin is poorly developed before 26 weeks' gestation, and ill neonates are at increased risk of developing skin and mucosal injury (eg, by suctioning or invasive procedures), allowing invasive bacteria access to deeper tissues or vascular spaces. Furthermore, mucosal surfaces and skin of infants in the NICU are more likely to be colonized with Gram-negative enteric rods, staphylococci, enterococci, and *Candida* species. NICU-acquired microbes are more likely to be pathogenic and resistant because of frequent exposure of hospitalized infants to antibiotic agents.

Data describing the epidemiology and incidence of health care–associated infections in NICUs can be obtained from 4 sources: (1) the National Healthcare Safety Network (previously known as the National Nosocomial Infections Surveillance system) at the Centers for Disease Control and Prevention (CDC); (2) the Pediatric Prevention Network at the National Association of Children's Hospitals and Related Institutions; (3) the Vermont Oxford Network; and (4) the National Institute for Child Health and Human Development Neonatal Research Network.

In addition to preterm birth,[6,7] risk factors associated with an increased rate of health care–associated infections include the presence of invasive devices (intravascular catheters, endotracheal tubes, orogastric tubes, urinary catheters, and drains), exposure to broad-spectrum antibiotic agents, parenteral nutrition,[8] overcrowding and poor staffing ratios, administration of steroids and histamine$_2$-receptor antagonists, and acuity of underlying illness. Furthermore, the lower the birth weight, the more invasive technology is used.[6,7]

Parenteral nutrition is commonly administered to the sickest infants through central venous catheters or peripherally inserted central catheters. The relationship between central line use and increased risk of infection has been demonstrated in multiple studies[9–11]; administration of lipids may be an independent risk factor for bacterial or fungal sepsis.[10]

The most common type of health care–associated infection within the NICU is a catheter-associated bloodstream infection.[3] Within the first 30 days after birth, coagulase-negative *Staphylococcus* species, *Staphylococcus aureus*, *Enterococcus* species, and Gram-negative enteric bacteria are the most common etiologic agents. After 30 days of age, coagulase-negative *Staphylococcus* species remain the most common pathogens; however, fungi, particularly *Candida* species and *Malassezia furfur*, have been noted with increasing frequency.[3] Central-line–related infections are, in large part, a result of problems with poor technique at the time of placement and ongoing care of the catheter site. Data suggest that the hub is a common source of contamination and subsequent infection.[12] Not surprisingly, the occurrence of catheter-associated bloodstream infections is highly related to the duration of catheter use and the number of times the catheter or hub is entered or opened.

Health care–associated lower respiratory tract infections and ventilator-associated pneumonia are of extreme importance for hospitalized infants because of their frequency and potential severity. Health care–associated pneumonia represents 6.8% to 32.3% of health care–associated infections in the NICU and is the second most frequent hospital-acquired infection in critically ill neonates.[7,13,14] The most recent National Healthcare Safety Network data indicate a pooled mean rate of ventilator-associated pneumonia from 0.7 to 2.2 per 1000 ventilator days.[7] However, rates varied among NICUs, with 90% of NICUs reporting rates between 2.1 and 7.3 per 1000 ventilator days. Variations in incidence likely reflect, in part, difficulty in making this diagnosis in infants with chronic lung disease. As with most health care–associated infections, birth weight and gestational age correlate inversely with the incidence of ventilator-associated pneumonia. Many of the risk factors for the development of health care–associated pneumonia in NICU patients are similar to those previously identified in adult patients, such as prolonged duration of mechanical ventilation, severe underlying cardiopulmonary disease, prolonged intravenous alimentation, and previous thoracoabdominal surgery.

Most bacterial health care–associated lower respiratory tract infections occur by aspiration of bacteria that colonize the oropharynx or the upper gastrointestinal tract. On rare occasions, health care–associated pneumonias may result from contiguous spread or a primary infection at a distant site. Under normal circumstances, the filtration system of the upper airway and the mucociliary clearance system of the large airways protect the lower respiratory tract from bacteria that may be present in the patient's environment or that reside in the upper respiratory tract. Endotracheal tubes bypass these initial host barrier defense mechanisms, providing direct access of bacteria and other pathogens to the lower respiratory tract. Uncuffed endotracheal tubes provide even easier access of microorganisms to the lower respiratory tract.[15–17] The aspiration of contaminated materials may be obvious or, more commonly, may be subclinical.[15–18] By using pepsin as a marker for aspiration, microaspiration has been detected in up to 92.8% of ventilated neonates.[18,19] Methylxanthines and bronchopulmonary dysplasia increase the frequency of microaspiration. Microaspiration is also more frequent in infants with severe bronchopulmonary dysplasia compared with those with moderate bronchopulmonary dysplasia.[18,19] Neonates who have either impaired swallowing mechanisms or anatomic abnormalities that prevent adequate protection of their airway are also at increased risk of aspiration.[15,16,20]

Dense bacterial polysaccharide biofilm can coat the endotracheal tubes, and polymicrobial flora become embedded into this film. Endotracheal suctioning can dislodge these aggregates of bacteria, providing a large bacterial inoculum directly into lower airways. Nasal continuous positive airway pressure (CPAP) does not bypass many of the protective barriers, does not require endotracheal suctioning, and reduces mechanical disruption of respiratory mucosa. This likely explains the lower risk of health care–associated pneumonia in neonates using nasal CPAP versus those treated with endotracheal intubation (1.8 vs 12.8 per 1000 nasal CPAP or ventilator days).[21] However, CPAP has been associated with an increased risk of Gram-negative infections.[22]

Skin and soft tissue infections are commonly observed in NICU patients. Neonates, especially those born preterm, have fragile skin, which is easily traumatized. Cellulitis, abscesses, and skin abrasions are frequently noted at sites of percutaneous puncture (lancets and scalp electrodes), in diaper or bandage areas, and at surgical incision sites. *S aureus* is by far the most common microorganism responsible for all skin and soft tissue infections in the NICU. The recent emergence of methicillin-resistant *S aureus*, both endemic health care–associated and community-associated strains, has made management of these infections complicated. Gram-negative enteric rods and yeasts are less commonly associated with skin and soft tissue infections than *S aureus*, but they are associated with surgical procedures, particularly those affecting the gastrointestinal tract.

DIAGNOSIS OF CENTRAL LINE–ASSOCIATED BLOODSTREAM INFECTIONS

The presence of a central venous catheter is a major risk factor for bloodstream infection. Coagulase-negative staphylococci are responsible for nearly 50% of catheter-related bloodstream infections. Other pathogens include Gram-negative organisms (~20%), *S aureus* (4% to 9%), *Enterococcus* species (3% to 5%), and *Candida* species (~10%).[23] Coagulase-negative staphylococci are skin commensals; therefore, interpretation of a blood culture result positive for this organism is difficult. The diagnosis is made even more problematic by the nonspecific signs of sepsis in the neonate. It is noteworthy that the databases of the National Healthcare Safety Network, Vermont Oxford Network, and the National Institute for Child Health and Human Development Network include infants with a single positive blood culture and clinical signs as "proven cases" of central line–associated bloodstream infection. Although many experts recommend obtaining both central line and peripheral blood cultures when evaluating neonatal patients for central line–associated bloodstream infection, a single blood culture sample is commonly obtained. In those situations, it may be difficult to determine whether the coagulase-negative *Staphylococcus* is the responsible pathogen or a contaminant, and the clinician will need to make a judgment on the basis of the laboratory data and response to treatment. The Infectious Diseases Society of America recommends that paired samples be drawn from the catheter and a peripheral vein (level of evidence: A-II).[24] Although this action may not be possible for all neonates, paired samples should be obtained whenever feasible. Neonates with a suspected central line–associated bloodstream infection should be treated with broad-spectrum antibiotic agents to cover both Gram-positive and Gram-negative pathogens. An algorithm for interpreting a positive blood culture result for coagulase-negative staphylococci is shown in Fig 1.

DIAGNOSIS OF HEALTH CARE–ASSOCIATED PNEUMONIA

Health care–associated pneumonia can have adverse clinical consequences, both from the infection itself and from

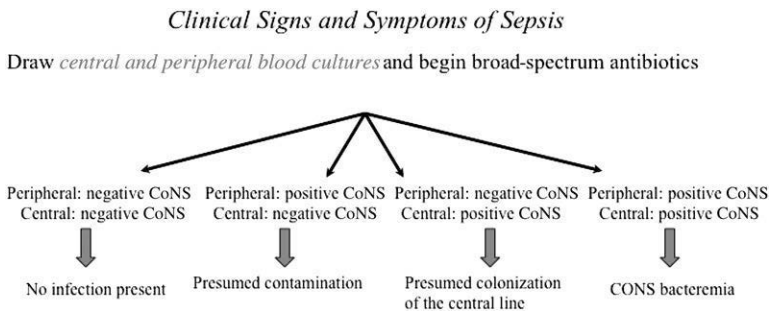

FIGURE 1
Algorithm for interpreting a positive blood culture result for coagulase-negative staphylococci (CONS).

its therapies. Health care–associated pneumonias in infants may result in increased exposure to broad-spectrum antibiotic agents, need for reintubation, increased duration of assisted ventilation, increased length and cost of hospitalization, secondary infections including sepsis, and even death.

The optimal method of diagnosing health care–associated pneumonia in neonates remains to be established. In neonates with underlying pulmonary disease, it may be difficult to differentiate between preexisting lung disease and health care–associated pneumonia or tracheitis. In general, the diagnosis of health care–associated pneumonia is made on the basis of evidence of respiratory decompensation with new and persistent infiltrates on a chest radiograph. Clinical signs suggesting that a health care–associated bacterial pneumonia has developed in an infant receiving mechanical ventilation include changes in the patient's respiratory status that are unexplained by other events and a significant increase in the quantity and quality of respiratory secretions. However, signs such as fever, leukocytosis, and changes in the quality and quantity of tracheobronchial secretions may occur for reasons other than the development of a health care–associated lower respiratory tract infection. Unfortunately, relying on clinical changes and chest radiographic findings for the diagnosis in a NICU setting may overestimate the true incidence of health care–associated pneumonia. Infants with atelectasis, congenital heart disease, bronchopulmonary dysplasia, pulmonary hemorrhage, pulmonary edema, and surgical procedures affecting the chest may have radiographic changes that are similar to changes seen with pneumonia. The National Healthcare Safety Network and CDC definition requires at least 48 hours of mechanical ventilation accompanied by new and persistent radiographic infiltrates after the initiation of mechanical ventilation. In addition to these criteria, infants younger than 1 year old must exhibit worsening gas exchange and at least 3 of the following: (1) temperature instability with no other recognized cause; (2) leukopenia (white blood cell count $<4000/mm^3$); (3) change in the character of sputum or increased respiratory secretions or suctioning requirements; (4) apnea, tachypnea, nasal flaring, or grunting; (5) wheezing, rales, rhonchi, or cough; or (6) bradycardia (<100 beats/min) or tachycardia (>170 beats/min).[25] Baltimore,[26] however, has pointed out that the CDC definitions were developed for epidemiologic surveillance and have not been validated for clinical diagnosis.

Laboratory tests, such as Gram stain or bacterial culture, documenting the presence of inflammation and pathogenic microorganisms in lower respiratory tract secretions may be helpful in establishing the presence of a health care–associated lower respiratory tract infection. However, in most cases, presence of bacteria in specimens obtained by suctioning the endotracheal tube represents colonization rather than an invasive infection, even when the culture is obtained immediately after intubation. In addition, the correlation between culture results obtained from endotracheal suction specimens and those from samples obtained directly from the lungs, pleural cavity, or blood is poor.[27,28]

When it is likely that a health care–associated bacterial pneumonia is present, a number of procedures can assist in establishing the etiologic agent. A Gram stain of a specimen obtained by suctioning through the endotracheal tube can provide evidence of an inflammatory (and potentially infectious) process in the lower respiratory tract.[29] The presence of an abundance of polymorphonuclear neutrophils or a significant increase in polymorphonuclear neutrophils from a previous Gram stain of the same secretions, regardless of the presence of a predominant bacterial organism, is supportive evidence that pneumonia is present but also may represent tracheitis. The presence of a single organism obtained by culture that is consistent with an organism identified on the Gram stain increases the likelihood that this agent is causally related to the health care–associated bacterial pneumonia.[29]

Numerous efforts have been made to develop techniques for obtaining specimens from the lower respiratory tract that can identify the bacteria responsible for the health care–associated pneumonia without interference by upper airway contamination. Transtracheal aspiration, transthoracic needle aspiration and biopsy, and bronchoscopy have been used in older children and

adults to obtain samples directly from the lower respiratory tract, but these procedures are generally contraindicated in neonates. Moreover, there is a high rate of false-positive results in children who have underlying pulmonary conditions that might be confused with pneumonia by their clinical and radiographic appearances.

Bronchoalveolar lavage is a reliable method for obtaining lower respiratory tract secretion samples in older children and adults.[30–32] However, its role in diagnosing ventilator-associated pneumonia in older children and adults has not been established, and experience in preterm infants is limited. In intubated neonates, tracheal aspirates may provide information similar to that which can be obtained by bronchoalveolar lavage. However, for neonates with rapidly progressing lower respiratory tract disease or in whom a diagnosis is not established with routine tracheal aspirate, a bronchoalveolar lavage may be indicated (if technically feasible).[33–35] The aspirated fluid can be centrifuged, and the pellet can be examined immediately for bacteria (Gram stain or acridine orange) and fungi (KOH or Calcofluor). Cultures and other molecular diagnostic testing (eg, direct fluorescent antibody assay, polymerase chain reaction assay) can be performed for aerobic bacteria, fungi, and viruses. The differential count of white blood cells from bronchoalveolar lavage fluid may also be helpful. Infants with bacterial or fungal infections are more likely to have a high proportion of granulocytes in bronchoalveolar lavage fluid.[33,36]

Isolation of the same bacterial pathogen from the blood and the lower respiratory tract usually confirms that this organism is the agent responsible for the health care–associated pneumonia. However, only approximately 2% to 5% of patients with health care–associated bacterial pneumonia have positive blood cultures.[36]

POLICY STATEMENT

Firearm-Related Injuries Affecting the Pediatric Population

The absence of guns from children's homes and communities is the most reliable and effective measure to prevent firearm-related injuries in children and adolescents. Adolescent suicide risk is strongly associated with firearm availability. Safe gun storage (guns unloaded and locked, ammunition locked separately) reduces children's risk of injury. Physician counseling of parents about firearm safety appears to be effective, but firearm safety education programs directed at children are ineffective. The American Academy of Pediatrics continues to support a number of specific measures to reduce the destructive effects of guns in the lives of children and adolescents, including the regulation of the manufacture, sale, purchase, ownership, and use of firearms; a ban on semiautomatic assault weapons; and the strongest possible regulations of handguns for civilian use.

SCOPE OF THE PROBLEM

Although rates have declined since the American Academy of Pediatrics (AAP) issued the original policy statement in 1992, firearm-related deaths continue as 1 of the top 3 causes of death in American youth.[1] As shown in Fig 1, the firearm-associated death rate among youth ages 15 to 19 has fallen from its peak of 27.8 deaths per 100 000 in 1994 to 11.4 per 100 000 in 2009, driven by a decline in firearm homicide rates.[1] No single study has adequately explained the decline in firearm-related homicide rates. Postulated reasons include improved socioeconomic conditions, violence prevention programs, decline in the crack/cocaine market, changes in legislation, declines in firearms availability for other reasons, and community policing. Nevertheless, firearm-associated death and disability rates remain unacceptably high.

Of all injury deaths of individuals 15 through 19 years of age in the United States in 2009, more than 1 (28.7%) in 4 were firearm related, and of those younger than 20 years, nearly 1 (19.5%) in 5 were firearm related.[1] These firearm deaths result from homicide, suicide, and unintentional injury (Fig 2). Black Americans are particularly affected; injuries from firearms were the leading cause of death among black males 15 through 34 years of age in 2009.[2] Although national data cannot fully document urban and rural differences in the patterns of injuries from firearms that involve children, local data indicate that children in rural areas as well as in urban areas are at risk for firearm-related mortality.[3–5]

The National Violent Death Reporting System (NVDRS), administered by the Centers for Disease Control and Prevention, provides detailed surveillance of all violent deaths in participating states. The NVDRS system uses sources of data to allow analysis of each death (homicides, suicides, and others), including the detailed history and circumstances of the fatal incident. Data concerning mental health, substance abuse, race, age group, previous history, method of injury, and relationship of suspect to victim are included. Suspects and multiple victims can be studied together, allowing for comparisons of victim and perpetrator characteristics.[6–8] The NVDRS can provide useful information concerning childhood mortality from firearms; limited raw data from this system are now available online.[1]

INTERNATIONAL COMPARISONS

The United States has the highest rates of firearm-related deaths (including homicide, suicide, and unintentional deaths) among high-income countries.[9] For youth 15 to 24 years of age, firearm homicide rates, as documented by Richardson and Hemenway,[9] were 35.7 times higher than in other countries. For children 5 to 14 years of age, firearm suicide rates were 8 times higher, and death rates from unintentional firearm injuries were 10 times higher in the United States than other high-income countries. The difference in rates may be related to the ease of availability of guns in the United States compared with other high-income countries. This is particularly true for suicides, as guns carry a high case-fatality rate.[10] Suicides among the young are typically impulsive,[11] and easy access to lethal weapons largely determines outcome.

ECONOMIC COSTS OF FIREARM-RELATED INJURY

Corso and colleagues[12] calculated the financial cost to society resulting from gun-related assaults and homicides in 2000. The amount totaled $17.4 billion, including $0.8 billion in direct medical costs and $16.6 billion in lost productivity. In the same year, self-inflicted firearm injuries and suicides cost society $16.4 billion, including

$16.3 billion in lost productivity and $0.1 billion in direct medical costs. The analysis found that average direct medical cost per case for nonfatal firearm assaults and self-inflicted injuries resulting in hospitalization were $24 353 and $7234 respectively.[12] The method for calculating the medical costs includes ambulance transport costs, coroner/medical examiner costs, emergency department costs, hospital readmission costs, and inpatient hospitalization and/or nursing home costs.[12] Work loss costs were calculated by the net present value of future wage earning and losses in household productivity.

Accessed June 8, 2012).

HOMICIDE

In 2009, 84.5% of all homicides of people 15 through 19 years of age were firearm-related.[1] Deaths of male individuals outnumber deaths of female individuals (Fig 3). Young black men from 15 through 34 years of age have the highest rates of firearm-related homicide.[1] In 2010 in the United States, 67.5% of all homicides were committed with a firearm, and in 68.5% of those cases, a handgun was used as the murder weapon.[13] Firearm homicide rates were higher in major urban areas than in the nation as a whole (5.2 per 100 000 vs 4.2 per 100 000). Within the 50 largest metropolitan areas, they were highest in the central cities (9.7 per 100 000).[3]

An understanding of the characteristics of firearm-related homicides is important when interventions are being planned. Most homicides occur during interpersonal conflict, typically between relatives, friends, or acquaintances.[13] Recognized risk factors for violence involving children and adolescents include exposure to family violence, history of antisocial behavior, depression, suicidal ideation, drug/alcohol use, poor school performance, bullying, and isolation from peer groups.[14] The occurrence of shootings in schools, although rare, deserves serious study and calls for local and national responses.

SUICIDE

Suicide Risk Among Adolescents and Firearm Availability

In 2009, suicide was the third leading cause of death for American youth 15 to 19 years of age. Firearms remained the most common method used for suicide in this age group, accounting for 736 deaths (3.4 per 100 000).[1] Of all common methods used for attempting suicide, firearms are the most lethal, with approximately a 90% mortality rate.[15] Adolescents are at a relatively high risk of attempting suicide as a consequence of their often impulsive behavior. Choosing a highly lethal method such as a firearm to attempt suicide leads to higher suicide fatality rates overall, in part because most survivors of serious suicide attempts do not die of renewed attempts.[16] Thus, easy access to firearms contributes to an increased risk of suicide among youth this age. Although handguns are used in most youth firearm suicides, long guns (shotguns and rifles) are also used in a large percentage of suicides in rural areas, where they are more widely available.[17,18] Strong evidence suggests that the presence of firearms in the home increases the risk of suicide among adolescents. A review of existing data from case-control studies and ecological data found that firearm availability plays a large role in increasing the risk of youth suicide.[19] Several individual-level and ecologic studies, including nationally representative studies, have corroborated these earlier findings.[20–24] The association of a gun in the home and increased risk of suicide among adolescents has been well documented. From a clinical perspective, it is important to note that this association is significant even in those teens without a previous psychiatric diagnosis.[25,26] The odds of suicide are particularly high if the gun is kept loaded.[25,26]

Data concerning the effects of laws restricting firearm ownership show varying results.[27–29] Interestingly, laws reducing child access, which primarily requires safe storage, appear to be associated with lower overall adolescent suicide rates, whereas purchase restrictions did not result in this reduction.[29] Other studies have

established the finding that safe storage of firearms reduces the risk of adolescent suicide.[30]

UNINTENTIONAL FIREARM-RELATED DEATHS

In 2009, 114 children and adolescents younger than 20 years died as a result of unintentional firearm-related injuries.[1] Perhaps surprisingly, 66 of these 114 unintentional deaths occurred in the 15- to 19-year age group. Fatal shootings are usually inflicted by other children or youth, typically friends or siblings.[31,32] There are few recent systemically collected data concerning the precise circumstances of unintentional firearm injury deaths among these 114 children.

NONFATAL FIREARM-RELATED INJURIES

According to data from emergency departments in the 66 hospitals in the National Electronic Injury Surveillance System All-Injury Program, an estimated 73 505 people of all ages were treated for nonfatal firearm-related injuries in US hospital emergency departments in 2010, among them 15 576 children and adolescents younger than 20 years.[1] Of those, 6236 (40%) required hospitalization for their injuries. Adolescents 15 to 19 years of age had nonfatal firearm injury rates nearly 3 times that of the general population (62.9 vs 23.9 per 100 000).[1] Most (79%) of the nonfatal injuries to adolescents were attributable to assault, and assault-related injuries were responsible for 84.5% of hospitalizations.[1]

ADOLESCENT CHARACTERISTICS AND ACCESS TO GUNS

The 2011 *National Youth Risk Behavior Surveillance* reported that 5.1% of students in grades 9 through 12 had carried guns during the past month, with boys more likely to report carrying guns than girls (8.6% vs 1.4%).[33] Well-established behavioral risk factors for carrying guns include gang membership, use of alcohol and other drugs, victimization by violence, and perpetration of violence.[34–36] As with other risk behaviors, adolescents substantially overestimate the percentage of their peers who carry guns, and interestingly, gun carrying is highly associated with that normative perception.[35] Adolescence is marked by a search for identity, independence, and autonomy. Accompanying characteristics may be curiosity, the strong influence of the peer group, rites of passage, belief in invincibility, impulsiveness, immaturity, mood swings, and substance abuse. The perception of danger by adolescents may be influenced by many factors, including the media, as well as the reality of their own lives. A view of the world as a dangerous place during this particularly vulnerable developmental period may lead to conflict, injury, and death, especially when access to guns is easy.

GUNS AND GUN OWNERSHIP

It is estimated that 57 million Americans owned 283 million firearms in 2004, representing 38% of all households and 26% of all adults having or owning at least 1 gun. Of these, 60% were long guns and the remaining 40% were handguns.[37] Of the handguns, 50% were revolvers, 35% were semiautomatic pistols, and 15% were other types.[37] More recently, there has been a troubling increase in serious and disabling injuries resulting from high-velocity nonpowder guns.[38]

Prevalence of gun ownership by household varies significantly geographically, with an estimated low of 5.2% in the District of Columbia to 62.8% of all households in Wyoming.[39] In a study of gun-owning Americans with children under 18 years of age, 21.7% stored a gun loaded, 31.5% stored a gun unlocked, and 8.3% stored at least 1 gun unlocked and loaded.[40] Household firearm owners with adolescents 13 through 17 years of age report leaving their firearms unlocked 41.7% of the time, compared with only 28.8% of household firearm owners with children 0 through 12 years of age.[40]

Most gun owners report the leading motivation for ownership is recreational; however, nearly three-quarters of handgun owners said self-protection was the primary reason for owning a gun.[41] Research in several US urban areas indicates that a gun stored in the home is associated with a threefold increase in the risk of homicide and a fivefold increase in the risk of suicide.[42–44] Evidence from Philadelphia suggests that firearm possession increases the risk of being shot in an assault. In a carefully conducted case-control study, Branas and colleagues found that people possessing a gun were more than 4 times more likely to be shot in an assault than those not in possession of a firearm.[45]

LEGAL ISSUES

A 2008 Supreme Court decision struck down the handgun ban in the District of Columbia, concluding that the second amendment to the US Constitution establishes individual rights to gun ownership.[46] In the subsequent 2010 Supreme Court case of *McDonald v the City of Chicago*, the Court ruled that the 14th Amendment extends the 2nd Amendment protections of the federal government to states and localities against laws that infringe on "the right to keep and bear arms."[47]

Because Chicago was the only locality in the country to possess an outright handgun ban, the *McDonald* ruling did not have an immediate effect on state and local gun laws outside the Chicago area. The ruling set the stage

for Second Amendment legal challenges to local and state gun laws, however, including laws requiring the safe storage of firearms and trigger locks, as well as laws aimed at protecting children from firearms. There have been and will likely continue to be a number of state and local legal challenges to restrictions on firearm acquisition and use in the United States. These include challenges to measures specifically pertaining to access to firearms by children. Pediatricians should, nonetheless, continue to provide anticipatory guidance to children and their families regarding keeping children safe from injury, including restriction of access to guns.

IMPLICATIONS OF DATA FOR PREVENTION STRATEGIES

The following summary of data suggests a number of intervention strategies:

- Firearm-related injuries are often fatal; primary prevention is essential.
- Suicide fatality rates increase if guns are present in the home.
- Access to guns increases the number of conflict-related deaths and injuries.
- Access to guns and unsafe storage practices creates risk of serious unintentional injury and death.
- Most firearm-related injuries and deaths of children and adolescents involve a handgun, but long guns are involved a large number of unintentional injuries and suicides, especially in rural areas.

Preventing Firearm Injuries in Children

A number of design options have been proposed to decrease the likelihood of unintentional injury by a firearm, as well as limiting access by unauthorized users. These include trigger locks, lock boxes, personalized safety mechanisms, and trigger pressures that are too high for young children.[48] A multisite study found that keeping a gun locked and keeping a gun unloaded have protective effects of 73% and 70%, respectively, with regard to risk of both unintentional injury and suicide for children and teenagers. These findings were consistent for both handguns and long guns (rifles and shotguns).[30]

Gun avoidance programs are designed to educate children as a way of reducing firearm injury (eg, Eddie Eagle, STAR); however, several evaluation studies have demonstrated that such programs do not prevent risk behaviors[49–51] and may even increase gun handling among children.[45] In contrast, results of a large national randomized controlled trial demonstrated that brief physician counseling directed at parents, combined with distribution of gunlocks, may be effective in promoting safer storage of guns in homes with children.[52] A recent randomized controlled trial found that a safe storage campaign with gun safe distribution was both feasible and effective at limiting household exposure to unlocked and loaded guns.[53]

A number of factors may be important in reducing exposure to violence and the results of that exposure in children and adolescents. Some curricula targeting younger children and those at low risk of violence have been evaluated and have shown positive results.[54] Resiliency-based violence-prevention strategies in preschool children have shown improvement in teacher interactional skills supporting children's resiliency and improvement in children's prosocial behaviors.[55] Other studies have shown that both family support and early childhood education result in reductions in delinquency[56]; however, one study has shown that, for seventh-grade children exposed to high levels of violence as victims or witnesses, a conflict-resolution class produced more anxiety, depression, and aggression.[57] School curricula aimed at reducing violence should be specific to the population and include evaluation components to determine their effectiveness.[58]

The AAP statement on youth violence prevention suggests many ways in which pediatricians and communities can respond to violence.[59] This policy endorses use of the *Connected Kids: Safe, Strong, Secure* violence-prevention program. This program provides counseling suggestions concerning a number of violence-related topics and parent information brochures specifically related to reducing unintentional injuries to young children and suicide risk among adolescents. The *Connected Kids* program was developed on the basis of expert opinion and focus groups of parents around the United States.[60–62] The clinical guide and parent information material provides parents with factual information from which they can make their own decisions. For parents of young children, handgun storage is placed in the context of preventing child access to other dangerous household products. Parents of adolescents have counseling and written materials that describe the relationship between the availability of lethal weapons and fatal teen suicide attempts. These concepts have been incorporated in the new *Bright Futures* toolkit, and pediatricians will find items concerning gun safety incorporated into relevant previsit questionnaires.[63] The AAP also advocates for reduction of television viewing by children, because media exposure results in increases in childhood and youth violence. In particular, media tends to romanticize the

use of firearms as a means of resolving conflicts. The AAP policy statement on media violence provides specific background information and recommendations for pediatricians.[64]

Pediatricians can benefit from knowing local community resources that assist with guidance when patients and families are at high risk of firearm-related injury. Pediatricians may partner with other community members and community-based organizations to identify and publicize these resources.

SUMMARY AND RECOMMENDATIONS

Firearm-related injury to children is associated with death and severe morbidity and is a significant public health problem. Child health care professionals can and should provide effective leadership in efforts to prevent gun violence, injury, and death. The AAP recognizes the importance of a variety of countermeasures (educational, environmental, engineering, enactment, enforcement, economic incentives, and evaluation) to dramatically curb the number of firearm-related injuries to children. The AAP makes the following recommendations, which reaffirm and expand on the 1992 and 2000 policy statements[65,66]:

1. The AAP affirms that the most effective measure to prevent suicide, homicide, and unintentional firearm-related injuries to children and adolescents is the absence of guns from homes and communities. Although the US Supreme Court ruling in the case of *McDonald v City of Chicago* struck down comprehensive local and statewide firearm bans, pediatricians should continue to advocate for the strongest possible legislative and regulatory approaches to prevent firearm injuries and deaths.
2. Health information for parents:
   a. Pediatricians and other child health care professionals are urged to counsel parents about the dangers of allowing children and adolescents to have access to guns inside and outside the home. The AAP recommends that pediatricians incorporate questions about the presence and availability of firearms into their patient history taking and urge parents who possess guns to prevent access to these guns by children. Safer storage of guns reduces injuries, and physician counseling linked with distribution of cable locks appear to increase safer storage. Nevertheless, the safest home for a child or adolescent is one without firearms.
   b. The presence of guns in the home increases the risk of lethal suicidal acts among adolescents. Health care professionals should counsel the parents of all adolescents to remove guns from the home or restrict access to them. This advice should be reiterated and reinforced for patients with mood disorders, substance abuse problems (including alcohol), or a history of suicide attempts.
3. The AAP urges that guns be subject to consumer product regulations regarding child access, safety, and design. In addition, the AAP continues to support law enforcement activities that trace the origins of firearms used in the commission of crimes and that these data be used to enforce regulations aimed at preventing illegal sales to minors.
   a. Evidence supports the effectiveness of regulation that limits child access to firearms.
   b. The AAP supports efforts to reduce the destructive power of handguns and handgun ammunition via regulation of the manufacture and importation of classes of guns. Engineering efforts (eg, personalized safety mechanisms and trigger locks) may be of benefit and need further study. Trigger locks, lock boxes, gun safes, and safe storage legislation are encouraged by the AAP. Other measures aimed at regulating access of guns should include legislative actions, such as mandatory waiting periods, closure of the gun show loophole, mental health restrictions for gun purchases, and background checks.
   c. The AAP recommends restoration of the ban on the sale of assault weapons to the general public.
4. The AAP supports the funding of research related to the prevention of firearm injury, including surveillance through the NVDRS; accurate evaluation of health care–based screening and intervention; and local, regional, and national efforts to identify and disseminate violence prevention resources.
5. The AAP supports the education of physicians and other professionals interested in understanding the effects of firearms and how to reduce the morbidity and mortality associated with their use.

POLICY STATEMENT

Health Care of Youth Aging Out of Foster Care

abstract

FREE

Youth transitioning out of foster care face significant medical and mental health care needs. Unfortunately, these youth rarely receive the services they need because of lack of health insurance. Through many policies and programs, the federal government has taken steps to support older youth in foster care and those aging out. The Fostering Connections to Success and Increasing Adoptions Act of 2008 (Pub L No. 110-354) requires states to work with youth to develop a transition plan that addresses issues such as health insurance. In addition, beginning in 2014, the Patient Protection and Affordable Care Act of 2010 (Pub L No. 111-148) makes youth aging out of foster care eligible for Medicaid coverage until age 26 years, regardless of income. Pediatricians can support youth aging out of foster care by working collaboratively with the child welfare agency in their state to ensure that the ongoing health needs of transitioning youth are met. *Pediatrics* 2012;130:1170–1173

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

BACKGROUND

Children and youth in the child welfare system in the United States frequently face multiple obstacles in accessing needed health care services. All adolescents face challenges as they move into adulthood, but most have nurturing families to provide stability and emotional and economic support. Approximately 66 000 individuals in foster care (16% of the foster care population) are aged 16 and 17 years of age, and another 17 000 are 18 through 20 years of age.[1] As youth in foster care mature into adulthood, they face enormous challenges, including lack of family support; educational deficiencies; employment and income problems; inadequate or inappropriate living arrangements; medical, dental, and mental health problems; and lack of health insurance.

HEALTH CHALLENGES FACED BY YOUTH IN FOSTER CARE

Youth in foster care face medical and mental health challenges at significantly higher rates than other children, often as a consequence of the circumstances that led to their removal from their home and sometimes exacerbated by their experiences in foster care.[2] These health issues include developmental delays, mental retardation, emotional adjustment problems, chronic medical problems, birth defects, substance abuse, and pregnancy. In the foster care population, more than 60% of youth will have mental health problems during their lifetime; 30% to 40% of adolescents are coping with mental health issues, including posttraumatic stress disorder; and

more than one-third of older adolescents have a chronic illness or disability.[3–5]

LACK OF HEALTH COVERAGE AMONG YOUTH AGING OUT OF FOSTER CARE

High rates of physical and emotional health needs mean that youth aging out of foster care require comprehensive health coverage that recognizes and addresses their unique needs. Unfortunately, research has shown that they rarely receive such services. The Northwest Foster Care Alumni Study, one of the most comprehensive studies to date of the status of youth aging out of foster care, revealed that only 47% of foster care alumni said they had health insurance when they exited foster care.[6] The Midwest Evaluation of the Adult Functioning of Former Foster Youth Study, which examined the progress of youth in 3 states where they received foster care for at least 18 months, found that 51% stated they had no health insurance coverage.[7] The third wave of Midwest Evaluation interviews, conducted when subjects were aged 21 years, revealed that only half of the young adults who had aged out of foster care had medical insurance, and only 39% had dental insurance. Approximately 20% had not received any medical or dental care in the past year, citing their lack of health insurance as the main reason.[8] Another study found that 55% of young adults who had exited the foster care system had no health insurance.[9] The percentage of young adults (average age, 20.2 years) who had exited foster care with no health insurance was double that of young adults who had not been in foster care. According to the US Census Bureau, 30% of all young adults 18 through 24 years of age do not have health insurance.[10] Multiple studies and surveys over the years show clearly that youth in foster care have 3 to 7 times as many chronic health conditions and behavior/mental health problems as do those who have not been in foster care; however, they are only about half as likely to have health insurance.

LAWS ON HEALTH CARE FOR YOUTH AGING OUT OF FOSTER CARE

Historically, the child welfare system has been a responsibility of states. Each state designs and administers its child welfare and foster care programs as well as other human service programs that support children, both in and out of foster care, at various stages along the path to adulthood. Although the federal government's role in the child welfare system has expanded over the years, states provide the care for children within their child welfare system. The primary responsibilities of state child welfare agencies are to ensure the safety of children who have been maltreated, find permanent homes for such children, and promote the health and well-being of children in foster care. Another primary responsibility is to prepare teenagers in foster care for independent living.

Through many policies and programs, the federal government has taken steps to support older youth in foster care. Beginning in 1986 with an amendment to Title IV-E of the Social Security Act, the Independent Living Initiative provided states with funds to prepare foster youth for independent living. The Adoption and Safe Families Act of 1997 (Pub L No. 105-89) promoted adoption and permanent homes for children, including older children and youth. The Foster Care Independence Act of 1999 (Pub L No. 106-169, John Chafee Foster Care Independence Program), which replaced the Independent Living Initiative, increased funding to states for the purpose of preparing older youth for independent living and gave states the option of extending Medicaid coverage for youth aging out of foster care through 20 years of age. The "Chafee option" also allows states to use some independent living funds for housing and requires that states provide some level of services and supports to young people 18 to 21 years of age who have left foster care.

The Chafee option was a turning point in its recognition of the need to better serve older youth during a critical transition in their lives. Previously, all states were responsible for ensuring that services, including health care services, were provided to youths in foster care until 18 years of age. Over the past decade, several states have exercised the "Chafee option" to extend Medicaid services to 21 years of age for children who age out of foster care. Of those that have not yet used the "Chafee option," many states provide health care coverage to children who leave foster care through a number of mechanisms, including state Medicaid waivers, Children's Health Insurance Program (CHIP) coverage, medically needy Medicaid coverage, and other sources.[11] Beginning in 2014, as a result of a provision in the Patient Protection and Affordable Care Act of 2010 (Pub L No. 111–148), all youth aging out of foster care will be eligible for Medicaid coverage until they reach 26 years of age, regardless of their income.

Beyond the concerns of continued health coverage, the federal government has also prioritized the need for states to more actively coordinate the health care and services that youth in foster care are receiving. The Fostering Connections to Success and Increasing Adoptions Act (Pub L No. 110-354) of 2008 requires states to work with youth to develop a transition plan within the 90 days before a youth ages out of foster care. The plan

should contain as much detail as the youth chooses and should address issues including housing, health insurance, education, mentoring, continuing support services, workforce supports, and employment services. With regard to health care, this transition plan should include arranging for enrollment in Medicaid if the youth meets eligibility criteria to maintain the medical home and ensure continuity of care.

In addition, the Fostering Connections to Success Act requires states to develop, in coordination and collaboration with the state Medicaid agency and in consultation with pediatricians and other experts, a plan for the ongoing oversight and coordination of health care services for all youth in foster care. The state health plan must ensure that, among other provisions, every child receives appropriate health screenings and follow-up, continuity of care using the medical home model, and oversight of medications for each child.*

FUTURE CHALLENGES

Although strengthened provisions on health care coverage and coordination of care have represented important progress on behalf of older youth in foster care, they have also created new challenges for the future. In the short term, extended coverage to 26 years of age will not begin until 2014, leaving a cohort of exiting youth until that time at risk for not seeing the same benefits as those who will follow them. Additionally, access to care will continue to be a concern, particularly if Medicaid payment rates do not improve. Of paramount concern is that adult medicine physicians and other clinicians will be reluctant to care for or may even close their practices to young adults aging out of foster care because of low payment rates. This may place greater pressure on pediatricians or family physicians to fill this service need, but it is likely that service gaps will remain.

RECOMMENDATIONS FOR PEDIATRICIANS AND OTHER PHYSICIANS

1. Pediatricians should continue to provide medical homes for youth in foster care.
2. Pediatricians should work collaboratively with child welfare workers to ensure youth in foster care receive the health care services they need.
3. Pediatricians and other physicians are encouraged be informed about their state's programs to provide health care coverage for older youth both in foster care and aging out of the foster care system.
4. Pediatricians should work with child welfare and other community partners to educate youth who are aging out of care before 2014 that they will become eligible for Medicaid coverage effective January 1, 2014.
5. Pediatricians and other physicians are encouraged to learn more about the health needs of youth aging out of foster care and to learn about resources of the American Academy of Pediatrics available to assist in meeting these needs (see Healthy Foster Care America Web site: www.aap.org/fostercare).
6. Pediatricians have a unique opportunity, as the primary source of health care for children in foster care, to teach youth at transition the skills needed to navigate the adult health care system. Pediatricians should help their young adult patients transfer their health records, understand their health issues, and link them with a new adult primary care physician as well as needed mental health, reproductive health, and dental services.[12] Adolescents often feel invulnerable at this stage of development, so youth leaving foster care may need help understanding why their ongoing health care should be a priority.
7. Especially for youth with special health care needs, pediatricians should work collaboratively with child welfare workers to help plan for transition from child welfare. The pediatrician brings a "whole child" perspective of health care for these youth. Working together ensures that these youth receive comprehensive health services.

RECOMMENDATIONS FOR PUBLIC POLICY

1. Pediatricians play a vital role in advocating on behalf of children and adolescents. Working in concert with the national American Academy of Pediatrics (AAP) on federal efforts and AAP chapters and districts on regional, state, and local efforts, pediatrician advocacy can ensure that the physical, mental, social, and emotional health needs of adolescents and young adults are appropriately represented when the issue of health care for youths aging out of foster care is addressed. States have made a large investment in ensuring that these children arrive at the doors of adulthood safely, and it is prudent to ensure that this investment is protected by making sound transition plans.
2. The AAP supports pediatrician and AAP chapter efforts at the state level to extend foster care eligibility

*For more information, please contact the American Academy of Pediatrics Division of State Government Affairs at stgov@aap.org or visit www.aap.org/fostercare.

for older youths from 18 to 21 years of age.

3. The AAP supports pediatrician and AAP chapter efforts at the state level to extend health care coverage for youths in foster care from 18 to 26 years of age, in advance of Medicaid coverage becoming mandatory for these youths in 2014.
4. The AAP supports pediatrician and AAP chapter efforts at the state level to improve Medicaid payment to ensure all youth have continuous access to health care in a medical home. In addition to providing appropriate and adequate Medicaid payment, states should consider implementing financial and other incentive programs (eg, expedited payment processing, performance payments, etc) to encourage more pediatricians to provide medical care to children and youth in foster care.
5. The AAP additionally supports federal, state, and local efforts that recognize the health care coverage needs of young adults who have exited foster care and who are engaged in education or training programs.

CLINICAL REPORT

Home Care of Children and Youth With Complex Health Care Needs and Technology Dependencies

abstract

FREE

Children and youth with complex medical issues, especially those with technology dependencies, experience frequent and often lengthy hospitalizations. Hospital discharges for these children can be a complicated process that requires a deliberate, multistep approach. In addition to successful discharges to home, it is essential that pediatric providers develop and implement an interdisciplinary and coordinated plan of care that addresses the child's ongoing health care needs. The goal is to ensure that each child remains healthy, thrives, and obtains optimal medical home and developmental supports that promote ongoing care at home and minimize recurrent hospitalizations. This clinical report presents an approach to discharging the child with complex medical needs with technology dependencies from hospital to home and then continually addressing the needs of the child and family in the home environment. *Pediatrics* 2012;129:996–1005

DME—durable medical equipment
PCP—primary care provider

INTRODUCTION

Enormous advances in neonatal, pediatric, and surgical care have led to the survival of a greater number of children and youth with special health care needs who are cared for at home.[1] The issues faced by these children and their families are often complex and include significant feeding and respiratory problems, often associated with technology dependencies. Many children and youth with special health care needs have intellectual disabilities, physical impairments, and sensory deficits that require specialized therapeutic and educational interventions. The overarching goal of home health care is to optimize each child's health and function while minimizing recurrent or prolonged hospitalizations through the provision of comprehensive, cost-effective, family-centered health care rendered in a nurturing home environment.[2] Caring for children with chronic conditions at home can be challenging to pediatricians but successful and rewarding when provided in the context of a coordinated, family-centered, and complete medical home.

Children and youth with special health care needs are defined as those who "have or are at increased risk of having a chronic physical, developmental, behavioral, or emotional condition and who also require health and related services of a type or amount beyond that required by children generally."[3] More than 10 million children in the United States meet this definition.[4] Diagnoses common to children and youth with special health care needs are numerous and include

preterm birth, congenital genetic and metabolic disorders, neurologic disorders, sequelae of severe infections, or trauma and malignancies. A subset of children with special health care needs has been recently termed "children with medical complexity," as defined by substantial health care needs, 1 or more chronic conditions, functional limitations often associated with technology assistance, and health care use. Technology dependency refers to the use of medical devices without which—if they were to fail or be discontinued—adverse health consequences and hospitalization would likely follow.[5] Examples include mechanical ventilators, intravenous catheters, tracheostomy tubes, enteral feeding devices, colostomy bags, and urinary catheters. The multifaceted medical, developmental, and psychosocial needs of children with such a diverse group of diagnoses typically require the expertise of many pediatric subspecialists and related health care providers in a coordinated system of care.[6]

Most children and youth with medical complexity are discharged to home after birth or hospital admissions for acute exacerbations or conditions because long-term hospitalization of such children is no longer a preferred option in our society.[7] As the acuity of hospitalized children has increased over time, so too has the severity and complexity of the unresolved medical conditions present on discharge.[8] Children are now frequently sent home to complete or continue interventions that formerly would have occurred in hospitals. They are discharged with complex medical interventions, including oxygen, tracheostomies with or without ventilators, enteral feeding tubes, intravenous infusions, dialysis, and complex medication regimens.

Part I of this report offers guidance on the hospital discharge of children and youth with medical complexity issues to home. Part II discusses how to optimally care for children with complex, chronic conditions at home after hospital discharge. The focus of this report is on the medical rather than the financial aspects of pediatric home care and is intended to provide an easily accessible resource for pediatricians. A more detailed resource from the American Academy of Pediatrics (*Guidelines for Pediatric Home Health Care*) is available for those who seek more comprehensive guidance on this subject.[9] Another resource discussing insurance changes helpful to families caring for children with special health care needs is the American Academy of Pediatrics clinical report "Parent-Provider-Community Partnerships: Optimizing Outcomes for Children With Disabilities."[10] This report addressed some of the changes mandated by the Affordable Care Act of 2009, the goal of which was to improve access to home care services for children with special health care needs.

PART I: TRANSITIONING FROM HOSPITAL TO HOME CARE

The primary care provider (PCP) should be intimately involved with discharge planning for children and youth with special health care needs. The 6 main issues to be addressed during this process are outlined in Table 1 and include the following: (1) establishing a partnership with the family and acute care providers to identify family and community resources available to support the transition process and ensure success at home; (2) defining, locating, and engaging a medical home; (3) ensuring adequate training of family and other care providers; (4) assisting in the selection of a home nursing agency and/or providers of supplies and equipment; (5) identifying respite care providers; and (6) opening communication with the school district so that the Individualized Education Plan process for school services can be initiated. Discharge planning should commence in a timely way, preferably as soon as the child is admitted.

Evaluating the Child, Family, Home, and Community

Not every child with medical complexity can be cared for at home. Instead, some children and families opt for out-of-home care, including care in foster homes, extended specialty hospitals (long-term acute care), or pediatric skilled nursing facilities.[11] Although the number and availability of congregate care options have decreased in recent years and may not be geographically feasible in some cases, out-of-home care continues to play an important role for children with severe disabilities who cannot be cared for at home. Each child should be evaluated to ensure that he or she is medically stable for home care. Although there is no clear definition of "stability" given the numerous underlying and complex issues involved, the child should have had no major changes made to the medical regimen for at least several days before discharge and should be tolerating feedings and current medications and have no new fevers or worrisome respiratory problems noted. At the time of hospital discharge, the child's care needs should be stable and predictable.

The needs, preferences, and resources of families of children with disabilities should be evaluated well in advance of hospital discharge.[12] A candid appraisal of the family's desire to provide complex care at home and of their skills, time, and energies is essential. The home should be evaluated to ensure that it is an adequate, safe, and accessible environment. Architectural barriers, including the ability to accommodate equipment such as wheelchairs, lift systems, hospital beds, or medical equipment, must be considered. Local emergency medical services, as well

TABLE 1 Issues Related to Planning for Home Care Before Discharge From the Hospital

A. Evaluating child, child's family, home, and community
  1. Child
    a. Child is medically stable for home care
  2. Family
    a. Family desires to have child at home
    b. Family has learned the necessary skills
    c. Family has the resources (time, energy, and finances) to provide care
    d. Family has considered palliative care and end-of-life care options
  3. Home
    a. The home environment is adequate, safe, and accessible
      (1) Structure
      (2) Electrical (eg, 3-pronged plugs, 220-V line)[a]
      (3) Access (eg, bathroom and ramps)
      (4) Heat, hot water, clean water supply
      (5) Air conditioning
      (6) Driveway/road accessibility
      (7) Other (eg, snow removal)
      (8) Telephone access[b]
  4. Community
    a. Community health nurse
    b. Home care nurses
    c. Therapists (eg, physical and occupational therapy)
    d. Ambulance/emergency medical services
    e. Specialty care
    f. Medical supply vendors
    g. Pharmacist
    h. School/early intervention program
    i. Counseling
    j. Support group(s)
    k. Palliative and hospice care where indicated
B. Finding a medical home
  1. PCP
  2. Roles and communication network
  3. Patient summary
    a. Plan for emergency care
    b. Medications
    c. Equipment
    d. Disposable supplies
    e. Advance care plan, out of hospital do-not-resuscitate order, where appropriate
C. Training the home caregivers
  1. Training schedule
  2. Actual care with supervision (trial home care)
D. Arranging home care nursing and developmental/educational services
  1. Nursing care coverage is outlined
  2. Alternative plans are made if nursing care is not available
  3. Arrangements with school or preschool programs for ongoing educational needs
E. Finding home care agencies for supplies and equipment
F. Insurance coverage
  1. Verify that adequate coverage will be provided
  2. Pursue alternative or additional coverage and benefits such as Medicaid waiver program and SSI
  3. Evaluate ability of family to pay for uncovered care (eg, transportation, electricity)

[a] Secondary power generators may be necessary; local power companies and emergency providers should be alerted on hospital discharge, to help prioritize responsiveness to emergencies.
[b] Arrangements should be made with telephone companies to ensure uninterrupted services. Internet services may also be required, especially for those parents who are hearing impaired and cannot easily communicate via telephone.

as heating and electrical providers, should be alerted to the specialized needs in homes of children with high medical complexity and fragility. Safe, accessible, and predictable means of transporting the child and essential equipment and supplies should be established. The community should be evaluated to ensure that it can provide the resources and support necessary to care for the child at home and support the family.

Finding a Medical Home

It is critical to identify a PCP who accepts the care of the child on hospital discharge and is willing to provide a medical home for the child with medical complexity as well as his or her family. Not every provider is proficient in managing children with complex, chronic conditions or willing to invest the time and energy that this responsibility demands.[13] The PCP should be knowledgeable about the child's conditions and treatments as well as community support services. A detailed and immediately accessible care plan should be developed jointly by the family, the PCP, and other care providers, with continuous updates as indicated. The PCP for children with complex conditions and disabilities who receive home care support should be provided with a comprehensive discharge summary that includes details of all the issues and events of the hospitalization and an accurate list of medications, therapies, equipment, and services that have been arranged before the discharge. The PCP should also know how communication will take place with other subspecialists involved in the child's care and how frequently the child will need visits with other providers and therapists.[14]

Training the Home Caregivers

Before the child's discharge, the caregivers (usually the parents but occasionally the grandparents or other family and friends) will require appropriate training to be able to render care for the child at home. Caregivers should be taught and should demonstrate competency in the care and use of enteral feeding tubes, tracheostomy care, respiratory treatments and supports (eg, nebulizers, ventilators), wound care, intravenous line care, and medication management. Cardiopulmonary resuscitation training is generally advisable. In addition to teaching the home

caregivers how to render care, teaching assessment skills is also essential. For example, it is important to know not only how to suction or change a tracheostomy tube but also when a child needs this intervention. Home caregivers should also have a clear understanding of when and how to call the PCP or specialist, should problems arise. Family preferences should be considered when developing care regimens, including timings for feeding and medication administration. Hospital schedules of administering enteral feedings every 2 hours around the clock indefinitely are generally unsustainable expectations that families are expected to adhere to at home. After a prolonged hospitalization, it is strongly recommended that the parents stay overnight for 1 to 2 days before discharge, allowing them to render all the child's care independently but with the support of hospital staff for questions and problem solving before the discharge.[12] Parents must demonstrate competency in the use of monitors that may be used in the home in preparation of transitioning from hospital to home. Standardized criteria for caregiver competencies and ongoing demonstration of skills are much needed.

Arranging Home Care Nursing and Developmental/Educational Services

Some children and youth with special health care needs have requirements that are so time-consuming and complex that parents alone cannot meet those needs without home nursing support.[12] Children who require intensive respiratory supports, such as those with tracheostomy and ventilator dependencies associated with high suctioning requirements, are likely to require private duty home nursing rather than brief and periodic skilled nursing visits. A nationwide shortage of qualified pediatric registered nurses and licensed practical nurses often complicates and delays discharge, as does ensuring coverage by insurance for such support.[15] The unique needs of children with complex, chronic conditions and their families who reside in rural areas with limited nursing and community resources should be anticipated and addressed. Parents should be actively involved in determining the child's care plan to ensure that the plan is feasible from their perspective in the context of their community. For example, parents who must work outside the home often elect to have home nursing during the day, whereas other families elect to have nighttime nursing so that they can sleep. However, some nursing agencies will not allow the nurse to be the only adult in the home and require that a family caregiver be present as well. In some limited areas, providers specially trained in the care of children with medical complexity may offer an additional care option for parents who are employed outside the home or who are full-time students themselves. Families and providers should have well-established contingency plans that are responsive to unanticipated interruptions in caregiving (family or home nursing care).

Children from birth to 3 years of age should be referred to local early intervention programs for developmental services.[16] Children with sensory deficits may require specialized referrals to programs that address visual and/or hearing impairments. Frequent and consistent communication between PCPs and early intervention providers is essential to optimize each child's medical, developmental, and functional outcomes. For school-aged children, it is often important to meet with the school, including the school nurse, to plan for appropriate educational, therapeutic, and medical services before discharge from the hospital.[17] For children requiring care for their tracheostomy or enteral feedings in school, training of the school personnel by hospital personnel should be considered before patient discharge.

Arranging Providers for Supplies and Durable Medical Equipment

Many large pediatric centers now have care coordinators/discharge planners (usually registered nurses) who arrange for home equipment such as oxygen, respiratory technologies, enteral feeding supplies, intravenous medications, specialized enemas, urinary catheters, and other durable medical equipment (DME) before discharge. The prescription of DME that supports safe and effective mobility, such as specialized beds, bath seats, lift systems, and adapted car seats, should also be completed collaboratively with interdisciplinary providers before hospital discharge.[18] The child's insurance coverage usually dictates which DME providers may be accessed, further influenced by geographic considerations. Early and meticulous discharge planning is essential to ensure that the appropriate supplies are ordered and delivered in a timely way so that they can be readily available for training of caregivers and use on discharge.

Insurance Coverage for Care at Home

At times, third-party payers fail to cover the costs of specialized pediatric private duty home care, leading to delayed or even canceled hospital discharges for children with complex, chronic conditions and technology dependencies.[19] Lack of coverage for home nursing or extended therapeutic services are not uncommon. Families may seek secondary insurance coverage through Medicaid to cover costs denied by primary commercial payers. Families often face financial hardship related to extensive medical bills from lengthy hospitalizations as well as lost revenue related to the need to reduce

employment outside of the home.[20] Some children with disabilities are eligible for Supplemental Security Income benefits, which may help meet the financial demands.[21] The financial implications of caring for children with special health care needs is further discussed in the American Academy of Pediatrics clinical report on parent-provider-community partnerships.[10]

PART II: CARING FOR CHILDREN AND YOUTH WITH MEDICAL COMPLEXITY AT HOME

As complicated as sending a child home from the hospital may be, sustaining the child and family at home can be an even greater challenge. The most common reasons for failure of home care are the lack of community and family resources, lack of financial resources, and emotional depletion of the family.[22] For simplicity, an approach to caring for children with complex, chronic conditions at home can be divided into 7 main areas: (1) defining the basic medical issues; (2) defining the developmental issues; (3) understanding the underlying diagnoses; (4) the role of the PCP and the medical home; (5) the needs of the family; (6) the ongoing home care agencies and services required; and (7) assessment of the community and educational services.

Defining the Basic Medical Issues

Nutrition is 1 of the most basic medical needs of every child. Many children with disabilities are unable to meet their nutritional requirements orally and rely on enteral or parenteral supports. At every visit, it is important to assess each child's growth by using readily available standardized growth curves.[23] It is important to consider the route of feeding as well as its safety and efficacy. For example, does the child who eats orally cough, choke, or demonstrate respiratory distress during or after meals? If so, obtaining a specialized feeding and swallowing evaluation, including videofluoroscopic studies, may be indicated. Alternatives to oral intake include feeding via gastrostomy tube (ie, g-tube), nasogastric tube, nasojejunal or jejunal tubes, or via intravenous catheter, such as total parenteral nutrition. Feedings via gastrostomy tube may be given as boluses or continuous infusions by using feeding pumps. Jejunal tube feedings must be administered continuously because bolus feedings are associated with abdominal pain, diarrhea, and dumping syndrome. Some children require specialized formulas, such as elemental or higher-calorie formulas, or supplements to increase the caloric or nutritional density of the diet. Because enteral feedings and delivery systems are medically necessary, they are generally covered by third-party payers.[24] A balanced intake of fiber and fluid is recommended for optimal bowel motility and evacuations. The need for consultations with dietitians and gastroenterologists should be determined by the child's feeding tolerance, nutritional status, and related concerns (eg, gastroesophageal reflux disease, dysmotility, constipation).

Respiratory issues can be frequent and often life-limiting challenges for children and youth with special health care needs.[25] Chronic lung disease may follow preterm delivery or result from chronic aspiration of feedings and secretions in children with neurologic disabilities. Children with neuromuscular conditions, such as muscular dystrophy, may need ventilator assistance (via continuous positive airway pressure, bilevel positive airway pressure, and tracheostomies with ventilators). Oxygen supplementation is frequently indicated for children with neurologic impairments as well as for those with complex congenital heart disease. Airway issues related to severe chronic airway obstruction in children with craniofacial anomalies or severe neuromuscular disorders may necessitate placement of a tracheostomy, often with continuous or intermittent ventilator support. Children may frequently require bronchodilators or long-term inhaled or systemic steroids, which can compromise growth and bone density. Other interventions such as regular pulmonary toilet, often with high-frequency chest wall oscillation (eg, the Vest Airway Clearance System [Hill-Rom, Minneapolis, MN] or Smartvest [Electromed Inc, New Prague, MN]) or mechanical insufflator-exsufflator (eg, CoughAssist [Phillips Respironics, Pittsburgh, PA]) devices, may be necessary. Typically, children with moderate to severe respiratory impairments benefit from ongoing input from pediatric pulmonologists. Preventive care should be a priority, including the provision of pneumococcal and annual influenza vaccines for at-risk children and their families.

Children with special health care needs receive 5 times the number of medications than do typical children.[26] These may include protein pump inhibitors for gastroesophageal reflux disease; prokinetic agents for dysmotility and remedies for chronic constipation; and bronchodilators, antiepileptics, spasmolytics, and behavioral medications such as stimulant, antipsychotic, or anxiolytic agents. All medications have the potential for adverse effects, and the use of multiple medications increases the risk of drug–drug interactions.[27] Maintaining current medication lists for the caregivers with clear dosing regimens is essential, and updated lists must be maintained in the medical home. This action facilitates timely refills, reduces risks of medication errors, and allows health care providers to regularly monitor for and address potential drug interactions. This is a critical role of the PCP in the care of children with complex conditions.

Complications of immobility can lead to secondary conditions in children

who are on bed rest or have decreased mobility.[28] Pediatricians and home care providers need to vigilantly avoid and otherwise identify and address early threats to skin integrity, such as decubitus ulcers[29] over pressure points, particularly the posterior occiput, sacrum, ischium, and heels. Immobility and lack of weight bearing also contributes to osteoporosis and increases the risk of pathologic fractures.[30] Musculoskeletal contractures and deformities can progress quickly; range-of-motion exercises should be routinely implemented in children who are nonambulatory, which may require input from the pediatric physical medicine specialist. Elimination disorders can be managed with careful attention to regular bowel and bladder emptying, facilitated with regular bowel programs, enemas, bladder irrigations, and intermittent catheterization as needed. Regulation of sleep-wake cycles is another strategy to minimize secondary conditions. Children may benefit from early intervention services and home occupational and physical therapy for the establishment of exercise regimens and to ensure that appropriate equipment is available to optimize mobility and minimize complications (eg, hospital beds, commodes, wheelchairs).

Pain in children with complex, chronic conditions may be caused by orthopedic, gastrointestinal, or neurologic issues. Their irritability and discomfort can be distressing to families and home care providers. It may be challenging to determine whether there is an underlying medical issue causing pain that requires intervention, particularly in a child with limited communication abilities.[31] Validated and reliable measures can be useful in assessing pain in children with cognitive impairments, such as the FLACC (Face, Legs, Activity, Cry and Consolability) Scale and the Pediatric Pain Profile (http://www.ppprofile.org.uk). Medical home providers may be called on to evaluate the child to rule out simple problems, such as otitis media, which may be easily treatable. Less obvious problems, such as urinary tract infections, dental abscesses, or pathologic fractures, may be contributing to discomfort and should be identified and treated. Consultations with palliative care providers might further benefit children with chronic pain and the families who care for them.[32]

Defining Developmental Issues

Many children with special health care needs have intellectual and physical disabilities that affect their overall health and development. If developmental disabilities are suspected on the basis of history, underlying diagnosis, or developmental screening results, it is critical to ensure that children receive appropriate educational and related services through an early intervention or adapted preschool program, often in collaboration with medically based habilitative therapies. Referrals for individualized habilitative services often require prescriptions from PCPs, particularly when coverage is requested for medically based (as opposed to educationally based) therapeutic services, and pediatricians may need to advocate for these services.[17] Lastly, barriers to development, such as impairments of vision and hearing, should be identified and managed promptly to maximize outcomes.

Understanding the Underlying Etiology of the Child's Conditions

Children and youth with special health care needs should be discharged from the hospital to home with a plan of care that clearly addresses the acute medical issues, any temporary or long-term changes to the chronic condition care plan, and family adaptation and training.[33] In addition, ongoing attention to the underlying chronic issues should not be overlooked. For some children, home care may be defined by a course of antibiotics and wound care, with discharge on resolution of the primary concern. For other children, an episode of acute pneumonia will resolve, but long-term respiratory failure and ventilator dependency will persist and require ventilation titration. Children with dependency on medical devices (including pacemakers, ventriculoperitoneal shunts, intravascular catheters, colostomies, and other devices) warrant close monitoring for device-related complications.

There are multiple etiologies of chronic pediatric conditions associated with special health care needs and disabilities. Sometimes, the underlying diagnosis is straightforward, and the child's needs are well understood. However, some children are discharged to home without a clearly established diagnosis, and the medical workup may still be in progress at discharge. Differentiating among time-limited acute conditions, chronic but stable conditions, and progressive and life-limiting conditions in children receiving home care ensures that the care rendered is appropriate to the needs of each individual.[33]

The Role of the Medical Home

Although pediatricians cannot be experts in every chronic condition of childhood, it is important that they update their knowledge regarding the individual children and youth with special health care needs in their practices. By reviewing the literature and consulting with specialists, pediatricians can quickly gain the needed expertise to manage and coordinate care, whether it is with interdisciplinary spina bifida or craniofacial teams or with individual specialists. Depending on the unique medical needs or community resources of a child, medical home providers may be either PCPs or pediatric subspecialists. An awareness of the recommended

frequency of follow-up visits with consultants further facilitates care coordination. Pediatric residency programs may need to reassess the training experiences for their residents so that future pediatricians have the needed expertise and comfort in providing medical homes for all children, including those with chronic conditions, disabilities, and complex home care needs. Medical homes should ensure coordination of care associated with technology dependencies among families of children and youth with special health care needs, home care providers, and community systems, including emergency medical services and utility companies.[34] Arrangements for uninterrupted power in homes of children with technology dependencies may include the provision of generators and prioritization by utility companies for immediate restoration of services in the event of disruptions.

The medical home office visit for children and youth with special health care needs, particularly with technology dependencies, needs to be carefully orchestrated, in terms of the frequency, duration, and content of visits. It can be useful to provide separate chronic condition management visits and well-child visits or schedule longer-than-routine visits, because acute issues too often crowd out much-needed time for routine pediatric care. A large examination room that accommodates the child, family, and caregiver (s) as well as wheelchairs and ventilators, as needed, should be available. Providers need to consider their own access to dietitians, care managers, social workers, and other support staff members who contribute substantially to the care of children and youth with special health care needs. A systematic method of communication among all providers should be established so that critical information is available during office visits. Electronic health records are increasingly used for this purpose. A detailed problem list and care plan, including the names and contact information for consulting specialists, should be regularly updated in the medical record. The medical home should also maintain a record of medications and refills, the preferred pharmacy, home care orders, referrals, and letters of medical necessity.[5] Home visits by pediatricians can offer a safe and efficient alternative to traditional office visits.

Each individual medical home needs to address payment for direct and indirect services rendered. A major disincentive in the current system of care is the lack of physician compensation for time invested in phone management, care coordination, completion of home care orders and recertifications, management of medication refills, and letters of medical necessity, although some insurance companies are starting to cover care coordination.[35] Children with chronic conditions and disabilities may be insured by Medicaid rather than by private insurance companies, and the effect of this policy on individual practices needs to be considered.

The Needs of the Family

Family-centered care is a critical component of the medical home for children and youth with special health care needs. Providers should periodically assess family caregiver skill and comfort in rendering care, particularly when technology dependencies are present, and offer opportunities to refresh or extend skills to grandparents and other close relatives or caregivers. The primary coordinator of care should be explicitly identified and may often be a parent. Providers should have regular conversations with the families regarding met and unmet home care staffing, equipment, and transportation needs.

The needs of parents in their roles as long-term caregivers as well as the unique needs of siblings of children with complex, chronic conditions and disabilities should be recognized, with appropriate referrals to community agencies (eg, Supplemental Security Income, Family Voices, disease-specific organizations, adapted sports and recreational programs). Families and providers should partner in care planning and proactive discussions regarding their child's prognosis, including explicit statement of family preferences regarding resuscitation status and end-of-life care. Referrals to palliative or hospice care providers and wish-granting organizations may be arranged according to family preferences. Formal and informal opportunities for respite care should be identified and accessed whenever possible.

The presence of a child with complex medical and developmental needs associated with technology dependencies and long-term home care most certainly affects the physical and emotional health and well-being of the parents, siblings, and other family members.[22,36] Siblings of children with disabilities may demonstrate behavioral problems or academic failures, as they often assume caregiving responsibilities and may have unmet needs for parental attention and support.[37] Family vacations may be canceled or postponed, parental attendance at important school or sports events may not occur, and sometimes even serious medical symptoms in the well sibling may go unattended. Siblings may sometimes be called on to assume caregiving roles for which they have not been appropriately trained or are not developmentally prepared. Pediatricians can assist these children and their families by being cognizant of these issues, seeing the well siblings for separate appointments where they can receive individualized attention, and sometimes meeting privately with the siblings to allow them to express their feelings. Because children

with disabilities are at increased risk of abuse and neglect, pediatricians should also be particularly attentive to child–family interactions and sensitive to early indications of maltreatment. In some instances, family support services and counseling are indicated.[38]

Ongoing Home Health Care Needs

Some children and youth with special health care needs have chronic conditions associated with complete and irreversible dependence on technology. As a consequence, they may require lifelong private duty nursing care. The provision of uninterrupted home care is threatened by national nursing shortages, limitations in the availability of skilled pediatric nurses in rural areas, and lack of funding.[19] Pediatric equipment is not universally available. Physicians need to provide frequent updates on orders, with an associated flurry of paperwork. Thus, home care services must be carefully monitored and maintained to ensure that the requirements of the children and youth with special health care needs and their families are safely and effectively met without interruption. Transitioning from pediatric to adult care providers also requires careful planning.

Community and Educational Services

Most children and youth with special health care needs are cared for by their families, with support from their medical homes, pediatric subspecialists, and communities. Community services should not be underestimated, as they offer developmental programs (eg, early intervention programs),[16] educational services,[39] and recreational opportunities.[10,40] Individualized education plans should include the provision of the nursing care (eg, enteral feedings, airway suctioning, medication administration) necessary during school hours so that each child can participate fully in school programs. Programs of adapted sports and recreation, specialized vacation camps, and community-based religious or cultural services offer additional opportunities for child and family participation in their communities. Table 2 lists issues that are important to monitor for children who are receiving home care.

CONCLUSIONS

Children with complex medical and developmental issues comprise a significant percentage of hospitalized pediatric patients and are being discharged to home with an ever-expanding range of complex medical and technology dependencies. Medical homes for children with complex home care needs must coordinate a team of providers toward the overarching goal of optimizing each child's health, development, and well-being. Pediatricians must understand the complexities of the child's underlying conditions, including ongoing medical needs, prognosis and end-of-life care, family needs, and available community resources. Medical homes may need to adapt routine practices and individualize their approaches to best orchestrate the multifaceted needs of children and youth with special health care needs, their parents and families, and health care systems. A systematic approach[10] to pediatric care with explicit care coordination, family-centered care, and advanced planning ensures the best outcomes and most rewarding experiences for children and youth with special health care needs, their families, and providers.

POLICY STATEMENT

HPV Vaccine Recommendations

abstract

FREE

On October 25, 2011, the Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention recommended that the quadrivalent human papillomavirus vaccine (Gardasil; Merck & Co, Inc, Whitehouse Station, NJ) be used routinely in males. The American Academy of Pediatrics has reviewed updated data provided by the Advisory Committee on Immunization Practices on vaccine efficacy, safety, and cost-effectiveness as well as programmatic considerations and supports this recommendation. This revised statement updates recommendations for human papillomavirus immunization of both males and females. *Pediatrics* 2012;129:602–605

INTRODUCTION

The American Academy of Pediatrics (AAP) recommends immunization against human papillomavirus (HPV) for all 11- through 12-year-old children as part of the adolescent immunization platform. Quadrivalent HPV vaccine (HPV4; Gardasil; Merck & Co, Inc, Whitehouse Station, NJ) is the only vaccine approved for males, and either HPV4 or bivalent HPV vaccine (HPV2; Cervarix; GlaxoSmithKline, Middlesex, UK) may be used in females. This brief policy statement supersedes the previous AAP "permissive recommendation" for use of HPV4 in males[1] and the retired 2007 policy statement.[2] A complete rationale is available in the statement from the Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention.[3]

BRIEF BACKGROUND AND RATIONALE

HPVs are the most common sexually transmitted viruses in the United States. The highest prevalence of HPV infection is found in sexually active adolescents and young adults. Most HPV infections are asymptomatic and resolve without complications within 2 years. However, persistent infection with high-risk HPV types is responsible for most cervical and anal cancers in females. In males, high-risk HPV types are responsible for a large proportion of cancers of the mouth and pharynx, which are increasing in recent years, and of anal and penile cancers. Each year in the United States, approximately 15 000 cases of cancer in females and 7000 cases of cancer in males are caused by HPV types 16 and 18. Of the cancers in males, the great majority are cancers of the oropharynx (approximately 5400), followed by anal cancer (approximately 1400) and penile cancer (approximately 300).

The rationale for routine HPV immunization at 11 through 12 years of age is twofold. First, optimal vaccine efficacy is derived if the vaccine is

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

administered before onset of sexual activity. The vaccine is inactive against HPV types previously acquired by the vaccine recipient. Second, antibody responses are highest at ages 9 through 15 years. Immunization of males provides direct benefit to males, including prevention of genital warts and anal cancer. Prevention of oropharyngeal cancer has not been studied but is biologically plausible. In addition, immunization of males is expected to provide indirect benefit for females through herd immunity. Four years after the initial recommendation for immunization of females, uptake of the HPV vaccine lags behind other vaccines offered in adolescence; results of the 2010 National Immunization Survey indicated 32% of females 13 through 17 years have completed the 3-dose series. The cost-effectiveness of male immunization is sensitive to a range of assumptions, such as vaccine efficacy, vaccine coverage of females, and the effect of HPV-associated diseases on quality of life. Recognizing low vaccine uptake among females and the preponderance of heterosexual transmission in the epidemiology of HPV, immunization of males becomes a cost-effective intervention for preventing disease caused by vaccine types of HPV in both genders.

Other interventions to reduce HPV infection and HPV-associated genital warts and malignancies include counseling of adolescents regarding sexuality, including abstinence and proper use of condoms, and circumcision of males. HPV is transmitted skin to skin, so protection by condoms is imperfect.[4–6]

As a sidebar, there is precedent for vaccines recommended by the AAP and the Advisory Committee on Immunization Practices for prevention of sexually transmitted infections and cancer and for immunization of all children to minimize infectious complications disproportionately affecting females during their reproductive years. Rubella vaccine (a component of the measles-mumps-rubella vaccine) is intended primarily to prevent fetal miscarriages and malformations after rubella infection during pregnancy, and hepatitis B virus vaccine prevents cirrhosis of the liver and hepatocellular carcinoma caused by hepatitis B virus acquired at time of birth or through later sexual exposure.

HPV VACCINES

HPV4 contains no viral DNA and is not infectious. It consists of bioengineered viruslike particles produced from the major capsid protein of HPV types 16 and 18, which are responsible for 70% of cases of cervical, 87% of anal, 60% of oropharyngeal, and 31% of penile cancers. In addition, the vaccine includes capsid proteins of types 6 and 11, which are responsible for 90% of genital warts and almost all cases of juvenile recurrent respiratory papillomatosis. Clinical trials have revealed the vaccine to be highly immunogenic, safe, and well tolerated in males and females 9 through 26 years of age. Antibody responses are at least twice as high in individuals of both genders 9 through 15 years of age as in those 16 through 26 years of age. HPV4 was licensed for use in females in 2006; antibodies have been shown to persist for at least 9 years. HPV4 was licensed for use in males in 2009; the duration of vaccine-induced antibodies is still under investigation but is known to be at least 5 years.

In sexually active female subjects 16 through 26 years of age, protection has been demonstrated against persistent infection; precancerous lesions of the cervix, vulva, and vagina; and genital warts caused by HPV types contained in the vaccine. The vaccine was recommended for females in 2007. In sexually active male subjects 16 through 26 years of age, vaccine efficacy was demonstrated against genital warts caused by vaccine types. HPV4 was permitted in males in 2010. Also in 2010, the US Food and Drug Administration added a new indication of prevention of anal cancer in males and females on the basis of data from an efficacy study in males. In new data from a substudy of high-risk sexually active young men (men who have sex with men), protection has been demonstrated against precancerous lesions of the anus. These data contribute to the current recommendation. The study did not have adequate power (too few penile or perineal precancerous lesions) to support benefit in preventing these precancerous conditions. No studies of HPV4 vaccine protection against oropharyngeal cancers or recurrent respiratory papillomatosis have been conducted.

HPV2, directed at HPV types 16 and 18, was licensed for use in females in 2009. This vaccine is highly immunogenic, safe, and well tolerated in females 9 through 26 years of age. Antibody responses are highest in girls 9 through 15 years of age. HPV2 is not licensed for use in males.

The safety of HPV4 was evaluated in 2 large phase III clinical trials in females, 1 phase III clinical trial in males, and several immunogenicity studies in adolescents. There is continued surveillance of potential adverse effects of HPV vaccine through the Vaccine Adverse Effect Reporting System as well as real-time surveillance of large health maintenance organization practices via the Vaccine Safety Datalink. Several other countries or communities conduct similar surveillance for adverse effects of HPV vaccines. The Food and Drug Administration requires postmarketing surveillance by vaccine manufacturers. After more than 40 million doses have been administered in the first 5 years of routine

administration in American girls, no discernible, vaccine-specific adverse effect, with the exception of rare anaphylaxis to vaccine components, has been detected.

RECOMMENDATIONS

1. Girls 11 through 12 years of age should be immunized routinely with 3 doses of HPV4 or HPV2, administered intramuscularly at 0, 1 to 2, and 6 months. The vaccines can be administered starting at 9 years of age at the discretion of the physician.
2. All girls and women 13 through 26 years of age who have not been immunized previously or have not completed the full vaccine series should complete the series.
3. Boys 11 through 12 years of age should be immunized routinely with 3 doses of HPV4, administered intramuscularly at 0, 1 to 2, and 6 months. The vaccine can be given starting at 9 years of age at the discretion of the physician.
4. All boys and men 13 through 21 years of age who have not been immunized previously or have not completed the full vaccine series should receive HPV4 vaccine.
5. Men 22 through 26 years of age who have not been immunized previously or have not completed the full vaccine series may receive HPV4 vaccine. Cost-efficacy models do not justify a stronger recommendation in this age group.
6. Special effort should be given to immunizing men who have sex with men up to 26 years of age who have not been immunized previously or have not completed the full vaccine series.
7. Previous sexual activity is not a contraindication to HPV immunization or completion of the immunization series. Patients infected with 1 HPV type may still benefit from protection against remaining HPV types in the vaccine. Testing for previous exposure to HPV is not recommended. HPV vaccine can be administered when a female patient has an abnormal or equivocal Papanicolaou test result. There is no known therapeutic (as opposed to prophylactic) benefit from the HPV vaccines.
8. HIV-infected people of either gender, 9 through 26 years of age, who have not been immunized previously or have not completed the full vaccine series should receive or complete their series with HPV4.
9. HPV vaccines can be administered at the same visit as all other recommended vaccines.
10. HPV vaccine can be administered in these special circumstances:
    a. when a patient is immunocompromised because of disease or medication
    b. when a female patient is breastfeeding
11. HPV vaccine is not recommended during pregnancy. The practitioner should inquire about pregnancy in sexually active female patients, but a pregnancy test is not required before starting the immunization series. If a vaccine recipient becomes pregnant, subsequent doses should be postponed until completion of the pregnancy. It is recommended that women who become pregnant while receiving HPV vaccine be reported to registries that have been developed to record data on outcomes (HPV2: 1-888-452-9622; HPV4: 1-800-986-8999).
12. Because HPV vaccine will not prevent infection attributable to all high-risk HPV types, cervical cancer screening recommendations (ie, Papanicolaou testing) should continue to be conducted in women who have received HPV vaccine.
13. Administration of HPV vaccine does not change current counseling recommendations for use of barrier methods for the prevention of HPV and other sexually transmitted infections as well as discussion about healthy choices about sexual activity, including condoms and abstinence.
14. HPV immunization of children 9 years of age and older should be covered by all public and private health insurers.

CONTRAINDICATIONS

HPV4 should not be given to people with a history of immediate hypersensitivity to yeast or to pregnant women.

PRECAUTIONS

Immunizations should be deferred for people with moderate or severe acute illness. Because syncope can occur in adolescents after injections and has been reported after HPV vaccine, vaccine recipients should sit or lie down for 15 minutes after administration.

IMPLEMENTATION

These updated recommendations for HPV immunization will have considerable operational and fiscal effect on pediatric practice. Therefore, the AAP has developed implementation guidance on supply, payment, coding, and liability issues; these documents can be found at www.aapredbook.org/implementation.

POLICY STATEMENT

Human Embryonic Stem Cell (hESC) and Human Embryo Research

abstract

FREE

Human embryonic stem cell research has emerged as an important platform for the understanding and treatment of pediatric diseases. From its inception, however, it has raised ethical concerns based not on the use of stem cells themselves but on objections to the source of the cells—specifically, the destruction of preimplantation human embryos. Despite differences in public opinion on this issue, a large majority of the public supports continued research using embryonic stem cells. Given the possible substantial benefit of stem cell research on child health and development, the American Academy of Pediatrics believes that funding and oversight for human embryo and embryonic stem cell research should continue. *Pediatrics* 2012;130:972–977

INTRODUCTION

In the past 10 years, significant progress has been made in basic and translational research using human embryonic stem cells (hESCs), with specific implications for pediatric diseases such as hypoxic-ischemic encephalopathy,[1] bone marrow failure syndromes,[2] leukemia,[3] and congenital heart disease.[4] Although the fundamental principle of stem cell research remains the same (ie, the development of undifferentiated cells into committed cell lineages for the purpose of tissue renewal and repair), the science has evolved to encompass many new applications, including cell-based therapies[5] and drug screening.[6,7] Although these new applications are intriguing, they remain in the early stages of development, and additional research is needed to make the transition from bench to therapeutics. It is anticipated that continued advances will have a substantial impact on the understanding and treatment of pediatric diseases.

hESCS

Three unique properties of hESCs are as follows: (1) they are unspecialized or undifferentiated; (2) they can differentiate into more specialized cell types, such as brain, bone marrow, or heart, depending on the developmental signals they receive (referred to as pluripotency); and (3) they can continue to divide and renew themselves for longer periods than differentiated cells.[8]

Current sources of hESCs include excess embryos that would have been discarded after a successful in vitro fertilization (IVF) process, from previously frozen embryos created as part of an earlier IVF

process, and from de novo synthesis. In addition, hESCs may be generated from embryos with arrested[9] or otherwise abnormal growth that would render them unsuitable for implantation. In these cases, the removal of the cells to form the stem cell line results in the destruction of the embryo. There is some recent evidence that hESC lines can be generated from 1 to 2 cells obtained by a biopsy procedure that does not require destruction of the embryo, but this procedure has not obviated the need to continue to derive stem cells in the traditional manner, which results in the destruction of an embryo.[10] Traditionally created embryonic stem cell lines are needed to serve as a comparison with the newly developed lines to establish whether they are indeed equivalent to traditionally developed lines. Moreover, although a single cell biopsy may be performed in IVF cases to test for genetic diseases, it is unclear whether it would be appropriate to transfer to a uterus an embryo that underwent such biopsy for the creation of stem cell lines. It is not known whether the biopsy makes the embryo less likely to implant. Women undergoing IVF typically choose to transfer to their uterus embryos with the highest likelihood of implantation and, eventually, healthy birth. If embryos that have undergone a biopsy for purposes unrelated to health are not going to be chosen for implantation and will be eventually discarded, then the single biopsy procedure does not result in "sparing" embryos (although it may result in a delay in destruction). Research is ongoing to identify novel and more efficient methods of obtaining stem cells from human embryos, and it is anticipated that this area will continue to evolve.

Once small numbers of embryonic stem cells have been isolated from human embryos, they are cultured in the laboratory to generate an ongoing source of cells, referred to as a cell line. Because of the unique self-renewing capacity of stem cells, the lines can often be maintained indefinitely. Because of constraints on the use of federal funds for research that results in the destruction of a human embryo, federal research grants involving hESCs entail the experimental manipulation of existing hESC lines and do not directly fund the acquisition of stem cells from the embryo. To maximize collaboration and access to hESC lines available nationally and internationally, the National Institutes of Health Office of Extramural Research maintains a publicly accessible registry that investigators may access to apply for funds pertaining to a particular cell line. State and private funding of stem cell research may not be similarly constrained.

ADULT STEM CELLS AND INDUCIBLE PLURIPOTENT STEM CELLS

In an attempt to find alternative sources for stem cells, several additional methods have been developed over the past 15 years. These include the isolation and genetic reprogramming of specific adult cells (usually skin fibroblasts) into inducible pluripotent stem cells (iPSCs). The development of these methods has not replaced the use of hESCs but has offered additional insight into the biology of cell differentiation, dedifferentiation, and aging in new biological models.

Most mature tissues have small populations of stem cells that facilitate continued tissue growth and repair. These were first recognized in bone marrow, and advances in their isolation and expansion have revolutionized the treatment of hematologic and other malignancies. Bone marrow transplantation with hematopoietic stem cells is now the standard of care for pediatric high-risk leukemia as well as for certain solid tumors, immune deficiencies, and metabolic disorders. Stem cells have also been identified in the brain, cardiac muscle, connective tissue, and bone. Most evidence suggests that these cells are not pluripotent, as are hESCs, but could be induced to accelerate their repair mechanism in cell-based regenerative therapy, such as the use of native neural stem cells to repair spinal cord injury.[11,12] Traditionally, this technology has been limited by the fact that adult stem cells are more differentiated, are harder to isolate from tissue, exist in relatively small numbers, and are more difficult to maintain in long-term culture when compared with hESCs.

The generation of iPSCs from adult cells represents a major advancement in the understanding of the molecular mechanisms of cell differentiation. In 2007, iPSCs were successfully generated from human fibroblasts by engineering them to express genes implicated in dedifferentiation and the maintenance of "stemness."[13] These cells were capable of differentiating into all 3 embryonic germ layers (endoderm, mesoderm, and ectoderm). It is anticipated that, as the technology evolves, iPSCs will have important implications for pediatric diseases, including the study of tumor differentiation,[14,15] hematopoiesis,[16,17] neurodegenerative disorders,[18] and damaged tissue regeneration.[19,20]

Opponents of funding for hESC research believe that advances in the use of iPSCs obviate the need for cells derived directly from the human embryo. Although the use of iPSCs appears to hold great promise, there is evidence that, when compared with embryonic cells, iPSCs tend to retain their "molecular identity" and may, therefore, be less stable and efficient

when programmed to develop into a particular cell line.[21] Their cellular growth parameters may also be altered and have an increased susceptibility to unregulated growth similar to a neoplastic process, raising cancer concerns. In addition, some iPSCs may be susceptible to silencing of genes required for fetal development and differentiation.[22] This concept of lineage bias will continue to be an active area of research requiring ongoing comparison of the pluripotency of iPSCs and hESCs. For example, the gene involved in fragile X syndrome, the most common inherited form of mental retardation in children, produces a protein vital to normal brain development in normal patients but acquires a silencing mutation in those with the disease. Researchers have shown that this gene functions normally in human embryonic cells and becomes silenced as the cells differentiate. In iPSCs, however, the gene is already silenced before the cells begin to differentiate.[23] The use of iPSCs in human trials is problematic, given the high level of manipulation of these cells and the resulting concerns about how they will function in vivo. Whether iPSCs will prove a useful substitute for hESCs has yet to be determined. At this time, comparative studies using iPSCs will require an ongoing source of hESCs, which are still considered the scientific gold standard for embryonic cell lines.[24]

hESC RESEARCH AND PEDIATRIC DISEASE

The American Academy of Pediatrics supports hESC research because current research reveals it may positively affect the treatment of pediatric diseases. In the past decade, several promising advances have been made with specific applications in pediatrics. hESCs have been programmed to differentiate into type II alveolar lung cells[25] capable of producing surfactant, optimizing gas exchange, and protecting against pathogen invasion. Continued developments in this area could enhance the treatment of neonatal lung disease, a leading cause of morbidity and mortality in preterm infants. Insulin-secreting populations of pancreatic islet cells have been developed.[26] Additional research is needed to stimulate these cells to produce enough insulin to be physiologically functional. If achieved, this could serve as a powerful therapy for children facing lifelong insulin replacement and morbidity associated with type I diabetes mellitus. A new technique for culturing hESCs has allowed for their differentiation into skin cells that expand rapidly and may serve as a replacement for autologous skin grafts[27] and their long-term cosmetic sequelae. A direct comparison of the tumor-killing capacity of natural killer cells derived from hESCs versus umbilical cord blood stem cells found hESCs to be more efficient at killing leukemias and solid tumors as well as protecting against metastasis and recurrence in an in vivo model.[28] Further work in this area will be particularly beneficial to children, in whom the late effects of cancer chemotherapy have been of increasing concern.

ETHICAL ISSUES

There are few ethical concerns raised about the use of isolated hESCs. Rather, concerns focus on the sources of the cells and, particularly, on the need to destroy a human embryo to derive the cell lines.[29] If the destruction of a human embryo is a morally wrong act, then the use of stem cells derived from the destruction of the embryo may also be morally problematic. Some people who object to the destruction of embryos do not similarly object to the use of stem cells derived from those embryos but see the 2 acts as separate. People who do object argue that the use of such stem cells is morally complicit.[30] In some ways, this concern may be time-limited (eventually, an alternative mechanism for deriving cell lines that does not result in the destruction of an embryo may be discovered). But, as pointed out earlier, even as new mechanisms are developed, traditionally derived stem cells must be used to set the standard against which to compare the newly derived lines.[24]

The moral status* of preimplantation ex utero human embryos may never be truly settled, and debates about the ethics of stem cell research are ongoing. Despite differences in public opinion on this issue, a majority of the public supports continued research using embryonic stem cells.[31] Those people who disagree may argue that preimplantation ex utero human embryos should be accorded equal moral status to fully developed humans, but others counter that they have lesser moral status. Those in the latter category may argue that preimplantation ex utero embryos have no moral status (because they lack relevant characteristics, such as sentience or ability to feel pain), or instead they may attempt to place embryos along a moral status hierarchy with other biologically alive entities, such as nonhuman animals. Even those who believe these embryos have little or no moral status may still believe they should be treated with respect or that there are certain limits to what may be done with a human embryo. Alternatively, those who believe that the preimplantation

*Moral status refers to the determination that an entity "counts" or that its interests must be taken into account, from a moral (as opposed to legal) point of view. Not all entities with moral status will have legal status (eg, nonhuman animals). Not all entities with legal status will have moral status (eg, corporations).

ex utero embryo has some moral status may determine that the interests of those who could benefit from future developed treatments weigh in favor of their use. In particular, they may find benefit in the use of embryos that are already destined for disposal. For the purposes of this policy statement, it is important to recognize that the moral status of preimplantation ex utero embryos is a point of debate and that any policy or regulatory oversight system should be sensitive to differing moral positions.

The American Academy of Pediatrics recognizes the ethical considerations inherent in hESC research but also recognizes the potential benefit to children of future discoveries, particularly children for whom successful treatment of their diseases is currently limited. At this time, research with hESCs offers a promising line of inquiry for many of these diseases. Because of the continued ethical debates in this context, a regulatory oversight framework should strive to find as much common ground as possible, although widespread agreement on all issues may be impossible. In a pluralistic society, minority views should be respected but should not necessarily determine policy. The development of stem cell lines through the destruction of preimplantation ex utero embryos and research on stem cell lines should be permitted. Public funding for such work should also be permitted. Although some may argue that their taxes should not be used to fund research to which they object, this is no different than the use of taxes to support other activities some taxpayers object to, such as military spending. Minority views can be respected, in part, by the promotion of research into ways to obtain hESCs without destroying embryos.

In addition to the debate about destruction of embryos, there are a number of other ethical issues that arise in this context. For example, there are ethical concerns regarding acquisition of embryos from different sources. The most common source is excess embryos from the IVF process. But embryos may also be created specifically for stem cell research. For those who believe that embryos have some moral status (whether it is equivalent to that of fully developed humans), the creation of embryos for research purposes may be more ethically problematic than the use of excess embryos that would otherwise be destroyed. Even those who believe the embryo has no moral status may be uneasy about creating them for purely research uses. Because there are fewer objections to the use of embryos already created, research in this area may be limited to cells derived from excess IVF embryos. This would be congruent with the view that embryos have some moral status as well as the view that embryos have little or no moral status but should nonetheless be treated with respect.

The use of excess IVF embryos creates other ethical issues. Couples undergoing IVF may be both emotionally and financially vulnerable. Care must be taken to ensure that the informed consent process for research donation has adequate protections. Under no circumstances should couples feel obligated to donate, and they should be fully informed about the relevant issues, including other choices they can make regarding their excess embryos. Moreover, couples should not feel that their IVF care is in any way dependent on their decision to donate. Finally, it would be improper to offer financial incentives to couples in exchange for donating their embryos for the creation of stem cells because such incentives raise concerns about undue inducement. In addition, for some, payment for embryos may seem to commodify children or even demonstrate disrespect for the embryo (although payment of money can also be viewed as a way of demonstrating respect). Because of the varying positions on this issue and the absence of a need to pay donors for any time, effort, or risk involved in creating the excess embryos, the American Academy of Pediatrics finds financial incentives to be inappropriate in this context. Payment for the time, effort, and risks involved in gamete donation raises different issues and is beyond the scope of this statement.

If embryos are created by using genetic material from multiple individuals, it may be unclear who should provide the consent for research. Most IVF clinics do not look to gamete donors specifically, but rather to the individuals (or individual) who are planning to use the embryos for reproductive purpose to make decisions about disposition, including research. Consent forms for gamete donation should make clear that the recipients will have this dispositional authority. Similarly, agreements between parties who are creating embryos should set forth terms of disposition at the outset of the process, including what to do in cases of disagreement, separation/divorce, or death. hESCs should only be derived from embryos donated for research under either a previous agreement or current consent from parties with dispositional authority.

CONCLUSIONS

In a pluralistic society, substantive disagreements may be addressed through the legislative or regulatory process. The National Institutes of Health has issued guidelines on human stem cell research that identify eligibility for federal funding (setting standards for donation, consent, and the use of cells derived before the guidelines took effect). The guidelines

serve as an important roadmap for using hESCs in research and attempt to strike an acceptable balance between the potential scientific benefits, the ethical issues and concerns surrounding this research, and the need for proper protection of human subjects. In addition to guidelines developed at the national or state level, it may be useful to create institutional stem cell oversight bodies which could ensure the application of legal restrictions and evaluate ethical issues that may arise in specific research proposals.

RECOMMENDATIONS

1. Given the substantial potential benefit on child health and development, the American Academy of Pediatrics believes that public funding and oversight for human embryo and embryonic stem cell research should continue. Funding for research that seeks to identify mechanisms to derive embryonic stem cells without resulting in the destruction of an embryo is also appropriate.
2. The American Academy of Pediatrics endorses the National Institutes of Health Guidelines on Human Stem Cell Research (http://stemcells.nih.gov/policy/2009guidelines.html), which identify eligibility for federal funding (setting standards for donation, consent, and the use of cells derived before the guidelines took effect). The guidelines serve as an important roadmap for using hESCs in research and strike an acceptable balance between the potential scientific benefits, the ethical issues and concerns surrounding this research, and the need for proper protection of human subjects. In particular, the American Academy of Pediatrics supports the following restrictions on hESC research:
   a. hESCs should be derived from embryos that were created by using IVF for reproductive purposes and are no longer needed for this purpose.
   b. The individuals who sought reproductive treatment must give voluntary written informed consent for the human embryos to be used for research purposes.
   c. No payments, cash or in kind, should be offered for donated embryos used for hESC derivation.
   d. There is a clear separation between the prospective embryo donor(s)'s decision to create human embryos for reproductive purposes and the prospective embryo donor(s)'s decision to donate human embryos for research purposes.

A policy statement describing the use of automated vision screening technology (instrument-based vision screening) is presented. Screening for amblyogenic refractive error with instrument-based screening is not dependent on behavioral responses of children, as when visual acuity is measured. Instrument-based screening is quick, requires minimal cooperation of the child, and is especially useful in the preverbal, preliterate, or developmentally delayed child. Children younger than 4 years can benefit from instrument-based screening, and visual acuity testing can be used reliably in older children. Adoption of this new technology is highly dependent on third-party payment policies, which could present a significant barrier to adoption. *Pediatrics* 2012;130:983–986

INTRODUCTION

With recent research and development of improved screening and refractive devices, this policy statement supplants the 2002 position paper[1] and is in accord with the overall vision screening policy of the American Academy of Pediatrics.[2] This statement is cosponsored by the American Academy of Ophthalmology, the American Association for Pediatric Ophthalmology and Strabismus, and the American Association of Certified Orthoptists.

The goal of vision screening is to detect subnormal vision or risk factors that threaten visual development, preferably at a time when treatment can be initiated to yield the highest benefit.[3] A primary goal of vision screening in young children is the detection of amblyopia or the risk factors for development of amblyopia, a neural deficit in vision that is estimated to be present in 1% to 4% of children.[4] Amblyopia can be caused by obscured images (eg, from infantile cataracts), misaligned images (eg, from constant strabismus), or defocused images (eg, from different refractive errors between the eyes, termed anisometropia). The hallmark of amblyopia is decreased visual acuity, typically monocular, for which no ocular structural disorder fully accounts. However, successful visual acuity testing by using a vision chart is highly dependent on patient age and screener experience. In children younger than 3 years, few professionals can reliably determine acuity in each eye by using a vision chart.[5] Therefore, for younger children, the preferred methodology is instrument-based detection of risk factors for amblyopia—primarily photoscreening and autorefraction.

PHOTOSCREENERS, AUTOREFRACTORS, AND OTHER INSTRUMENTS

Instrument-based screening, if performed and interpreted correctly by appropriately trained individuals, usually identifies the presence and magnitude of optical and physical abnormalities of the eyes; it is quick and requires minimal cooperation from the child. Instrument-based screening systems typically produce a hard copy or digital record for inclusion in the patient record to document that screening was performed and, in some cases, provide an interpretation of the data.

Photoscreening uses optical images of the eye's red reflex to estimate refractive error, media opacity, ocular alignment, and other factors, such as ocular adnexal deformities (eg, ptosis), all of which put a child at risk for developing amblyopia. Photoscreening instruments, which assess both eyes simultaneously, have been found to be useful for screening children,[6–10] and their output is interpreted by operators, by a central reading center, or by computer.

Autorefraction involves optically automated skiascopy methods or wavefront technology (Shack-Hartmann) to evaluate the refractive error of each eye. The National Institutes of Health–sponsored Vision in Preschoolers Study[7] systematically evaluated instrument-based screening methods and compared them with visual acuity–based screening when administered by licensed eye-care professionals. For the conditions most important to detect and treat early and for a specificity of 90%, autorefraction had sensitivity of 81% to 88%, with the use of specified referral criteria. For these conditions, visual acuity testing had 77% sensitivity at 90% specificity. A disadvantage of autorefractors is that they typically measure only 1 eye at a time, limiting their ability to detect strabismus in the absence of abnormal refractive error. However, in contrast to tabletop autorefractors, which are difficult to use with very young children, portable, handheld autorefractors are useful for screening young children.[7,11–15] Autorefraction data yield numeric results that are analyzed by the evaluator or by the instrument itself to determine if a child passes or fails the screening.

Other instruments have been or are being developed to objectively evaluate the eye or visual system for the presence of risk factors for amblyopia. These instruments are, at present, without a sufficient evidence base for recommendation.

As with any screening device, the sensitivity and specificity will depend on the referral criteria used. Alterations in referral criteria result in an inverse relationship between sensitivity and specificity, such that high detection of at-risk children (ie, high sensitivity) risks excessive overreferrals (ie, low specificity), and minimization of overreferrals (ie, high specificity) reduces detection of at-risk children (ie, low sensitivity).

Both photoscreening and autorefraction offer hope in improving vision-screening rates in preverbal children, preliterate children, and those with developmental delays, who are the most difficult to screen. Children younger than 4 years can benefit from instrument-based screenings. For children 4 to 5 years of age, photoscreening and autorefraction have not been shown to be superior or inferior to visual acuity testing with the use of vision charts.[7] In children older than 5 years, visual acuity testing by using vision charts can be used reliably and should be performed every 1 to 2 years.[2]

BARRIERS TO THE USE OF INSTRUMENT-BASED VISUAL SCREENING

Although all of the aforementioned instruments are available for use in a primary care setting, all of them involve substantial costs to the primary care practice. The instruments themselves often cost thousands of dollars, in addition to the costs of printers and supplies for each test performed. There are additional indirect costs, including space and staff time required to perform these tests, as well as physician time to interpret them. High initial capital investments for these instruments may be reduced if suppliers offer a leasing option as an alternative to purchasing equipment, but these costs must still be calculated into the total costs of performing the test. Although *Current Procedural Terminology* codes are available for such devices, there is never a guarantee of payment from third-party payers, even if the appropriate code is used. Historically, when such codes increase in frequency, third-party payers simply cease paying them. Additionally, visual screening is often inappropriately bundled into a global fee for the health maintenance visit, despite the fact that this is a separately identifiable service with real costs and established relative value units (RVUs). The adoption of any such technology will be highly dependent on the payment decisions of third-party payers. Primary care physicians will likely be slow to adopt these new technologies, despite their merit, if they are expected to absorb the cost without adequate payment for their up-front costs and their time. A level-1 *Current Procedural Terminology* code, 99174 with RVU 0.69, has been assigned to photoscreening. The adequacy of such an RVU depends on the cost of the screening device.

RECOMMENDATIONS

- Vision screening should be performed at an early age and at regular intervals with age-appropriate, valid methods, ideally within the

medical home. The goal remains to identify and treat preventable visual impairment at the earliest feasible age.

- Photoscreening and handheld autorefraction may be electively performed in children 6 months to 3 years of age, allowing earlier detection of conditions that may lead to amblyopia, as well as in older children who are unable or unwilling to cooperate with routine acuity screening.
- Photoscreening and handheld autorefraction are recommended as an alternative to visual acuity screening with vision charts from 3 through 5 years of age, after which visual acuity screening with vision charts becomes more efficient and less costly in the medical home. Adequate payment for instrument-based vision-screening services must be ensured if there is to be widespread adoption of this recommendation.
- Alternatively, the use of vision charts and standard physical examination techniques to assess amblyopia in children 3 to 5 years of age in the medical home remains a viable practice at the present time.
- There is no recommendation for mass screening at this time.
- Vision screening is a separately identifiable service and should not be bundled into the global code of well-child care. Adequate payment for photoscreening and handheld autorefraction must be ensured if there is to be widespread adoption of this recommendation.
- Regardless of the type of photoscreening or autorefraction system used, it is recommended that the evaluator know how to apply the technology properly and understand the limitations of the test in relation to the population being tested.
- The American Academy of Pediatrics, American Academy of Ophthalmology, American Association for Pediatric Ophthalmology and Strabismus, and American Association of Certified Orthoptists advocate additional research of photoscreening and handheld autorefraction devices and other vision screening methods to elucidate the validity of results, efficacy, cost-effectiveness, and payment policies for identifying amblyogenic factors in different age groups and subgroups of children. The goal remains to eliminate preventable childhood visual impairment.

abstract

FREE

Provision of risk-appropriate care for newborn infants and mothers was first proposed in 1976. This updated policy statement provides a review of data supporting evidence for a tiered provision of care and reaffirms the need for uniform, nationally applicable definitions and consistent standards of service for public health to improve neonatal outcomes. Facilities that provide hospital care for newborn infants should be classified on the basis of functional capabilities, and these facilities should be organized within a regionalized system of perinatal care. *Pediatrics* 2012;130:587–597

OBJECTIVE

This revised policy statement reviews the current status of the designation of levels of newborn care definitions in the United States, which were delineated in a 2004 policy statement by the American Academy of Pediatrics (AAP).[1] Since publication of the 2004 policy statement, new data, both nationally and internationally, have reinforced the importance of well-defined regionalized systems of perinatal care, population-based assessment of outcomes, and appropriate epidemiologic methods to adjust for risk. This revised statement updates the designations to provide (1) a basis for comparison of health outcomes, resource use, and health care costs, (2) standardized nomenclature for public health, (3) uniform definitions for pediatricians and other health care professionals providing neonatal care, and (4) a foundation for consistent standards of service by institutions; state health departments; and state, regional, and national organizations focused on the improvement of perinatal care.

BACKGROUND

The availability of neonatal intensive care has improved the outcomes of high-risk infants born either preterm or with serious medical or surgical conditions.[2–4] Many of these improvements can be attributed to the concept and implementation of regionalized systems of perinatal care, broadly articulated in the 1976 March of Dimes report "Toward Improving the Outcome of Pregnancy" (TIOP I).[5] The TIOP I report included criteria that stratified maternal and neonatal care into 3 levels of complexity and recommended referral of high-risk patients to higher-level centers with the appropriate resources and personnel to address the required increased complexity of care. However, since the initial TIOP I report was published more than 3 decades ago, there have been signs of deregionalization, including (1)

an increase in the number of NICUs and neonatologists, without a consistent relationship to the percentage of high-risk infants, (2) a proliferation of small NICUs in the same regions as large NICUs,[6–11] and (3) failure of states to reach the Healthy People 2010 goal that 90% of deliveries of very low birth weight (VLBW; <1500 g) infants occur at level III facilities.[12,13]

In the environment of deregionalization, preterm birth rates have increased 13% overall from 1990 to 2010 (10.6%–12.0%) as a result of a variety of factors, including increases in elective early cesarean deliveries, multiple births, advanced maternal age, and complications of pregnancy.[14–20] The majority of the increase in the preterm birth rate (>70%) is attributable to late preterm births.[21] Infants born late preterm can experience significant morbidity that may result in the need for specialized care and advanced neonatal services.[22,23] An increase in the supply of specialty staff[24,25] and availability of new neonatal therapies (eg, bubble continuous positive airway pressure), have expanded the scope of care in level II facilities.[26] Some have expressed concern that level II hospitals have expanded their scope of care without sufficient evidence of favorable outcome. Because most infant deaths in the United States occur among the most immature infants in the first few days after birth,[27,28] improvements in regionalized systems may reduce mortality among the most preterm newborn infants.

REVIEW OF THE LITERATURE ON NEONATAL LEVELS OF CARE SINCE THE 2004 AAP POLICY STATEMENT

In 2004, the AAP defined neonatal levels of care, including 3 distinct levels with subdivisions in 2 of the levels.[1] Level I centers provided basic care; level II centers provided specialty care, with further subdivisions of IIA and IIB centers; and level III centers provided subspecialty care for critically ill newborn infants with subdivisions of level IIIA, IIIB, and IIIC facilities. Data published since the 2004 statement have informed the development of the levels of care in this new policy statement.

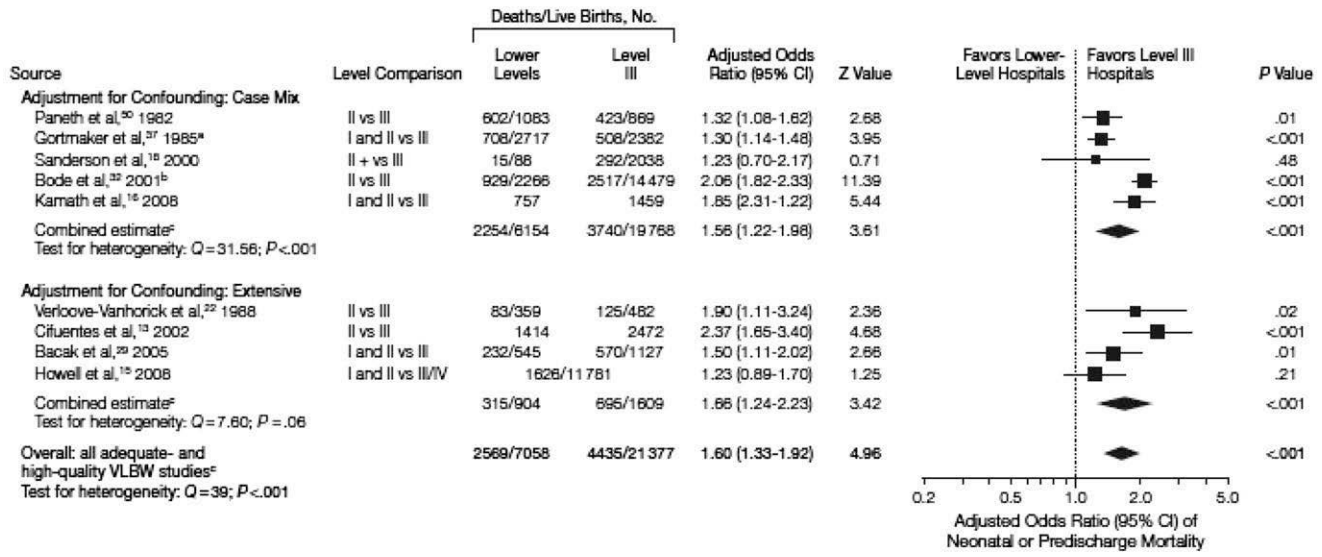
A meta-analysis of the published literature from 1978 to 2010 clearly demonstrates improved outcomes for VLBW infants and infants <32 weeks' gestational age born in level III centers. Lasswell et al reviewed 41 English-language US and international studies, which included >113 000 VLBW infants and found that VLBW infants born at non–level III hospitals had a 62% increase in odds of neonatal or predischarge mortality compared with those born at level III hospitals (adjusted odds ratio [aOR], 1.62; 95% confidence interval [CI], 1.44–1.83). Subset comparisons of studies identifying infants <32 weeks' gestation and extremely low birth weight (ELBW) infants (<1000 g) demonstrated similar effects (aOR, 1.55; 95% CI, 1.21–1.98; aOR, 1.64; 95% CI, 1.14–2.36, respectively). When only higher-quality studies were included, the findings were consistent (VLBW aOR, 1.60; 95% CI, 1.33–1.92; <32 weeks' gestation aOR, 1.42; 95% CI, 1.06–1.88; ELBW aOR, 1.80; 95% CI, 1.31–2.36). The effect of level of care on VLBW mortality did not vary by decade of publication[29]; hence, the risk of death for VLBW infants born in level I or II facilities remained higher than those born within a level III facility. Figures 1, 2, and 3 summarize the findings of these studies.

As Lasswell and colleagues found, part of the difficulty in collecting evidence to provide accurate assessments of VLBW outcomes has been in obtaining appropriate standardized measures. Heterogeneity among studies on neonatal levels of care suggests the need for a quality standard for comparison which includes the following elements: (1) population-based studies within well-defined geographic regions, (2) clear definitions of the "intervention" or hospital level of care, and (3) appropriate adjustment for confounding factors to include maternal social and demographic risk factors, pregnancy and perinatal risks, and severity of illness at delivery.

Current Controversies in Levels of Care Designation

Although little debate exists on the need for advanced neonatal services for the most immature and surgically complex neonates, ongoing controversies exist regarding which facilities are qualified to provide these services and what is the most appropriate measure for such qualification. These issues are, in general, based on the need for comparison of facility experience (measured by patient volume or census), location (inborn/outborn deliveries, regional perinatal center, or children's hospital), or case mix (including stillbirths, delivery room deaths, and complex congenital anomalies).

Several studies have explored the topic of center experience as measured by volume or census of VLBW infants.[30–35] Phibbs et al conducted a population-based retrospective cohort study of 48 237 California VLBW infants to examine differences in neonatal mortality among NICUs with various levels of care and patient volumes. When compared with high-volume, high-level centers, the odds ratio of death was 1.19 (range, 1.04–1.37) for level IIIB, IIIC, or IIID centers with <100 annual admissions, 1.78 (range, 1.35–2.34) for level IIIA centers with 26 to 50 annual admissions, and 2.72 (range, 2.37–3.12) for level I centers with <10 annual admissions. The authors also found that the percentage of VLBW infants delivered in level IIIB, IIIC, or IIID centers decreased from 36% in 1991 to 22% in



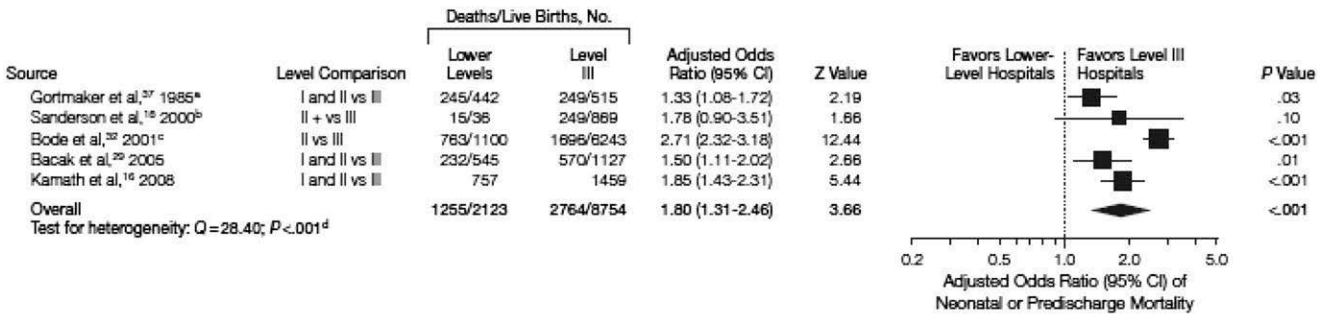
Case mix indicates adjustment for demographic and/or socioeconomic status variables; extensive indicates adjustment for case mix plus maternal/perinatal risk factors and infant illness severity. CI indicates confidence interval. Size of data markers indicates size of study population.
[a] Included data are for urban populations and combine reported black/white race strata and birth weight strata (750-1000 g and 1001-1500 g).
[b] Included data combine reported birth date interval strata (1980-1984, 1985-1989, and 1990-1994) and birth weight strata (500-1000 g and 1001-1500 g).
[c] Raw death counts are not reported in Cifuentes et al[13] and Kamath et al[16] and are not stratified by hospital level in Howell et al.[15] These studies are not included in combined death/birth counts.

FIGURE 1

Meta-analysis of adequate- and high-quality publications on VLBW infants, stratified by level of adjustment for confounding. (Reprinted with permission from Lasswell S, Barfield WD, Rochat R, Blackmon L. Perinatal regionalization for very low birth weight and very preterm infants: a meta-analysis. *JAMA.* 2010;304[9]:992–1000.[29])

2000 and estimated that shifting VLBW births in urban areas (92% of VLBW births) to level IIIC or IIID centers with >100 annual admissions would have prevented 21% of VLBW deaths in 2000.[30] In a secondary data analysis, Chung et al found that deregionalization of California perinatal services resulted in 20% of VLBW deliveries occurring in level I and level II hospitals, with lower-volume hospitals having the highest odds of mortality.[31]

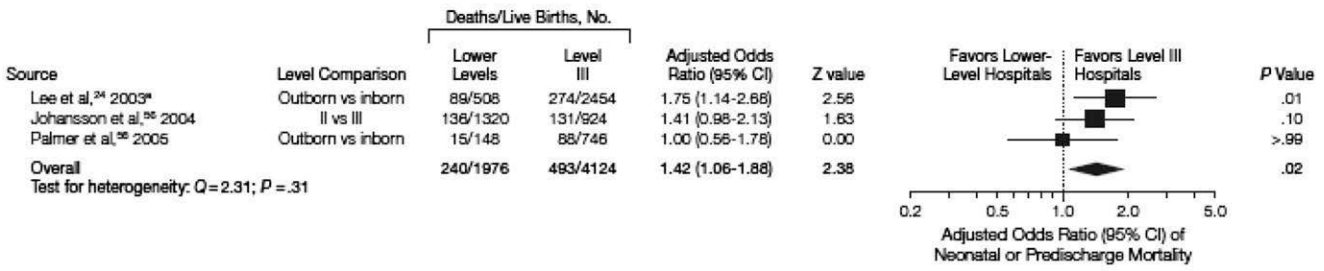
A population-based study of 4379 VLBW infants who were born between 1991 and 1999 in Lower Saxony, Germany, evaluated neonatal mortality in relation to both the annual volume of births and NICU volume.[32] There was an increased odds of mortality in centers with annual NICU admissions of fewer than 36 VLBW infants; the largest



CI indicates confidence interval. Size of data markers indicates size of study population.
[a] Included data are for urban populations and combine reported black/white race strata.
[b] Included data combine reported birth weight strata (500-749 g and 750-1000 g).
[c] Included data combine reported birth date interval strata (1980-1984, 1985-1989, and 1990-1994).
[d] The study by Kamath et al[16] does not report raw death count data and is not included in combined death/birth counts.

FIGURE 2

Meta-analysis of adequate- and high-quality publications on ELBW infants. (Reprinted with permission from Lasswell S, Barfield WD, Rochat R, Blackmon L. Perinatal regionalization for very low birth weight and very preterm infants: a meta-analysis. *JAMA.* 2010;304[9]:992–1000.[29])



CI indicates confidence interval. Size of data markers indicates size of study population. Inborn infants are those born in a level III hospital; outborn infants are those born in a lower-level hospital then transferred to a level III hospital.
[a] Included data combine reported gestational age strata (<26 weeks, 27-29 weeks, and 30-31 weeks).

FIGURE 3

Meta-analysis of adequate- and high-quality publications on very preterm infants (<32 weeks' gestation). (Reprinted with permission from Lasswell S, Barfield WD, Rochat R, Blackmon L. Perinatal regionalization for very low birth weight and very preterm infants: a meta-analysis. *JAMA.* 2010;304[9]:992–1000.[29])

effect on mortality was for infants born at less than 29 weeks' gestation.

Other studies assessing NICU volume suggest caution in using this measure as an effective indicator of quality of care. Rogowski and colleagues assessed the potential usefulness of NICU volume as a quality indicator among 94 110 VLBW infants entered into the Vermont Oxford Network database between 1995 and 2000 and compared NICU volume with other indicators based on hospital characteristics and patient outcomes.[33] They found that although annual volume explained 9% of the variation in hospital mortality rates, other hospital characteristics explained another 7%. They suggested that direct measures based on patient outcomes are more useful quality indicators than volume for the purpose of selective referral.

Several studies assessed the effects of level of care, patient volume, and racial disparities on mortality of VLBW infants based on births in minority-serving hospitals. Morales[34] and Howell[35] evaluated mortality of VLBW infants born in minority-serving hospitals. In both studies, neonatal level of care and patient volume were each independently associated with mortality, suggesting that delivery of all VLBW infants at high-volume hospitals would reduce black-white disparities in VLBW mortality rates. Rogowski and colleagues further suggest that the quality of care in poor-outcome hospitals could be improved through collaborative quality improvement, and evidence-based selective referral.[36]

Several studies have compared the short-term outcome of VLBW infants born in centers with level III units (inborn) compared with those born at lower level centers and soon transferred to a higher level (level III or children's hospital; outborn). Many of these studies are retrospective and may be subject to selection bias because infants who were transferred most likely had the highest chance of survival and thus gave the impression of lower mortality.[24] In a secondary analysis of a randomized placebo-controlled study of preemptive morphine analgesia on neonatal outcomes, Palmer et al compared neonatal mortality as related to place of birth for 894 infants who were born at 23 to 32 weeks' gestation. Outborn babies were more likely to have severe intraventricular hemorrhage ($P = .0005$), and this increased risk persisted after controlling for severity of illness. However, when adjusted for antenatal steroids, the effect of birth center was no longer significant.[37]

Evaluating and controlling for confounding variables and "case-mix" presents another set of challenges because these factors vary by population. For example, race and insurance status may have more of an effect on birth outcomes in the United States[34–36,38] than in countries with a more homogenous population and universal national health care.[39] There are also potential confounding factors for which measurement is frequently lacking, such as parental wishes regarding aggressive resuscitation of an infant. Arad et al noted that parental wishes varied by religious affiliation in their 2-hospital study. Because religious affiliation was unequally distributed between the 2 hospitals, fewer attempts at resuscitation may have been made at the level III hospital, with a result of improved survival at the level II facility.[40] More comprehensive studies controlling for confounding factors are needed.

Measured outcomes other than VLBW mortality (notably, fetal mortality, postdischarge mortality, and long-term physical and neurodevelopmental outcomes) may offer important information in assessing the evidence for newborn levels of care and perinatal regionalization. Studies measuring the effect of hospital level of birth on fetal

and neonatal outcomes stratified by gestational age, as well as by birth weight, are also helpful, because gestational age is a better gauge of fetal maturity.[41–44] Although some studies include stillbirths and intrapartum fetal deaths, measurement and surveillance of fetal death varies widely.[3] Congenital anomalies are often excluded from studies of perinatal regionalization but should be considered in the provision of risk appropriate care.[45]

Additional studies are also needed to assess the effectiveness and potential cost savings of centralizing expensive technologies and provider expertise for relatively rare conditions at a few locations and to assess the effectiveness, including costs, of antenatal transport.

IMPORTANCE OF NEONATAL LEVELS OF CARE

Provision of Standardized Nomenclature for Public Health

Since 2004, efforts have been made to improve the comparison of health outcomes by hospital facility through the use of standardized nomenclature on the US birth certificate. The National Center for Health Statistics at the Centers for Disease Control and Prevention has worked with states to use the newly revised US Standard Certificate of Birth.[46] This 2003 revised certificate defines a NICU as a "hospital facility or unit staffed and equipped to provide continuous mechanical ventilatory support for a newborn infant." It also includes information on the use of antenatal therapies and postpartum surfactant, which may be useful in monitoring population-based utilization of technologies at birth.[47] In an analysis of 16 states using the revised certificate of birth, Barfield et al found that overall, 77.3% of VLBW infants were admitted to NICUs; this estimate varied by state and ranged from 63.7% in California to 93.4% in North Dakota. Among VLBW infants of Hispanic mothers, 71.8% were admitted to NICUs, compared with 79.5% of VLBW infants of non-Hispanic black mothers and 80.5% of VLBW infants of non-Hispanic white mothers. In multivariable analysis, preterm delivery, multiple gestation, and cesarean delivery were associated with higher prevalence of NICU admission among VLBW infants.[13] State variations in the receipt of intensive care for VLBW infants may explain, in part, variation in VLBW outcomes across the country.

Use of Uniform Definitions of Levels of Care for Pediatricians and Other Health Care Professionals

Variation in definition, criteria, and state enforcement still occurs despite the TIOP I guidelines. Blackmon et al conducted an extensive review of all 50 states and the District of Columbia governmental Web sites to assess state definitions and levels terminology, functional and utilization criteria, regulatory compliance and funding measures, and citation of AAP documents on levels of neonatal care. The authors found that state definitions, criteria, compliance, and regulatory mechanisms for the specific type of care neonatal centers provide varied considerably, and they suggested a consistent national approach.[48] Lorch et al assessed all 50 states and the District of Columbia to identify state certificate of need (CON) legislation, a mechanism that regulates the expansion of NICU facilities and NICU beds. Thirty states regulated the construction of NICUs through CON programs, and non-CON program states were associated with more NICU facilities and more NICU beds (relative risk, 2.06; 95% CI, 1.74–2.45; and relative risk, 1.96; 95% CI, 1.89–2.03, respectively). In large metropolitan areas, non-CON states had higher infant mortality for all birth weight groups.[49]

The Maternal and Child Health Bureau of the Health Resources and Services Administration has worked with state Title V agencies to document the percentage of VLBW infants delivered in level III hospitals or subspecialty perinatal clinics. In 2009, only 5 states met the goal of at least 90% of VLBW infants delivered at high-risk facilities.[12] Yet, the interpretation and reporting of these facilities may be inconsistent as some states had unclear facility definitions or included level II facilities in their reporting. Recently, several states, in partnership with national organizations, have taken more definitive action in defining and regulating organization of perinatal care.[50]

Development of Consistent Standards of Service

Efforts by quality-improvement collaboratives, health services researchers, and public health officials will continue to improve the standards by which to measure quality of care.[51,52] Quality-improvement activities have begun to flourish at all levels to improve maternal and perinatal health and ideally prevent preterm births; this includes provider-level quality-improvement activities, hospital-level performance measures, and regional, state, and national performance measures.[53] Organizations such as the March of Dimes have promoted standard definitions of levels of care since the introduction of perinatal regionalization in the 1970s, reaffirmed its importance in 1993 (TIOP II),[54] and included the concept of quality care for the prevention of preterm birth with a new TIOP (TIOP III) in 2010.[53]

DEFINITIONS OF LEVELS OF NEONATAL CARE

The updated classification consists of basic care (level I), specialty care (level II), and subspecialty intensive care (level III, level IV; Table 1). These definitions reflect the overall evidence for risk-appropriate care through the availability of appropriate personnel, physical space, equipment, technology, and

TABLE 1 Definitions, Capabilities, and Provider Types: Neonatal Levels of Care

Level of Care	Capabilities	Provider Types[a]
Level I Well newborn nursery	• Provide neonatal resuscitation at every delivery • Evaluate and provide postnatal care to stable term newborn infants • Stabilize and provide care for infants born 35–37 wk gestation who remain physiologically stable • Stabilize newborn infants who are ill and those born at <35 wk gestation until transfer to a higher level of care	Pediatricians, family physicians, nurse practitioners, and other advanced practice registered nurses
Level II Special care nursery	Level I capabilities plus: • Provide care for infants born ≥32 wk gestation and weighing ≥1500 g who have physiologic immaturity or who are moderately ill with problems that are expected to resolve rapidly and are not anticipated to need subspecialty services on an urgent basis • Provide care for infants convalescing after intensive care • Provide mechanical ventilation for brief duration (<24 h) or continuous positive airway pressure or both • Stabilize infants born before 32 wk gestation and weighing less than 1500 g until transfer to a neonatal intensive care facility	Level I health care providers plus: Pediatric hospitalists, neonatologist, and neonatal nurse practitioners.
Level III NICU	Level II capabilities plus: • Provide sustained life support • Provide comprehensive care for infants born <32 wks gestation and weighing <1500 g and infants born at all gestational ages and birth weights with critical illness • Provide prompt and readily available access to a full range of pediatric medical subspecialists, pediatric surgical specialists, pediatric anesthesiologists, and pediatric opthalmologists • Provide a full range of respiratory support that may include conventional and/or high-frequency ventilation and inhaled nitric oxide • Perform advanced imaging, with interpretation on an urgent basis, including computed tomography, MRI, and echocardiography	Level II health care providers plus: Pediatric medical subspecialists[b], pediatric anesthesiologists[b], pediatric surgeons, and pediatric opthalmologists[b].
Level IV Regional NICU	Level III capabilities plus: • Located within an institution with the capability to provide surgical repair of complex congenital or acquired conditions • Maintain a full range of pediatric medical subspecialists, pediatric surgical subspecialists, and pediatric anesthesiologists at the site • Facilitate transport and provide outreach education	Level III health care providers plus: Pediatric surgical subspecialists

[a] Includes all providers with relevant experience, training, and demonstrated competence.
[b] At the site or at a closely related institution by prearranged consultative agreement.

organization.[55] Each level reflects the minimal capabilities, functional criteria, and provider type required. Currently, there are 148 specialty care units and 809 subspecialty care units self-identified in the 2009 AAP perinatal section directory.

Level I

Level I facilities (well newborn nurseries) provide a basic level of care to neonates who are low risk. They have the capability to perform neonatal resuscitation at every delivery and to evaluate and provide routine postnatal care for healthy newborn infants. In addition, they can care for preterm infants at 35 to 37 weeks' gestation who are physiologically stable and can stabilize newborn infants who are less than 35 weeks of gestation or who are ill until they can be transferred to a facility at which specialty neonatal care is provided. Because late preterm infants (34–36 weeks' gestation) are at risk for increased neonatal morbidity and mortality, more evidence is needed to determine their outcomes by level of care.

Level II

Care in a specialty-level facility (level II) should be reserved for stable or

moderately ill newborn infants who are born at ≥32 weeks' gestation or who weigh ≥1500 g at birth with problems that are expected to resolve rapidly and who would not be anticipated to need subspecialty-level services on an urgent basis. These situations usually occur as a result of relatively uncomplicated preterm labor or preterm rupture of membranes. There is limited evidence to support the specific subdivision of level II care, in part because of the lack of studies with well-defined subdivisions. Level II facilities should take into consideration geographic constraints and population size when assessing the staffing resources needed to care appropriately for moderately ill newborn infants.

Level II nurseries may provide assisted ventilation on an interim basis until the infant's condition either soon improves or the infant can be transferred to a higher-level facility. Delivery of continuous positive airway pressure should be readily available by experienced personnel, and mechanical ventilation can be provided for a brief duration (less than 24 hours). Level II nurseries must have equipment (eg, portable x-ray machine, blood gas analyzer) and personnel (eg, physicians, specialized nurses, respiratory therapists, radiology technicians, laboratory technicians) continuously available to provide ongoing care as well as to address emergencies. Referral to a higher level of care should occur for all infants when needed for pediatric surgical or medical subspecialty intervention.

Level III

Evidence suggests that infants who are born at <32 weeks' gestation, weigh <1500 g at birth, or have medical or surgical conditions, regardless of gestational age, should be cared for at a level III facility. Designation of level III care should be based on clinical experience, as demonstrated by large patient volume, increasing complexity of care, and availability of pediatric medical subspecialists and pediatric surgical specialists. Subspecialty care services should include expertise in neonatology and also ideally maternal-fetal medicine, if mothers are referred for the management of potential preterm birth. Level III NICUs are defined by having continuously available personnel (neonatologists, neonatal nurses, respiratory therapists) and equipment to provide life support for as long as necessary. Facilities should have advanced respiratory support and physiologic monitoring equipment, laboratory and imaging facilities, nutrition and pharmacy support with pediatric expertise, social services, and pastoral care.

Level III facilities should be able to provide ongoing assisted ventilation for 24 hours or more, which may include conventional ventilation, high-frequency ventilation, and inhaled nitric oxide. Level III facility capabilities should also be based on a region's consideration of geographic constraints, population size, and personnel resources. If geographic constraints for land transportation exist, the level III facility should ensure availability of rotor and fixed-wing transport services to quickly and safely transfer infants requiring subspecialty intervention.[56] Potential transfer to higher-level facilities or children's hospitals, as well as back-transport of recovering infants to lower-level facilities, should be considered as clinically indicated.

A broad range of pediatric medical subspecialists and pediatric surgical specialists should be readily accessible on site or by prearranged consultative agreements. Prearranged consultative agreements can be performed by using telemedicine technology and/or telephone consultation, for example, from a distant location.[50] Pediatric ophthalmology services and an organized program for the monitoring, treatment, and follow-up of retinopathy of prematurity should be readily available in level III facilities.[57] Level III units should have the capability to perform major surgery on site or at a closely related institution, ideally in close geographic proximity. Because the outcomes of less complex surgical procedures in children, such as appendectomy or pyloromyotomy, are better when performed by pediatric surgeons compared with general surgeons, it is recommended that pediatric surgical specialists (including anesthesiologists with pediatric expertise) perform all procedures in newborn infants.[58]

Level III facilities should have the capability to perform advanced imaging with interpretation on an urgent basis, including CT, MRI, and echocardiography. Level III facilities should collect data to assess outcomes within their facility and to compare with other levels.

Level IV

Level IV units include the capabilities of level III with additional capabilities and considerable experience in the care of the most complex and critically ill newborn infants and should have pediatric medical and pediatric surgical specialty consultants continuously available 24 hours a day. Level IV facilities would also include the capability for surgical repair of complex conditions (eg, congenital cardiac malformations that require cardiopulmonary bypass with or without extracorporeal membrane oxygenation). More evidence is needed to assess the risk of morbidity and mortality by level of care for newborn infants with complex congenital cardiac malformations. A recent study by Burstein et al[59] was not able to note a difference in postoperative morbidity or mortality

associated with dedicated pediatric cardiac ICUs versus NICUs and PICUs but did not separately assess the newborn and postneonatal periods. Although specific supporting data are not currently available, it is thought that concentrating the care of such infants at designated level IV centers will allow these centers to develop the expertise needed to achieve optimal outcomes.

Not all level IV hospitals need to act as regional centers; however, regional organization of perinatal health care services requires that there be coordination in the development of specialized services, professional continuing education to maintain competency, facilitation of opportunities for transport and back-transport,[60] and collection of data on long-term outcomes to evaluate both the effectiveness of delivery of perinatal health care services and the safety and efficacy of new therapies. These functions usually are best achieved when responsibility is concentrated in a single regional center with both perinatal and neonatal subspecialty services. In some cases, regional coordination may be provided adequately by the collaboration of a children's hospital with a subspecialty perinatal facility that is in close geographic proximity.[61]

STANDARDS OF SERVICE FOR HOSPITALS PROVIDING NEONATAL CARE

Current evidence indicates that family and cultural considerations are important for care of sick neonates.[62–65] These considerations include family- and patient-centered care, culturally effective care, family-based education, and opportunities for back-transport to level II facilities or transfer to the family's local community facility when medically and socially indicated.[64–67]

SUMMARY AND RECOMMENDATIONS

1. Regionalized systems of perinatal care are recommended to ensure that each newborn infant is delivered and cared for in a facility most appropriate for his or her health care needs, when possible, and to facilitate the achievement of optimal health outcomes.
    - Because VLBW and/or very preterm infants are at increased risk of predischarge mortality when born outside of a level III center, they should be delivered at a level III facility unless this is precluded by the mother's medical condition or geographic constraints.
2. The functional capabilities of facilities that provide inpatient care for newborn infants should be classified uniformly on the basis of geographic and population parameters in collaboration with state health departments, as follows:
    - Level I: a hospital nursery organized with the personnel and equipment to perform neonatal resuscitation, evaluate and provide postnatal care of healthy newborn infants, provide care for infants born at 35 to 37 weeks' gestation who remain physiologically stable, and stabilize ill newborn infants or infants born at less than 35 weeks' gestational age until transfer to a facility that can provide the appropriate level of neonatal care.
    - Level II: a hospital special care nursery organized with the personnel and equipment to provide care to infants born at 32 weeks' gestation or more and weighing 1500 g or more at birth who have physiologic immaturity, such as apnea of prematurity, inability to maintain body temperature, or inability to take oral feedings; who are moderately ill with problems that are expected to resolve rapidly and are not anticipated to need subspecialty services on an urgent basis; or who are convalescing from a higher level of intensive care. A level II center has the capability to provide continuous positive airway pressure and may provide mechanical ventilation for brief durations (less than 24 hours).
    - Level III: a hospital NICU organized with personnel and equipment to provide continuous life support and comprehensive care for extremely high-risk newborn infants and those with critical illness. This includes infants born weighing <1500 g or at <32 weeks' gestation. Level III units have the capability to provide critical medical and surgical care. Level III units routinely provide ongoing assisted ventilation; have ready access to a full range of pediatric medical subspecialists; have advanced imaging with interpretation on an urgent basis, including CT, MRI, and echocardiography; have access to pediatric ophthalmologic services with an organized program for the monitoring, treatment, and follow-up of retinopathy of prematurity; and have pediatric surgical specialists and pediatric anesthesiologists on site or at a closely related institution to perform major surgery. Level III units can facilitate transfer to higher-level facilities or children's hospitals, as well as back-transport recovering infants to lower-level facilities, as clinically indicated.
    - Level IV units have the capabilities of a level III NICU and

are located within institutions that can provide on-site surgical repair of serious congenital or acquired malformations. Level IV units can facilitate transport systems and provide outreach education within their catchment area.

3. The functional capabilities of facilities that provide inpatient care for newborn infants should be classified uniformly and with clear definitions that include requirements for equipment, personnel, facilities, ancillary services, training, and the organization of services (including transport) for the capabilities of each level of care.
4. Population-based data on patient outcomes, including mortality, morbidity, and long-term outcomes, should be obtained to provide level-specific standards for patients requiring various categories of specialized care, including surgery.

TECHNICAL REPORT

Male Circumcision

abstract

FREE

Male circumcision consists of the surgical removal of some, or all, of the foreskin (or prepuce) from the penis. It is one of the most common procedures in the world. In the United States, the procedure is commonly performed during the newborn period. In 2007, the American Academy of Pediatrics (AAP) convened a multidisciplinary workgroup of AAP members and other stakeholders to evaluate the evidence regarding male circumcision and update the AAP's 1999 recommendations in this area. The Task Force included AAP representatives from specialty areas as well as members of the AAP Board of Directors and liaisons representing the American Academy of Family Physicians, the American College of Obstetricians and Gynecologists, and the Centers for Disease Control and Prevention. The Task Force members identified selected topics relevant to male circumcision and conducted a critical review of peer-reviewed literature by using the American Heart Association's template for evidence evaluation.

Evaluation of current evidence indicates that the health benefits of newborn male circumcision outweigh the risks; furthermore, the benefits of newborn male circumcision justify access to this procedure for families who choose it. Specific benefits from male circumcision were identified for the prevention of urinary tract infections, acquisition of HIV, transmission of some sexually transmitted infections, and penile cancer. Male circumcision does not appear to adversely affect penile sexual function/sensitivity or sexual satisfaction. It is imperative that those providing circumcision are adequately trained and that both sterile techniques and effective pain management are used. Significant acute complications are rare. In general, untrained providers who perform circumcisions have more complications than well-trained providers who perform the procedure, regardless of whether the former are physicians, nurses, or traditional religious providers.

Parents are entitled to factually correct, nonbiased information about circumcision and should receive this information from clinicians before conception or early in pregnancy, which is when parents typically make circumcision decisions. Parents should determine what is in the best interest of their child. Physicians who counsel families about this decision should provide assistance by explaining the potential benefits and risks and ensuring that parents understand that circumcision is an elective procedure. The Task Force strongly recommends the creation, revision, and enhancement of educational materials to assist parents of male infants with the care of circumcised and uncircumcised penises. The Task Force also strongly recommends the development of educational materials for providers to enhance practitioners' competency in discussing circumcision's benefits and risks with parents.

The Task Force made the following recommendations:

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

- Evaluation of current evidence indicates that the health benefits of newborn male circumcision outweigh the risks, and the benefits of newborn male circumcision justify access to this procedure for those families who choose it.
- Parents are entitled to factually correct, nonbiased information about circumcision that should be provided before conception and early in pregnancy, when parents are most likely to be weighing the option of circumcision of a male child.
- Physicians counseling families about elective male circumcision should assist parents by explaining, in a nonbiased manner, the potential benefits and risks and by ensuring that they understand the elective nature of the procedure.
- Parents should weigh the health benefits and risks in light of their own religious, cultural, and personal preferences, as the medical benefits alone may not outweigh these other considerations for individual families.
- Parents of newborn boys should be instructed in the care of the penis, regardless of whether the newborn has been circumcised or not.
- Elective circumcision should be performed only if the infant's condition is stable and healthy.
- Male circumcision should be performed by trained and competent practitioners, by using sterile techniques and effective pain management.
- Analgesia is safe and effective in reducing the procedural pain associated with newborn circumcision; thus, adequate analgesia should be provided whenever newborn circumcision is performed.
    - Nonpharmacologic techniques (eg, positioning, sucrose pacifiers) alone are insufficient to prevent procedural and postprocedural pain and are not recommended as the sole method of analgesia. They should be used only as analgesic adjuncts to improve infant comfort during circumcision.
    - If used, topical creams may cause a higher incidence of skin irritation in low birth weight infants, compared with infants of normal weight; penile nerve block techniques should therefore be chosen for this group of newborns.
- Key professional organizations (AAP, the American Academy of Family Physicians, the American College of Obstetricians and Gynecologists, the American Society of Anesthesiologists, the American College of Nurse Midwives, and other midlevel clinicians such as nurse practitioners) should work collaboratively to:
    - Develop standards of trainee proficiency in the performance of anesthetic and procedure techniques, including suturing;
    - Teach the procedure and analgesic techniques during postgraduate training programs;
    - Develop educational materials for clinicians to enhance their own competency in discussing the benefits and risks of circumcision with parents;
    - Offer educational materials to assist parents of male infants with the care of both circumcised and uncircumcised penises.
- The preventive and public health benefits associated with newborn male circumcision warrant third-party reimbursement of the procedure.

The American College of Obstetricians and Gynecologists has endorsed this technical report. *Pediatrics* 2012;130: e756–e785

INTRODUCTION AND BACKGROUND

Statement of the Issue

The American Academy of Pediatrics' (AAP) statement on circumcision of the newborn penis was last issued in May 1999.[1] The *Circumcision Policy Statement* recognized the health benefits of circumcision but did not deem the procedure to be a medical necessity for the well-being of the child. Since that time, substantial contributions have been made to the peer-reviewed literature concerning circumcision of males and its possible benefits. For this reason, in 2007, the AAP formed a Task Force charged with reviewing current evidence on male circumcision and updating the policy on this procedure to provide guidance to AAP membership regarding the circumcision of newborn males.

The American College of Obstetricians and Gynecologists has endorsed this technical report.

Background

Male circumcision consists of the surgical removal of some, or all, of the foreskin (or prepuce) from the penis. It is one of the most common procedures in the world. In the United States, the procedure is most frequently performed during the newborn period. Elective circumcision performed soon after the newborn period is generally a result of deferral because of low birth weight or illness in the newborn. Circumcision after the newborn period is most commonly performed because of the infant's low birth weight or illness precluded newborn circumcision. Other infants are circumcised later in life because of the occurrence of tight phimosis and/or urinary tract infection (UTI).

The 3 most common operative methods of circumcision for the newborn male include: the Gomco clamp, the Plastibell device, and the Mogen clamp (or variations derived from the same

principle on which each of these devices is based). The elements that are common to the use of each of these devices to accomplish circumcision include the following: estimation of the amount of external skin to be removed; dilation of the preputial orifice so that the glans can be visualized to ensure that the glans itself is normal; bluntly freeing the inner preputial epithelium from the epithelium of the glans; placing the device (at times a dorsal slit is necessary to do so); leaving the device in situ long enough to produce hemostasis; and removal of the foreskin.

The extent of this practice in the United States has been estimated by various federally sponsored national surveys, each of which has its strengths and limitations; thus, multiple measures of circumcision prevalence and incidence are presented. There are large population measures of male circumcision in the United States, measuring either the occurrence (ie, incidence) of male circumcision among newborns or the existence of the circumcised state among representative samples of males in the United States at a particular period in time (ie, prevalence). The findings of these studies are qualitatively similar and consistently estimate the rate of male circumcision to range from 42% to 80% among various populations.[2–6]

A recent Centers for Disease Control and Prevention (CDC) study assessed trends in the incidence of in-hospital newborn male circumcision from 1999 to 2010 using 3 independent sources of discharge data on in-patient hospitalizations: the National Center for Health Statistics' National Hospital Discharge Survey (NHDS), the Agency for Healthcare Research and Quality's National Inpatient Sample (NIS), and the SDI Health's Charge Data Master (CDM).[2,3] These sources were used to estimate the incidence of newborn male circumcision in the first month of life. Overall from 1999 to 2010, the CDC's weighted analysis found that the approximate percentage of newborn US males who were circumcised was approximately 59.1% according to the NHDS, 57.8% according to the NIS, and 55.8% according to the CDM. The incidence of newborn male circumcision decreased over time in all 3 data sources: from 62.5% in 1999 to 56.9% in 2008 according to the NHDS; from 63.5% in 1999 to 56.3% in 2008 according to the NIS; and from 58.4% in 2001 to 54.7% in 2010 according to the CDM (Fig 1). A key limitation is that these incidence rates were derived from hospital-based surveys and do not include out-of-hospital circumcisions; thus, these data sources underestimate the actual rate of newborn male circumcision in the first month of life.

NIS

The NIS is a database of 5 to 8 million hospital inpatient stays drawn from states that participate in the Healthcare Cost and Utilization Project (HCUP). In 2008, these states comprised 95% of the US population. The NIS is used to track and analyze national trends in health care utilization, delivery, and outcomes via a 20% stratified sample of 1000 community hospitals. Weights are provided to calculate national estimates.[4]

The NIS indicates that circumcision was performed in 57% of male newborn hospitalizations between 1998 and 2005. NIS data from 1988 to 2008 indicate that the rate of circumcision performed during newborn male delivery hospitalizations increased significantly from 48% in 1988–1991, to 61% in 1997–2000,[5] then declined from 61% to 56% in 2000–2008[6] (Fig 1). Circumcision rates were highest in the Midwestern states (74%), followed by the Northeastern (67%) and Southern states (61%). The lowest circumcision rates were found in the Western states (30%) (Table 1).[3]

NHANES

The NHANES provides a snapshot of the health and nutritional status of the US population aged 14 to 59 years at the time of the survey, by using a probability sample of persons aged 0 to over 60 years. Prevalence of male circumcision is derived from participant self-report and is thus subject to misclassification. From 1999 to 2004, NHANES found that, of the 6174 men surveyed, 79% of men reported being circumcised, including 88% of non-Hispanic white men, 73% of non-Hispanic black men, 42% of Mexican-American men, and 50% of men of other races/ethnicities[6] (Fig 2).

However, prevalence rates are limited by the accuracy of the examiner and/or the self-report.[7,8] These findings underscore the necessity of using a standardized clinical examination for establishing circumcision status for the purpose of research on circumcision. It also highlights the potential difficulty of advising on care of the circumcised and uncircumcised penis when an individual and/or clinician may not know which condition is present.

Ethical Issues

The practice of medicine has long respected an adult's right to self-determination in health care decision-making. This principle has been operationalized through the doctrine of informed consent. The process of informed consent obligates the clinician to explain any procedure or treatment and to enumerate the risks, benefits, and alternatives so the patient can make an informed choice. As a general rule, minors in the United States are not considered competent to provide legally binding consent regarding their health care, and parents

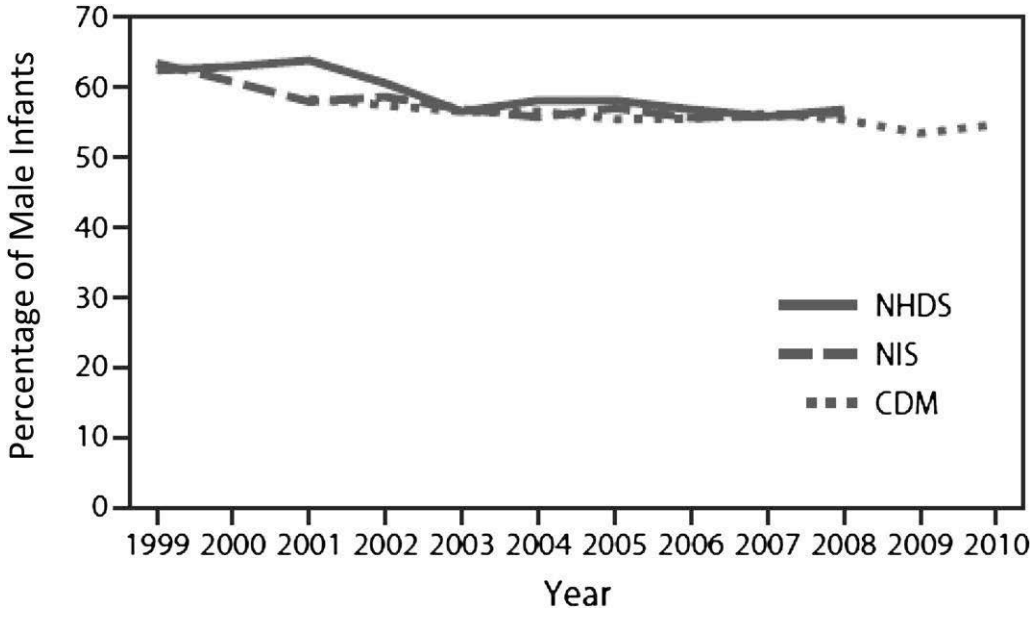

FIGURE 1
Incidence of in-hospital newborn male circumcision, according to data source; United States, 1999–2010.[2,3]

or guardians are empowered to make health care decisions on their behalf.[9] In most situations, parents are granted wide latitude in terms of the decisions they make on behalf of their children, and the law has respected those decisions except where they are clearly contrary to the best interests of the child or place the child's health, well-being, or life at significant risk of serious harm.[10]

Parents and physicians each have an ethical duty to the child to attempt to secure the child's best interest and well-being.[11] Reasonable people may disagree, however, as to what is in the best interest of any individual patient or how the potential medical benefits and potential medical harms of circumcision should be weighed against each other. This situation is further complicated by the fact that there are social, cultural, religious, and familial benefits and harms to be considered as well.[12] It is reasonable to take these nonmedical benefits and harms for an individual into consideration when making a decision about circumcision.[13]

TABLE 1 Multivariate Cox Proportional Hazards Regression of Selected Factors Associated With Circumcision Among Male Newborn Delivery Hospitalizations, United States, 1998–2005[2]

Characteristic	Weighted % of Male Infant Circumcisions	Adjusted Prevalence Rate Ratios (95% CI)
Hospital region		
Midwest	74	3.53 (3.23–3.87)
Northeast	67	2.90 (2.64–3.18)
South	61	2.80 (2.56–3.07)

Rural	56	1.00
Newborn health status		
Term, healthy	61	1.22 (1.20–1.23)
Not term, healthy	54	1.00

In cases such as the decision to perform a circumcision in the newborn period (where there is reasonable disagreement about the balance between medical benefits and harms, where there are nonmedical benefits and harms that can result from a decision on whether to perform the procedure, and where the procedure is not essential to the child's immediate well-being), the parents should determine what is in the best interest of the child. In the pluralistic society of the United States, where parents are afforded wide authority for determining what constitutes appropriate child-rearing and child welfare, it is legitimate for the parents to take into account their own cultural, religious, and ethnic traditions, in addition to medical factors, when making this choice.[11]

Physicians who counsel families about this decision should assist parents by objectively explaining the potential benefits and risks of circumcising their infant.[10] Because some families may opt to circumcise as part of religious or traditional practice, discussion should also encompass risks and benefits of

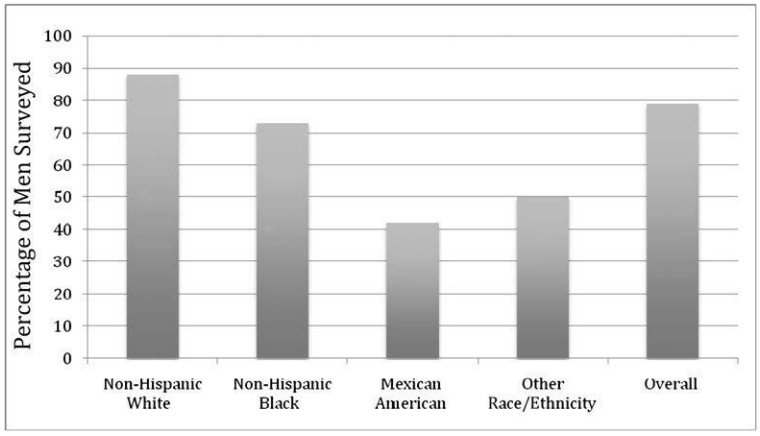

FIGURE 2
Prevalence of male circumcision, according to self-report; United States, 1999–2004.[5]

having a medical professional perform this procedure in a clinical setting versus having it performed by a traditional/religious provider in a nonmedical environment.

Parents may wish to consider whether the benefits of the procedure can be attained in equal measure if the procedure is delayed until the child is of sufficient age to provide his own informed consent. These interests include the medical benefits; the cultural and religious implications of being circumcised; and the fact that the procedure has the least surgical risk and the greatest accumulated health benefits if performed during the newborn period. Newborn males who are not circumcised at birth are much less likely to elect circumcision in adolescence or early adulthood. Parents who are considering deferring circumcision should be explicitly informed that circumcision performed later in life has increased risks and costs. Furthermore, deferral of the procedure also requires longer healing time than if performed during the newborn period and requires sexual abstinence during healing. Those who are already sexually active by the time they have the procedure lose some opportunities for the protective benefit against sexually transmitted infection (STI) acquisition, including HIV; moreover, there is the risk of acquiring an STI if the individual is sexually active during the healing process. (See the section entitled Sexually Transmitted Diseases, Including HIV.)

Finally, there is a moral obligation to take reasonable steps to reduce the risk of harm associated with the performance of any surgical intervention. These include ensuring that the providers who perform circumcision have adequate training and demonstrate competence in performing the procedure; the provision of adequate procedural analgesia and postprocedural pain control; and that the risks of infection are minimized through appropriate infection control measures, such as a sterile environment and sterilized instruments.[14] The Task Force advises against the practice of mouth-to-penis contact during circumcision, which is part of some religious practices, because it poses serious infectious risk to the child.

TASK FORCE ON MALE CIRCUMCISION

Committee Membership and Research Questions

In December 2007, the AAP formed a multidisciplinary workgroup of AAP members and other stakeholders to evaluate the evidence on male circumcision and update the AAP's recommendations in this area. The Task Force included AAP representatives from specialty areas, including anesthesiology/pain management, bioethics, child health care financing, epidemiology, fetus and newborn medicine, infectious diseases (including pediatric AIDS), and urology. The Task Force also included members of the AAP Board of Directors and liaisons representing the American Academy of Family Physicians (AAFP), the American College of Obstetricians and Gynecologists (ACOG), and the CDC. The Task Force's evidence review was supplemented by an independent, AAP-contracted, physician and doctoral-level epidemiologist who was also part of the entire evidence review process.

Literature Search Overview

The Task Force members identified the following topics and questions as relevant to male circumcision and to be addressed through a critical review of the peer-reviewed literature:

- What is the current epidemiology of male circumcision in the United States?
- What are the most common procedures and techniques for newborn male circumcision?
- What best supports the parental decision-making process regarding circumcision?
- What is the association between male circumcision and both morbidity and sexual function/satisfaction?
- What is the impact of anesthesia and analgesia?
- What are the common complications and the complication rates associated with male circumcision?
- What workforce issues affect newborn male circumcision?

- What are the trends in financing and payment for elective circumcision?

The group agreed on parameters for reviewing the literature on associations between male circumcision and other outcomes. The literature review comprised analytic studies (including meta-analyses) in the topic areas in English-language, peer-reviewed, scientific literature. The Task Force evaluated studies that addressed the identified clinical questions, including all meta-analyses; all randomized controlled trials; and all case-control, prospective and retrospective cohort, and cross-sectional studies based on the American Heart Association's template for evidence evaluation (see the following section). Case reports, case series, ecological studies, reviews, and opinions were excluded from the review. Although case reports and case series are important for generating hypotheses, the Task Force limited itself to reviewing analytic studies. The Task Force compiled and vetted Medical Subject Headings, which are defined by the National Library of Medicine.

Searches were conducted in Medline, Cochrane Database, and Embase for the period 1995 through 2010. The literature search produced 1388 abstracts that were reviewed by both the epidemiologist and the Task Force chair, and those citations meeting the established criteria were included; ultimately, 1014 articles were included in the review (Table 2). A second search was conducted in April 2010, which yielded 42 additional citations, of which 17 were included. All 1031 accepted articles were reviewed by the contracted physician epidemiologist and at least 1 Task Force member; any differences were resolved by consensus. In 2011, individual Task Force members also identified other key articles that appeared in the peer-reviewed literature; these articles were consulted in the preparation of the current report and cited accordingly. These additional articles did not affect the findings of the Task Force. Areas in which there were no analytic studies available for the time period of interest are noted as such within this document.

Evidence Quality and Use in Forming Recommendations

Articles were reviewed by using the American Heart Association's template for evidence evaluation.[15] The articles were also assigned a level of evidence (Table 3) based on the methodology used. Among those with evidence levels 1 through 4, the reviewers assessed the quality of the evidence as "excellent," "good," "fair," or "poor" depending on how well the methodology was applied. Articles with an evidence level of 5 or higher were not included in this review. A critical assessment was made of each article/source in terms of the research design and methods, by using the American Heart Association's template (Table 4).

RESULTS

As a result of these findings, the Task Force made the following recommendations, which are described further in the following text:

- Evaluation of current evidence indicates that the health benefits of newborn male circumcision outweigh the risks, and the benefits of newborn male circumcision justify access to this procedure for those families who choose it.
- Parents are entitled to factually correct, nonbiased information about circumcision that should be provided before conception and early in pregnancy, when parents are most likely to be weighing the option of circumcision of a male child.
- Physicians counseling families about elective male circumcision should assist parents by explaining, in a nonbiased manner, the potential benefits and risks, and by ensuring that they understand the elective nature of the procedure.
- Parents should weigh the health benefits and risks in light of their own religious, cultural, and personal preferences, as the medical benefits alone may not outweigh these other considerations for individual families.
- Parents of newborn boys should be instructed in the care of the penis at the time of discharge from the newborn hospital stay, regardless of whether the newborn has been circumcised or not.
- Elective circumcision should be performed only if the infant's condition is stable and healthy.
- Male circumcision should be performed by trained and competent practitioners, by using sterile techniques and effective pain management.
- Analgesia is safe and effective in reducing the procedural pain associated with newborn circumcision; thus, adequate analgesia should be provided whenever newborn circumcision is performed.
    - Nonpharmacologic techniques (eg, positioning, sucrose pacifiers) alone are insufficient to prevent procedural and postprocedural pain and are not recommended as the sole method of analgesia. They should be used only as analgesic adjuncts to improve infant comfort during circumcision.
    - If used, topical creams may cause a higher incidence of skin irritation in low birth weight infants, compared with infants of normal weight; penile nerve block techniques should therefore be chosen for this group of newborns.

7	Extrapolations from existing data collected for other purposes, theoretical analyses (excluded from review)
8	Rational conjecture (common sense); common practices accepted before evidence-based guidelines (excluded from review)

Parental Decision-Making

- Task Force Recommendations:
  - Parents are entitled to factually correct, nonbiased information about circumcision that should be provided before conception and early in pregnancy, when parents are most likely to be weighing the option of circumcision of a male child.
  - Physicians counseling families about elective male circumcision should assist parents by explaining, in a nonbiased manner, the potential benefits and risks, and by ensuring that they understand the elective nature of the procedure.
  - Parents should weigh the health benefits and risks in light of their own religious, cultural, and personal preferences, as the medical benefits alone may not outweigh these other considerations for individual families.

The decision of whether to circumcise a male newborn is frequently made early in the pregnancy and even before conception.[16–18] In a cross-sectional study of parents of 55 male infants presenting to a family practice clinic for a well-child visit, 80% of parents reported that the circumcision decision was made before a discussion occurred with the clinician about this issue. Only 4% of parents reportedly discussed circumcision with their clinician before the pregnancy.[16] This finding is substantiated by the 2009 AAP survey of 1620 members with a response rate of 57%, in which most respondents reported that parents of newborn male patients generally do not seek their pediatrician's recommendation regarding circumcision; only 5% reported that "all" or "most" parents "are uncertain about circumcision and seek their recommendation" about the procedure.[19] There is fair evidence that parental decisions about circumcision are shaped more by family and sociocultural influences than by discussion with medical clinicians or by parental education.[16,20]

In 4 cross-sectional studies with fair evidence, US parents most often reported that they chose to have their newborn son circumcised for health/medical benefits, including hygiene and cleanliness of the penis (reported by 39.6%, 46%, 53%, and 67%, respectively).[16,17,21,22] Social concerns (such as having a father or brother who was circumcised) were also an important reason given for newborn male circumcision (22.8%, 23.5%, 28%, and 37%). Religious requirements for circumcision, such as those of the Jewish and Islamic faiths, were ranked less highly in importance (11%, 12.1%, 13%, and 19%). Although one of these studies was small and included only 55 patients drawn from a homogeneous population,[16] the findings coincide with the 3 larger and more diverse studies.

For parents to receive nonbiased information about male circumcision in time to inform their decisions, clinicians need to provide this information at least before conception and/or early in the pregnancy, probably as a

TABLE 4 Assessment of Research Design and Methods

Component of Study and Rating	Excellent	Good	Fair	Poor	Unsatisfactory
Design and Methods	Highly appropriate sample or model, randomized, proper controls AND outstanding accuracy, precision, and data collection in its class	Highly appropriate sample or model, randomized, proper controls OR outstanding accuracy, precision, and data collection in its class	Adequate design but possibly biased OR adequate under the circumstances	Small or clearly biased population or model OR weakly defensible in its class, limited data or measures	Anecdotal, no controls, off target end points OR not defensible in its class, insufficient data or measures

curriculum item in childbirth classes. Information to assist in parental decision-making should be made available as early as possible. For this reason, obstetrician-gynecologists and family physicians who manage prenatal care probably have a more pivotal role in this decision than do pediatricians. *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents*, Third Edition, supports prenatal pediatric visits, at which time pediatricians can provide counseling about male circumcision (http://brightfutures.aap.org). Medical benefits and risks need to be presented accurately and in a nonbiased fashion so families can make a decision in light of their own cultural, religious, and personal preferences.

There is fair evidence that there are financial barriers to the circumcision decision in the United States; when the procedure is not covered by insurance, parents are less likely to choose to have their child circumcised.[21] This finding does not seem to be true in Canada, where the prevalence of circumcision did not change after circumcision for ritual, religious, cultural, or cosmetic reasons was delisted from insurance benefits in 1994.[17,23]

Care of the Circumcised Versus Uncircumcised Penis

- Task Force Recommendations:
  - Parents of newborn boys should be instructed in the care of the penis at the time of discharge from the newborn hospital stay, regardless of whether the newborn has been circumcised or not.

This review found no systematic studies in infants and children on the care of the uncircumcised versus circumcised penis.

Parents of newborn boys should be instructed in the care of the penis at the time of discharge from the newborn hospital stay, regardless of whether they choose circumcision or not. The circumcised penis should be washed gently without any aggressive pulling back of the skin.[24] The noncircumcised penis should be washed with soap and water. Most adhesions present at birth spontaneously resolve by age 2 to 4 months, and the foreskin should not be forcibly retracted. When these adhesions disappear physiologically (which occurs at an individual pace), the foreskin can be easily retracted, and the whole penis washed with soap and water.[25]

Circumcision reduces the bacteria that accumulate under the prepuce which can cause UTIs and, in the adult male, can be a reservoir for bacteria that cause STIs. In an internally controlled study with fair evidence, researchers cultured the periurethral and glandular sulcus of 50 children aged 1 to 12 weeks before and 4 weeks after circumcision and found the pathogenic bacteria largely disappeared after circumcision (33 children had pathogenic bacteria before circumcision and 4 had pathogenic bacteria after circumcision).[26]

In adults and children, there is fair evidence that periurethral flora contains fewer pathogens after circumcision than before circumcision.[26,27] Because these studies looked at cultures 1 time (4 weeks after the circumcision), the long-term significance of the findings is unclear.

Penile wetness (defined as the observation of a diffuse homogeneous film of moisture on the surface of the glans and coronal sulcus) is considered a marker for poor penile hygiene and is more prevalent in uncircumcised than in circumcised men.[28] Penile wetness has been associated with HIV infection in 1 cross-sectional study, although the temporal relationship is unclear and the evidence level is fair.[29] A related study with fair evidence assessed the frequency of washing the whole penis (including retracting the foreskin for uncircumcised men) and found that not always washing the whole penis was approximately 10 times more common in uncircumcised than in circumcised men.[30] The relationship between penile wetness and thorough washing of the penis is unclear and, because the studies were conducted in STI clinics, the findings may not be generalizable to the population at large.

Male Circumcision and Diseases, Morbidities, and Sexual Function/ Satisfaction

STIs, Including HIV

- Task Force Recommendation:
  - Evaluation of the current evidence indicates that the health benefits of newborn male circumcision outweigh the risks, and the benefits of newborn male circumcision justify access to this procedure for those families who choose it.

The most notable research contributions to the literature since 1995 are studies of male circumcision and the acquisition of HIV and the transmission of other STIs. Review of the literature revealed a consistently reported protective effect of 40% to 60% for male circumcision in reducing the risk of HIV acquisition among heterosexual males in areas with high HIV prevalence due to heterosexual transmission (ie, Africa).

There is also good evidence from randomized controlled trials that male circumcision is associated with a lower prevalence of human papillomavirus (HPV) infection[31,32] and herpes simplex virus type 2 (HSV-2) transmission,[31,33] as well as a decreased likelihood of bacterial vaginosis (BV) in female partners.[80] The evidence for male circumcision being protective against syphilis is less strong,[65–68] however, and male circumcision was not found to be associated with decreased risk of gonorrhea[84,85,91–93] or chlamydia.[84–89]

It is biologically plausible that the circumcised state may confer protection against STIs (including HIV). Possible mechanisms for the protective effect of circumcision include the fact that the foreskin's thin inner surface is susceptible to microtears and abrasions (especially during sexual activity), which provides a port of entry for pathogens. The foreskin also contains a high density of HIV target cells (ie, Langerhans cells, CD4 T cells, macrophages), which facilitates HIV infection of host cells. The preputial space provides an environment that is thought to "trap" pathogens and bodily secretions and favor their survival and replication.[26,27,34] The circumcised male has no foreskin and may likely provide a less welcoming environment for such substances. In addition, STI-containing secretions have increased contact time in the prospective uncircumcised male host, which may increase the likelihood of transmission and infection. The exposed surfaces of the uncircumcised penis do not offer the same physical barrier to resist infection that the highly keratinized surface of a circumcised penis does. Finally, the higher rates of sexually transmitted genital ulcerative disease (eg, HSV-2) observed in uncircumcised men may also increase susceptibility to HIV infection, as the presence of genital ulcers, irrespective of circumcision status, increases the likelihood of HIV acquisition.[35–37]

HIV

The CDC estimates that 1.2 million people in the United States are living with HIV, the virus that causes AIDS, which is incurable. Approximately 50 000 Americans are newly infected with HIV each year; more than 619 000 people in the United States have died of AIDS since the epidemic began.[38] In the United States, HIV/AIDS predominantly affects men who have sex with men (MSM), who account for almost two-thirds (61%) of all new infections. Heterosexual exposure accounts for 27% of new HIV infections, and injection drug use accounts for 9% of new HIV cases. In other parts of the world (eg, Africa), heterosexual transmission is far more common.[39]

Fourteen studies provide fair evidence that circumcision is protective against heterosexually acquired HIV infection in men.[40–53] One study with fair evidence found that male circumcision before puberty (specifically before 12 years of age) is more protective than circumcision occurring at a later age.[50] Three large randomized controlled trials provide good evidence of such protection.[54–56] A cross-sectional study with fair evidence is neutral regarding the relationship between circumcision and HIV infection.[57] Two other studies with a cross-sectional design provide fair evidence that circumcision increases the risk of HIV infection, although one of these studies highlights the HIV risks associated with circumcision performed outside the hospital setting and without sterile equipment and medically trained personnel.[58,59]

A recently published study from the CDC provides good evidence that, in the United States, male circumcision before the age of sexual debut would reduce HIV acquisition among heterosexual males.[60] Although individual sexual practices are difficult to predict in the newborn period, the majority of US males are heterosexual and could benefit from male circumcision. Mathematical modeling by the CDC shows that, taking an average efficacy of 60% from the African trials, and assuming the protective effect of circumcision applies only to heterosexually acquired HIV, there would be a 15.7% reduction in lifetime HIV risk for all males. This is taking into account the proportion of HIV that is acquired through heterosexual sex and reducing that by 60%. The percent reduction in HIV cases was determined by assessing the proportion of new cases of HIV infection that could be prevented by analyzing which infections would be presumed to occur in uncircumcised males and what the reduction would be if those who would not already be circumcised

would be circumcised. The proportions of transmissions prevented are lower than in Africa because a higher proportion of US HIV transmission occurs between MSM. In addition, a portion of the population would be circumcised without any policy change, and the prevented cases would only occur in the additional circumcised males. This ranges from an estimated 8% reduction in non-Hispanic white males to an estimated 21% reduction among non-Hispanic black males. The CDC study suggests that newborn circumcision performed in the United States to prevent HIV infection is cost-effective without consideration of other health benefits. The CDC recommendations state that all parents of newborn males should be given the choice of circumcision.

Specific HIV Risk Populations

MSM

The association of circumcision and the decreased likelihood of HIV acquisition applies to heterosexual males. Circumcision seems to be less likely to protect MSM, however, and has not been associated with decreased acquisition of HIV among MSM.[61] There is fair evidence from 1 study that there is a protective effect of circumcision from HIV infection in MSM; however, this study used self-report to establish circumcision status.[62] One study with fair evidence is neutral regarding the relationship between circumcision and HIV infection in MSM.[61] It is probable that the differences found in the level of protection (or lack of protection) by studies of MSM are confounded by the fact that MSM commonly perform both receptive and insertive sex. It is not known to what extent circumcision may be protective against HIV transmission for MSM who practice insertive sex versus for those who engage in receptive sex.

Heterosexual Women

Women account for 23% of new HIV infections in the United States; HIV infection in women is primarily attributed either to heterosexual contact or injection drug use.[38] Two prospective cohort studies with fair evidence looked at the relationship between a woman's risk of HIV infection and whether her primary male partner is circumcised. The first study describes a protective effect but had considerable loss-to-follow-up and possible misclassification of the partners' circumcision status.[63] The other study showed nonsignificant protection in the high-risk group (ie, women who were more likely to have ever engaged in sex work; to have reported 2 or more partners in the last 3 months; and/or to have had a higher median lifetime number of sex partners) but neither protection nor increased risk in the study population as a whole.[64] A meta-analysis with good evidence of data from 1 randomized controlled trial (RCT) and 6 longitudinal analyses found little evidence that male circumcision directly reduces their female partner's risk of acquiring HIV (summary relative risk: 0.8 [95% confidence interval (CI): 0.53–1.36]); however, male circumcision's protective effect did not reach a level of statistical significance.[65] One Ugandan RCT study with good evidence found that, at 24 months, the risk of HIV infection among women whose male partners were circumcised was 21.7% compared with 13.4% for female partners of uncircumcised men.[66]

Ulcerative STIs

Genital ulcers are notable both because of the morbidity and mortality associated with the causative organism and because the presence of the ulcer itself facilitates the transmission of HIV.

Syphilis

From 2009 to 2010, there were 13 604 cases of early latent syphilis reported to the CDC and 18 079 cases of late and late latent syphilis. The rate of primary and secondary syphilis in 2010 was 4.5 cases per 100 000 individuals, 2.2% lower than the 2009 rate. "The total number of cases of syphilis (primary and secondary, early latent, late, late latent, and congenital) reported to CDC increased 2.2% (from 44,830 to 45,834 cases) during 2009–2010."[67] A large percentage of syphilis cases occur in MSM; in 2010, 67% of the reported primary and secondary syphilis cases were among MSM.[67]

The balance of evidence suggests that male circumcision is protective against syphilis.[68–70] One meta-analysis with good evidence describes a protective effect (relative risk: 0.67 [95% CI: 0.54–0.83]), but there is considerable heterogeneity among the studies included.[68] An additional cohort study with fair evidence found that circumcised men were significantly less likely to have active syphilis at the point of study recruitment; when the men were followed up prospectively for 2 years, a protective effect was also observed but was nonsignificant.[69] Good evidence from a large RCT reported no reduction or trend toward reduction for male circumcision and the incidence of syphilis[71]; however, the extent to which protection might be afforded, and among which specific populations, is difficult to determine.

Genital Herpes

Genital herpes is an STI commonly manifested by recurrent genital ulcers caused by HSV-1 or HSV-2. HSV may not be clinically evident despite infection. Approximately 16.2% of US individuals aged 14 to 49 years have HSV-2.[31,72] Case reporting data for genital HSV are not available, but 2005–2008 NHANES data indicate that the percentage of NHANES participants aged 20 to 49 years who reported having

been diagnosed with genital herpes at some point was 18.9%.[72]

One meta-analysis with good evidence found some protective effect of circumcision against HSV-2 of borderline statistical significance.[68] Good evidence of the protective effect of male circumcision is available from two of the large randomized controlled trials in Africa. In the South African study, the incidence of HSV-2 was 34% lower in circumcised men.[73] In the Uganda study, the risk of HSV-2 infection (adjusted for other factors) was 28% lower in circumcised men.[71] There is fair evidence from 1 study that male circumcision protects female partners against HSV-2 infection.[33] Two studies with fair evidence found that there is no effect of circumcision on the risk of HSV-2 acquisition.[6,74]

Chancroid

Chancroid is a bacterial disease spread through sexual contact. It is rare in the United States, with a total of 24 cases reported in 2010 (a rate of 0.08 case per 100 000 individuals).[75]

The literature search produced no individual studies since 1995 exploring the relationship between male circumcision and chancroid. One meta-analysis with good evidence found that 6 of 7 older studies (85%) described circumcision as having a protective effect against chancroid. This meta-analysis did not provide a summary value for the relationship due to differences in the definition and ascertainment of outcomes and variability among the comparison groups.[68] One methodologically poor meta-analysis found no effect of male circumcision on chancroid.[76]

Lymphogranuloma Venereum and Granuloma Inguinale (Donovanosis)

The CDC reports that the frequency of lymphogranuloma venereum infection is thought to be rare in industrialized countries, although its identification is not always obvious; the number of cases of this infection in the United States is unknown.[77] Granuloma inguinale is a genital ulcerative disease that is rare in the United States but endemic in some tropical and developing areas. The lesions might develop secondary bacterial infection or can coexist with other sexually transmitted pathogens.

The literature search produced no studies since 1995 exploring the relationship between male circumcision and lymphogranuloma venereum or granuloma inguinale. One meta-analysis provided fair evidence that genital ulcerative disease was more common in uncircumcised men but not to a statistically significant degree.[78] One cross-sectional study with fair evidence found that male circumcision was protective against genital ulcers, but the findings were based on respondents self-reporting a history of genital ulcerative disease and may not be accurate.[79]

Nonulcerative STIs

Nonulcerative STIs generally cause inflammation and scarring along the reproductive tract. Untreated infection can cause cancer, can interfere with reproduction, and can negatively impact newborn health. Additionally, these infections can facilitate the transmission of HIV.

BV

BV is a condition "in women where the normal balance of bacteria in the vagina is disrupted and replaced by an overgrowth of certain bacteria."[80] BV is common among pregnant women; an estimated 1 080 000 pregnant women have BV annually.

There is good evidence from 1 large randomized controlled trial that male circumcision is protective against BV in female partners.[81] A small prospective cohort study with good evidence also found that male circumcision, among other factors, was protective against BV in female partners.[82] A cross-sectional study with fair evidence found no effect but may have lacked the power to detect an effect.[83]

Chlamydia

Chlamydia is the most commonly reported notifiable disease in the United States and the most common STI reported to the CDC, with 1 307 893 chlamydial infections (426.0 cases per 100 000 individuals) reported to the CDC in 2010.[84]

The balance of evidence does not reveal any relationship between circumcision and chlamydia infection.[85–87] The 1 prospective cohort study with fair evidence showed a protective effect, but the study had a composite end point with several STIs combined and used self-report of STI as the outcome (increasing the possibility of misclassification).[88] Two studies with fair evidence explored the effect of male circumcision on chlamydia infection in female partners. The first, a prospective cohort study, found a nonsignificant increased risk in the female partners of circumcised men.[89] The second, a cross-sectional study, found a significantly decreased risk of chlamydia infection among women with circumcised male sexual partners, but a possible selection bias may have affected results because only 51.8% of subjects had specimens for analysis.[90]

Gonorrhea

Gonorrhea is the second most commonly reported STI in the United States, with 309 341 cases reported to the CDC (a rate of 100.8 cases per 100 000 individuals) in 2010.[91]

The evidence does not demonstrate any relationship between circumcision and gonorrheal infection.[85,86,92–94] The

studies that show a protective effect are either barely significant or have poorly defined or self-reported outcomes, thus offering only a fair level of evidence.[79,88]

HPV

HPV is among the most commonly occurring STIs in the United States and can lead to the development of cancers, including cervical cancer. The population-based data from NHANES 2003–2006 indicate that the overall prevalence of high- and low-oncogenic risk HPV types was 42.5% among US women aged 14 to 59 years. The prevalence of infection was lower for the 2 viral types with the highest risk of causing cancer, however, at 4.7% for HPV type 16 and 1.9% for HPV type 18.[95]

There is good evidence that male circumcision is protective against all types of HPV infection (nononcogenic and oncogenic). Two prevalence studies with good evidence found a 30% to 40% reduction in risk of infection among circumcised men.[96,97] These studies fail to provide information on the risk of acquiring HPV and may reflect persistence of HPV rather than acquisition of infection. Four studies provide fair evidence that male circumcision protects against HPV.[98–101] The selection of anatomic sites sampled may influence the results.[98]

Good evidence of the protective effect of male circumcision against HPV is available from two of the large randomized controlled trials in Africa. In the South African study, the prevalence of high-risk HPV was 32% lower in circumcised men.[102] In the Uganda study, the risk of oncogenic HPV infection (adjusted for other factors) was 35% lower in circumcised men.[71]

There is also good evidence that male circumcision reduces the risk of male-to-female transmission of high-risk HPV from HIV-uninfected men. In the Uganda randomized controlled trial, the prevalence of high-risk HPV infection was 28% lower in female partners of circumcised HIV-uninfected men, while the incidence was 23% lower.[32] Good evidence from another Uganda randomized controlled trial of male circumcision in HIV-infected men indicates that a circumcision did not reduce the risk of male-to-female transmission of high-risk HPV from HIV-infected men.[103]

Male Circumcision and UTIs

According to the CDC, "A urinary tract infection (UTI) is an infection involving any part of the urinary system, including urethra, bladder, ureters, and kidney."[104] UTIs are the most common type of health care–associated infection reported to the National Healthcare Safety Network among US individuals. The majority of UTIs in males occur during the first year of life. In children, UTIs usually necessitate a physician visit and may involve the possibility of an invasive procedure and hospitalization.

Most available data were published before 1995 and consistently show an association between the lack of circumcision and increased risk of UTI. Studies published since 1995 have similar findings. There is good evidence from 2 well-conducted meta-analyses[105,106] and a cohort study[107] that UTI incidence among boys under age 2 years is reduced in those who were circumcised compared with uncircumcised boys. The data from randomized controlled trials are limited. However, there are large cohort and case-controlled studies with similar findings. Given that the risk of UTI among this population is approximately 1%, the number needed to circumcise to prevent UTI is approximately 100. The benefits of male circumcision are, therefore, likely to be greater in boys at higher risk of UTI, such as male infants with underlying anatomic defects such as reflux or recurrent UTIs.

There is fair evidence from 5 observational studies that UTI incidence among boys under age 2 years is reduced in circumcised infant boys, compared with uncircumcised boys under the age of 2.[108–112] The degree of reduction is between threefold and 10-fold in all studies.

There is fair evidence from a prospective study that there is a decreased prevalence of uropathogens in the periurethral area 3 weeks after circumcision, compared with similar cultures taken at the time of circumcision.[113] By using these rates and the increased risks suggested from the literature, it is estimated that 7 to 14 of 1000 uncircumcised male infants will develop a UTI during the first year of life, compared with 1 to 2 infants among 1000 circumcised male infants.

There is a biologically plausible explanation for the relationship between an intact foreskin and an increased association of UTI during infancy. Increased periurethral bacterial colonization may be a risk factor for UTI.[114] During the first 6 months of life, there are more uropathogenic organisms around the urethral meatus of uncircumcised male infants than around those of circumcised male infants (this colonization decreases in both groups after the first 6 months).[115] In addition, an experimental preparation found that uropathogenic bacteria adhered to, and readily colonized, the mucosal surface of the foreskin but did not adhere to the keratinized skin surface of the foreskin.[116]

Cancer

Penile Cancer

Penile cancer is rare, and rates seem to be declining. In the United States, Surveillance, Epidemiology, and End

Results data indicate that the incidence of primary, malignant penile cancer was 0.58 case per 100 000 individuals for 1993 to 2002, a decline from 0.84 case per 100 000 individuals from 1973 to 1982.[117] An analysis of the Danish Cancer Registry found that the incidence of epidermoid cancer of the penis (excluding scrotal, epididymal, and nonepidermoid) declined from a rate of 1.15 cases per 100 000 individuals from 1943 to 1947 to 0.82 case per 100 000 individuals in 1988 to 1990.[118]

Thus, declines have been noted in nations with both low and high circumcision rates (Denmark and the United States, respectively). Declines are not explained by changing patterns in circumcision utilization; it is thought that socioeconomic and economic development factors (including effects on hygiene habits) may have an important role.

The literature review yielded 2 case-control studies; although the studies were well designed, the evidence level for case-control studies is only deemed to be fair.[119,120] These studies show an association between circumcision and a decreased likelihood of invasive penile cancer. For all men with penile cancer (carcinoma in situ and squamous cell carcinoma), the absence of circumcision confers an increased risk with an odds ratio (OR) of 1.5, although this finding was not significant (P = .07), with a CI of 1.1–2.2.[119] An OR indicates the odds of an event happening in 1 group divided by the odds of an event happening in another group. An OR of 1 thus means that there is an equal chance for the event to occur in each group. When separated into squamous cell carcinoma and carcinoma in situ, the absence of circumcision was a risk factor for invasive squamous cell carcinoma (OR: 2.3 [CI: 1.3–4.1]) but not for carcinoma in situ (OR: 1.1 [CI not provided]).

Phimosis is a condition in which the foreskin cannot be fully retracted from the penis. A history of phimosis alone confers a significantly elevated risk of invasive cancer (OR: 11.4). In fact, in men with an intact prepuce and no phimosis, there is a decreased risk of invasive penile cancer (OR: 0.5). When excluding phimosis, the risk disappears, which suggests that the benefit of circumcision is conferred by reducing the risk of phimosis and that the phimosis is responsible for the increased risk. Other forms of penile injury or irritation likewise can pose a significant risk factor for cancer. There is accumulating evidence that circumcised men have a lower prevalence of oncogenic (high-risk) and nononcogenic (low-risk) HPV when compared with uncircumcised men, and this may be another means by which circumcision has a protective effect against invasive penile cancer (as discussed in the earlier STI section).

It is difficult to establish how many male circumcisions it would take to prevent a case of penile cancer, and at what cost economically and physically. One study with good evidence estimates that based on having to do 909 circumcisions to prevent 1 penile cancer event, 2 complications would be expected for every penile cancer event avoided.[121] However, another study with fair evidence estimates that more than 322 000 newborn circumcisions are required to prevent 1 penile cancer event per year.[122] This would translate into 644 complications per cancer event, by using the most favorable rate of complications, including rare but significant complications.[123] The clinical value of the modest risk reduction from circumcision for a rare cancer is difficult to measure against the potential for complications from the procedure. In addition, these findings are likely to decrease with increasing rates of HPV vaccination in the United States.

Cervical Cancer

Up to 12 000 new cases of cervical cancer are diagnosed in the United States annually. Cervical cancer is a leading cause of death for women in developing countries; more than 80% of all cervical cancer deaths occur in developing countries.[124] Persistent HPV infection with high-risk (ie, oncogenic) types (HPV types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 73, and 82) is the main prerequisite to developing cervical squamous carcinoma.

The association of cervical cancer, penile HPV infection, and circumcision was studied in an article of fair quality that found a protective effect of male circumcision against cervical cancer in the female partner(s) of men who have multiple female partners.[100] There was a lower incidence of HPV detection in circumcised men compared with uncircumcised men (5.5% and 19.6%, respectively). The OR for men who self-reported having been circumcised and who had penile HPV was 0.37 (95% CI: 0.16–0.85). In women whose partner had more than 6 lifetime sexual partners, male circumcision lowered her odds of cervical cancer significantly (OR: 0.42). The overall rate of cervical cancer for women who currently had circumcised male partners was not significantly decreased. Thus, the contribution of male circumcision to prevention of cervical cancer is likely to be small.

Penile Dermatoses and Phimosis

Penile dermatoses encompass a wide range of genital skin diseases, some of which are rarer than others. These diseases can include psoriasis, inflammation (ie, balanitis, balanoposthitis), infections (ie, superficial skin and soft tissue infections such as cellulitis), lichen sclerosis, lichen planus, lichen simplex, seborrheic dermatitis, atopic

eczema, and irritant dermatitis, among others.

From 1995 to 2011, all publications addressing this concern were case series and were therefore excluded from the literature forming the current analysis. Before 1995, a New Zealand prospective cohort study with good evidence explored rates of penile problems for 635 boys from birth to 8 years of age.[125] Four types of penile problems were defined: first was the number of episodes of inflammation of the penis experienced by the child. Penile inflammation included balanitis, meatitis, inflammation of the prepuce, and conditions in which the penis was described as sore or inflamed without any further diagnostic elaboration. The second type was the number of episodes of phimosis experienced by the child. These episodes included every time medical attention was sought for phimosis and associated symptoms. Episodes in which the child was brought to medical attention for "tight" or "non-retractable" foreskin but was not treated were not classified as phimosis, due to the likelihood that most of these attendances resulted from parental anxiety or uncertainty about the development of the foreskin rather than any pathologic condition in the child. The third type was inadequate circumcision requiring repair or recircumcision. Fourth was postoperative infection after circumcision from birth to 8 years of age by circumcision status. Findings were inconclusive for the first year of life; the adjusted rate of problems experienced was 5.2 penile problems per 100 circumcised boys over the study period, compared with 1.2 penile problems in uncircumcised boys at risk. From ages 1 through 8 years, the rates were 6.5 penile problems per 100 circumcised boys over the study period, compared with 17.2 penile problems per 100 uncircumcised boys.

Sexual Function and Penile Sexual Sensitivity

The literature review does not support the belief that male circumcision adversely affects penile sexual function or sensitivity, or sexual satisfaction, regardless of how these factors are defined.

Sexual Satisfaction and Sensitivity

Literature since 1995 includes 2 good-quality randomized controlled trials that evaluated the effect of adult circumcision on sexual satisfaction and sensitivity in Uganda and Kenya, respectively.[126,127] Among 5000 Ugandan participants, circumcised men reported significantly less pain on intercourse than uncircumcised men.[126] At 2 years' postcircumcision, sexual satisfaction had increased significantly from baseline measures in the control group (from 98% at baseline to 99.9%); satisfaction levels remained stable among the circumcised men (98.5% at baseline, 98.4% 2 years after the procedure). This study included no measures of time to ejaculation or sensory changes on the penis. In the Kenyan study (which had a nearly identical design and similar results), 64% of circumcised men reported much greater penile sensitivity postcircumcision.[127] At the 2-year follow-up, 55% of circumcised men reported having an easier time reaching orgasm than they had precircumcision, although the findings did not reach statistical significance. The studies' limitation is that the outcomes of interest were subjective, self-reported measures rather than objective measures.

Other studies in the area of function, sensation, and satisfaction have been less rigorous in design, and they fail to provide evidence that the circumcised penis has decreased sensitivity compared with the uncircumcised penis. There is both good and fair evidence that no statistically significant differences exist between circumcised and uncircumcised men in terms of sexual sensation and satisfaction.[128–131] Sensation end points in these studies included subjective touch and pain sensation, response to the International Index of Erectile Function, the Brief Male Sexual Function Inventory, pudendal nerve evoked potentials, and Intravaginal Ejaculatory Latency Times (IELTs).

There is fair evidence that men circumcised as adults demonstrate a higher threshold for light touch sensitivity with a static monofilament compared with uncircumcised men; these findings failed to attain statistical significance for most locations on the penis, however, and it is unclear that sensitivity to static monofilament (as opposed to dynamic stimulus) has any relevance to sexual satisfaction.[132] There is fair evidence from a cross-sectional study of Korean men of decreased masturbatory pleasure after adult circumcision.[133]

Sexual Function

There is both good and fair evidence that sexual function is not adversely affected in circumcised men compared with uncircumcised men.[131,134–136] There is fair evidence that no significant difference exists between circumcised and uncircumcised men in terms of sexual function, as assessed by using the IELT.[129]

Limitations to consider with respect to this issue include the timing of IELT studies after circumcision, because studies of sexual function at 12 weeks postcircumcision by using IELT measures may not accurately reflect sexual function at a later period. Also, the self-report of circumcision status may impact study validity. This could be in an unpredictable direction, although it is most likely that the effect would be to cause an underestimation of the association. Other biases include

participants' ages and any coexisting medical conditions.

Analgesia and Anesthesia

- Task Force Recommendation:
  - Trained and competent practitioners, by using sterile techniques and effective pain management, should perform male circumcision. Analgesia is safe and effective in reducing the procedural pain associated with newborn circumcision; thus, adequate analgesia should be provided whenever newborn circumcision is performed.
  - Nonpharmacologic techniques (eg, positioning, sucrose pacifiers) alone are insufficient to prevent procedural and postprocedural pain and are not recommended as the sole method of analgesia. They should be used only as analgesic adjuncts to improve infant comfort during circumcision.
  - If used, topical creams may cause a higher incidence of skin irritation in low birth weight infants, compared with infants of normal weight, so penile nerve block techniques should be chosen for this group of newborns.

The analgesics used for newborn circumcision include nonpharmacologic and pharmacologic (topical and nerve blocks) techniques. The Task Force's review included nonnutritive sucking, a pacifier dipped in sucrose, acetaminophen, topical 4% lidocaine (ie, LMX4 cream), a eutectic mixture of lidocaine-prilocaine local anesthetic (EMLA), subcutaneous ring block, and the dorsal penile nerve block (DPNB). These methods, which reduce the pain and stress of newborn circumcision, are representative of the principles discussed in the AAP *Policy Statement on Prevention and Management of Pain in the Neonate*, which was updated in 2006.[137,138] There are no evidence-based recommendations that state there is persistent pain that must be treated after the local preprocedure anesthetic wears off.

Analgesia is safe and effective in reducing the procedural pain associated with newborn circumcision, as indicated by changes in heart rate, oxygen saturation, facial action, crying, and other measures.[139–145] Therefore, adequate analgesia should be provided when newborn circumcision is performed. Topical 4% lidocaine, DPNB, and a subcutaneous ring block are all effective options, although the latter may provide the most effective analgesia. In addition there is good evidence that infants circumcised without analgesia exhibit a stronger behavioral pain response to subsequent routine immunization at 4 to 6 months of age, compared with both infants circumcised with analgesia and with uncircumcised infants.[145]

The literature search did not produce any reports of local anesthetic toxicity, such as seizures or cardiovascular instability, among the newborns receiving either local anesthetic injections or topical applications (ie, topical 4% lidocaine).

Nonpharmacologic Techniques

There is good evidence that oral sucrose and oral analgesics are not different from placebo or environmental modification in their ability to control pain.[141,142,144] There is good evidence that a more physiologic positioning of the infant in a padded environment may decrease distress during the procedure.[146] There is fair evidence that sucrose on a pacifier has been demonstrated to be more effective than water alone for decreasing crying during circumcision.[147–149] Nonpharmacologic techniques alone are insufficient to prevent procedural pain, however. Positioning and a sucrose pacifier should be used as analgesic adjuncts to improve infant comfort during circumcision but are not recommended as the sole method of analgesia.

Topical Local Anesthesia Techniques

There is good evidence that topical anesthesia with lidocaine-prilocaine (which contains 2.5% lidocaine and 2.5% prilocaine) or 4% lidocaine is superior to no anesthesia in preventing pain during male circumcision.[150]

There is good evidence from a prospective cohort study that lidocaine-prilocaine cream attenuates the pain response to circumcision (as measured by using heart rate, oxygen saturation, facial actions, and time and characteristics of crying) when applied 60 to 90 minutes before the procedure.[150,151] There is fair evidence from an RCT that lidocaine-prilocaine cream attenuates the pain response to circumcision, although it was less effective in doing so than DPNB or ring block.[152] There is good evidence that topical 4% lidocaine is as effective as lidocaine-prilocaine at preventing pain.[140,153] Topical 4% lidocaine has the advantage of having a faster onset of action (2 g applied 30 minutes before circumcision, compared with 1 to 2 hours before circumcision for lidocaine-prilocaine). Both topical preparations require coverage with plastic wrap to keep the cream in place. Topical 4% lidocaine is the preferred topical local anesthetic (over lidocaine-prilocaine) because there is no risk of methemoglobinemia.

The most common complications reported with analgesic techniques were an 8% to 14% incidence of erythema, swelling, and blistering associated with topical analgesia.[142,150,153,154] There is fair evidence that adverse effects of topical anesthetic creams are

infrequent and include only either minor skin reactions (ie, erythema, swelling) or, more rarely, blistering (especially in low birth weight infants).[154] For this reason, penile nerve block techniques should be chosen for low birth weight infants. There is good and fair evidence that both reactions are less common with 4% lidocaine than with lidocaine-prilocaine cream.[142,150,153–155]

There is a theoretical risk of methemoglobinemia with lidocaine-prilocaine.[152] However, when methemoglobin has been measured after lidocaine-prilocaine application, the level, although elevated, was not clinically significant.[150] Nevertheless, there have been isolated case reports of clinically significant methemoglobinemia involving prolonged application time or use in premature infants.[156,157,158]

DPNB

Most commonly, DPNB consists of injections of 0.4 mL of 1% lidocaine without epinephrine on both sides of the base of the penis. Systemic lidocaine levels obtained with use of this technique reached peak concentrations at 60 minutes after injection and were well below toxic ranges.[159]

There is good evidence that DPNB is effective in reducing the behavioral and physiologic indicators of pain caused by circumcision, regardless of the device used.[144] There is good evidence that DPNB is superior to lidocaine-prilocaine in relieving pain during and after circumcision in newborns.[142,160–162] One good-quality prospective cohort study of 491 newborn circumcisions measured complications of DPNB analgesia; it reported an 11% incidence of bruising and a 0.2% incidence of hematoma, none of which required any change in management.[163] Another good-quality, blinded, randomized controlled trial found a 43% incidence of small hematomas in preterm and term newborns circumcised by using DPNB.[142]

Subcutaneous Ring Block

Two studies with fair evidence found that the subcutaneous circumferential ring block (0.8 mL of 1% lidocaine without epinephrine injected at the base or midshaft of the penis) is effective in mitigating pain and its consequences during circumcision of newborns.[164]

One study presented fair evidence that the ring block was superior to using no anesthesia but found a 5% failure rate with the technique (1 in 20 ring block infants had heart rate and behavioral pain scores that were above the control mean during at least 50% of the measured intervals, while 19 of 20 had heart rate and pain scores less than the control mean). There were no hematomas in the infants receiving ring blocks. A second ring block study had fair evidence that the method was superior to either DPNB or lidocaine-prilocaine cream for pain relief in newborn circumcision, as the ring block seemed to prevent crying and increases in heart rate during all phases of the circumcision, with less crying and lower heart rates during foreskin separation and incision than seen with DPNB or lidocaine-prilocaine.[152] No complications have been reported in the use of this simple and highly effective technique.

Analgesia and Anesthesia for a Circumcision After the Newborn Period

In the United States, after the newborn period, general anesthesia is used during male circumcision because the surgical procedure takes longer and involves hemostasis and the suturing of skin edges. Use of adjuvant local anesthetic techniques in addition to general anesthesia provides longer-lasting postoperative analgesia, minimizes the need for intraoperative or postoperative opioid administration, reduces adverse postoperative events such as nausea and vomiting, and decreases recovery time. Long-lasting analgesia is achieved with either penile nerve block, by using any of the methods mentioned earlier, or caudal epidural analgesia in infants and children up to 3 years of age.

General anesthesia carries a low risk of mortality (1 death per 400 000 instances of general anesthesia). The risk of adverse events (especially respiratory events) during general anesthesia remains higher in infants under 1 year of age.[165] These risks are minimized when the procedure is performed in infants in their optimal state of health (no active reactive airway disease or upper respiratory infection) and in a facility familiar with the anesthesia care of infants.[166] Additional concerns associated with surgical circumcision in older infants include time lost by parents and patients from work and/or school.

Caudal Block

Caudal block (CB) with bupivacaine is an anesthetic technique used for postoperative analgesia for circumcision in infants and older children up to 3 years of age, as an alternative to ring block and DPNB techniques. There is good and fair evidence that there is a longer time to first postoperative urination after CB without adverse clinical consequences.[167,168] There is good evidence for a high incidence of mild postoperative motor block and delay in walking after the CB procedure (21% to 44%) in older children.[167,169,170] Caudal analgesia may be less available in facilities that do not treat many pediatric patients.

DPNB

The reported failure rate of DPNB is 1% to 10%.[171–175] When DPNB is used

without general anesthesia in boys 3 to 5 years of age, the technique has a failure rate of 15%; for boys aged 6 and older, the failure rate is 1.5%.[175] There is good and fair evidence that incidence of hematoma with DPNB ranges from 0.001% to 24%; several studies report rates of approximately 6%.[174–177] One study with fair evidence reports a 0.001% rate of "improper needle position with bleeding" and a similar number of "medication errors."[176] Studies with good and fair evidence report a 12% to 83% rate of edema in the area of injection of the local anesthetic after DPNB.[174,175,177]

Subcutaneous Ring Block

There is good evidence for the reported 8% failure rate using the ring block.[168] In children, edema and distortion of tissue layers after the ring block make surgery more difficult, compared with using a CB to prevent postoperative pain.[178]

Comparison of Methods

DPNB, subcutaneous ring block, and CB techniques may be used in conjunction with general anesthesia depending on the age of the child and are also used to provide postcircumcision analgesia. There is good evidence that there is no difference in the quality of postoperative analgesia or parent satisfaction between DPNB and CB using bupivacaine.[169] A comparison of CB with or without a subcutaneous ring block with bupivacaine showed good evidence that CB with a subcutaneous ring block had significantly longer duration of postoperative analgesia.[168] A technique describing ultrasound guidance for correct needle placement for DPNB in children under general anesthesia describes lower pain scores in the first postoperative hour and a longer interval until rescue analgesia was required.[179,180]

Complications and Adverse Events

- Task Force Recommendation:
  - Elective circumcision should be performed only if the infant's condition is stable and healthy.
  - Male circumcision should be performed by trained and competent practitioners, by using sterile techniques and effective pain management.

The true incidence of complications after newborn circumcision is unknown, in part due to differing definitions of "complication" and differing standards for determining the timing of when a complication has occurred (ie, early or late). Adding to the confusion is the comingling of "early" complications, such as bleeding or infection, with "late" complications such as adhesions and meatal stenosis. Also, complication rates after an in-hospital procedure with trained personnel may be far different from those of the developing world and/or by untrained ritual providers. For the purposes of this document, complications are grouped in terms of the timing of the procedure. (Citations for the following statements below are provided in the section after this summary.)

Significant acute complications are rare, occurring in approximately 1 in 500 newborn male circumcisions. Acute complications are usually minor and most commonly involve bleeding, infection, or an imperfect amount of tissue removed. Late complications do occur, most commonly adhesions, skin bridges, and meatal stenosis. There are 2 schools of thought regarding the cause of penile adhesions, which are common after circumcision. One is that fine adhesions represent incomplete lysis of physiologic adhesions at the time of circumcision; the other is that the fine adhesions occur because of raw serosa surfaces. It is unknown how often these late complications require surgical repair; this area requires further study.

In general, the specific technique used does not afford a significant difference in risk of complications. However, boys undergoing circumcisions in medical facilities in industrialized settings performed by trained practitioners have fewer complications than boys in nonindustrialized nations who have circumcisions performed by poorly trained (or untrained) practitioners in nonmedical surroundings. If circumcision is performed, it is imperative that those providing the service have adequate training in the method used and resources for and practice of adequate analgesia and infection control.

Contraindications to newborn circumcision include significantly premature infants, those with blood dyscrasias, individuals who have a family history of bleeding disorders, and those who have congenital abnormalities such as hypospadias, congenital chordee, or deficient shaft skin such as penoscrotal fusion or congenital buried penis. In addition, before performing newborn male circumcision, the clinician should confirm that vitamin K has been administered, in accordance with standard practice of newborn care.[181]

Newborn Elective Circumcision

Two large US hospital-based studies with good evidence estimate the risk of significant acute circumcision complications in the United States to be between 0.19% and 0.22%.[121,123] Bleeding was the most common complication (0.08% to 0.18%), followed by infection (0.06%) and penile injury (0.04%). For comparison, an audit of 33 921 tonsillectomies found an incidence of hemorrhage of 1.9% among children aged 0 to 4 years.[182] An Israeli prospective cohort study with fair evidence examined 19 478 male infants born in 2001 who were

circumcised primarily by trained, ritual providers in nonmedical settings, and reported similarly low complication rates. The overall complication rate was 0.34%, including bleeding in 0.08% and infection in 0.01%.[183] Approximately one-third of the identified complications were immediate (ie, bleeding, infection, penile injury), whereas two-thirds occurred later (ie, excess foreskin, penile torsion, shortage of skin, phimosis, inclusion cyst).

There is fair evidence of a more frequent complication rate of 3.1% in a study based on abstraction of 1951 hospital medical (rather than billing) records on newborn circumcision in Atlanta.[184] In this study, complications were found to be much more common, with bleeding occurring in 2.1%, although most reports of bleeding were mild in nature. Likewise, a review with fair evidence of 1000 newborn circumcisions by using the Gomco clamp in a hospital setting in Saudi Arabia found an overall complication rate of 1.9%.[185] Bleeding occurred in 0.6%, infection in 0.4%, and redundant prepuce in 0.3%.

Late complications of newborn circumcision include excessive residual skin (incomplete circumcision), excessive skin removal, adhesions (natural and vascularized skin bridges), meatal stenosis, phimosis, and epithelial inclusion cysts. These complications are considered "late," as opposed to "acute" (or immediate) complications such as bleeding or infection, which may still present during infancy but not during the immediate postprocedural time frame. In 1 outpatient-based study of 214 boys with poor evidence, the complications seen included adhesions (observed in 55 boys [25.6%]), redundant residual prepuce (44 boys [20.1%]), balanitis (34 boys [15.5%]), skin bridge (9 boys [4.1%]), and meatal stenosis (1 boy [0.5%]).[76]

Outside the United States, a cross-sectional study from Nigeria of 370 consecutive male infants (322 of whom had been circumcised) attending an infant welfare clinic for immunization with fair evidence reported an overall complication rate of 20.2%.[186] Complications included redundant prepuce (12.9%), excessive skin removal (5.9%), skin bridge (4.1%), and buried penis (0.4%). The majority of the procedures (81%) were performed in the hospital; 19% were performed at home. Nurses performed 56% of procedures (n = 180), physicians performed 35% (n = 113), and traditional circumcisers performed 9% (n = 29). The Israeli study noted earlier with fair evidence reported a late complication of redundant prepuce in 0.2% of the 19 478 male infants studied.[183]

There is good evidence that circumcision of a premature infant is associated with an increased risk of later-occurring complications (ie, poor cosmesis, increased risk of trapped penis, adhesions). There is also good evidence that circumcision of a newborn who has a prominent suprapubic fat pad or penoscrotal webbing has a higher risk for the same long-term complications.[187] One prospective study with fair evidence examined the natural course of penile adhesions after circumcision and found that adhesions disappeared at some point 6 months postcircumcision without intervention, except for thick adhesions (called "bridging adhesions"). The authors recommended lysis for skin bridges.[188]

Post-newborn Circumcision

There have been few reports of acute complications after non-newborn circumcision in the United States. Furthermore, there are no adequate studies of late complications in boys undergoing circumcision in the post-newborn period; this area requires more study.

Although adverse outcomes are rare among non-newborn circumcisions, the incidence tends to be orders of magnitude greater for boys circumcised between 1 and 10 years of age, compared with those circumcised as newborns.[189] As noted, general anesthesia, which is used for procedures performed after the newborn period, confers additional risk.

The most common surgical complication is excessive bleeding (eg, bleeding that did not stop with local pressure, perhaps requiring a suture), reported in 0.6% of 1742 male infants.[184] Contact burns were reported with electrocautery when used with metal, and it should not be used with the Gomco clamp in newborn circumcisions because it can cause devastating burns.[184,190,191] A study with fair evidence reviewed the records of 476 boys undergoing circumcision during childhood and found that complications occurred in 8 records (1.7%), of which 3 were related to anesthesia.[192] The most common surgical complication was excessive bleeding in 0.6%. In another report with fair evidence, which examined 267 patients who had circumcision by using topical glue rather than skin sutures, excessive bleeding occurred in 0.75% of cases.[193]

European centers report an overall complication rate of 1.2% to 3.8% for circumcisions performed in boys during the newborn or non-newborn period.[194–196] In a study with fair evidence of trained medical personnel in the United Kingdom, the rate of bleeding was 0.8% and of infection was 0.3%. In this study of a historical cohort of over 75 boys aged 0 to 14 years, 0.5% required surgical repair.[195]

In a Turkish prospective cohort study of 700 boys with fair evidence, bleeding

was reported in 2.2% of cases and infection in 1.3% of boys circumcised in a hospital, versus a bleeding rate of 3.6% and an infection rate of 2.7% in boys undergoing a nonhospital-based mass religious procedure, despite the latter procedure being performed by trained personnel.[196]

There are no adequate analytic studies of late complications in boys undergoing circumcision in the post-newborn period. An Iranian cross-sectional study with good evidence reported a late complication rate of 7.4%, including redundant skin in 3.6%, excessive skin removal in 1.3%, and meatal stenosis in 0.9%.[197]

Major Complications

The majority of severe or even catastrophic injuries are so infrequent as to be reported as case reports (and were therefore excluded from this literature review). These rare complications include glans or penile amputation,[198–206] transmission of herpes simplex after mouth-to-penis contact by a mohel (Jewish ritual circumcisers) after circumcision,[207–209] methicillin-resistant *Staphylococcus aureus* infection,[210] urethral cutaneous fistula,[211] glans ischemia,[212] and death.[213]

Medical Versus Traditional Providers

In general, untrained providers create more complications when performing male circumcision than do well-trained providers, regardless of whether they are physicians, nurses, or traditional religious providers. Physicians in a hospital setting generally have fewer complications than traditional providers in the community setting.

A prospective study in Kenya with good evidence found an overall complication rate of 35% in 443 children and young men aged 5 to 21 years who had traditional circumcision performed in a village or household setting, compared with an overall complication rate of 17% in those whose circumcision was performed by trained providers in a medical setting such as a hospital, health center, or physician's office.[214] The most common complications were bleeding and infection; excessive pain, lacerations, torsion, and erectile dysfunction were also observed. A study in Turkey with fair evidence studied a historical cohort and found a significantly higher rate of complications when male circumcision was performed by traditional circumcisers, compared with those performed by physicians; complication rates were 85% for traditional providers versus 2.6% for physicians.[215]

A study in Israel with fair evidence found there was no difference in the rate of complications in newborn circumcision between hospital-based physicians and well-trained, home-based ritual circumcisers (mohels).[183]

Complications With Different Methods of Male Circumcision

There have been few studies comparing the 3 most commonly used techniques for male circumcision in the United States (the Gomco clamp, the Plastibell device, and the Mogen clamp). Steps common to all 3 include estimation of the amount of external skin to be removed; dilation of the preputial orifice so the glans can be visualized to ensure that the glans itself is normal; bluntly freeing the inner preputial epithelium from the epithelium of the glans; placing the device; leaving the device in place long enough to produce hemostasis; and surgically removing the foreskin.

Gomco Clamp

The Gomco clamp was specifically designed for performing circumcisions. In this procedure, "the foreskin is cut lengthwise through the stretched tissue (dorsal slit) to allow space to insert the circumcision device. The bell of the Gomco clamp is placed over the glans, and the foreskin is pulled over the bell. The base of the Gomco clamp is placed over the bell, and the Gomco clamp's arm is fitted. After the surgeon confirms correct fitting and placement (and the amount of foreskin to be excised), the nut on the Gomco clamp is tightened and left in place for 3 to 5 minutes to allow hemostasis to occur, then the foreskin is removed using a scalpel. The Gomco's base and bell are then removed."[216]

One study of the Gomco clamp with fair evidence reviewed 1000 newborn circumcisions in a hospital setting in Saudi Arabia and found an overall complication rate of 1.9%.[185] Bleeding occurred in 0.6% of cases, infection in 0.4%, and redundant prepuce in 0.3%. Another study of 521 newborn male circumcisions performed at a Houston outpatient clinic with fair evidence reported a 2.9% incidence of phimosis (trapped penis) after newborn circumcision using the Gomco clamp.[217]

Plastibell Device

Plastibell circumcision involves a surgical procedure in which a plastic ring is inserted under the foreskin, and a tie is placed over the ring to provide hemostasis. The ring remains on the penis for several days until the tissue necroses and the ring falls off spontaneously. Bleeding ranged from 0.8% to 3% of cases; infection occurred in 2.1% of cases.[218] Urinary retention[219,220] and problems with the Plastibell ring have been reported in 3.6% of cases.[221] Studies of the Plastibell device with fair and good evidence found, overall, that complications range from 2.4% to 5%.[218,221–223]

Mogen Clamp

The Mogen clamp is a device consisting of 2 flat blades that have a limited

(slit-like) space between them and a mechanism that draws the blades together and locks them in place. The slit is limited to 3 mm to allow the foreskin, but not the glans, to cross the opening. The preputial adhesions are gently taken down by a probe and the glans pushed downward, thereby protecting it from the blades. The prepuce distal to the glans is drawn into the slit between the blades and positioned. The blades are locked together, crushing the skin and creating hemostasis. The skin is excised from above the clamp. The clamp is removed and the skin pushed proximally into proper position.

There were no specific studies of complications of the Mogen because complications are rare; thus, one can only rely on available case reports of amputation.[201,202,222–228]

Comparison

A study with fair evidence evaluated the use of the Gomco versus the Plastibell device in 350 newborn infants.[229] The incidence of infection was higher with the Gomco clamp (2%) versus a lower complication rate (1.3%) with the Plastibell device. Adhesions were also more common with the Gomco clamp, at a rate of 20% vs 6.6% for the Plastibell device.

Stratification of Risks

Based on the data reviewed, it is difficult, if not impossible, to adequately assess the total impact of complications, because the data are scant and inconsistent regarding the severity of complications. For example, studies that report bleeding as a complication do not uniformly report how frequently the bleeding was controlled with local measures versus requiring a transfusion or surgical intervention. Similarly, infection is rarely further divided into local tissue infection versus bacteremia or sepsis. Financial costs of care, emotional tolls, or the need for future corrective surgery (with the attendant anesthetic risks, family stress, and expense) are unknown.

Some reports have attempted to compare potential benefits of circumcision with reported complication rates. One study with good evidence attempted to estimate complication rates compared with benefits from male circumcision. Based on an estimate that 100 circumcisions must be performed to prevent 1 UTI, and 909 circumcisions must be performed to prevent 1 case of penile cancer, the study yields an estimate of 1 complication for every 5 UTIs prevented and 2 complications for every 1 case of penile cancer prevented.[121] Assuming an overall minor adverse event rate for newborn circumcision of 0.2%, and a severe adverse event rate of 0.005%, another study with fair evidence estimated that over 322 000 newborn male circumcisions are required to prevent 1 case of penile cancer per year.[122] Similar modeling for HIV, herpes, and HPV in the United States is not available.

A recently published CDC study found that male circumcision before the age of sexual debut was cost-effective for the prevention of HIV.[60] The study did not take into account the positive benefits of newborn circumcision for other conditions such as costs of caring for UTIs.[106,107,110,112,230–233] It also did not include recent evidence that circumcision (either as an infant or later in life) is associated with reduced risk for other STIs, penile and cervical cancers, phimosis, and penile dermatoses.[36,88,234,235] The authors did not include adverse effects that make newborn circumcision less cost-effective, such as bleeding, infection, and revision. Considering all these factors, however, the authors concluded that male circumcision was a cost-effective strategy for HIV prevention in the United States.[60]

Workforce Development and Male Circumcision

- Task Force Recommendations:
  - Physicians counseling families about elective male circumcision should assist parents by explaining, in a nonbiased manner, the potential benefits and risks, and by ensuring that they understand the elective nature of the procedure.
  - Parents are entitled to factually correct, nonbiased information about circumcision that should be provided before conception and early in pregnancy, when parents are most likely to be weighing the option of circumcision of a male child.
  - Parents of newborn boys should be instructed in the care of the penis at the time of discharge from the newborn hospital stay, regardless of whether the newborn is circumcised or not.
  - Male circumcision should be performed by trained and competent practitioners, by using sterile techniques and effective pain management. Analgesia is safe and effective in reducing the procedural pain associated with newborn circumcision; thus, adequate analgesia should be provided whenever newborn circumcision is performed.
  - Key professional organizations (AAP, AAFP, ACOG, the American Society of Anesthesiologists, the American College of Nurse Midwives, and other midlevel clinicians such as

nurse practitioners) should work collaboratively to:

- Develop standards of trainee proficiency in performance of anesthetic and procedure techniques, including suturing;
- Teach the procedure and analgesic techniques during postgraduate training programs;
- Develop educational materials for clinicians to enhance practitioners' competency in discussing the benefits and risks of circumcision with parents;
- Offer educational materials to assist parents of male infants with the care of both circumcised and uncircumcised penises.

Workforce Development and Parental Decision-making

There is fair evidence that some clinicians do not convey current or medically accurate information about circumcision to parents, either verbally or in written materials.[18] Providing information about the risks and benefits of circumcision does not seem to lead to lower circumcision rates.[236]

Parents are entitled to factually correct, nonbiased information about circumcision and should receive this information from clinicians before conception and/or early in pregnancy, which is when they are making choices about circumcision. As noted, in 2009, the AAP surveyed members on their attitudes and practices around circumcision.[19] According to the responses, 67% of pediatricians reported discussing the pros and cons of circumcision with parents. Almost two-thirds (62%) reported that they made no recommendation regarding circumcision to the majority of their patients; 18% responded recommending to all or most of their patients' parents that circumcision be performed; 7% reported recommending to all or nearly all of the parents of newborn males that circumcision not be performed.

As described earlier, there is fair evidence that parental decision-making about circumcision tends to occur well before the child's birth. Thus, information to assist in parental decision-making should be made available as early as possible, even as part of guidance to parents before conception occurs. For this reason, obstetrician-gynecologists and family physicians who manage women's health and prenatal care probably have a more pivotal role in this decision than do pediatricians. Public health authorities have an important role in educating the public on the role of newborn male circumcision in disease prevention.

Workforce Development and Provision of Circumcision

In the United States, obstetricians, family physicians, and pediatricians are the principal clinicians who perform newborn circumcisions in medical settings; there is no single system of training or credentialing for circumcision in use nationwide.[237] There is good and fair evidence of considerable variation in provider type by region and by hospital,[238–240] with midwives performing circumcision in some locations.[18,241]

Training curricula for teaching newborn circumcision in departments of pediatrics[237,242] and family medicine[243] have been described but do not provide information on how widely used they are or the trainings' results and/or effectiveness. One pediatric program's training consisted of the resident performing 3 to 5 circumcisions with assistance from a faculty instructor, 3 to 5 circumcisions under direct observation but without hands-on faculty involvement, and 2 test circumcisions for grading and departmental credentialing.[242] The other 2 programs did not describe actual resident experience performing a circumcision.

Most residency training programs in the respective specialties teach techniques, including the Gomco clamp, Mogen clamp, and Plastibell device.[238] As of 2006, 97% of programs that included training in performance of circumcision taught the use of either local or topical anesthetics for circumcision analgesia, an increase from 45% to 74% in 1998.[238–240] Although case studies were excluded from this review, it was noted that 2 record reviews with fair evidence addressed the need for circumcision revision based on the medical discipline of the physician who performed the original procedure.[241,244]

None of the articles reviewed addressed current or future workforce needs, which seems to depend on the number of surgeries being performed, the future demand, and reimbursement for the procedure. Sustaining a workforce that is capable of counseling families and performing the newborn male circumcision procedure safely is increasingly important, as the number of clinicians who are able to perform this procedure is likely to decline with curtailment of Medicaid coverage for it in various states.

The Task Force strongly recommends the creation, revision, and enhancement of educational materials to assist parents of male infants with the care of both circumcised and uncircumcised penises. The Task Force also strongly recommends the development of educational materials for clinicians to enhance practitioners' competency in discussing the benefits and risks of circumcision with parents. A structured decision-making tool that clinicians can use to help

parents complete would assist in the decision of whether to circumcise or not. To this end, the Task Force recommends that key professional organizations (AAP, ACOG, AAFP, American Society of Anesthesiologists, American College of Nurse Midwives, and other entities supporting midlevel clinicians) work together to develop a consensus plan about which groups are best suited to perform circumcisions in newborn males; teach the procedure and analgesic techniques during postgraduate training programs; and develop standards of trainee proficiency. In addition, health departments should be involved in the dissemination of educational materials and coordinating educational efforts with professional organizations.

Financing Newborn Male Circumcision

- Task Force recommendation:
    1. The preventive and public health benefits associated with newborn male circumcision warrant third-party reimbursement of the procedure.

The CDC estimates that, from 2005 to 2006, the average cost of providing newborn male circumcision (including physician- and facility-related costs) ranged from $216 to $601 across the nation.[60] Hospitals in states where Medicaid covers routine newborn male circumcision have circumcision rates that are 24% higher than hospitals in states without such coverage.[23] As of 2009, 15 states did not cover newborn male circumcision in their Medicaid programs; 2 additional states had variable coverage dependent on the enrollment plan.[245] There seems to be a relationship between circumcision incidence and third-party payment.

Circumcised newborns are more likely to be privately insured than publicly insured infants.[246] The weighted rates of circumcision over the 13-year period from 1991 to 2005 were 40.8% for Medicaid clients versus 43.3% for the uninsured and 64.4% for insured newborns.[5] The associations with insurance status were independent of race/ethnicity and socioeconomic status in this study.[246]

As noted, a recent cost-effectiveness analysis by the CDC concluded that newborn circumcision is a societal cost-saving HIV prevention intervention.[60] African-American and Hispanic males in the United States are disproportionately affected by HIV and other STIs, and thus would derive the greatest benefit from circumcision; the HIV prevention evidence for non-Hispanic white males was not as strong as for African-American and Hispanic males. However, the African-American and Hispanic populations are the most likely to have Medicaid coverage.[247] In 2010, 50% of Hispanic children (up to age 18 years) and 54% of African-American children were covered by Medicaid, compared with 23% of white children.[248] Thus, recent efforts by state Medicaid programs to curb payment for newborn male circumcision affect those populations that could benefit the most from the procedure.[60] The CDC authors recommended that: "Financial barriers that prevent parents from having the choice to circumcise their male newborns should be reduced or eliminated."

AREAS FOR FUTURE RESEARCH

In the course of its work, the Task Force identified important gaps in our knowledge of male circumcision and urges the research community to seriously consider these gaps as future research agendas are developed. Although it is clear that there is good evidence on the risks and benefits of male circumcision, it will be useful for this benefit to be more precisely defined in a US setting and to monitor adverse events. Specifically, the Task Force recommends additional studies to better understand:

- The performance of elective male circumcisions in the United States, including those that are hospital-based and nonhospital-based, in infancy and subsequently in life.
- Parental decision-making to develop useful tools for communication between providers and parents on the issue of male circumcision.
- The impact of male circumcision on transmission of HIV and other STIs in the United States because key studies to date have been performed in African populations with HIV burdens that are epidemiologically different from HIV in the United States.
- The risk of acquisition of HIV and other STIs in 0- to 18-year-olds, to help inform the acceptance of the procedure during infancy versus deferring the decision to perform circumcision (and thus the procedure's benefits) until the child can provide his own assent/consent. Because newborn male circumcision is less expensive and more widely available, a delay often means that circumcision does not occur. It will be useful to more precisely define the prevention benefits conferred by male circumcision to inform parental decision-making and to evaluate cost-effectiveness and benefits of circumcision, especially in terms of numbers needed to treat to prevent specific outcomes.
- The population-based incidence of complications of newborn male circumcision (including stratifications according to timing of procedure, type of procedure, provider type, setting, and timing of complications [especially severe and nonacute complications]).
- The impact of the AAP Male Circumcision policy on newborn male

circumcision practices in the United States and elsewhere.

- The extent and level of training of the workforce to sustain the availability of safe circumcision practices for newborn males and their families.

CONCLUSIONS

This technical report provides recommendations regarding the practice of male circumcision, particularly in the newborn period. It emphasizes the primacy of parental decision-making and the imperative for those who perform male circumcisions to be adequately trained and use both effective sterile techniques and pain management. The report evaluated current evidence regarding the effect of male circumcision on the prevention of STIs (including HIV), UTIs, cancer, and other morbidities. Evidence about complications resulting from male circumcision and the use of analgesia and anesthesia were also discussed.

The Task Force concluded that the health benefits of newborn male circumcision outweigh the risks and justify access to this procedure for families who choose it.

The Task Force also made the following recommendations:

- Evaluation of current evidence indicates that the health benefits of newborn male circumcision outweigh the risks, and the benefits of newborn male circumcision justify access to this procedure for those families who choose it.
- Parents are entitled to factually correct, nonbiased information about circumcision that should be provided before conception and early in pregnancy, when parents are most likely to be weighing the option of circumcision of a male child.
- Physicians counseling families about elective male circumcision should assist parents by explaining, in a nonbiased manner, the potential benefits and risks, and by ensuring that they understand the elective nature of the procedure.
- Parents should weigh the health benefits and risks in light of their own religious, cultural, and personal preferences, as the medical benefits alone may not outweigh these other considerations for individual families.
- Parents of newborn boys should be instructed in the care of the penis at the time of discharge from the newborn hospital stay, whether the newborn is circumcised or not.
- Elective circumcision should be performed only if the infant's condition is stable and healthy.
- Trained and competent practitioners, by using sterile techniques and effective pain management, should perform male circumcision.
- Analgesia is safe and effective in reducing the procedural pain associated with newborn circumcision; thus, adequate analgesia should be provided whenever newborn circumcision is performed.
    - Nonpharmacologic techniques (such as positioning and sucrose pacifiers) alone are insufficient to prevent procedural and postprocedural pain and are not recommended as the sole method of analgesia. They should be used only as analgesic adjuncts to improve infant comfort during circumcision.
    - If used, topical creams may cause a higher incidence of skin irritation in low birth weight infants, compared with infants of normal weight, so penile nerve block techniques should be chosen for this group of newborns.
- Key professional organizations (AAP, AAFP, ACOG, the American Society of Anesthesiologists, the American College of Nurse Midwives, and other midlevel clinicians such as nurse practitioners) should work collaboratively to:
    - Develop standards of trainee proficiency in performance of anesthetic and procedure techniques, including suturing;
    - Teach the procedure and analgesic techniques during postgraduate training programs;
    - Develop educational materials for clinicians to enhance practitioners' competency in discussing the benefits and risks of circumcision with parents;
    - Offer educational materials to assist parents of male infants with the care of both circumcised and uncircumcised penises.
- The preventive and public health benefits associated with newborn male circumcision warrant third-party reimbursement of the procedure.

CLINICAL REPORT

Management of Neonates With Suspected or Proven Early-Onset Bacterial Sepsis

abstract

FREE

With improved obstetrical management and evidence-based use of intrapartum antimicrobial therapy, early-onset neonatal sepsis is becoming less frequent. However, early-onset sepsis remains one of the most common causes of neonatal morbidity and mortality in the preterm population. The identification of neonates at risk for early-onset sepsis is frequently based on a constellation of perinatal risk factors that are neither sensitive nor specific. Furthermore, diagnostic tests for neonatal sepsis have a poor positive predictive accuracy. As a result, clinicians often treat well-appearing infants for extended periods of time, even when bacterial cultures are negative. The optimal treatment of infants with suspected early-onset sepsis is broad-spectrum antimicrobial agents (ampicillin and an aminoglycoside). Once a pathogen is identified, antimicrobial therapy should be narrowed (unless synergism is needed). Recent data suggest an association between prolonged empirical treatment of preterm infants (≥5 days) with broad-spectrum antibiotics and higher risks of late onset sepsis, necrotizing enterocolitis, and mortality. To reduce these risks, antimicrobial therapy should be discontinued at 48 hours in clinical situations in which the probability of sepsis is low. The purpose of this clinical report is to provide a practical and, when possible, evidence-based approach to the management of infants with suspected or proven early-onset sepsis. *Pediatrics* 2012;129:1006–1015

KEY WORDS

early-onset sepsis, antimicrobial therapy, group B streptococcus, meningitis, gastric aspirate, tracheal aspirate, chorioamnionitis, sepsis screen, blood culture, lumbar puncture, urine culture, body surface cultures, white blood count, acute phase reactants, prevention strategies

ABBREVIATIONS

CFU—colony-forming units
CRP—C-reactive protein
CSF—cerebrospinal fluid
GBS—group B streptococci
I/T—immature to total neutrophil (ratio)
PMN—polymorphonuclear leukocyte
PPROM—preterm premature rupture of membranes

INTRODUCTION

"Suspected sepsis" is one of the most common diagnoses made in the NICU.[1] However, the signs of sepsis are nonspecific, and inflammatory syndromes of noninfectious origin mimic those of neonatal sepsis. Most infants with suspected sepsis recover with supportive care (with or without initiation of antimicrobial therapy). The challenges for clinicians are threefold: (1) identifying neonates with a high likelihood of sepsis promptly and initiating antimicrobial therapy; (2) distinguishing "high-risk" healthy-appearing infants or infants with clinical signs who do not require treatment; and (3) discontinuing antimicrobial therapy once sepsis is deemed unlikely. The purpose of this clinical report is to provide a practical and, when possible, evidence-based approach to the diagnosis and management of early-onset sepsis, defined by the National Institute of Child Health and Human Development and Vermont Oxford Networks as sepsis with onset at ≤3 days of age.

PATHOGENESIS AND EPIDEMIOLOGY OF EARLY-ONSET SEPSIS

Before birth, the fetus optimally is maintained in a sterile environment. Organisms causing early-onset sepsis ascend from the birth canal either when the amniotic membranes rupture or leak before or during the course of labor, resulting in intra-amniotic infection.[2] Commonly referred to as "chorioamnionitis," intra-amniotic infection indicates infection of the amniotic fluid, membranes, placenta, and/or decidua.

Group B streptococci (GBS) can also enter the amniotic fluid through occult tears. Chorioamnionitis is a major risk factor for neonatal sepsis. Sepsis can begin in utero when the fetus inhales or swallows infected amniotic fluid. The neonate can also develop sepsis in the hours or days after birth when colonized skin or mucosal surfaces are compromised. The essential criterion for the clinical diagnosis of chorioamnionitis is maternal fever. Other criteria are relatively insensitive. When defining intra-amniotic infection (chorioamnionitis) for clinical research studies, the diagnosis is typically based on the presence of maternal fever of greater than 38°C (100.4°F) and at least two of the following criteria: maternal leukocytosis (greater than 15 000 cells/mm^3), maternal tachycardia (greater than 100 beats/minute), fetal tachycardia (greater than 160 beats/minute), uterine tenderness, and/or foul odor of the amniotic fluid. These thresholds are associated with higher rates of neonatal and maternal morbidity.

Nonetheless, the diagnosis of chorioamnionitis must be considered even when maternal fever is the sole abnormal finding. Although fever is common in women who receive epidural anesthesia (15%–20%), histologic evidence of acute chorioamnionitis is very common in women who become febrile after an epidural (70.6%).[3] Furthermore, most of these women with histologic chorioamnionitis do not have a positive placental culture.[3] The incidence of clinical chorioamnionitis varies inversely with gestational age. In the National Institute of Child Health and Human Development Neonatal Research Network, 14% to 28% of women delivering preterm infants at 22 through 28 weeks' gestation exhibited signs compatible with chorioamnionitis.[4] The major risk factors for chorioamnionitis include low parity, spontaneous labor, longer length of labor and membrane rupture, multiple digital vaginal examinations (especially with ruptured membranes), meconium-stained amniotic fluid, internal fetal or uterine monitoring, and presence of genital tract microorganisms (eg, *Mycoplasma hominis*).[5]

At term gestation, less than 1% of women with intact membranes will have organisms cultured from amniotic fluid.[6] The rate can be higher if the integrity of the amniotic cavity is compromised by procedures before birth (eg, placement of a cerclage or amniocentesis).[6] In women with preterm labor and intact membranes, the rate of microbial invasion of the amniotic cavity is 32%, and if there is preterm premature rupture of membranes (PPROM), the rate may be as high as 75%.[7] Many of the pathogens recovered from amniotic fluid in women with preterm labor or PPROM (eg, *Ureaplasma* species or *Mycoplasma* species) do not cause early-onset sepsis.[8–10] However, both *Ureaplasma* and *Mycoplasma* organisms can be recovered from the bloodstream of infants whose birth weight is less than 1500 g.[11] When a pathogen (eg, GBS) is recovered from amniotic fluid, the attack rate of neonatal sepsis can be as high as 20%.[12] Infants born to women with PPROM who are colonized with GBS have an estimated attack rate of 33% to 50% when intrapartum prophylaxis is not given.[13]

The major risk factors for early-onset neonatal sepsis are preterm birth, maternal colonization with GBS, rupture of membranes >18 hours, and maternal signs or symptoms of intra-amniotic infection.[14–16] Other variables include ethnicity (ie, black women are at higher risk of being colonized with GBS), low socioeconomic status, male sex, and low Apgar scores. Preterm birth/low birth weight is the risk factor most closely associated with early-onset sepsis.[17] Infant birth weight is inversely related to risk of early-onset sepsis. The increased risk of early-onset sepsis in preterm infants is also related to complications of labor and delivery and immaturity of innate and adaptive immunity.[18]

DIAGNOSTIC TESTING FOR SEPSIS

The clinical diagnosis of sepsis in the neonate is difficult, because many of the signs of sepsis are nonspecific and are observed with other noninfectious conditions. Although a normal physical examination is evidence that sepsis is not present,[19,20] bacteremia can occur in the absence of clinical signs.[21] Available diagnostic testing is not helpful in deciding which neonate requires empirical antimicrobial therapy but can assist with the decision to discontinue treatment.[22]

Blood Culture

A single blood culture in a sufficient volume is required for all neonates with suspected sepsis. Data suggest that 1.0 mL of blood should be the minimum volume drawn for culture when a single pediatric blood culture bottle is used. Dividing the specimen in half and inoculating aerobic and anaerobic bottles is likely to decrease the sensitivity. Although 0.5 mL of blood has previously been considered acceptable, in vitro data from Schelonka et al demonstrated that 0.5 mL would not reliably detect low-level bacteremia

(4 colony-forming units [CFU]/mL or less).[23] Furthermore, up to 25% of infants with sepsis have low colony count bacteremia (≤4 CFU/mL), and two-thirds of infants younger than 2 months of age have colony counts <10 CFU/mL.[24,25] Neal et al demonstrated that more than half of blood specimens inoculated into the aerobic bottle were less than 0.5 mL.[26] A study by Connell et al indicated that blood cultures with an adequate volume were twice as likely to yield a positive result.[27] A blood culture obtained through an umbilical artery catheter shortly after placement for other clinical indications is an acceptable alternative to a culture drawn from a peripheral vein.[28] The risk of recovering a contaminant is greater with a blood culture drawn from an umbilical vein.[29] There are, however, data to suggest that a blood culture drawn from the umbilical vein at the time of delivery using a doubly clamped and adequately prepared segment of the cord is a reliable alternative to a culture obtained peripherally.[30]

Urine Culture

A urine culture should not be part of the sepsis workup in an infant with suspected early-onset sepsis.[31] Unlike urinary tract infections in older infants (which are usually ascending infections), urinary tract infections in newborn infants are attributable to seeding of the kidney during an episode of bacteremia.

Gastric Aspirates

The fetus swallows 500 to 1000 mL of amniotic fluid each day. Therefore, if there are white blood cells present in amniotic fluid, they will be present in gastric aspirate specimens at birth. However, these cells represent the maternal response to inflammation and have a poor correlation with neonatal sepsis.[32] Gram stains of gastric aspirates to identify bacteria are of limited value and are not routinely recommended.[33]

Body Surface Cultures

Bacterial cultures of the axilla, groin, and the external ear canal have a poor positive predictive accuracy. They are expensive and add little to the evaluation of an infant with possible bacterial sepsis.[34,35]

Tracheal Aspirates

Cultures and Gram stains of tracheal aspirate specimens may be of value if obtained immediately after endotracheal tube placement.[36] Once an infant has been intubated for several days, tracheal aspirates are of no value in the evaluation of sepsis.[37]

Lumbar Puncture

The decision to perform a lumbar puncture in a neonate with suspected early-onset sepsis remains controversial. In the high-risk, healthy-appearing infant, data suggest that the likelihood of meningitis is extremely low.[38] In the infant with clinical signs that are thought to be attributable to a noninfectious condition, such as respiratory distress syndrome, the likelihood of meningitis is also low.[39] However, in bacteremic infants, the incidence of meningitis may be as high as 23%.[40,41] Blood culture alone cannot be used to decide who needs a lumbar puncture, because blood cultures can be negative in up to 38% of infants with meningitis.[42,43] The lumbar puncture should be performed in any infant with a positive blood culture, infants whose clinical course or laboratory data strongly suggest bacterial sepsis, and infants who initially worsen with antimicrobial therapy. For any infant who is critically ill and likely to have cardiovascular or respiratory compromise from the procedure, the lumbar puncture can be deferred until the infant is more stable.

Cerebrospinal fluid (CSF) values indicative of neonatal meningitis are controversial. In studies that have excluded infants with "traumatic taps" (or nonbacterial illnesses), the mean number of white blood cells in uninfected preterm or term infants was consistently <10 cells/mm^3.[44–50] Cell counts 2 standard deviations from the mean were generally less than 20 cells/mm^3.[46] In a study by Garges et al, the median number of white blood cells in infants who were born at greater than 34 weeks' gestation and had bacterial meningitis was 477/mm^3.[43] In contrast, the median number of white blood cells in infants who were born at less than 34 weeks' gestation and had meningitis was 110/mm^3.[51] Infants with meningitis attributable to Gram-negative pathogens typically have higher CSF white blood cell counts than do infants with meningitis attributable to Gram-positive pathogens.[52] Adjusting the CSF white blood cell count for the number of red blood cells does not improve the diagnostic utility (loss of sensitivity with marginal gain in specificity).[53] In addition, the number of bands in a CSF specimen does not predict meningitis.[54] With a delay in analysis (>2 hours), white blood cell counts and glucose concentrations decrease significantly.[55]

Protein concentrations in uninfected, term newborn infants are <100 mg/dL.[44–50] Preterm infants have CSF protein concentrations that vary inversely with gestational age. In the normoglycemic newborn infant, glucose concentrations in CSF are similar to those in older infants and children (70%–80% of a simultaneously obtained blood specimen). A low glucose concentration is the CSF variable with the greatest specificity for the diagnosis of meningitis.[43,51] Protein concentrations are higher and glucose concentrations are lower in term than in preterm infants with meningitis. However, meningitis occurs in infants with normal CSF values, and some of these infants have high bacterial inocula.[43,51]

Peripheral White Blood Cell Count and Differential Count

Total white blood cell counts have little value in the diagnosis of early-onset sepsis and have a poor positive predictive accuracy.[56,57] Many investigators have analyzed subcomponents of the white blood cell count (neutrophil indices)—absolute neutrophil count, absolute band count, and immature to total neutrophil (I/T)ratio—to identify infected infants. Like most diagnostic tests for neonatal sepsis, neutrophil indices have proven most useful for excluding infants without infection rather than identifying infected neonates. Neutropenia may be a better marker for neonatal sepsis and has better specificity than an elevated neutrophil count, because few conditions besides sepsis (maternal pregnancy-induced hypertension, asphyxia, and hemolytic disease) depress the neutrophil count of neonates.[58] The definitions for neutropenia vary with gestational age,[58–61] type of delivery (infants born by cesarean delivery without labor have lower counts than infants delivered vaginally),[61] site of sampling (neutrophil counts are lower in samples from arterial blood),[62] and altitude (infants born at elevated altitudes have higher total neutrophil counts).[63] In late preterm and term infants, the definition for neutropenia most commonly used is that suggested by Manroe et al ($<1800/mm^3$ at birth and $<7800/mm^3$ at 12–14 hours of age).[58] Schmutz et al reinvestigated these reference ranges using modern cell-counting instrumentation in 30 254 infants born at 23 to 42 weeks' gestation.[61] Infants with diagnoses known to affect neutrophil counts (eg, those born to women with pregnancy-induced hypertension or those with early-onset sepsis) were excluded. In this study, the lower limits of normal for neutrophil values at birth were $3500/mm^3$ in infants born at >36 weeks' gestation, $1000/mm^3$ in infants born at 28 through 36 weeks' gestation, and $500/mm^3$ in infants born at <28 weeks' gestation. Peak values occurred at 6 to 8 hours after birth; the lower limits of normal at that time were $7500/mm^3$, $3500/mm^3$, and $1500/mm^3$ for infants born at >36 weeks' gestation, 28 to 36 weeks' gestation, and <28 weeks' gestation, respectively.[61] It is noteworthy that the study by Schmutz et al was performed at 4800 feet above sea level, whereas that of Manroe et al was performed at 500 feet above sea level.

The absolute immature neutrophil count follows a similar pattern to the absolute neutrophil count and peaks at approximately 12 hours of life. The number of immature neutrophils increases from a maximal value of 1100 cells/mm^3 at birth to 1500 cells/mm^3 at 12 hours of age.[58] Absolute immature counts have a poor sensitivity and positive predictive accuracy for early-onset sepsis.[22] Furthermore, if exhaustion of bone marrow reserves occurs, the number of immature forms will remain depressed.[64]

The I/T ratio has the best sensitivity of any of the neutrophil indices. However, with manual counts, there are wide interreader differences in band neutrophil identification.[65] The I/T ratio is <0.22 in 96% of healthy preterm infants born at <32 weeks' gestational age.[66] Unlike the absolute neutrophil count and the absolute band count, maximum normal values for the I/T ratio occur at birth (0.16) and decline with increasing postnatal age to a minimum value of 0.12.[58] In healthy term infants, the 90th percentile for the I/T ratio is 0.27.[59] A single determination of the I/T ratio has a poor positive predictive accuracy (approximately 25%) but a very high negative predictive accuracy (99%).[66] The I/T ratio may be elevated in 25% to 50% of uninfected infants.[67]

Exhaustion of bone marrow reserves will result in low band counts and lead to falsely low ratios. The timing of the white blood cell count is critical.[68] Counts obtained 6 to 12 hours after birth are more likely to be abnormal than are counts obtained at birth, because alterations in the numbers (and ratios) of mature and immature neutrophils require an established inflammatory response. Therefore, once the decision is made to start antimicrobial therapy soon after birth, it is worth waiting 6 to 12 hours before ordering a white blood cell count and differential count.[68,69]

Platelet Counts

Despite the frequency of low platelet counts in infected infants, they are a nonspecific, insensitive, and late indicator of sepsis.[70,71] Moreover, platelet counts are not useful to follow clinical response to antimicrobial agents, because they often remain depressed for days to weeks after a sepsis episode.

Acute-Phase Reactants

A wide variety of acute-phase reactants have been evaluated in neonates with suspected bacterial sepsis. However, only C-reactive protein (CRP) and procalcitonin concentrations have been investigated in sufficiently large studies.[72,73] CRP concentration increases within 6 to 8 hours of an infectious episode in neonates and peaks at 24 hours.[74,75] The sensitivity of a CRP determination is low at birth, because it requires an inflammatory response (with release of interleukin-6) to increase CRP concentrations.[76] The sensitivity improves dramatically if the first determination is made 6 to 12 hours after birth. Benitz et al have demonstrated that excluding a value at birth, 2 normal CRP determinations (8–24 hours after birth and 24 hours later) have a negative predictive accuracy of 99.7% and a negative likelihood ratio of 0.15 for proven neonatal sepsis.[76] If CRP determinations remain persistently normal, it is strong evidence that bacterial sepsis is unlikely, and antimicrobial agents can be safely discontinued. Data are insufficient to recommend following sequential CRP

concentrations to determine the duration of antimicrobial therapy in an infant with an elevated value (≥1.0 mg/dL).

Procalcitonin concentrations increase within 2 hours of an infectious episode, peak at 12 hours, and normalize within 2 to 3 days in healthy adult volunteers.[77] A physiologic increase in procalcitonin concentration occurs within the first 24 hours of birth, and an increase in serum concentrations can occur with noninfectious conditions (eg, respiratory distress syndrome).[78] Procalcitonin concentration has a modestly better sensitivity than does CRP concentration but is less specific.[73] Chiesa and colleagues have published normal values for procalcitonin concentrations in term and preterm infants.[79] There is evidence from studies conducted in adult populations, the majority of which focused on patients with sepsis in the ICU, that significant reductions in use of antimicrobial agents can be achieved in patients whose treatment is guided by procalcitonin concentration.[80]

Sepsis Screening Panels

Hematologic scoring systems using multiple laboratory values (eg, white blood cell count, differential count, and platelet count) have been recommended as useful diagnostic aids. No matter what combination of tests is used, the positive predictive accuracy of scoring systems is poor unless the score is very high. Rodwell et al described a scoring system in which a score of 1 was assigned to 1 of 7 findings, including abnormalities of leukocyte count, total neutrophil count, increased immature polymorphonuclear leukocyte (PMN) count, increased I/T ratio, immature to mature PMN ratio >0.3, platelet count ≤150 000/mm^3, and pronounced degenerative changes (ie, toxic granulations) in PMNs.[81] In this study, two-thirds of preterm infants and 90% of term infants with a hematologic score ≥3 did not have proven sepsis.[81] Furthermore, scores obtained in the first several hours after birth have been shown to have poorer sensitivity and negative predictive value than scores obtained at 24 hours of age.[67] Sepsis screening panels commonly include neutrophil indices and acute-phase reactants (usually CRP concentration). The positive predictive value of the sepsis screen in neonates is poor (<30%); however, the negative predictive accuracy has been high (>99%) in small clinical studies.[22] Sepsis screening tests might be of value in deciding which "high-risk" healthy-appearing neonates do not need antimicrobial agents or whether therapy can be safely discontinued.

TREATMENT OF INFANTS WITH SUSPECTED EARLY-ONSET SEPSIS

In the United States, the most common pathogens responsible for early-onset neonatal sepsis are GBS and *Escherichia coli*.[17] A combination of ampicillin and an aminoglycoside (usually gentamicin) is generally used as initial therapy, and this combination of antimicrobial agents also has synergistic activity against GBS and *Listeria monocytogenes*.[82,83] Third-generation cephalosporins (eg, cefotaxime) represent a reasonable alternative to an aminoglycoside. However, several studies have reported rapid development of resistance when cefotaxime has been used routinely for the treatment of early-onset neonatal sepsis,[84] and extensive/prolonged use of third-generation cephalosporins is a risk factor for invasive candidiasis.[85] Because of its excellent CSF penetration, empirical or therapeutic use of cefotaxime should be restricted for use in infants with meningitis attributable to Gram-negative organisms.[86] Ceftriaxone is contraindicated in neonates because it is highly protein bound and may displace bilirubin, leading to a risk of kernicterus. Bacteremia without an identifiable focus of infection is generally treated for 10 days.[87] Uncomplicated meningitis attributable to GBS is treated for a minimum of 14 days.[88] Other focal infections secondary to GBS (eg, cerebritis, osteomyelitis, endocarditis) are treated for longer durations.[88] Gram-negative meningitis is treated for minimum of 21 days or 14 days after obtaining a negative culture, whichever is longer.[88] Treatment of Gram-negative meningitis should include cefotaxime and an aminoglycoside until the results of susceptibility testing are known.[87,88]

The duration of antimicrobial therapy in infants with negative blood cultures is controversial. Many women receive antimicrobial agents during labor as prophylaxis to prevent early-onset GBS infections or for management of suspected intra-amniontic infection or PPROM. In those instances, postnatal blood cultures may be sterile (false negative). When considering the duration of therapy in infants with negative blood cultures, the decision should include consideration of the clinical course as well as the risks associated with longer courses of antimicrobial agents. In a retrospective study by Cordero and Ayers, the average duration of treatment in 695 infants (<1000 g) with negative blood cultures was 5 ± 3 days.[89] Cotten et al have suggested an association with prolonged administration of antimicrobial agents (>5 days) in infants with suspected early-onset sepsis (and negative blood cultures) with death and necrotizing enterocolitis.[90] Two recent papers also support this association.[91,92]

PREVENTION STRATEGIES FOR EARLY-ONSET SEPSIS

The only intervention proven to decrease the incidence of early-onset neonatal sepsis is maternal treatment with intrapartum intravenous antimicrobial agents for the prevention of GBS infections.[93] Adequate prophylaxis is defined as penicillin (the preferred agent), ampicillin, or cefazolin given for

≥4 hours before delivery. Erythromycin is no longer recommended for prophylaxis because of high resistance rates. In parturients who have a nonserious penicillin allergy, cefazolin is the drug of choice. For parturients with a history of serious penicillin allergy (anaphylaxis, angioedema, respiratory compromise, or urticaria), clindamycin is an acceptable alternative agent, but only if the woman's rectovaginal GBS screening isolate has been tested and documented to be susceptible. If the clindamycin susceptibility is unknown or the GBS isolate is resistant to clindamycin, vancomycin is an alternative agent for prophylaxis. However, neither clindamycin nor vancomycin has been evaluated for efficacy in preventing early-onset GBS sepsis in neonates. Intrapartum antimicrobial agents are indicated for the following situations[93]:

1. Positive antenatal cultures or molecular test at admission for GBS (except for women who have a cesarean delivery without labor or membrane rupture)
2. Unknown maternal colonization status with gestation <37 weeks, rupture of membranes >18 hours, or temperature >100.4°F (>38°C)
3. GBS bacteriuria during the current pregnancy
4. Previous infant with invasive GBS disease

Management guidelines for the newborn infant have been published[93] and are available online (http://www.cdc.gov/groupbstrep/guidelines/index.html).

CLINICAL CHALLENGES

Challenge 1: Identifying Neonates With Clinical Signs of Sepsis With a "High Likelihood" of Early-Onset Sepsis Who Require Antimicrobial Agents Soon After Birth

Most infants with early-onset sepsis exhibit abnormal signs in the first 24 hours of life. Approximately 1% of infants will appear healthy at birth and then develop signs of infection after a variable time period.[21] Every critically ill infant should be evaluated and receive empirical broad-spectrum antimicrobial therapy after cultures, even when there are no obvious risk factors for sepsis. The greatest difficulty faced by clinicians is distinguishing neonates with early signs of sepsis from neonates with noninfectious conditions with relatively mild findings (eg, tachypnea with or without an oxygen requirement). In this situation, data are insufficient to guide management. In more mature neonates without risk factors for infection who clinically improve over the first 6 hours of life (eg, need for oxygen is decreasing and respiratory distress is resolving), it is reasonable to withhold antimicrobial therapy and monitor the neonates closely. The 6-hour window should not be considered absolute; however, most infants without infection demonstrate some improvement over that time period. Any worsening of the infant's condition should prompt starting antimicrobial agents after cultures have been obtained.

Challenge 2: Identifying Healthy-Appearing Neonates With a "High Likelihood" of Early-Onset Sepsis Who Require Antimicrobial Agents Soon After Birth

This category includes infants with 1 of the risk factors for sepsis noted previously (colonization with GBS, prolonged rupture of membranes >18 hours, or maternal chorioamnionitis). GBS is not a risk factor if the mother has received adequate intrapartum therapy (penicillin, ampicillin, or cefazolin for at least 4 hours before delivery) or has a cesarean delivery with intact membranes in the absence of labor.[93] The risk of infection in the newborn infant varies considerably with the risk factor present. The greatest risk of early-onset sepsis occurs in infants born to women with chorioamnionitis who are also colonized with GBS and did not receive intrapartum antimicrobial agents. Early-onset sepsis does occur in infants who appear healthy at birth.[21] Therefore,

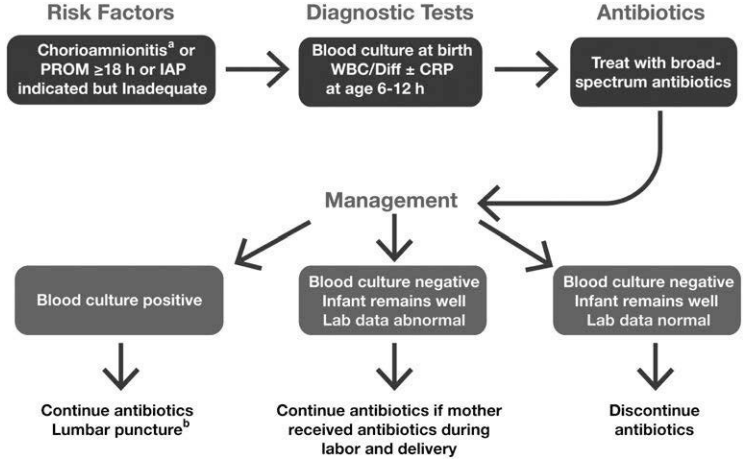

FIGURE 1

Evaluation of asymptomatic infants <37 weeks' gestation with risk factors for sepsis. [a]The diagnosis of chorioamnionitis is problematic and has important implications for the management of the newborn infant. Therefore, pediatric providers are encouraged to speak with their obstetrical colleagues whenever the diagnosis is made. [b]Lumbar puncture is indicated in any infant with a positive blood culture or in whom sepsis is highly suspected on the basis of clinical signs, response to treatment, and laboratory results. IAP, intrapartum antimicrobial prophylaxis; WBC, white blood cell; Diff, differential white blood cell count.

some clinicians use diagnostic tests with a high negative predictive accuracy as reassurance that infection is not present (allowing them to withhold antimicrobial agents). The decision of whether to treat a high-risk infant depends on the risk factors present, the frequency of observations, and gestational age. The threshold for initiating antimicrobial treatment generally decreases with increasing numbers of risk factors for infection and greater degrees of prematurity. Suggested algorithms for management of healthy-appearing, high-risk infants are shown in Figs 1, 2, and 3. Screening blood cultures have not been shown to be of value.[21]

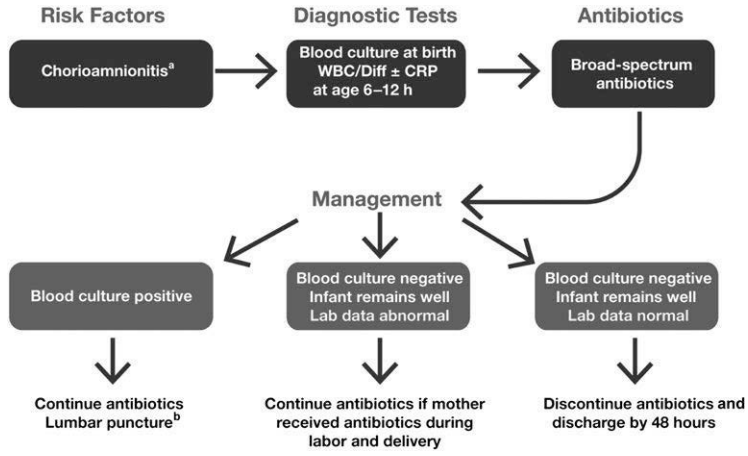

FIGURE 2

Evaluation of asymptomatic infants ≥37 weeks' gestation with risk factors for sepsis. [a]The diagnosis of chorioamnionitis is problematic and has important implications for the management of the newborn infant. Therefore, pediatric providers are encouraged to speak with their obstetrical colleagues whenever the diagnosis is made. WBC, white blood cell; Diff, differential white blood cell count.

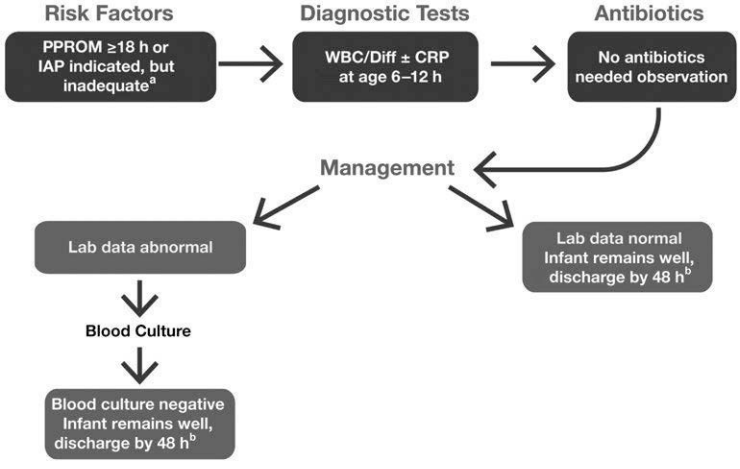

FIGURE 3

Evaluation of asymptomatic infants ≥37 weeks' gestation with risk factors for sepsis (no chorioamnionitis). [a]Inadequate treatment: Defined as the use of an antibiotic other than penicillin, ampicillin, or cefazolin or if the duration of antibiotics before delivery was <4 h. [b]Discharge at 24 h is acceptable if other discharge criteria have been met, access to medical care is readily accessible, and a person who is able to comply fully with instructions for home observation will be present. If any of these conditions is not met, the infant should be observed in the hospital for at least 48 h and until discharge criteria are achieved. IAP, intrapartum antimicrobial prophylaxis; WBC, white blood cell; Diff, differential white blood cell count.

CONCLUSIONS

The diagnosis and management of neonates with suspected early-onset sepsis are based on scientific principles modified by the "art and experience" of the practitioner. The following are well-established concepts related to neonatal sepsis:

1. Neonatal sepsis is a major cause of morbidity and mortality.
2. Diagnostic tests for early-onset sepsis (other than blood or CSF cultures) are useful for identifying infants with a low probability of sepsis but not at identifying infants likely to be infected.
3. One milliliter of blood drawn before initiating antimicrobial therapy is needed to adequately detect bacteremia if a pediatric blood culture bottle is used.
4. Cultures of superficial body sites, gastric aspirates, and urine are of no value in the diagnosis of early-onset sepsis.
5. Lumbar puncture is not needed in all infants with suspected sepsis (especially those who appear healthy) but should be performed for infants with signs of sepsis who can safely undergo the procedure, for infants with a positive blood culture, for infants likely to be bacteremic (on the basis of laboratory data), and infants who do not respond to antimicrobial therapy in the expected manner.
6. The optimal treatment of infants with suspected early-onset sepsis is broad-spectrum antimicrobial agents (ampicillin and an aminoglycoside). Once the pathogen is identified, antimicrobial therapy should be narrowed (unless synergism is needed).
7. Antimicrobial therapy should be discontinued at 48 hours in clinical situations in which the probability of sepsis is low.

CLINICAL REPORT

Medical Staff Appointment and Delineation of Pediatric Privileges in Hospitals

abstract

FREE

The review and verification of credentials and the granting of clinical privileges are required of every hospital to ensure that members of the medical staff are competent and qualified to provide specified levels of patient care. The credentialing process involves the following: (1) assessment of the professional and personal background of each practitioner seeking privileges; (2) assignment of privileges appropriate for the clinician's training and experience; (3) ongoing monitoring of the professional activities of each staff member; and (4) periodic reappointment to the medical staff on the basis of objectively measured performance. We examine the essential elements of a credentials review for initial and renewed medical staff appointments along with suggested criteria for the delineation of clinical privileges. Sample forms for the delineation of privileges can be found on the American Academy of Pediatrics Committee on Hospital Care Web site (http://www.aap.org/visit/cmte19.htm). Because of differences among individual hospitals, no 1 method for credentialing is universally applicable. The medical staff of each hospital must, therefore, establish its own process based on the general principles reviewed in this report. The issues of medical staff membership and credentialing have become very complex, and institutions and medical staffs are vulnerable to legal action. Consequently, it is advisable for hospitals and medical staffs to obtain expert legal advice when medical staff bylaws are constructed or revised. *Pediatrics* 2012;129:782–787

INTRODUCTION

Credentialing is the formal recognition of professional and technical competence. The process involves 2 distinct elements: it establishes what information is necessary to confirm professional and technical competence including mechanisms for the verification of the information received by the hospital, and it evaluates the information received with reference to an applicant.[1]

"The delineation of clinical privileges is the process whereby the medical staff evaluates and recommends that an individual practitioner be allowed to provide specific patient care services in the institution. A clinical privilege is a specific grant or permission by a hospital for an individual practitioner to perform diagnostic or therapeutic procedures or other patient care services within well-defined limits."[1]

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

The role of the hospital in credentialing its staff was first laid out by The Joint Commission on the Accreditation of Hospitals (later renamed The Joint Commission) in 1953 and has been regularly updated since then. This process is distinct from the recognition of competence within a specialty, which is the purview of the various members of the American Board of Medical Specialties.

Medical staff membership is not synonymous with clinical privileges. Medical staff membership involves the practitioner's organizational rights and responsibilities. A member of the medical staff is not entitled to perform procedures or treat patients simply by virtue of being a member of the medical staff.[1]

CREDENTIALING PRINCIPLES

The medical staff of each hospital is responsible for establishing its own procedures for credentialing.[2] These procedures must be reviewed by a lawyer who is familiar with these issues.[3] The authority of the hospital to grant, change, or revoke clinical privileges is based on several principles:

1. The practice of medicine, including pediatrics, within a hospital is not a right of every physician but rather a privilege extended by the hospital in accordance with applicable law.
2. The hospital and its governing board are responsible for the safety of its patients and the quality of care provided by its staff.
3. The hospital must ensure that all members of its health care team are competent and qualified to provide the services for which they have been granted privileges.
4. The organized medical staff of the hospital is entrusted by the governing board with the responsibility of recommending that only competent practitioners treat patients in the hospital.

Certain elements are required in every hospital's credentialing process:

1. The credentialing process must be thorough, fair, and timely and must involve unbiased and good-faith review by peers within or outside the hospital as appropriate to the individual candidate. Any possible malicious use of the peer-review process is not acceptable.
2. The entire credentialing process must be clearly described in the medical staff bylaws. This must include a description of mechanisms for appeal and guaranteed due process for disputes concerning disciplinary actions and for changes or revocation of privileges. The medical staff bylaws should incorporate provisions of the Health Care Quality Improvement Act of 1986,[4] requirements of state laws that define immunities and protections for the hospital and peer-review committee members from various legal liabilities, and other related legislation.[2]
3. Criteria for specific clinical privileges must be well defined and based on up-to-date national and local standards.
4. Confidentiality and protection of the information used in credentialing and peer review, subject to applicable law, must be incorporated into the process.
5. The credentialing process should take into account the standards recommended by The Joint Commission, the Hospital Medical Staff Section of the American Medical Association, state and federal agencies, or other appropriate accrediting organizations.[2]

Credentialing standards have been updated to include 3 new concepts. Credentialing should be informed by the 6 areas of "general competencies" developed by the Accreditation Council for Graduate Medical Education. Focused professional practice evaluation allows the medical staff to focus on a specific aspect of a practitioner's performance, such as when competence is suggested but additional information is needed for confirmation. Examples of this are proctoring or peer review of cases. Lastly, ongoing professional practice evaluation provides for continuous evaluation rather than the traditional biannual renewal process.[2,5] Examples of this are direct observation and monitoring patient outcomes. The credentialing process must not allow conflicts of interest (economic or otherwise) to impair due process.

In some communities, the credentialing process for medical staffs of area hospitals, surgical centers, and health insurance companies has been consolidated and standardized under a centralized data collection and storage agency, such as the state or local medical society. This allows only 1 application and data verification for applications to more than 1 hospital. However, each hospital is still required to determine the applicant's qualifications for clinical privileges. The American Academy of Pediatrics approves of this model as a method that simplifies the process yet maintains its rigor. Although credentialing standards have been used as a method of quality assurance, a recent study reveals no correlation between stringency of hospital credentialing policies and clinical outcomes.[5]

INITIAL APPOINTMENT

When a practitioner applies for medical staff membership the first time, the medical staff must verify the practitioner's training, experience, and qualifications. This involves verifying the following documents from primary sources or approved secondary sources if applicable:

1. Medical staff category requested
2. Current license in the state of practice
3. Other active state licenses
4. Drug Enforcement Administration certificate
5. Medical school education
6. Residency and fellowship training
7. Practice experience
8. Board certification, recertification, or other measure of ongoing competency
9. Basic life support or other lifesaving course (eg, pediatric advanced life support, neonatal resuscitation program) documentation of completion
10. Settled or pending litigation
11. Felony convictions and criminal background checks
12. Involuntary license or medical staff resignations, suspensions, disciplinary actions, or denials
13. Sanctions received from professional organizations
14. National Practitioners Data Bank (NPDB) and Federation of State Medical Boards Physician information
15. Disciplinary Data Bank information
16. Malpractice coverage verification, if required
17. Current physical, mental, or substance abuse issues that may affect patient care, as allowed by the Americans With Disabilities Act (ADA)[6]; this information can be obtained after the applicant is determined to meet all other qualifications for medical staff membership[7]
18. Signed release of liability form from the practitioner
19. Other information, as determined by the individual hospital or department[2]

The NPDB serves as a central repository of information about health care practitioners' malpractice payments, professional membership restrictions, and adverse actions regarding licenses or hospital privileges. Hospitals are required to check with the NPDB for all new medical staff appointments. They are also required to report any actions that affect the clinical privileges such as reduction, restriction, suspension, or revocation of clinical privileges for at least 31 days; voluntary resignation while peer review is taking place or instead of peer review; and the denial of clinical privileges to a new or existing medical staff member when a peer review judgment is involved. Between 5% and 30% of privileging and licensure applications involving an NPDB report were not granted "as requested," suggesting the NPDB data are important to the process. Unfortunately, underreporting was also evident: 60% to 75% of reportable actions were not reported, limiting the information to which health care entities have access.[8]

In addition to concrete data about the applicant's accomplishments, information from peers should be obtained regarding the practitioner's ability to work with other staff, patients, and students, if applicable. Hospitals may require that each applicant be covered by a minimum limit of medical liability insurance as a condition of membership on the medical staff. This may be waived for practitioners not participating in patient care (eg, retired physicians). For the hospital to verify the information, the applicant must sign a statement allowing the hospital to collect the information and releasing the hospital and references or sources from liability. Hospitals must ensure that all information collected and decisions regarding credentialing are kept confidential.

Depending on state law and hospital or medical staff bylaws, medical staff membership may include nonphysician licensed independent practitioners, such as psychologists, podiatrists, physician assistants, nurse practitioners, midwives, optometrists, dentists, and others who provide direct patient care. Advanced practice nurses also must be credentialed by the department of nursing. Advanced practice nurses who do not provide direct patient care are not credentialed through the medical staff.[9] Guidelines for the practice and requirements for the supervision of nonphysician independent licensed practitioners and residents-in-training must be defined clearly in the medical staff bylaws and include the same level of fairness and rigor as those applied to physicians.[2,10] A physician providing telemedicine services must be credentialed by the hospital receiving the telemedicine services (ie, where the patient is receiving care).[2]

Criteria for granting or restricting medical staff appointment cannot be based on gender; race or ethnic group; creed; national origin; sexual orientation; membership in professional societies; membership in a prepaid, closed-panel group practice; or solely economic factors. Criteria for medical staff appointment should relate to standards of patient care and to the objectives, purposes, and resources of the institution.

The ADA covers hospital employees and may cover physicians with staff privileges. The ADA prohibits discrimination against qualified job applicants and traditional employees who, with or without reasonable accommodation, can perform the essential functions of their job. It may apply to hospital medical staff matters involving independent contractor physicians. As a result of the ADA, questions regarding personal health issues and alcohol and illegal drug use cannot be asked at the time of initial staff application. A conditional offer of medical staff membership can be made contingent on the

applicant providing personal health information meeting certain criteria. In all issues when accommodations are requested for disabilities, the most important factor is the safety of the patient.[7]

Economic credentialing has been defined by the American Medical Association as "the use of economic criteria in determining an individual's qualification for initial and continuing hospital medical staff membership or privileges that is unrelated to the quality of care or professional competency." Measures that have an economic component in addition to improving quality, such as length of stay and ICU days, may be used in credentialing decisions. Several states have laws that prohibit use of economic credentialing,[11,12] although in most states, it is still legal and physicians need to be aware of the ramifications of participating in potentially competing entities.[13] In this regard, the American Academy of Pediatrics states that pediatricians should not be excluded from patient care panels solely on an economic basis.[14]

Initial medical staff membership starts with a provisional or temporary appointment for a defined period of time. This allows direct observation of the practitioner's clinical skills, patient management style, and manner of care. The need for proctoring and mentoring for new medical staff members should be established by each department. Appointments must be renewed at a minimum of every 2 years, but processes must also allow for interval evaluation as needed.[2] Medical staff membership is awarded in several categories on the basis of the amount and type of patient care the practitioner delivers. There may be categories for hospital-based ambulatory care only, for full staff including ambulatory and inpatient care, and for those who no longer provide direct patient care in the hospital setting. Nonphysician licensed independent practitioners or residents-in-training may form other categories.

If a hospital medical staff decides to deny initial appointment or reappointment or deny, limit, or suspend privileges, due process and protection must be provided in accordance with customary legal principles and hospital bylaws. This must include procedural due process, which is defined as whether the rules are administered properly and applied equally to all staff members, and substantive due process. The latter is concerned with whether the rules and criteria stated in the bylaws are reasonable, fair, and not arbitrary and whether the decision made by the medical staff or hearing panel is based on the weight of relevant and reliable evidence and only on that evidence presented to the medical staff or hearing panel. Nonphysician licensed independent practitioners also must have similar due process and protection.[2]

DELINEATION OF CLINICAL PRIVILEGES

A major portion of the credentialing process is the delineation of clinical privileges. By this process, the medical staff evaluates and recommends that an individual practitioner is allowed to provide specific patient care services in the hospital on the basis of the mission and needs of the hospital and the practitioner's training, experience, and skills. Privileges may be denied to an applicant if the hospital does not have the facilities for the requested procedure (eg, a pediatric cardiologist who requests privileges for cardiac catheterization from a hospital that does not have catheterization facilities).[15]

Departments within the hospital are responsible for defining the minimum education, training, and experience that a practitioner must possess to deliver care of varying complexity or perform specific procedures. Experience may be defined as cumulative or as a certain volume in a period of time. This definition may be applied across departments when patients are cared for by practitioners of different disciplines (such as pediatrics and nursing for nurse practitioners). Once criteria are established, these must be written and applied equitably across practitioners from different specialties (such as pediatrics, family practice, and surgery). Criteria for clinical privileges are based on the complexity of care needed by the patient, such as routine inpatient care, routine newborn care, subspecialty care, or intensive care. Criteria for privileges for procedures can be based on the levels of care, documentation of training, and continued competence in the procedures. Research has revealed that skills in some procedures, such as laparoscopy or surgical procedures, improve with repeated use until a set number is reached.[16,17] Other data have revealed that patient outcomes are improved for some procedures when a minimum number is performed in a hospital.[16,18] Competency for procedures also can be determined by evaluation of performance under clinical conditions (proctorship). Checklists may be used by the practitioner requesting privileges to document levels of care and procedures requested.

Questions are often raised on how one determines that an applicant is competent to care for children in the hospital if the applicant is not a pediatrician or pediatric-trained specialist or subspecialist. Skill levels for individual practitioners caring for children can be determined by reviewing training and experience. Experience in procedures performed on children should also be documented. Standards for assessing competencies of nonpediatric physicians should be defined

and rigorous and meet uniformed standards of care for children regardless of the physician's training.

As new procedures and treatment modalities develop, guidelines for clinical privileges must also develop. New procedures and treatment modalities can be divided into major new procedures, such as endoscopy or laparoscopic surgery, or minor changes, such as a new way to perform laparoscopic surgery. Practitioners wishing to be granted privileges in a major new procedure or treatment modality not inherent in their residency or fellowship training (such as use of ultrasonography or providing sedation) must document sufficient hands-on-training to be deemed competent. Physicians may gain this training through supervised training programs. A practitioner may also gain provisional privileges allowing him or her to perform the procedure under the supervision of another practitioner skilled in the procedure (proctoring).[19,20] Data from some new procedures have revealed that the complication rate decreases significantly and competency increases significantly after a certain number of the procedures are performed.[17,21] Guidelines for competency in new procedures or treatment modalities must be developed on the basis of a review of the literature and the technical aspects of the procedure. Once the guidelines are successfully met by the practitioner, full privileges are granted.

REAPPOINTMENT

Standards from The Joint Commission state that reappointment must occur at least every 2 years. This reappointment is based on ongoing monitoring of information concerning the practitioner's professional performance, judgment, and clinical or technical skills.[2] The content of the reappointment request must be defined in the medical staff bylaws. The minimum information required from the practitioner includes:

1. Medical staff category requested
2. Current license in the state of practice
3. Other active state licenses
4. Drug Enforcement Administration certificate
5. Continuing medical education credit, as required
6. Original certification date and certification renewal dates
7. Current cardiopulmonary resuscitation or other lifesaving course (eg, pediatric advanced life support, neonatal resuscitation program) documentation of completion
8. Settled or pending litigation
9. Felony convictions
10. Involuntary license or medical staff resignations, suspensions, disciplinary actions, or denials
11. Sanctions received from professional organizations
12. NPDB and Federation of State Medical Boards Physician Disciplinary Data Bank information
13. Malpractice coverage verification, if required
14. Quality assurance or continuing quality improvement activities and results
15. Listing of all hospitals where the practitioner holds privileges and any changes in this status
16. Signed release of liability form from the practitioner
17. Current physical, mental, or substance abuse issues that may affect patient care, as allowed by ADA

In most cases, information should be reviewed in a similar manner to that occurring for initial appointment. If an applicant for reappointment rarely cares for patients in the hospital facility, the medical staff office may need to request information from another hospital where the applicant is more active to help delineate appropriate clinical privileges or consider modifying the appointment to that of ambulatory-care only. If concerns are raised about reappointment or granting initial clinical privileges because of irregularities in clinical activity profile or quality assurance, this information needs to be reviewed by peers and the department head in a confidential manner, as defined in medical staff bylaws. If concerns persist, the review committee or medical staff must communicate these concerns to the applicant in a confidential manner, as defined by the medical staff bylaws. Due process, as defined in the medical staff bylaws, must be followed.

It is the responsibility of each member of the medical staff to raise any concerns about physician performance because of waning skills, mental or physical health problems, or substance abuse that affects patient care. These must be investigated in a confidential and fair manner, as defined in the medical staff bylaws, without waiting for the next reappointment.

The process of credentialing and granting of privileges must be seen as 1 way for hospitals to help ensure that their patients receive quality care. Pediatricians or pediatric-trained specialists and subspecialists must be involved in defining guidelines to ensure that children receive optimal care.

SPECIAL CIRCUMSTANCES

Hospitals should have an established policy on emergency privileges that allow current medical staff members to practice beyond their existing privileges to save a life, limb, or organ. Likewise, there should be a policy for disaster privileges that enable practitioners outside the current medical staff to treat patients in the case of a disaster in the community.[2]

CLINICAL REPORT

Neonatal Drug Withdrawal

Mark L. Hudak, MD, Rosemarie C. Tan, MD,, PhD, THE COMMITTEE ON DRUGS, and THE COMMITTEE ON FETUS AND NEWBORN

abstract

Maternal use of certain drugs during pregnancy can result in transient neonatal signs consistent with withdrawal or acute toxicity or cause sustained signs consistent with a lasting drug effect. In addition, hospitalized infants who are treated with opioids or benzodiazepines to provide analgesia or sedation may be at risk for manifesting signs of withdrawal. This statement updates information about the clinical presentation of infants exposed to intrauterine drugs and the therapeutic options for treatment of withdrawal and is expanded to include evidence-based approaches to the management of the hospitalized infant who requires weaning from analgesics or sedatives. *Pediatrics* 2012;129:e540–e560

KEY WORDS

opioid, methadone, heroin, fentanyl, benzodiazepine, cocaine, methamphetamine, SSRI, drug withdrawal, neonate, abstinence syndrome

ABBREVIATIONS

CNS—central nervous system
DTO—diluted tincture of opium
ECMO—extracorporeal membrane oxygenation
FDA—Food and Drug Administration
5-HIAA—5-hydroxyindoleacetic acid
ICD-9—International Classification of Diseases, Ninth Revision
NAS—neonatal abstinence syndrome
SSRI—selective serotonin reuptake inhibitor

INTRODUCTION

Use and abuse of drugs, alcohol, and tobacco contribute significantly to the health burden of society. The 2009 National Survey on Drug Use and Health reported that recent (within the past month) use of illicit drugs, binge or heavy alcohol ingestion, and use of tobacco products occurred in 8.7%, 23.7%, and 27.7%, respectively, of the population 12 years or older.[1] Numerous case reports have documented the use of a variety of drugs by women of childbearing age (Table 1). Intrauterine exposure to certain drugs may cause congenital anomalies and/or fetal growth restriction, increase the risk of preterm birth, produce signs of withdrawal or toxicity in the neonate, or impair normal neurodevelopment.[2] Fetal exposure to marijuana, the illicit drug most commonly used by pregnant women, does not cause clinically important neonatal withdrawal signs but may have subtle effects on long-term neurobehavioral outcomes.[3] With the use of computer-assisted interviewing techniques that preserved confidentiality, the 2009 National Survey on Drug Use and Health noted that 4.5% of pregnant women 15 to 44 years of age reported recent use of illicit drugs (eg, marijuana, cocaine, hallucinogens, heroin, methamphetamines, and nonmedical use of prescription drugs). Binge or heavy drinking in the first trimester was reported by 11.9%, and recent tobacco use was reported by 15.3%. Rates of recent illicit drug use and smoking were lower among pregnant compared with nonpregnant women across all age groups, except for those 15 to 17 years of age. In the latter age group, the rates of illicit drug use and smoking were higher among those who were pregnant compared with those who were not pregnant (15.8% vs 13.0% and 20.6% vs 13.9%, respectively). The reported rates of illicit drug use most likely underestimate true rates, because the percentage of pregnant women who report the recent use of illicit drugs on screening interviews can

TABLE 1 Major Drugs of Abuse[a]

Opioids	CNS Stimulants	CNS Depressants	Hallucinogens
Agonists	Amphetamines	Alcohol	Indolealkylamines (LSD, psilocin, psilocybin, DMT, DET)
Morphine	Dextroamphetamine (Dexedrine)	Barbiturates	Phenylethylamines (mescaline, peyote)
Codeine	Methamphetamine	Benzodiazepines	Phenylisopropylamines (MDA, MMDA, MDMA, MDEA)
Methadone	Amphetamine sulfate	Other sedative-hypnotics	Inhalants
Meperidine (Demerol)	Amphetamine congeners	Methaqualone (Quaalude)	Solvents and aerosols (glues, gasoline, paint thinner, cleaning solutions, nail polish remover, Freon)
Oxycodone (Percodan, OxylR, Percolone, Roxicodone, Percocet, OxyContin)	Benzphetamine (Didrex)	Glutethimide (Doriden)	Nitrites
Propoxyphene (Darvon)	Diethylpropion (Tenuate)	Chloral hydrate	Nitrous oxide
Hydromorphone (Dilaudid)	Fenfluramine	Cannabinoids	
Hydrocodone (Lortab, Vicodin)	Phendimetrazine (Adipost, Bontril, Prelu-2)	Marijuana	
Fentanyl (Sublimaze)	Phentermine (Adipex-P, Zantryl)	Hashish	
Tramadol (Ultram, Ultracet)	Cocaine		
Heroin	Methylphenidate (Ritalin, Concerta)		
Antagonists	Pemoline (Cylert)		
Naloxone (Narcan)	Phenylpropanolamine		
Naltrexone (ReVia)	Phencyclidines		
Mixed Agonist-Antagonists	Nicotine		
Pentazocine (Talwin)			
Buprenorphine (Buprenex)			

DET, diethyltryptamine; DMT, dimethyltryptamine; LSD, lysergic acid diethylamide; MDA, methylenedioxyamphetamine; MDEA, 3,4-methylenedioxyethamphetamine; MDMA, 3,4-methylenedioxymethamphetamine (ecstasy); and MMDA, 3-methoxy-4,5-methylenedioxyamphetamine.

[a] Adapted from Milhorn.[160]

be substantially lower than that determined by drug screening using biological samples. For infants, the use of *International Classification of Diseases, Ninth Revision* (*ICD-9*)-based hospital discharge databases to determine the incidence of neonatal drug withdrawal secondary to intrauterine exposure has in the past underestimated the incidence of this condition.[4] Data compiled by the Agency for Healthcare Research and Quality and by the Florida Department of Health attest to an increased incidence and/or recognition of neonatal withdrawal syndrome (ICD-9 code 779.5). Nationally, the number of infants coded at discharge with neonatal withdrawal increased from 7653 in 1995 to 11 937 in 2008. In Florida, the number of newborns discharged with ICD-9 code 779.5 climbed by more than 10-fold, from 0.4 to 4.4 discharges per 1000 live births, from 1995 to 2009. An indeterminate part of these observed increases has resulted from more liberal use of prescription opiates in pregnant women to palliate a wide variety of etiologies of acute or chronic pain. In a recent report, chronic use of narcotic prescriptions (use for $\geq$1 intrapartum month) among pregnant women cared for at a single clinic increased fivefold from 1998 to 2008, and 5.6% of infants delivered to these women manifested signs of neonatal withdrawal.[5]

Signs characteristic of neonatal withdrawal have been attributed to intrauterine exposure to a variety of drugs (Table 2). Other drugs cause signs in neonates because of acute toxicity. Chronic in utero exposure to a drug (eg, alcohol) can lead to permanent phenotypical and/or neurodevelopmental-behavioral abnormalities consistent with drug effect. Signs and symptoms of withdrawal worsen as drug levels decrease, whereas signs and symptoms of acute toxicity abate with drug elimination. Clinically important neonatal withdrawal most commonly results from intrauterine opioid exposure. The constellation of clinical findings associated with opioid withdrawal has been termed the neonatal abstinence syndrome (NAS). Among neonates exposed to opioids in utero, withdrawal signs will develop in 55% to 94%.[6–9] Neonatal withdrawal signs have also been described in infants exposed antenatally to benzodiazepines,[10,11] barbiturates,[12,13] and alcohol.[14,15]

COCAINE AND OTHER STIMULANTS

An abstinence syndrome after intrauterine exposure to central nervous system (CNS) stimulants such as cocaine and amphetamine has not been clearly defined. Many studies that have assessed behavior and neurologic signs in cocaine-exposed infants have used scoring systems that were designed to evaluate opioid withdrawal. Neurobehavioral abnormalities[16,17] frequently occur in neonates with intrauterine cocaine exposure, most frequently on the second or third postnatal days.[18] These abnormalities may include irritability, hyperactivity, tremors, high-pitched cry, and excessive sucking. Because cocaine or its metabolites may be detected in neonatal urine

TABLE 2 Maternal Nonnarcotic Drugs That Cause Neonatal Psychomotor Behavior Consistent With Withdrawal

Drug	Signs	Onset of Signs	Duration of Signs[a]	Ref. No.
Alcohol	Hyperactivity, crying, irritability, poor suck, tremors, seizures; onset of signs at birth, poor sleeping pattern, hyperphagia, diaphoresis	3–12 h	18 mo	14,15
Barbiturates	Irritability, severe tremors, hyperacusis, excessive crying, vasomotor instability, diarrhea, restlessness, increased tone, hyperphagia, vomiting, disturbed sleep; onset first 24 h of life or as late as 10–14 d of age	1–14 d	4-6 mo with prescription	12,13
Caffeine	Jitteriness, vomiting, bradycardia, tachypnea	At birth	1-7 d	161
Chlordiazepoxide	Irritability, tremors; signs may start at 21 d	Days–weeks	9 mo; 11/2 mo with prescription	11
Clomipramine	Hypothermia, cyanosis, tremors; onset 12 h of age		4 d with prescription	162
Diazepam	Hypotonia, poor suck, hypothermia, apnea, hypertonia, hyperreflexia, tremors, vomiting, hyperactivity, tachypnea (mother receiving multiple drug therapy)	Hours–weeks	8 mo; 10–66 d with prescription	10
Ethchlorvynol	Lethargy, jitteriness, hyperphagia, irritability, poor suck, hypotonia (mother receiving multiple drug therapy)		Possibly 10 d with prescription	163
Glutethimide	Increased tone, tremors, opisthotonos, high-pitched cry, hyperactivity, irritability, colic		6 mo	164
Hydroxyzine	Tremors, irritability, hyperactivity, jitteriness, shrill cry, myoclonic jerks, hypotonia, increased respiratory and heart rates, feeding problems, clonic movements (mother receiving multiple drug therapy)		5 wk with prescription	58
Meprobamate	Irritability, tremors, poor sleep patterns, abdominal pain		9 mo; 3 mo with prescription	165
SSRIs	Crying, irritability, tremors, poor suck, feeding difficulty, hypertonia, tachypnea, sleep disturbance, hypoglycemia, seizures	Hours–days	1–4 wk	31–33,35

[a] Prescription indicates the infant was treated with pharmacologic agents, and the natural course of the signs may have been shortened.

for as long as 7 days after delivery,[18] observed abnormalities in exposed infants may reflect drug effect rather than withdrawal. In an unmasked study, 6%, 14%, and 35% of infants exposed to cocaine only, heroin only, or cocaine plus heroin, respectively, qualified for treatment on the basis of scoring.[19] Several studies that used masked evaluators found that cocaine-exposed infants had either no[20,21] or minimal[22] withdrawal signs compared with cocaine-naïve infants (ie, those never exposed). Eyler et al[16] conducted a prospective controlled study of 3 groups of infants: 1 group had no documented exposure to cocaine by history or by maternal and infant urine testing; a second group was cocaine exposed but had negative urine screening at birth; and a third group had cocaine metabolites detected in neonatal urine. Observers masked to infant status performed assessments using the Brazelton Neonatal Behavioral Assessment Scale.[23] Infants who were positive for cocaine metabolites did not differ significantly from metabolite-negative infants with a history of exposure nor from cocaine-naïve infants. These findings supported neither a withdrawal nor a drug toxicity syndrome. Cocaine-exposed infants have been described as having a higher incidence of abnormal auditory brainstem responses and EEGs, compared with nonexposed infants.[24,25] In another study, infants with heavy exposure to cocaine had similar Brazelton findings at 2 to 3 days of age as did infants with light or no exposure; however, by 17 days of age, heavily exposed infants were more excitable and demonstrated poorer state regulation.[26] No published studies have carefully evaluated pharmacologic treatment of infants with signs attributable to prenatal cocaine exposure.

Methamphetamine abuse has been reported among pregnant women,[27] although overall rates are low compared with cocaine and appear to have decreased in the general population between 2006 and 2008.[1] Methamphetamine is an extremely potent sympathomimetic agent that induces euphoria and increases alertness and self-confidence, because it produces a massive efflux of dopamine in the CNS. Pregnant women who abuse methamphetamine are at increased risk of preterm birth, placental abruption, fetal distress, and intrauterine growth restriction at rates similar to those for pregnant women who use cocaine. In 1 study, only 4% of infants exposed to methamphetamine were treated for drug withdrawal, but it was not possible to exclude concomitant abuse of other drugs as contributory in all cases.[27] There are reports of long-term adverse neurotoxic effects of in utero methamphetamine exposure on behavior, cognitive skills, and physical dexterity.[28,29]

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Selective serotonin reuptake inhibitors (SSRIs) are a class of antidepressant medications that became available for widespread clinical use in 1988. SSRIs

(eg, fluoxetine [Prozac], paroxetine [Paxil], sertraline [Zoloft], citalopram [Celexa], escitalopram [Lexapro], and fluvoxamine [Luvox]) are now the most frequently used drugs to treat depression both in the general population and in pregnant women.[30] Case reports,[31] adverse drug reaction reports,[32] and prospective studies[33,34] linked third-trimester use of SSRIs in pregnant women to a constellation of neonatal signs that include continuous crying, irritability, jitteriness, and/or restlessness; shivering; fever; tremors; hypertonia or rigidity; tachypnea or respiratory distress; feeding difficulty; sleep disturbance; hypoglycemia; and seizures.[35] The onset of these signs ranged from several hours to several days after birth and usually resolved within 1 to 2 weeks. In 1 infant exposed to paroxetine, signs persisted through 4 weeks of age.[36] In severely affected infants, a short-term course of chlorpromazine provided measurable relief of symptoms.[36]

Several authors have discussed whether these signs are better explained by serotonin syndrome (attributable to increased serotonin concentration in the intersynaptic cleft) or by SSRI withdrawal (attributable to a relative hyposerotonergic state).[30,32,35,37–40] In adults, treatment with a single SSRI may cause mild to moderate serotonin syndrome, but severe signs are more likely to occur when 2 or more drugs that increase serotonin concentration by different mechanisms are prescribed.[35] In adults, serotonin syndrome is characterized by the following triad of clinical signs: changes in mental status (agitation, confusion); autonomic hyperactivity (fever, tachycardia, tachypnea, diaphoresis, mydriasis); and neuromuscular abnormalities (tremor, clonus, hyperreflexia, hypertonia). On the other hand, serotonin withdrawal in adults manifests with subjective symptoms that include anxiety, headache, nausea, fatigue, low mood, and, rarely, extrapyramidal signs such as dystonia. Hence, in most cases, the clinical syndrome reported among neonates born to mothers on SSRI treatment is consistent with a gradual resolution of a hyperserotonergic condition rather than with the evolution of a hyposerotonergic state. Still, in a few cases, drug withdrawal may be a better explanation.[35]

Biochemical studies that correlate serial serum SSRI (or active metabolite) concentrations and markers of CNS serotonin activity (eg, 5-hydroxyindoleacetic acid [5-HIAA], a metabolite of serotonin) with changes in clinical signs could be helpful in differentiating toxicity from withdrawal. In adults, cerebrospinal fluid concentrations of 5-HIAA (but not serum concentrations of serotonin) correlate inversely with increased CNS serotonin activity that results from SSRI treatment. One prospective study compared concentrations of SSRI and active metabolites at birth, 2 days of life, and 2 weeks of life; cord blood monoamine and metabolite; and serial serotonergic scores in infants born to mothers on treatment with SSRIs and those of SSRI-naïve control infants.[39] The infants born to mothers on SSRIs had an average serotonergic score fourfold greater than SSRI-naïve infants. Cord blood 5-HIAA concentrations were inversely related to the initial serotonergic score, and the resolution of neonatal signs correlated with rapid declines in serially measured serum SSRI and metabolite concentrations.[39] These results do support drug toxicity rather than drug withdrawal as the cause of clinical signs. Recent authors have suggested the terms "serotonin discontinuation syndrome"[34] or "prenatal antidepressant exposure syndrome."[41]

Although 1 study reported decreased pain reactivity at 2 months of age in infants with prenatal exposure to SSRIs,[42] several recent reviews have not identified adverse neurodevelopmental outcomes among infants born to women treated with SSRIs during pregnancy.[30,34,43,44] SSRI treatment should be continued during pregnancy at the lowest effective dose, because withdrawal of medication may have harmful effects on the mother-infant dyad. Clinicians should be aware that infants are at risk for manifesting clinical signs of drug toxicity or withdrawal over the first week of life and arrange for early follow-up after the initial hospital discharge. Ideally, recommendations about lactation and breastfeeding should be made in consideration of what is known about the differences among drugs in a therapeutic class vis-à-vis the ratio of human milk to maternal plasma drug concentration, the likely total daily infant drug dose (as a fraction of the daily maternal drug dose normalized for weight), and the ratio of infant to maternal plasma drug concentration. However, in the absence of known adverse effects (eg, diminished suck, sleep disturbances, decreased growth), what constitutes an acceptable fractional drug dose or ratio of plasma concentrations is arbitrary—is 0.10 acceptable but 0.20 not? Paroxetine is the only SSRI for which the ratio of infant to maternal plasma concentrations is low and uniformly <0.10.[45] Fortinguerra et al[46] documented that paroxetine, sertraline, and fluvoxamine are minimally excreted in human milk and provide the infant <10% of the maternal daily dose (normalized for weight). Yet, Weissman et al[45] cite studies in which 6% and 33% of the reported paired infant to maternal plasma concentration ratios for sertraline and fluvoxamine, respectively, are >0.10. A mother on treatment with an SSRI who desires to nurse her infant should be counseled about the

benefits of breastfeeding as well as the potential risk that her infant may continue to be exposed to a measureable level of the SSRI with unknown long-term effects.

OPIOIDS

Opioids are a class of natural, endogenous, and synthetic compounds that activate primarily μ-opioid (but also κ- and δ-opioid) receptors in the CNS to produce supraspinal analgesia. Other acute effects include sedation, euphoria, miosis, respiratory depression, and decreased gastrointestinal motility. Prolonged use results in physical and psychological dependence. As a class, opioids demonstrate a narrow therapeutic index. On the other hand, the interpatient range of dose necessary to achieve a similar therapeutic effect is fairly wide because of genetic differences in pharmacokinetics and pharmacodynamics.[47] Morphine is 1 of many natural opioids that can be extracted from the opium poppy. Codeine, heroin (diacetylmorphine), hydromorphone (Dilaudid), fentanyl (Sublimaze), and methadone are examples of synthetic opioids. Endogenous opioids include enkephalins, endorphins, and endomorphins. The term opiate refers to a subclass of alkaloid opioids. Methadone exerts secondary effects by acting as an *N*-methyl-D-aspartate receptor antagonist, blocking the actions of glutamate, the primary excitatory neurotransmitter in the CNS. Opioids acutely inhibit the release of noradrenaline at synaptic terminals. With chronic opioid exposure, tolerance develops as the rate of noradrenaline release over time increases toward normal. Abrupt discontinuation of exogenous opioids results in supranormal release of noradrenaline and produces the autonomic and behavioral signs and symptoms characteristic of withdrawal.

Opioid abuse in pregnant women presents additional risks for the fetus and newborn. Opioids are small lipophilic molecular weight compounds that cross placental and blood-brain barriers. Active or passive maternal detoxification is associated with increased risk of fetal distress and fetal loss. Maintenance programs with methadone (a full μ-opioid agonist and a Food and Drug Administration [FDA] schedule II controlled substance) for pregnant women can sustain opioid concentrations in the mother and fetus in ranges that minimize opioid craving, suppress abstinence symptomatology, block heroin-induced euphoria, and prevent fetal stress. Other benefits from this once controversial treatment are optimization of prenatal care and general maternal physical and mental health, as well as anticipation of potential withdrawal signs in the newborn infant. Disadvantages of methadone include the extremely unlikely achievement of successful detoxification after delivery and a more severe and prolonged course of NAS compared with heroin exposure. These issues have encouraged the development of other synthetic opioids as alternative treatments to methadone.

Subsequent to the Drug Addiction Treatment Act of 2000 that allowed office-based treatment of addiction by using FDA schedule III to V drugs, the synthetic opioid buprenorphine (a partial μ-opioid agonist) was approved by the FDA in 2002 as a schedule III controlled substance for the treatment of opioid dependence. Neither methadone nor buprenorphine is approved for use in pregnant women, and both are categorized by the FDA as class C pregnancy drugs. Nonetheless, buprenorphine, either alone (Subutex) or in combination with naloxone (Suboxone), has been used both as a first-line treatment of heroin addiction and as a replacement drug for methadone. Recent results from the Maternal Opioid Treatment: Human Experimental Research study suggest that buprenorphine has some advantages to methadone as a treatment of opioid addiction in pregnant women. Infants born to mothers treated with buprenorphine had shorter hospital stays (10 vs 17.5 days), had shorter treatment durations for NAS (4.1 vs 9.9 days), and required a lower cumulative dose of morphine (1.1 vs 10.4 mg) compared with infants born to mothers on methadone maintenance.[48]

CLINICAL PRESENTATION OF OPIOID WITHDRAWAL

The clinical presentation of NAS varies with the opioid, the maternal drug history (including timing of the most recent use of drug before delivery), maternal metabolism, net transfer of drug across the placenta, placental metabolism (W. Snodgrass, MD, PhD, personal communication, 2008), infant metabolism and excretion, and other factors. In addition, maternal use of other drugs and substances such as cocaine, barbiturates, hypnotics-sedatives, and cigarettes may influence the severity and duration of NAS. Because opioid receptors are concentrated in the CNS and the gastrointestinal tract, the predominant signs and symptoms of pure opioid withdrawal reflect CNS irritability, autonomic overreactivity, and gastrointestinal tract dysfunction (Table 3). Excess environmental stimuli and hunger will exacerbate the perceived severity of NAS.

Onset of signs attributable to neonatal withdrawal from heroin often begins within 24 hours of birth, whereas withdrawal from methadone usually commences around 24 to 72 hours of age.[49] For both opioids, evidence of withdrawal may be delayed until 5 to 7 days of age or later, which is typically after hospital discharge.[50] For

TABLE 3 Clinical Features of the Neonatal Narcotic Abstinence Syndrome

Neurologic Excitability	Gastrointestinal Dysfunction
Tremors	Poor feeding
Irritability	Uncoordinated and constant sucking
Increased wakefulness	Vomiting
High-pitched crying	Diarrhea
Increased muscle tone	Dehydration
Hyperactive deep tendon reflexes	Poor wt gain
Exaggerated Moro reflex	Autonomic signs
Seizures	Increased sweating
Frequent yawning and sneezing	Nasal stuffiness
	Fever
	Mottling
	Temperature instability

infants exposed to buprenorphine, 1 study found that onset of withdrawal peaked at 40 hours and that signs were most severe at 70 hours of age.[51] The different time courses reflect variations in the half-lives of drug elimination. However, if 1 week or longer has elapsed between the last maternal opioid use and delivery of the infant, the incidence of neonatal withdrawal is relatively low.[52] The incidence and severity of NAS are greater in infants exposed to methadone compared with those exposed to buprenorphine[48] or heroin. Still, severe withdrawal has been described in 0 to 50% of buprenorphine-exposed infants.[53–55] In the acute phase, seizures have occurred in 2% to 11% of infants withdrawing from opioids[49,50,56]; however, abnormal EEG results without overt seizure activity have been reported in >30% of neonates.[57,58] Subacute signs of opioid withdrawal may last up to 6 months.[59]

Seizures also may be associated with withdrawal from a variety of nonnarcotic drugs (eg, barbiturates,[12,14] alcohol,[14] and sedative-hypnotics[60,61]). The mechanism and significance of seizures associated with withdrawal are unclear. Withdrawal from ethanol begins early, in general, during the first 3 to 12 hours after delivery.[12,15] Diagnosis of sedative withdrawal is more difficult, because classically it appears after the first few days of life. Barbiturate withdrawal has a median onset of 4 to 7 days, but a wide range from days 1 through 14.[12,13] Other sedative-hypnotics have exhibited even later onset, including as late as day 12 for diazepam[10] and day 21 for chlordiazepoxide.[11]

Studies of the relationship between maternal methadone dose and the incidence and severity of NAS have provided contradictory findings. Some studies demonstrated that larger maternal methadone dosages in late pregnancy were associated with greater neonatal concentrations and increased risk of withdrawal,[8,9,62–68] but others refuted a correlation.[69–74] This lack of consensus is explained in part by different approaches to the management of antenatal methadone maintenance therapy. There were substantial variations in the mean and range of daily methadone dose in the populations studied. Studies that found no correlation tended to enroll infants born to mothers who had been prescribed higher doses of methadone (50–200 mg/day), whereas those that did note a relationship between maternal dose and NAS sequelae reported lower maternal doses (eg, <50 mg/day) or included women undergoing partial detoxification.[67] Another potential explanatory factor is the significant interindividual variability in maternal methadone metabolism.[75] As a result, cumulative fetal exposure can be expected to vary among infants born to mothers on equivalent methadone regimens.

Methadone concentrations in cord blood and at 48 hours of age,[72] as well as the rate of decline in neonatal serum concentration,[65] appear to correlate with NAS signs. Kuschel et al[72] found that infants who required rescue treatment had lower cord blood methadone concentrations and that, in all but 1 infant, methadone concentrations were undetectable in the serum at 48 hours. Doberczak[65] noted that faster declines in postnatal blood methadone concentrations were associated with more severe CNS withdrawal.

Preterm Infants

Preterm infants have been described as being at lower risk of drug withdrawal with less severe and/or prolonged courses. Infants born at <35 weeks' gestation whose mothers received methadone maintenance had significantly lower total and CNS abstinence scores than did term infants of mothers receiving similar methadone dosages.[64] In a more recent study, lower gestational age correlated with a lower risk of neonatal withdrawal.[68] The apparent decreased severity of signs in preterm infants may relate to developmental immaturity of the CNS, differences in total drug exposure, or lower fat depots of drug. Alternatively, the clinical evaluation of the severity of abstinence may be more difficult in preterm infants, because scoring tools to describe withdrawal were largely developed in term or late preterm infants.[76,77] In a retrospective study, Dysart et al[78] compared the length of hospital stay, duration of medication, and cumulative medication exposure for preterm and term infants born to mothers enrolled in a methadone maintenance program. Infants were evaluated by using an abstinence scoring system[77] and treated uniformly

with a neonatal opiate solution. All adverse outcomes were reduced in the preterm cohort.

Abuse of Multiple Drugs

The abuse of multiple drugs during pregnancy is not uncommon,[79] but its effect on the occurrence and severity of neonatal abstinence is controversial. In 1 study, abstinence scores of infants whose mothers abused cocaine and methadone were similar to the scores of infants whose mothers received high-dose maintenance methadone.[64] In another study, the neurobehavioral scores of infants exposed to intrauterine cocaine were similar to those of infants exposed to both cocaine and methadone.[80] Conversely, an unmasked study reported higher abstinence scores in infants exposed to both cocaine and heroin in comparison with those exposed to heroin or cocaine alone.[19] Infants born to mothers maintained on methadone who were also heavy smokers (>20 cigarettes per day) demonstrated higher withdrawal scores that peaked later than infants born to light smokers.[81]

A 1989 case report linked the administration of naloxone for the treatment of apnea in a baby born to a mother with recent methadone ingestion to the onset of seizures. The seizures resolved after morphine treatment but did not respond to administration of phenobarbital or diazepam.[82] For this reason, maternal use of opiates during pregnancy has remained a relative contraindication to the use of naloxone for the treatment of apnea or hypoventilation during the transition period after birth.

DIFFERENTIAL DIAGNOSIS

The presence of maternal characteristics known to be associated with drug abuse during pregnancy can be considered an indication to screen for intrauterine drug exposure. These characteristics include absent, late, or inadequate prenatal care; a previously documented or admitted history of drug abuse; a previous unexplained late fetal demise; precipitous labor; abruptio placentae; hypertensive episodes; severe mood swings; cerebrovascular accidents; myocardial infarction; and repeated spontaneous abortions.[80,83–88] The legal implications of testing and the need for consent from the mother may vary among the states.[89] Each hospital should consider adopting a policy for maternal and newborn screening to avoid discriminatory practices and to comply with local laws.

Withdrawal signs in the newborn may mimic other conditions, such as infection, hypoglycemia, hypocalcemia, hyperthyroidism, intracranial hemorrhage, hypoxic-ischemic encephalopathy, and hyperviscosity.[90] If none of these diagnoses is readily apparent, a detailed maternal drug history should be obtained that includes interviewing the mother about drug use and abuse by her partner, friends, and parents, in addition to queries about the mother's prescription and nonprescription drug use.[90,91] Because maternal self-reporting underestimates drug exposure and maternal urine screening during pregnancy fails to identify many cases of drug use,[83] appropriate neonatal drug screening should be performed. Conversely, no clinical signs should be attributed solely to drug withdrawal on the basis of a positive maternal history without a careful assessment to exclude other causes.

Screening is most commonly accomplished by using neonatal urine specimens. A urine sample must be collected as soon as possible after birth, because many drugs are rapidly metabolized and eliminated.[90,92,93] Even so, a positive urine screening result may only reflect recent drug use. Alcohol is detectable in neonatal urine for 6 to 16 hours after the last maternal ingestion. Amphetamines, benzodiazepines, cocaine metabolites, and opioids are usually cleared within 1 to 3 days after birth. Marijuana and cocaine metabolites may be detectable for weeks, depending on maternal usage.[94]

Drugs that are excreted in the hepatobiliary system as well as drugs excreted by the fetal kidneys into the amniotic fluid are concentrated in meconium. Hence, meconium analysis is most useful when the history and clinical presentation strongly suggest neonatal withdrawal, but the maternal and neonatal urine screening results are negative. Drawbacks of testing for drugs in meconium are that it is not typically performed by hospitals and that results are often not available for days to weeks. Meconium must be collected before it is contaminated by transitional, human milk, or formula stools—otherwise, the assay may not be valid or the reference laboratory may reject the sample. Assay of meconium, although not conclusive if the results are negative, is more likely to identify infants of drug-abusing mothers than is the testing of infant or maternal urine.[95,96] Other specimens that have been tested in research laboratories are maternal and neonatal hair.[97,98] Recently, testing of umbilical cord tissue by using drug class-specific immunoassays was shown to be in concordance with testing of paired meconium specimens at rates of 97%, 95%, 99%, and 91% for the detection of amphetamines, opiates, cocaine, and cannabinoids, respectively.[99] The availability of this tissue from the moment of birth (in contrast to the inherent delay in collecting urine or meconium) may foster the adoption of this method of testing.

ASSESSMENT AND NONPHARMACOLOGIC TREATMENT

Several semiobjective tools are available for quantifying the severity of

neonatal withdrawal signs. Clinicians have used discrete or serial scores to assist with therapeutic decisions. The Lipsitz tool, also known as the Neonatal Drug Withdrawal Scoring System,[76] was recommended in the 1998 American Academy of Pediatrics statement "Neonatal Drug Withdrawal,"[100] probably because it is a relatively simple metric with good sensitivity for identifying clinically important withdrawal. The modified Neonatal Abstinence Scoring System (Fig 1),[101] is the predominant tool used in the United States.[102] This more comprehensive instrument assigns a cumulative score based on the interval observation of 21 items relating to signs of neonatal withdrawal.[103] In 1 study, administration of this scoring system with infants verified not to have been exposed to prenatal opiates by meconium analysis resulted in a stable median score of 2 during each of the first 3 days of life, with 95th percentile scores of 5.5 and 7 on days 1 and 2, respectively.[104] Infants at risk for NAS should be carefully monitored in the hospital for the development of signs consistent with withdrawal. The appropriate duration of hospital observation is variable and depends on a careful assessment of the maternal drug history. An infant born to a mother on a low-dose prescription opiate with a short half-life (eg, hydrocodone; average half-life, 4 hours) may be safely discharged if there are no signs of withdrawal by 3 days of age, whereas an infant born to a mother on an opiate with a prolonged half-life (eg, methadone) should be observed for a minimum of 5 to 7 days. Initial treatment of infants who develop early signs of withdrawal is directed at minimizing environmental stimuli (both light and sound) by placing the infant in a dark, quiet environment; avoiding autostimulation by careful swaddling; responding early to an infant's signals;

adopting appropriate infant positioning and comforting techniques (swaying, rocking); and providing frequent small volumes of hypercaloric formula or human milk to minimize hunger and allow for adequate growth. Caloric needs may be as high as 150 to 250 cal/kg per day because of increased energy expenditure and loss of calories from regurgitation, vomiting, and/or loose stools.[105,106] The infant needs to be carefully observed to recognize fever, dehydration, or weight loss promptly. The goals of therapy are to ensure that the infant achieves adequate sleep and nutrition to establish a consistent pattern of weight gain and begins to integrate into a social environment. Maternal screening for comorbidities, such as HIV or hepatitis C virus infections and polydrug abuse, needs to be performed. Additional supportive care in the form of intravenous fluids, replacement electrolytes, and gavage feedings may be necessary to stabilize the infant's condition in the acute phase and obviate the need for pharmacologic intervention. When possible, and if not otherwise contraindicated, mothers who adhere to a supervised drug treatment program should be encouraged to breastfeed so long as the infant continues to gain weight. Breastfeeding or the feeding of human milk has been associated with less severe NAS that presents later and less frequently requires pharmacologic intervention.[107,108] Methadone is present in very low concentrations in human milk. Cumulative daily intake of methadone in fully breastfed infants has been estimated to range from 0.01 to 0.15 mg/day in the first 30 days of life[109] and 0.15 to 0.30 mg/day between 30 and 180 days of age.[110] Similarly, the amount of buprenorphine excreted in human milk is small. Although more information is needed to evaluate long-term neurodevelopmental outcome of infants exposed to small quantities of buprenorphine, there is no clear reason to discourage breastfeeding in mothers who adhere to methadone or buprenorphine maintenance treatment.[111]

Each nursery should adopt a protocol for the evaluation and management of neonatal withdrawal, and staff should be trained in the correct use of an abstinence assessment tool. In a recent survey of accredited US neonatology fellowship programs, only 55% had implemented a written NAS protocol, and only 69% used a published abstinence scoring system.[102]

RATIONALE AND COMPARATIVE EVIDENCE FOR PHARMACOLOGIC TREATMENT

Drug therapy is indicated to relieve moderate to severe signs of NAS and to prevent complications such as fever, weight loss, and seizures if an infant does not respond to a committed program of nonpharmacologic support. Since the introduction of the abstinence scales in 1975, published reports have documented that the decision to initiate pharmacologic treatment has been based on single or serial withdrawal scores. However, no studies to date have compared the use of different withdrawal score thresholds for initiating pharmacologic intervention on short-term outcomes (eg, severity and duration of withdrawal signs, weight gain, duration of hospitalization, need for pharmacologic treatment, or cumulative drug exposure). Withdrawal from opioids or sedative-hypnotic drugs may be life-threatening, but ultimately, drug withdrawal is a self-limited process. Unnecessary pharmacologic treatment will prolong drug exposure and the duration of hospitalization to the possible detriment of maternal-infant bonding. The only clearly defined benefit of pharmacologic treatment is the short-term amelioration of clinical signs. Studies have not addressed whether long-term morbidity related to neonatal drug withdrawal is decreased by pharmacologic management of affected infants, or whether continued postnatal drug exposure augments the risk of neurobehavioral and other morbidities. It is possible that pharmacologic therapy of the infant may introduce or reinforce a maternal disposition to rely on drugs for the treatment of infant discomfort or annoying behavior.[112]

Clinicians have treated NAS with a variety of drug preparations, including opioids (tincture of opium, neonatal morphine solution, methadone, and paregoric), barbiturates (phenobarbital), benzodiazepines (diazepam, lorazepam), clonidine, and phenothiazines (chlorpromazine). Information pertinent to the use of these drug preparations in infants is well summarized in the previous American Academy of Pediatrics statement.[100] Recent surveys have documented that, in accord with the recommendations of that statement, 94% of UK and 83% of US clinicians use an opioid (morphine or methadone) as the drug of first choice. The majority of practitioners use phenobarbital as a second drug if the opiate does not adequately control withdrawal signs.[102,113] Daily doses of morphine ranged from 0.24 mg/kg per day to 1.3 mg/kg per day.[113] Paregoric is no longer used, because it contains variable concentrations of other opioids, as well as toxic ingredients such as camphor, anise oil, alcohol, and benzoic acid.[100] The use of diazepam has also fallen into disfavor because of a documented lack of efficacy compared with other agents and because of its adverse effects on infant suck and swallow reflexes.[114–116]

Meta-analyses of published trials regarding the pharmacologic treatment of neonatal withdrawal are available.[117,118] In 2 Cochrane meta-analyses, either an opioid[117] or a sedative[118] drug treatment

was compared with a control treatment that could include a nonpharmacologic intervention, a placebo treatment, or another opioid and/or sedative drug. The authors prospectively designated 4 primary outcomes (failure of treatment to control withdrawal signs; incidence of seizures; survival; and neurodevelopmental outcome) for meta-analysis. Treatment failure was defined variously as the inability of the treatment to maintain abstinence scores within a preset "safe" level and/or the need to add another drug therapy. Some studies did not report primary outcomes and instead quantified secondary outcomes (eg, duration of treatment, duration of hospitalization, rate of weight gain, etc).

Seven studies of opioid treatment that enrolled a total of 585 infants were identified between 1983 and 2004. Methodologic flaws were common and included quasirandom patient allocation; substantial and often unexplained differences in allocation of patients to treatment groups; imbalances in group characteristics after randomization; failure to mask study treatments; and failure to mask outcome measurements. In the single study that assessed oral morphine treatment versus supportive therapy only, 3 consecutive Finnegan scores $\geq$8 prompted institution of the intervention.[119] No significant effect of morphine was found on the rate of treatment failure. Oral morphine significantly increased the duration of treatment and the length of hospital stay, but it did reduce the number of days required to regain birth weight and duration of supportive care. Four studies compared treatment failures of opioids (paregoric, oral morphine, or methadone) with phenobarbitone.[8,119–121] Neither the meta-analysis nor any individual study identified a significant difference in treatment failure. One study reported a lower incidence of seizures in the opioid (paregoric) treatment group.[122] No consistent trends in secondary outcomes were observed, although 1 study reported a shorter duration of therapy in the phenobarbitone compared with the paregoric treatment group,[123] and another made the opposite observation when the opioid used was oral morphine.[121] Three studies individually and in combination reported significantly lower rates of treatment failure in infants assigned to opioid (paregoric or methadone) compared with diazepam therapy[8,114,120] but did not define differences in secondary outcomes. No studies reported mortality or neurodevelopmental outcomes.

A second Cochrane review analyzed 6 trials involving 305 infants published between 1969 and 2002 in which sedative treatment of NAS was compared with a nonopioid therapy. Methodologic concerns were similar to the opioid treatment trials. In the sole study of phenobarbitone versus supportive care, no difference in treatment failure was found, but treatment significantly increased the duration of therapy and hospital stay.[119] A small study that allocated infants already treated with diluted tincture of opium (DTO) to phenobarbitone as a second drug versus no additional treatment identified no infants in either group with treatment failure but observed significant reductions in the duration of hospitalization (38 vs 79 days) and the maximal daily dose of opioid in the phenobarbitone-treated infants.[124] Infants were discharged from the hospital once they were no longer taking opioids. However, the mean duration of phenobarbitone treatment was 3.5 months. Of 3 studies that compared phenobarbitone and diazepam treatment, 1 found a significantly lower rate of treatment failure in the phenobarbitone group.[8,114,120] One study of phenobarbitone versus chlorpromazine[125] found no differences in primary or secondary outcomes.

Since 2004, a number of small studies of varying methodologic quality have compared pharmacologic treatments. In a prospective randomized double-masked study, Langenfeld et al[126] could not identify differences in duration of treatment, duration of hospitalization, or in weight gain (g/day) in infants treated with either DTO or oral morphine drops. A retrospective study found no difference in length of hospitalization in infants with NAS who were treated with methadone or oral morphine solution, but did correlate higher maternal methadone doses with longer lengths of stay.[127] Ebner et al[128] examined the incidence of NAS in infants born to mothers maintained with methadone, morphine, or buprenorphine and compared phenobarbital and oral morphine treatments in affected infants. Sixty-eight percent of infants born to mothers maintained on methadone required pharmacologic treatment at a mean age of 58 hours, compared with 82% of infants at a mean age of 33 hours in the morphine group and 21% of infants at a mean age of 34 hours in the buprenorphine group. The duration of treatment was significantly shorter for infants who received morphine compared with infants who were treated with phenobarbital. A randomized comparison trial of sublingual buprenorphine versus neonatal opium solution for the treatment of NAS showed a nonsignificant reduction in length of treatment and duration of hospitalization in the buprenorphine group.[129] Buprenorphine therapy was well tolerated.

Clonidine is an α_2-adrenergic receptor agonist that has been used in combination with an opioid or other drug in older children and adults to reduce withdrawal symptoms.[130,131] Via a negative feedback mechanism, clonidine

reduces CNS sympathetic outflow and palliates symptoms of autonomic overactivity such as tachycardia, hypertension, diaphoresis, restlessness, and diarrhea. Cessation of clonidine treatment can result in a rebound of autonomic activity. Reported experience with clonidine as a primary or adjunctive treatment of NAS is limited but promising. In a small case series, 6 of 7 infants with NAS showed significant resolution of signs when treated with oral clonidine.[132] In a randomized double-masked controlled trial, Agthe et al[133] compared the efficacy and safety of treating NAS with DTO plus oral clonidine (1 μg/kg every 3 hours) versus DTO plus placebo in 80 infants with prenatal exposure to methadone and/or heroin. The combination therapy significantly reduced the median length of treatment of all infants and for infants exposed to methadone, but more infants in the DTO/clonidine group required resumption of DTO after initial discontinuation. The mean total dose of morphine over the treatment course was ~60% lower in the combination therapy group. No clinically significant differences in feeding, weight gain or loss, heart rate, or blood pressure were observed. In another case series, oral clonidine was administered either as a primary or adjunctive therapy for the prevention or treatment of narcotic withdrawal in infants on intravenous fentanyl or infants with antenatal exposure to opiates.[134] In all cases, treatment was successful and clonidine was discontinued without sequelae after a mean duration of 7 days. In a retrospective case series, infants who had evidence of NAS attributable to antenatal methadone exposure had lower severity scores and required fewer days of drug therapy and hospitalization if they had been treated with a combination of clonidine and chloral hydrate rather than a combination of morphine and phenobarbital.[135]

A recently published case series from France that used a historical cohort for a comparison has suggested that the treatment of NAS with the phenothiazine, chlorpromazine, as a single drug may be more effective than treatment with morphine.[136] Infants treated with oral morphine had significantly longer median durations of treatment and hospitalization in comparison with infants treated with chlorpromazine. No adverse affects were reported.

OUTCOME

Assessment of potential long-term morbidity specifically attributable to neonatal drug withdrawal and its treatment is difficult to evaluate. Few studies have followed drug-exposed children beyond the first few years of life. Confounding variables, such as environment and dysfunctional caregivers, complicates the interpretation of outcomes. In a small study, developmental scores on the mental index on the Bayley Scales of Infant Development were not affected by the severity of withdrawal or the treatment chosen.[114] Mean scores on the Bayley Scales of Infant Development were similar for all infants treated for withdrawal, including those receiving phenobarbital, paregoric, or a combination therapy. Scores of infants whose withdrawal was too mild to qualify for pharmacologic intervention were also similar.

Fourteen drug-exposed infants with withdrawal-associated seizures were reported by Doberczak et al.[25] The abstinence scores for 5 of these infants were <7 (the cutoff for treatment); hence, they received no pharmacologic therapy before the onset of seizures. Thirteen of the 14 infants were offspring of mothers enrolled in a methadone treatment program; however, the success of maternal treatment was not described. Of the 14 infants with seizures, 12 were available for evaluation at 1 year of age; results of neurologic examinations were normal in 9 of the 12 infants evaluated. EEG results were abnormal in 9 neonates; however, subsequent EEGs for 7 of 8 of these infants normalized during follow-up. Mean scores on the Bayley Scales of Infant Development were also normal by 1 year of age, similar to matched controls that were drug exposed, but in whom withdrawal-associated seizures did not develop.[24] Withdrawal-associated seizures seem to be primarily myoclonic, to respond to opiates, and to carry no increased risk of poor outcome. Withdrawal-associated seizures in neonates are different from those associated with other causes. Based on the depression of norepinephrine and dopamine observed with methadone exposure in animal models, withdrawal seizures are speculated to be attributable to lowered levels of neurotransmitters.[137,138] The normalization of the EEG and normal neurologic development are believed to reflect recovery of normal neurotransmitter concentrations during early infancy. Bandstra et al[139] have comprehensively reviewed outcomes of infants and toddlers who were exposed prenatally to opioids and cocaine.

MANAGEMENT OF ACQUIRED OPIOID AND BENZODIAZEPINE DEPENDENCY

One of the cornerstones in caring for critically ill children is to provide adequate and safe analgesia, sedation, amnesia, and anxiolysis by using both pharmacologic and nonpharmacologic measures. Pharmacologic treatment typically includes medications in the opioid and benzodiazepine drug classes. However, if these drugs cannot safely be discontinued within a few days, physical dependence on 1 or both of these classes of medication can develop and manifest with signs

and symptoms of withdrawal on acute dosage reduction or cessation of therapy. Infants who undergo complex surgery, who require prolonged medical intensive care for conditions such as respiratory failure or persistent pulmonary hypertension, or who are supported with extracorporeal membrane oxygenation (ECMO) therapy are among those at greatest risk of acquired drug dependency.

Extended treatment with opioids via continuous intravenous infusion results in drug tolerance. Even short-term opioid exposure alters the number and affinity of receptors in key neuronal centers so that an escalation of the opioid infusion rate (which produces an increase in opioid plasma concentrations) becomes necessary to achieve the same physiologic effect.[140] By itself, the development of tolerance does not predict physical dependency or withdrawal.[141] Cumulative exposure to fentanyl, quantified by the total dose in milligrams per kilogram or the number of consecutive days of treatment, correlated with the likelihood of withdrawal.[140,142,143] By using a multiple logistic regression analysis, Arnold et al[140] found that the duration of ECMO therapy was an even more powerful predictor of withdrawal than was cumulative fentanyl exposure. Katz et al[142] reported that among 23 mechanically ventilated children aged 1 week to 22 months (mean, 6 months) who were treated for >24 hours with a continuous fentanyl infusion, 13 of 23 children (57%) developed withdrawal as defined by a Finnegan score ≥8. In this prospective study, a cumulative fentanyl exposure in excess of 2.5 mg/kg or 9 days of therapy was 100% predictive of withdrawal. More recently, in a prospective study of 19 neonates treated with fentanyl for a minimum of 24 hours, Dominquez et al[143] documented that a cumulative fentanyl dose ≥415 μg/kg predicted withdrawal with 70% sensitivity and 78% specificity and that an infusion duration ≥8 days was 90% sensitive and 67% specific for withdrawal. In adults, concomitant treatment with neuromuscular paralytic agents or propofol for >24 hours also increased the likelihood of withdrawal.[144] Signs and symptoms of withdrawal from fentanyl commence within 24 hours of cessation of therapy.

The refinement of pain management in children over the past 2 decades has witnessed an expansion of the use of opioids in the intensive care setting. As a result, more children have been treated for actual or potential withdrawal symptoms as a comorbidity of hospitalization. Fentanyl, a pure μ-opioid receptor antagonist, has become the opioid of choice because of its rapid onset of action, short duration of effect (half-life of 0.5–1 hour), excellent potency, and minimal acute adverse effects. However, fentanyl has not been demonstrated to be safer or more effective than morphine for the provision of long-term analgesia. Indeed, 1 study has reported that patients who were treated prospectively with a continuous morphine infusion during ECMO experienced a significantly lower need for supplemental analgesia, a lower rate of dependency, and a shorter hospital stay compared with a previous group of patients treated with fentanyl during ECMO.[145]

Practitioners have employed a variety of strategies to treat or, in high-risk patients, to prevent signs and symptoms of opioid withdrawal in infants and children. Carr and Todres[146] reported success with a gradual taper of the opioid infusion rate. Children who had received continuous opioid infusions for more than a week required 2 to 3 weeks for complete weaning. One disadvantage of this approach was that intravenous access had to be maintained for the entire course of treatment. Tobias et al[147] were among the first investigators to describe treatment of opioid withdrawal by conversion to enteral methadone. Methadone was chosen as the opioid of choice because of its excellent oral bioavailability (70%–100%) and long half-life (19–41 hours), which allowed for long intervals between doses.[148] In this initial report, 3 symptomatic patients who had been exposed to continuous or bolus opioids for up to 7 weeks were transitioned to a methadone regimen of 0.1 mg/kg, orally, every 12 hours. Dose reduction by 10% to 20% of the initial dose per week resulted in successful weaning in 4 to 6 weeks.

In 2000, Robertson and et al[149] reported the outcomes of 10 children 6 months to 18 years of age who had received >7 days of opioids (range, 7–53 days). An amount of methadone, equipotent to the existing daily fentanyl or morphine dose, was determined. This amount was reduced by a factor of 6 because of the longer half-life of methadone to calculate the initial total daily methadone dose. Protocols specified 2 different weaning schedules, depending on whether the patient had been treated with opioids (fentanyl or morphine) for either 7 to 14 days or for >14 days. Treatment intervals were gradually lengthened from every 6 hours to every 24 hours when methadone was discontinued. Outcomes of these patients were compared with recent control patients who had also been treated with enteral methadone but not under a standard protocol. Among the protocol patients, there were no treatment failures. Weaning was accomplished in a median of 9 days (range, 5–10 days), which was significantly less than the median of 20 days (range, 9–31 days) observed in the nonprotocol children. Concurrent use of benzodiazepines occurred in 6 of the protocol children, compared

with 3 of the nonprotocol group, so that the decreased taper time on protocol was unlikely to have been confounded by other drug therapy. Weaning and discontinuation from benzodiazepines were successful during the methadone taper in all protocol patients.

Meyer et al[150] described a protocol for rescue therapy in 29 patients 1 day to 20 years of age on admission who developed withdrawal during the course of nonstandardized tapers of prolonged continuous fentanyl infusion. Withdrawal was defined as the observation of 3 consecutive Finnegan scores $\geq$8 obtained at 2-hour intervals. The daily fentanyl dose for the period 24 to 48 hours before withdrawal symptoms was used to calculate an equipotent dose of morphine sulfate. Morphine was administered as a bolus dose every 4 hours and titrated to effect (Finnegan score consistently <8) over 12 to 24 hours. An equipotent amount of methadone was then determined by using the effective morphine dose. Three loading doses of methadone at 12-hour intervals were administered. Afterward, doses were given every 24 hours and weaned by 10% per day. Ten patients were receiving concomitant treatment with a benzodiazepine or chloral hydrate, but these medications were not weaned during the methadone taper. Twenty-five of 29 patients successfully completed this taper over 10 days. Three patients required 21 days, and 1 patient died of sepsis. Sixteen of the patients were discharged from the hospital and completed methadone tapers on an outpatient basis. Nine of the patients had been started on clonidine during the phase of nonstandardized opioid weaning in unsuccessful attempts to prevent withdrawal. A subsequent randomized double-blind follow-up study by the same group of investigators[151] found that in a group of 37 fentanyl-treated patients, a 5-day methadone taper was as successful as the longer 10-day course (13 of 16 vs 17 of 21 [not significant]) in discontinuing opioid infusions without causing withdrawal. In contrast to their previous study, a standardized taper of lorazepam was allowed in 17 of the 37 patients while on the methadone protocol. Only 1 of these 17 patients who underwent dual tapers required rescue treatment with an increased dose of opioids.

Several factors potentially complicate the adoption of the protocols reported by Robertson, Meyer, and Berens (see Table 4) into routine neonatal clinical practices. Most obvious is that these studies were conducted in a PICU setting; few neonates were included, and their outcomes were not separately analyzed. Other investigators have emphasized that the Finnegan instrument common to all 3 studies has been validated only in term infants undergoing withdrawal secondary to in utero opioid exposure.[152,153] Therefore, the use of this tool may have underestimated withdrawal symptomatology in an older pediatric population. A third concern is that opioids and benzodiazepines are often used concurrently in the same patient, yet symptoms of opioid and benzodiazepine withdrawal overlap to a great extent. Hence, current instruments will not reliably differentiate whether withdrawal symptoms stem from relative opioid or benzodiazepine abstinence.[153] Other scales have been proposed for children and are in various stages of evaluation, including the Opioid and Benzodiazepine Withdrawal Scale,[151] the Sedation Withdrawal Score,[154] and the Sophia Benzodiazepine and Opioid Withdrawal Checklist.[155]

At this time, no optimal pharmacologic regimen for the prevention or treatment of acquired opioid and/or benzodiazepine dependency can be recommended, because the necessary comparative studies of safety and efficacy are not available.[156] Hence, it is even more incumbent on the practitioner to prescribe pharmacologic interventions with the goal of achieving the desired therapeutic effect by using the fewest drugs at the lowest doses and for the shortest durations possible.

Nonetheless, because many critically ill infants and children do receive treatment with prolonged courses of opioids and benzodiazepines, the following practices are reasonable based on the available evidence:

1. Each clinical unit can establish a threshold level of cumulative exposure to opioids and benzodiazepines above which drug dependency can be expected to occur with a likelihood that justifies anticipatory initiation of a weaning protocol. For example, setting a threshold at a cumulative fentanyl exposure of >2 mg/kg or >7 days' duration would predict a likelihood of dependency >50% but <100%.[141,142]
2. Infants with a cumulative exposure to opioids or benzodiazepines below the thresholds for initiation of weaning protocols can undergo a rapid taper of these medications over a 24- to 48-hour period. Many such children will not subsequently exhibit drug dependency.
3. Signs and symptoms of withdrawal will develop within 24 hours of discontinuation or during the course of a rapid taper of an opioid. If this occurs, 1 of the rescue approaches in Table 4 can be chosen as a guide to facilitate conversion to enteral methadone management and to initiate a weaning strategy, with 2 caveats. Infants on very high daily doses of continuous intravenous opioid may require less than the

TABLE 4 Weaning Protocols by Using Conversion of Continuous Opioid Infusions to Enteral Methadone and for Conversion of Midazolam (Versed) Infusion to Enteral Lorazepam (Ativan)

Robertson et al[149]
Conversion of continuous intravenous fentanyl of 7–14 d duration to enteral methadone: 1. By using the current hourly infusion rate, calculate the 24-h fentanyl dose. 2. Multiply the daily fentanyl dose by a factor of 100 to calculate the equipotent amount of methadone (ratio of potencies assumed to be fentanyl: methadone = 100:1). 3. Divide this amount of methadone by 6 (a correction for the longer half-life of methadone) to calculate an initial total daily dose of methadone, and on day 1 provide this amount orally in 4 divided doses every 6 h for 24 h. 4. Day 2: Provide 80% of original daily dose in 3 divided oral doses every 8 h for 24 h. 5. Day 3: Provide 60% of original daily dose in 3 divided oral doses every 8 h for 24 h. 6. Day 4: Provide 40% of original daily dose in 2 divided oral doses every 12 h for 24 h. 7. Day 5: Provide 20% of original daily dose × 1. 8. Day 6: Discontinue methadone. Conversion of continuous intravenous fentanyl greater than 14 d duration to enteral methadone: 1. Repeat steps 1–2 above. 2. Days 1–2: Divide the dose of methadone by 6 (a correction for the longer half-life of methadone) and on day 1 provide this amount orally in 4 divided doses every 6 h for 48 h. 3. Days 3–4: Provide 80% of original daily dose in 3 divided oral doses every 8 h for 48 h. 4. Days 5–6: Provide 60% of original daily dose in 3 divided oral doses every 8 h for 48 h. 5. Days 7–8: Provide 40% of original daily dose in 2 divided oral doses every 12 h for 48 h. 6. Days 9–10: Provide 20% of original daily dose once per day for 48 h. 7. Day 11: Discontinue methadone. For patients on continuous intravenous morphine, proceed as above but do not multiply the daily fentanyl dose by 100, because morphine and methadone are nearly equipotent.
Meyer and Berens[150]
Conversion of continuous intravenous fentanyl to intermittent intravenous morphine: 1. By using the target hourly infusion rate of fentanyl, calculate the 24-h fentanyl dose. 2. Multiply the daily fentanyl dose by a factor of 60 to calculate the equipotent dose of morphine (ratio of potencies assumed to be fentanyl: morphine = 60:1). 3. Divide the dose of morphine by 4 (correcting for the longer half-life of morphine) and on day 1 administer this amount intravenously in 6 divided doses every 4 h. 4. Titrate the morphine dose for adequate effect over 12 to 24 h. Conversion of intermittent intravenous morphine to enteral methadone: 1. Multiply the dose of morphine given every 4 h by 2 (ratio of potencies assumed to be morphine: methadone = 2:1) to determine an equipotent amount of methadone. 2. Provide this amount of methadone as an oral dose every 12 h for 3 doses. 3. Double this amount of methadone and provide as a single oral dose per day at bedtime. 4. Provide 90% of the initial dose on day 2, 80% on day 3, etc, so that the last dose of methadone (10% of the original dose) is given on day 10.
Protocols at Wolfson Children's Hospital, Jacksonville, Florida
Conversion of continuous intravenous fentanyl >7 d duration to enteral methadone: 1. By using the current hourly infusion rate, calculate the 24-h fentanyl dose. 2. Multiply the daily fentanyl dose by a factor of 100 to calculate the equipotent amount of methadone (ratio of potencies assumed to be fentanyl: methadone = 100:1). 3. Divide this amount of methadone by 8–12 (a correction for the longer half-life of methadone) to calculate an initial total daily dose of methadone (not to exceed 40 mg/day). 4. Days 1–2: Provide the total daily dose of methadone orally in 4 divided doses every 6 h for 48 h. At the time of the second methadone dose, reduce the fentanyl infusion rate to 50%; at the time of the third dose, reduce the fentanyl infusion rate to 25%; and after the fourth methadone dose, discontinue the fentanyl infusion. 5. Days 3–4: Provide 80% of original daily dose in 3 divided oral doses every 8 h for 48 h. 6. Days 5–6: Provide 60% of original daily dose in 3 divided oral doses every 8 h for 48 h. 7. Days 7–8: Provide 40% of original daily dose in 2 divided oral doses every 12 h for 48 h. 8. Days 9–10: Provide 20% of original daily dose once per day for 48 h. 9. Day 11: Discontinue methadone. Conversion of continuous intravenous midazolam >7 d duration to enteral lorazepam: 1. By using the current hourly infusion rate, calculate the 24-h midazolam dose. 2. Because lorazepam is twice as potent as midazolam and has a sixfold longer half-life, divide the 24 h midazolam dose by 12 to determine the daily lorazepam dose. 3. Divide the calculated lorazepam dose by 4 and initiate every 6 h oral treatments with the intravenous product or an aliquot of a crushed tablet. 4. Wean lorazepam by 10% to 20% per day. The dosage interval can also be increased gradually to every 8 h, then every 12 h, then every 24 h, and then every other day before lorazepam is discontinued.

TABLE 4 Continued

Robertson et al[149]
Summary of Conversion Of Intravenous Opioids to Enteral Methadone

1. Tobias et al[147]: Converted 2 patients on morphine (0.1–0.15 mg/kg q3h) and 1 patient on fentanyl (1–2 μg/kg every 1–2 h) to methadone at a starting dose of 0.2 mg/kg per day.
2. Robertson et al[149]: 1 μg/kg per h fentanyl = 0.4 mg/kg per day methadone.
3. Meyer and Berens[150]: 1 μg/kg per h fentanyl = 0.24 mg/kg per day methadone.
4. Wolfson Children's Hospital: 1 μg/kg per h fentanyl = 0.2–0.3 mg/kg per day methadone.

calculated methadone equivalent to achieve a successful conversion. Also, the rate of weaning should be adjusted on the basis of careful continuing clinical assessment. Eighty percent of children can be successfully weaned from methadone completely within 5 to 10 days.

4. Signs and symptoms of withdrawal from benzodiazepine therapy can be delayed. Intravenous benzodiazepines can be converted to oral lorazepam (Table 4). The required time for weaning can be expected to be proportional to the duration of intravenous benzodiazepine treatment.
5. Infants and children at risk for withdrawal are prudently observed in the hospital for signs and symptoms. Each clinical unit can choose 1 assessment tool and train staff to minimize individual variability in scoring.
6. Discharge from the hospital for infants and very young children is prudently delayed until they are free of withdrawal signs and symptoms for a period of 24 to 48 hours after complete cessation of opioids. Earlier discharge of an older child can be individualized in consideration of the child's overall clinical status, the home environment, and the availability of adequate and prompt follow-up.
7. No clinical studies to date support the premise that initiation of clonidine, chloral hydrate, or continuous intravenous low-dose naloxone[157,158] during the course of continuous opioid infusions will reduce the likelihood or severity of opioid dependency.

CLINICAL HIGHLIGHTS

1) Each nursery that cares for infants with neonatal withdrawal should develop a protocol that defines indications and procedures for screening for maternal substance abuse. In addition, each nursery should develop and adhere to a standardized plan for the evaluation and comprehensive treatment of infants at risk for or showing signs of withdrawal.
2) Screening for maternal substance abuse is best accomplished by using multiple methods, including maternal history, maternal urine testing, and testing of newborn urine and/or meconium specimens that are in compliance with local laws. The screening of biological samples is an adjunct to provide additional information helpful in the ongoing medical care of the infant. The duration of urinary excretion of most drugs is relatively short, and maternal or neonatal urinary screening only addresses drug exposure in the hours immediately before urine collection. Thus, false-negative urine results may occur in the presence of significant intrauterine drug exposure. Although newborn meconium screening also may yield false-negative results, the likelihood is lower than with urinary screening. The more recent availability of testing of umbilical cord samples may be considered a viable screening tool, because it appears to reflect in utero exposures comparable to meconium screening.
3) Drug withdrawal should be considered in the differential diagnosis for infants in whom compatible signs develop. Physicians should be aware of other potential diagnoses that need to be evaluated and, if confirmed, treated appropriately.
4) Nonpharmacologic supportive measures that include minimizing environmental stimuli, promoting adequate rest and sleep, and providing sufficient caloric intake to establish weight gain should constitute the initial approach to therapy.
5) Signs of drug withdrawal can be scored by using a published abstinence assessment tool. Infants with confirmed drug exposure who are unaffected or demonstrating minimal signs of withdrawal do not require pharmacologic therapy. Caution should be exercised before instituting pharmacologic therapy that could lengthen the duration of hospitalization and interfere with maternal-infant bonding.

Together with individualized clinical assessment, the serial and accurate use of a withdrawal assessment tool may facilitate a decision about the institution of pharmacologic therapy and thereafter can provide a quantitative measurement that can be used to adjust drug dosing.

6) The optimal threshold score for the institution of pharmacologic therapy by using any of the published abstinence assessment instruments is unknown.

7) Breastfeeding and the provision of expressed human milk should be encouraged if not contraindicated for other reasons.[111,159]

8) Pharmacologic therapy for withdrawal-associated seizures is indicated. Other causes of neonatal seizures must also be evaluated.

9) Vomiting, diarrhea, or both associated with dehydration and poor weight gain in the absence of other diagnoses are relative indications for treatment, even in the absence of high total withdrawal scores.

10) The limited available evidence from controlled trials of neonatal opioid withdrawal supports the use of oral morphine solution and methadone when pharmacologic treatment is indicated. Growing evidence suggests that oral clonidine is also effective either as a primary or adjunctive therapy, but further prospective trials are warranted. Dosing regimens are listed in Table 5. With respect to other drug treatments and clinical situations, a number of important caveats apply. Treatment with paregoric is contraindicated, because this preparation contains multiple opiates in addition to morphine, as well as other potentially harmful compounds (alcohol, anise). Morphine prescriptions should be written as milligrams of morphine per kilogram and not as milliliters of DTO per kilogram. Tincture of opium contains a 25-fold higher concentration of morphine than do available oral morphine solutions; hence, it increases the likelihood of drug error and morphine overdose. The relative efficacy and safety of buprenorphine for the treatment of NAS require additional comparative study. The optimal pharmacologic treatment of infants who are withdrawing from sedatives or hypnotics is unknown. Finally, there is also insufficient evidence to state whether an infant born to a mother with multiple drug abuse who meets criteria for pharmacologic therapy of withdrawal signs is best treated with an opioid, a barbiturate, a medication from another drug class, or a combination of drugs from different classes.

11) Physicians need to be aware that the severity of withdrawal signs, including seizures, has not been proven to be associated with differences in long-term outcome after intrauterine drug exposure. Furthermore, treatment of drug withdrawal may not alter the long-term outcome.

12) Given the natural history of withdrawal, it is reasonable for neonates with known antenatal exposure to opioids and benzodiazepines to be observed in the hospital for 4 to 7 days. After discharge, outpatient follow-up should occur early and include reinforcement of the education of the caregiver about the risk of late withdrawal signs.

13) Neonates cared for in ICUs who have developed tolerance to opioids and benzodiazepines as a result of an extended duration of treatment can be converted to an equivalent regimen of oral methadone and lorazepam. Doses may be increased as necessary to achieve patient comfort. These medications can then be reduced by 10% to 20% of the initial dose every 1 to 2 days on the basis of clinical response and serial assessments by using a standardized neonatal abstinence instrument.

14) Significant gaps in knowledge concerning the optimal treatment strategy (including the criteria for instituting pharmacologic therapy, the drug of first choice, and the strategy for weaning) of infants with neonatal withdrawal should be addressed in well-designed randomized controlled studies that are adequately powered to assess short-term outcomes and to provide for long-term follow-up.

CLINICAL REPORT

Organic Foods: Health and Environmental Advantages and Disadvantages

abstract

FREE

The US market for organic foods has grown from $3.5 billion in 1996 to $28.6 billion in 2010, according to the Organic Trade Association. Organic products are now sold in specialty stores and conventional supermarkets. Organic products contain numerous marketing claims and terms, only some of which are standardized and regulated.

In terms of health advantages, organic diets have been convincingly demonstrated to expose consumers to fewer pesticides associated with human disease. Organic farming has been demonstrated to have less environmental impact than conventional approaches. However, current evidence does not support any meaningful nutritional benefits or deficits from eating organic compared with conventionally grown foods, and there are no well-powered human studies that directly demonstrate health benefits or disease protection as a result of consuming an organic diet. Studies also have not demonstrated any detrimental or disease-promoting effects from an organic diet. Although organic foods regularly command a significant price premium, well-designed farming studies demonstrate that costs can be competitive and yields comparable to those of conventional farming techniques. Pediatricians should incorporate this evidence when discussing the health and environmental impact of organic foods and organic farming while continuing to encourage all patients and their families to attain optimal nutrition and dietary variety consistent with the US Department of Agriculture's MyPlate recommendations.

This clinical report reviews the health and environmental issues related to organic food production and consumption. It defines the term "organic," reviews organic food-labeling standards, describes organic and conventional farming practices, and explores the cost and environmental implications of organic production techniques. It examines the evidence available on nutritional quality and production contaminants in conventionally produced and organic foods. Finally, this report provides guidance for pediatricians to assist them in advising their patients regarding organic and conventionally produced food choices. *Pediatrics* 2012;130:e1406–e1415

DEFINITION AND REGULATION OF ORGANIC FOODS

Definition

Organic farming uses an approach to growing crops and raising livestock that avoids synthetic chemicals, hormones, antibiotic agents, genetic engineering, and irradiation. In the United States, the US Department of Agriculture (USDA) has implemented the National Organic Program (NOP)[1] in response to the Organic Foods Production Act of 1990.[2] The NOP set labeling standards that have been in effect since October 2002. NOP standards for organic food production include many specific requirements for both crops and livestock. To qualify as organic, crops must be produced on farms that have not used most synthetic pesticides, herbicides, and fertilizer for 3 years before harvest and have a sufficient buffer zone to decrease contamination from adjacent lands. Genetic engineering, ionizing radiation, and sewage sludge is prohibited. Soil fertility and nutrient content is managed primarily with cultivation practices, crop rotations, and cover crops supplemented with animal and crop waste fertilizers. Pests, weeds, and diseases are managed primarily by physical, mechanical, and biological controls instead of with synthetic pesticides and herbicides. Exceptions are allowed if substances are on a national approved list. Organic livestock must be reared without the routine use of antibiotic agents or growth hormones (GHs) and must be provided with access to the outdoors. If an animal is treated for disease with antibiotic agents, it cannot be sold as organic. Preventive health practices include vaccination and vitamin and mineral supplementation. The USDA certifies organic products according to these guidelines. Organic farmers must apply for certification, pass a test, and pay a fee. The NOP requires annual inspections to ensure ongoing compliance with these standards.

Labeling

Consumers are confronted with a wide range of food product marketing terms, some regulated and some not (Table 1). The labeling requirements of the NOP apply to raw, fresh products and processed products that contain organic agricultural ingredients. These labeling requirements are based on the percentage of organic ingredients in a product.[3] Products labeled "100% organic" must contain only organically produced ingredients and processing aids (excluding water and salt). Products labeled "organic" must consist of at least 95% organically processed ingredients (excluding water and salt); the remaining 5% of ingredients may be conventional or synthetic but must be on the USDA's approved list. Processed products that contain at least 70% organic ingredients can use the phrase "made with organic ingredients" and list up to 3 of the organic ingredients or food groups on the principal display panel. For example, soup made with at least 70% organic ingredients and only organic vegetables may be labeled either "soup made with organic peas, potatoes, and carrots" or "soup made with organic vegetables."

Related Terms

The NOP places no restrictions on the use of truthful labeling claims, such as "no drugs or growth hormones used," "free range," or "sustainably harvested."[3] The USDA regulates the term "free range" for poultry products; to use this term, producers must demonstrate that the poultry has been allowed "access to the outside."[4] According to Consumers Union's evaluation, this means that a poultry product comes from a bird that had at least 5 minutes of access to the outdoors each day.[4,5] No standard definition exists for all other products

TABLE 1 Commonly Used Food Product Marketing Terms

Term	Definition
100% organic	Must contain only organically produced ingredients and processing aids (excluding water and salt).
Organic	Must consist of at least 95% organically produced ingredients (excluding water and salt). Any remaining product ingredients must consist of nonagricultural substances approved on the National List.
Made with organic ingredients	Must contain at least 70% organic ingredients.
Natural	A product containing no artificial ingredient or added color and that is only minimally processed (a process that does not fundamentally alter the raw product). The label must explain the use of the term.
Free range	Producers must demonstrate to the USDA that the poultry has been allowed access to the outside.
No hormones (pork or poultry)	Hormones are not allowed in raising hogs or poultry. Therefore, the claim "no hormones added" cannot be used on the labels of pork or poultry unless it is followed by a statement that says "Federal regulations prohibit the use of hormones."
No hormones (beef)	The term "no hormones administered" may be approved for use on the label of beef products if sufficient documentation is provided to the USDA by the producer showing no hormones have been used in raising the animals.
No antibiotics (red meat and poultry)	The terms "no antibiotics added" may be used on labels for meat or poultry products if sufficient documentation is provided by the producer to the USDA demonstrating that the animals were raised without antibiotics.
Certified	"Certified" implies that the USDA's Food Safety and Inspection Service and the Agriculture Marketing Service have officially evaluated a meat product.
Chemical free	This term is not allowed to be used on a label.

There are no restrictions on use of other truthful labeling claims, such as "no drugs or growth hormones used," or "sustainably harvested."

carrying the "free range" label, such as beef, pork, or eggs; the use of the term, however, is allowed.

The term "natural" or "all natural" is defined by the USDA for meat and poultry and means that the products contain no artificial flavoring, color ingredients, chemical preservatives, or artificial or synthetic ingredients and are "minimally processed." Minimally processed means that the raw product was not fundamentally altered. Additional USDA definitions of other labeling terms can be found in publicly available USDA fact sheets.[4]

The term "raw" milk refers to unpasteurized milk. All milk certified as organic by the USDA is pasteurized. Raw milk can contain harmful bacteria, such as *Salmonella* species, *Escherichia coli* O157:H7, *Listeria* species, *Campylobacter* species, and *Brucella* species, and has been repeatedly associated with outbreaks of disease caused by these pathogens. The American Academy of Pediatrics, US Food and Drug Administration, and Centers for Disease Control and Prevention advise consumers not to consume raw milk.[6–8]

SCOPE OF CONSUMER USE, PRICES, AND TRENDS IN ORGANIC FOOD

In 2008, more than two-thirds of US consumers bought some organic products, and more than one-quarter bought organic at least weekly. The amount of US acreage dedicated to organic crops has doubled since 1997.[9] Consumers choose organic food in the belief that organic foods are more nutritious, have fewer additives and contaminants, and are grown more sustainably.[10] Some studies[11,12] suggest that families with children and adolescents or younger consumers in general are more likely to buy organic fruits and vegetables than are other consumers.[13] The factor most consistently associated with the increased propensity to purchase organic food is the level of consumer education.[14–21] Organic products, however, cost up to 40% more.

NUTRITIONAL QUALITY OF ORGANIC VERSUS CONVENTIONAL FOOD

Produce

Consumers believe that organic produce is more nutritious than conventionally grown produce, but the research to support that belief is not definitive. Many studies have demonstrated no important differences in carbohydrate or vitamin and mineral content.[22] Some studies have found lower nitrate content in organic foods versus conventionally grown foods, which is potentially desirable because of the association of nitrates with increased risk of gastrointestinal cancer and, in infants, methemoglobinemia. Higher vitamin C concentrations were found in organic leafy vegetables, such as spinach, lettuce, and chard versus the same conventionally produced vegetables in 21 of 36 (58%) studies.[22] Other studies have found higher total phenols in organic produce versus conventionally grown produce and have postulated health benefits from antioxidant effects.[23]

Several attempts have been made to review the relevant literature and draw conclusions on organic versus conventional foods, but the results are conflicting.[24–28] A large systematic review published in 2009 found that fewer than 20% of 292 articles with potentially relevant titles met criteria for quality, leaving only 55 studies to assess. The authors highlighted the fact that the nutrient content of produce is affected by numerous factors, including the geographic location of the farm, local soil characteristics, climactic conditions that can vary by season, maturity at time of harvest, and storage and time to testing after harvest. Because of the large number of nutrients reported in various articles, the authors grouped the nutrients into large categories. They found no significant differences in most nutrients, with the exception of higher nitrogen content in conventional produce and higher titratable acidity and phosphorus in organic produce.[29] Better-quality research that accounts for the many confounding variables is needed to elucidate potential differences in nutrients and the clinical importance of nutrients that may be different. At this time, however, there does not appear to be convincing evidence of a substantial difference in nutritional quality of organic versus conventional produce.

Milk

The composition of dairy products, including milk, is affected by many factors, including differences caused by genetic variability and cattle breed; thus, the results of studies assessing milk composition must be interpreted with caution. In general, milk has the same protein, vitamin, trace mineral content, and lipids from both organically and conventionally reared cows. Fat-soluble antioxidants and vitamins present in milk come primarily from the natural components of the diet or from the synthetic compounds used to supplement the feed ingested by lactating cows.[30]

One recent study examined antibiotic and microorganism content, hormone concentrations, and nutritional values of milk in 334 samples from 48 states labeled as organic, not treated with bovine GH (referred to as "GH-free"), or conventional. This study found that milk labeled "conventional" had lower bacterial counts than milk that was organic or GH-free, although this was not clinically significant. Estradiol and progesterone concentrations were lower in conventional milk than in organic milk, but GH-free milk had progesterone concentrations similar to conventional

milk and estradiol concentrations similar to organic milk. Macronutrient composition was similar, although organic milk had 0.1% more protein than the other 2 milk types.[31]

Several studies have demonstrated that organic milk has higher concentrations of antioxidants and polyunsaturated fatty acids. However, it is important to recognize that the composition of milk is strongly related to what the cows eat. This differs by time of year (outdoors in the summer, indoor forage in the winter) and whether the farms are high or low input. High-input farms supplement the diets of cattle with proprietary minerals and vitamins. Low-input farms use methods similar to those used in organic farming but do not follow all the restrictions prescribed by organic farming standards; they use mineral fertilizers but at lower levels than used by conventional high-input systems. One study comparing milk from all 3 production systems found milk from both the low-input organic and low-input nonorganic systems generally had significantly higher concentrations of nutritionally desirable unsaturated fatty acids (conjugated linoleic acid and omega-3 fatty acids) and fat-soluble antioxidants compared with milk from the high-input systems; milk derived from cows in both organic certified and nonorganic low-input systems was significantly higher in conjugated linoleic acid content than was milk from conventional high-input systems.[32]

HORMONES

GH

Hormone supplementation of farm animals, especially with GH, is one of the major reasons consumers state they prefer to buy organic foods. Bovine GH (ie, recombinant bovine somatotropin) increases milk yield by 10% to 15% and is lipotropic in cows. Because GH is degraded in the acidic stomach environment, it must be given by injection. GH is species-specific, and bovine GH is biologically inactive in humans. Because of this, any bovine GH in food products has no physiologic effect on humans, even if it were absorbed intact from the gastrointestinal tract. In addition, 90% of bovine GH in milk is destroyed during the pasteurization process. There is no evidence that the gross composition of milk (fat, protein, and lactose) is altered by treatment with bovine GH, nor is there any evidence that the vitamin and mineral contents of milk are changed by GH treatment.[31]

GH treatment of cows may actually have environmental benefits. GH increases milk production per cow, which could theoretically decrease the number of cows needed to produce a given amount of milk, with resultant need for fewer cows and, thus, less cultivated land needed to feed the cows. In addition, fewer cows would result in the production of less manure with resultant reduced methane production and less carbon dioxide production, with a resultant salutary effect on global warming.[33]

Sex Steroids

Treatment of cattle with sex steroids increases lean muscle mass, accelerates the rate of growth, and is an efficient way to increase meat yield. Estrogens are usually given by implantation of estrogen pellets into the skin on the underside of the ear, and the ear is discarded during slaughter. Unlike GH, sex steroids are not species-specific and may be given orally without degradation in the stomach. In 1998, the Food and Agriculture Organization of the United Nations and World Health Organization jointly concluded that meat from estradiol-treated animals was safe on the basis of data obtained from residue levels in meat from studies performed in the 1970s and 1980s using radioimmunoassay methods. One study demonstrated concentrations of estrogens found in meat residues were low and overlapped with concentrations found in untreated cows.[34] Gas chromatography measurements of sex steroids progesterone, testosterone, 17β estradiol, and estrone and their metabolites in meat products, fish, poultry, milk, and eggs revealed insignificant amounts compared with daily production of these steroids in adults and children.[35] Furthermore, 98% to 99% of endogenous sex steroids are bound by sex-hormone-binding globulin, rendering them metabolically inactive as only the unbound (free) forms of sex steroids are metabolically active. Synthetic sex steroids (zeranol, melengestrol, and trenbolone) commonly used in animals have lower affinities to sex-hormone-binding globulin and, therefore, are potentially more metabolically active unbound sex steroids. These hormones do not occur naturally in humans, and although the concentrations of these hormones are low in cattle, the biological effects in humans, if any, are unknown.

Ingestion of milk from estrogen-treated cows appears to be safe for children. Estradiol and estrone concentrations in organic and conventional 1%, 2%, and whole milk were the same, although the concentrations of sex steroids were higher as the fat content of the milk increased and were lower than endogenous production rates in humans. Estradiol concentrations in milk ranged from 0.4 to 1.1 pg/mL, and estrone concentrations ranged from 2.9 to 7.9 pg/mL, with the lowest concentrations in skim milk and the highest in whole milk.[36]

Endogenous estradiol concentrations are as high as 80 pg/mL in 2- to 4-month-old female infants and 40 pg/mL in 2- to 4-month-old male infants. Human milk has estradiol concentrations

as high as 39 pg/mL and estrone (which has approximately half the potency of estradiol) concentrations as high as 1177 pg/mL. Human colostrum has even higher estrogen concentrations of 500 pg/mL and 4000 to 5000 pg/mL for estradiol and estrone, respectively. Cow milk, by comparison, has estradiol concentrations of 4 to 14 pg/mL and estrone concentrations of 34 to 55 pg/mL.[37,38]

It has been postulated that ingested estrogen in food derived from sex-hormone-treated animals may play a role in earlier development of puberty and increasing risk of breast cancer. However, no studies have supported this hypothesis in humans. Studies in animals demonstrating carcinogenic and teratogenic effects of estrogens used high doses of estradiol and cannot be extrapolated to the low doses of sex steroids found in the food supply. Estrogen concentrations in the myometrium, breast, and vagina of postmenopausal women, although still low, are higher than those found in serum, and additional studies are needed to determine the significance of these low concentrations of sex steroids in estrogen-sensitive tissues.[39]

An association has been found between red meat consumption in high school girls and the development of breast cancer later in life. A 7-year prospective longitudinal study of 39 268 premenopausal women 33 to 53 years of age who filled out a comprehensive diet history of foods eaten while in high school in the 1960s and 1970s revealed a linear association between each additional 100 g of red meat consumed in high school per day with the risk of developing hormone-receptor-positive premenopausal tumors (relative risk, 1.36; 95% confidence interval, 1.08–1.70; $P = .008$). Red meat ingestion did not increase the risk of hormone-receptor-negative tumors. Although this intriguing study, which suggested that higher red meat consumption in adolescence may increase breast cancer risk, tracked cases of cancer prospectively after the dietary history was obtained, it was limited by a number of factors, including the dependence on subjects' long-term memory of amount of food eaten decades previously, the likelihood that hormone concentrations in meat were higher in that period, and the lack of direct measurement of hormonal exposure.[40] Longitudinal prospective studies are needed to compare the risk of breast cancer in women who eat meat from hormone-treated animals with the risk in women who eat meat from untreated animals.

Endocrine disrupters, chemicals that interfere with hormone signaling systems, are pervasive in our environment. Among the most commonly found endocrine disrupters are bisphenol A, found in industrial chemicals and plastics; phthalates, found in personal care items such as cosmetics; and lavender and tea tree oil, found in many hair products, soaps, and lotions; all have estrogenic properties. Endocrine disrupters are postulated to be involved in the increased occurrence of genital abnormalities among newborn boys and precocious puberty in girls. Recent literature on sex steroid concentrations and their physiologic roles during childhood indicate that concentrations of estradiol in prepubertal children are lower than originally thought and that children are extremely sensitive to estradiol and may respond with increased growth and/or breast development even at serum concentrations below the current detection limits.[41] No threshold has been established below which there are no hormonal effects on exposed children. Furthermore, the daily endogenous production rates of sex steroids in children estimated by the Food and Drug Administration in 1999 and still used in risk assessments are highly overestimated and should be reevaluated by using current assays.[41] It is therefore important to determine the relative importance of hormone treatment of animals in the context of other environmental endocrine disrupters through long-term longitudinal studies in children.

NONTHERAPEUTIC USE OF ANTIBIOTIC AGENTS

Conventional animal husbandry frequently includes the administration of antibiotic agents in nontherapeutic doses to livestock to promote growth and increase yields. Between 40% and 80% of the antimicrobial agents used in the United States each year are used in food animals, three-quarters of which is nontherapeutic. Many of these agents are identical or similar to drugs used in humans.[42] Evidence is clear that such nontherapeutic use promotes the development of drug-resistant organisms in the animals and that these organisms then colonize the intestines of people living on farms where this practice occurs.[43] Evidence is also ample that human disease caused by antibiotic-resistant organisms spread through the food chain.[44] Because organic farming prohibits the nontherapeutic use of antibiotic agents, it could contribute to a reduction in the threat of human disease caused by drug-resistant organisms.

SYNTHETIC CHEMICAL EXPOSURE

Pesticides

Pesticides have a host of toxic effects that range from acute poisonings to subtle subclinical effects from long-term, low-dose exposure.[45] Organophosphate pesticides are commonly used in agriculture, and poisoning is a persistent problem in the agricultural setting. From 1998 to 2005, 3271 cases of agricultural occupational acute pesticide poisoning were

reported to the California Department of Pesticide Regulation and the National Institute of Occupational Health's SENSOR-Pesticides program. This constitutes a rate of 56 cases per 100 000 full-time equivalents, 38 times the rate observed in nonagricultural occupations.[46] Chronic exposure among farm workers has been associated with numerous adult health problems, including respiratory problems, memory disorders, dermatologic conditions, depression, neurologic deficits including Parkinson disease, miscarriages, birth defects, and cancer.[47–50] Prenatal organophosphate pesticide exposure has been associated with adverse birth outcomes, such as decreased birth weight and length[51] and smaller head circumference.[52] A large prospective birth cohort study that measured pesticide exposure in pregnant farm workers in California and followed their offspring found lower mental development index scores at 24 months of age[53] and attentional problems at 3.5 and 5 years of age.[54] An analysis of cross-sectional data from the NHANES has demonstrated that within the range of exposure in the general US population, the odds of attention-deficit/hyperactivity disorder for 8- to 15-year-old children were increased 55% with a 10-fold increase in urinary concentrations of the organophosphate metabolite dimethyl alkylphosphate.[55]

The National Research Council reported in 1993 that the primary form of exposure to pesticides in children is through dietary intake.[56] Organic produce consistently has lower levels of pesticide residues than does conventionally grown produce,[57] and a diet of organic produce reduces human exposure. Several studies have clearly demonstrated that an organic diet reduces children's exposure to pesticides commonly used in conventional agricultural production. A small longitudinal cohort of children who regularly consumed conventional produce demonstrated that urinary pesticide residues were reduced to almost nondetectable levels (below 0.3 μg/L for malathion dicarboxylic acid, for example) when they were changed to an organic produce diet for 5 days.[58] In addition, residues varied with seasonal intake of produce, suggesting that dietary intake of organophosphate pesticides represented the major source of exposure in these young children.[59]

Although a common practice, rinsing conventionally farmed produce reduces some but not all pesticide residues on produce to varying degrees but has not been proven to decrease human exposure.[60]

Pesticide metabolite concentrations observed in studies that examined exposure in farming communities as well as in residential settings were in the same range as those observed in subjects consuming conventional produce in studies of biological exposure measures for organic versus conventional produce diets. For instance, the median concentration observed for malathion urinary metabolites in female farm workers whose offspring had significantly lower mental development index scores at 24 months of age was 0.82 μg/L,[53] which is close to the median concentration found in children in the initial conventional diet phase of the organic diet study of 1.5 μg/L, discussed previously.[58] Ranges for other pesticide metabolites were similar.

Although chronic pesticide exposure and measurable pesticide metabolite concentrations seem undesirable and potentially unhealthy, no studies to date have experimentally examined the causal relationship between exposure to pesticides directly from conventionally grown foods and adverse neurodevelopmental health outcomes. Most of the research implicating pesticides in these adverse health outcomes is from case-control or cross-sectional studies. These studies are limited by a number of factors, including difficulties measuring past exposures and the lack of a positive temporal relationship between exposure and outcome. It is difficult to directly extrapolate from these studies and draw conclusions about potential toxicity at the levels of pesticide exposure documented from dietary intake of conventional produce. Data derived from large prospective cohort studies may address some of these shortcomings.

ENVIRONMENTAL IMPACT AND PRODUCTION EFFICIENCY OF ORGANIC VERSUS CONVENTIONAL FARMING METHODS

Environmental Impact

A major subject in the organic debate is whether organic farming methods have less impact on the environment, can be equally as productive, and can be no more expensive than conventional approaches. A variety of surveys and studies have attempted to compare these issues for organic and conventional farming methods. Many believe that organic farming is less damaging to the environment because organic farms do not use or release synthetic pesticides into the environment, some of which have the potential to harm soil, water, and local terrestrial and aquatic wildlife.[61] In addition, it is thought that organic farms are better than conventional farms at sustaining diverse ecosystems, including populations of plants, insects, and animals, because of practices such as crop rotation. When calculated either per unit area or per unit of yield, organic farms use less energy and produce less waste.[62,63] Organically managed soil has been demonstrated to be of higher quality and have higher water retention, which may increase yields for organic farms in drought years.[64]

Production Efficiency

Critics of organic farming methods believe that organic farms require more land to produce the same amount of food as conventional farms. One study found a 20% smaller yield from organic farms.[65] Another study from the Danish Environmental Protection Agency found that, area for area, organic farms of potatoes, sugar beets, and seed grass produce as little as half the output as their conventional farm counterparts.[66]

It remains controversial whether organic farming is able to provide adequate food supply to sustain the world population. Norman Borlaug, considered to be the father of the "green revolution" and winner of the Nobel Peace Prize, believes that organic farming alone is incapable of feeding the world population and needs to be used in conjunction with genetically modified food.[67] On the other hand, a meta-analysis of 292 studies designed to assess the efficiency of both organic and conventional farming concluded that organic methods could produce enough food on a global per-capita basis to sustain the current human population and potentially an even larger population without increasing the agricultural land base.[68]

The largest prospective farming study to date is a comparative trial of more than 20 years' duration conducted by researchers from Cornell University. This study, conducted in Pennsylvania, compared various conventional and organic farming approaches in a controlled prospective design in which confounding influences such as weather and moisture were similar in the different systems. Over 20 years of observation, the organic fields had productivity that was generally comparable to the conventional fields, while avoiding environmental pollution with herbicides and pesticides and reducing fossil fuel consumption by 30%. Although costs were higher primarily because of increased labor costs (15%), the return for the organic plots was higher because of the higher prices commanded at the marketplace.[64]

THE DIFFERENCE IN PRICE OF ORGANIC VERSUS CONVENTIONAL FOODS

One major concern with organic food is its higher price to consumers. Organic products typically cost 10% to 40% more than similar conventionally produced products.[69] A number of factors contribute to these higher costs, including higher-priced organic animal feed, lower productivity, and higher labor costs because of the increased reliance on hand weeding. Of potential concern is that the higher price of organically produced fruits and vegetables might lead consumers to eat less of these foods, despite the well-established literature documenting the health benefits of eating fruits and vegetables, including lower rates of obesity, cardiovascular disease, and certain types of cancer. Fifty-five percent of children born in the United States are eligible for food packages under the Special Supplemental Nutrition Program for Women, Infants, and Children, and these food packages are currently giving families approximately $10 a month to spend on fruits and vegetables, so the money must be used wisely to maximize spending capacity for healthy foods.

SUMMARY

To demonstrate superiority of 1 food production method over another, it is important to show an advantage in terms of improved individual health or an important societal advantage. Organic diets have been convincingly demonstrated to expose consumers to fewer pesticides associated with human disease. Nontherapeutic use of antibiotic agents in livestock contributes to the emergence of resistant bacteria; thus, organic animal husbandry may reduce the risk of human disease attributable to resistant organisms. There is sound evidence that organic foods contain more vitamin C (ascorbic acid) and phosphorus than do conventional foods, but there is no direct evidence that this provides meaningful nutritional benefits to children eating organic foods compared with those who eat conventionally grown food products. Well-designed farming studies demonstrate that comparable yields can be achieved with organic farming techniques and that organic farming has a lower environmental impact than do conventional approaches. However, no well-powered human studies have directly demonstrated health benefits or disease protection as a result of consuming an organic diet. Such studies would be difficult to perform and require large prospective cohort populations or, better, randomly assigning subjects to interventions that increase organic versus conventional food intakes. Additional data are needed to identify relationships between diet and pesticide exposure and individual health outcomes. Pediatricians should incorporate this evidence when discussing the health and environmental impact of organic foods and organic farming while continuing to encourage all patients and their families to attain optimal nutrition and dietary variety by choosing a diet high in fresh fruits and vegetables, consistent with the USDA's MyPlate recommendations.

Key Points

1. Nutritional differences between organic and conventional produce appear minimal, but studies examining this have been limited by inadequate controls for the many subtle potential confounders, such as moisture, maturity of the produce, and measurement techniques.

No direct evidence of a clinically relevant nutritional difference between organic and conventional produce exists.

2. Organic produce contains fewer pesticide residues than does conventional produce, and consuming a diet of organic produce reduces human exposure to pesticides. It remains unclear whether such a reduction in exposure is clinically relevant.
3. Organic animal husbandry that prohibits the nontherapeutic use of antibiotic agents has the potential to reduce human disease caused by drug-resistant organisms.
4. There is no evidence of clinically relevant differences in organic and conventional milk.
   a. There are few, if any, nutritional differences between organic and conventional milk. There is no evidence that any differences that may exist are clinically relevant.
   b. There is no evidence that organic milk has clinically significant higher bacterial contamination levels than does conventional milk.
   c. There is no evidence that conventional milk contains significantly increased amounts of bovine GH. Any bovine GH that might remain in conventional milk is not biologically active in humans because of structural differences and susceptibility to digestion in the stomach.
5. Organic farming approaches in practice are usually more expensive than conventional approaches, but in carefully designed experimental farms, the cost difference can be mitigated.
6. The price differential between organic and conventional food might be reduced or eliminated as organic farming techniques advance and as the prices of petroleum products, such as pesticides and herbicides, as well as the price of energy, increase.
7. Organic farming reduces fossil fuel consumption and reduces environmental contamination with pesticides and herbicides.
8. Large prospective cohort studies that record dietary intake accurately and measure environmental exposures directly will likely greatly enhance understanding of the relationship between pesticide exposure from conventional foods and human disease and between consumption of meat from hormone-treated animals and the risk of breast cancer in women.

Advice for Pediatricians

1. Encourage patients and their families to eat an optimally health-promoting diet rich in fruits, vegetables, whole grains, and low-fat or fat-free milk and dairy products.
2. When approached by families interested in consuming organic foods, review key facts presented in this report to address the full range of relevant nutrition, human health, environmental, and cost issues. Be explicit about areas in which scientific evidence is strong as well as those in which it is uncertain.
3. When advice is sought by families concerned with the potential health impact of pesticide residues in food, direct them toward reliable resources that provide information on the relative pesticide content of various fruits and vegetables. Two such examples include:
   a. *Consumer Reports* article (September 2008) "Fruits and Vegetables, When to Buy Organic" (http://www.consumerreports.org/health/healthy-living/diet-nutrition/healthy-foods/organic-foods/overview/when-to-buy-organic.htm) and
   b. Environmental Working Group's "Shopper's Guide to Pesticides" (http://www.foodnews.org).

POLICY STATEMENT

Patient- and Family-Centered Care and the Pediatrician's Role

abstract

Drawing on several decades of work with families, pediatricians, other health care professionals, and policy makers, the American Academy of Pediatrics provides a definition of patient- and family-centered care. In pediatrics, patient- and family-centered care is based on the understanding that the family is the child's primary source of strength and support. Further, this approach to care recognizes that the perspectives and information provided by families, children, and young adults are essential components of high-quality clinical decision-making, and that patients and family are integral partners with the health care team. This policy statement outlines the core principles of patient- and family-centered care, summarizes some of the recent literature linking patient- and family-centered care to improved health outcomes, and lists various other benefits to be expected when engaging in patient- and family-centered pediatric practice. The statement concludes with specific recommendations for how pediatricians can integrate patient- and family-centered care in hospitals, clinics, and community settings, and in broader systems of care, as well. *Pediatrics* 2012;129:394–404

INTRODUCTION

Patient- and family-centered care is an innovative approach to the planning, delivery, and evaluation of health care that is grounded in a mutually beneficial partnership among patients, families, and providers that recognizes the importance of the family* in the patient's life. When patient- and family-centered care is practiced it shapes health care policies, programs, facility design, evaluation of health care, and day-to-day interactions among patients, families, physicians, and other health care professionals. Health care professionals who practice patient- and family-centered care recognize the vital role that

*Family is broadly defined. The following serves as an example of such a definition: "We all come from families. Families are big, small, extended, nuclear, multigenerational, with one parent, two parents and grandparents. We live under one roof or many. A family can be as temporary as a few weeks, as permanent as forever. We become part of a family by birth, adoption, marriage, or from a desire for mutual support. As family members, we nurture, protect, and influence one another. Families are dynamic and are cultures unto themselves, with different values and unique ways of realizing dreams. Together, our families become the source of our rich cultural heritage and spiritual diversity. Each family has strengths and qualities that flow from individual members and from the family as a unit. Our families create neighborhoods, communities, states, and nations." (New Mexico's Memorial Task Force on Children and Families and the Coalition for Children, 1990)

families play in ensuring the health and well-being of children† and family members of all ages. These practitioners acknowledge that emotional, social, and developmental support are integral components of health care. They respect each child and family's innate strengths and cultural values and view the health care experience as an opportunity to build on these strengths and support families in their caregiving and decision-making roles. Patient- and family-centered approaches lead to better health outcomes and wiser allocation of resources as well as to greater patient and family satisfaction. It should be noted that the term "family-centered care," is replaced with the term "patient- and family-centered care," to more explicitly capture the importance of engaging the family and the patient in a developmentally supportive manner as essential members of the health care team. Patient- and family-centered care in pediatrics is based on the understanding that the family is the child's primary source of strength and support and that the child's and family's perspectives and information are important in clinical decision-making. Practitioners of patient- and family-centered care are keenly aware that positive health care experiences in provider/family partnerships can enhance parents' confidence in their roles and, over time, increase the competence of children and young adults to take responsibility for their own health care, particularly in anticipation of the transition to adult service systems.

"During the past decade, family advocates have promoted family-centered care, 'the philosophies, principles and practices that put the family at the heart or center of services; the family is the driving force.'"[1] This is in harmony with, but different from, "…family pediatrics [family-oriented care]" as outlined in the American Academy of Pediatrics (AAP) Task Force on Family, which "…extends the responsibilities of the pediatrician to include screening, assessment, and referral of parents for physical, emotional, or social problems or health risk behaviors that can adversely affect the health and emotional or social well-being of their child."[1] This policy statement specifically defines the expectations of patient- and family-centered care.

CORE PRINCIPLES OF PATIENT- AND FAMILY-CENTERED CARE

Patient- and family-centered care is grounded in collaboration among patients, families, physicians, nurses, and other professionals in clinical care as well as for the planning, delivery, and evaluation of health care, and in the education of health care professionals and in research, as well. These collaborative relationships are guided by the following principles:

1. Listening to and respecting each child and his or her family. Honoring racial, ethnic, cultural, and socioeconomic background and patient and family experiences and incorporating them in accordance with patient and family preference into the planning and delivery of health care.
2. Ensuring flexibility in organizational policies, procedures, and provider practices so services can be tailored to the needs, beliefs, and cultural values of each child and family and facilitating choice for the child and family about approaches to care.[2]
3. Sharing complete, honest, and unbiased information with patients and their families on an ongoing basis and in ways they find useful and affirming, so that they may effectively participate in care and decision-making to the level they choose. Health information for children and families should be available in the range of cultural and linguistic diversity in the community and take into account health literacy. In hospitals, conducting physician rounds in the patients' rooms with nursing staff and family present can enhance the exchange of information and encourage the involvement of the family in decision-making.[3–6]
4. Providing and/or ensuring formal and informal support (eg, peer-to-peer support) for the child and family during each phase of the child's life. Such support is provided so that Health Insurance Portability and Accountability Act and other relevant ethical and legal guidelines are followed.
5. Collaborating with patients and families at all levels of health care: in the delivery of care to the individual child; in professional education, policy making, program development, implementation, and evaluation; and in health care facility design. As part of this collaboration, patients and families can serve as members of child or family advisory councils, committees, and task forces dealing, for example, with operational issues in health care facilities; as collaborators in improving patient safety; as participants in quality-improvement initiatives; and as leaders or coleaders of peer-support programs.[7,8] In the area of medical research, patients and families should have voices at all levels in shaping the research agenda, in determining how children and families participate in research, and in deciding how research findings will be shared with children and families.[9]
6. Recognizing and building on the strengths of individual children and families and empowering them to discover their own strengths, build confidence, and participate in making

†In accordance with the policies of the AAP, references to "child" and "children" in this document includes infants, children, adolescents, and young adults up to age 21.

choices and decisions about their health care.[7,10–12]

A self-assessment tool is available for families to evaluate whether the care they are receiving fits into the realm of family-centered care and also can be used by pediatricians to evaluate the care they deliver.[13]

HISTORY OF PATIENT- AND FAMILY-CENTERED CARE

Patient- and family-centered care emerged as an important concept in health care during the second half of the 20th century, at a time of increasing awareness of the importance of meeting the psychosocial and developmental needs of children and of the role of families in promoting the health and well-being of their children.[14–24] Much of the early work focused on hospitals; for example, as research emerged about the effects of separating hospitalized children from their families, many institutions adopted policies that welcomed family members to be with their child around the clock and also encouraged their presence during medical procedures. The Maternal and Child Health Bureau of the Health Resources and Service Administration played an active role in furthering the involvement of families and the support of family issues and service needs. Federal legislation of the late 1980s and 1990s,‡ much of it targeted at children with special needs, provided additional validation of the importance of family-centered principles.[7,10] Family-centered care has long been a characteristic of an effective medical home.[25] Family Voices, founded in 1992, advocates for family-centered, community-based services for children with special health care needs.[26] Building on the work begun in the previous decade, the Institute for Family-Centered Care (now the Institute for Patient- and Family-Centered Care) was also founded in 1992 to foster the development of partnerships among patients, families, and health care professionals and to provide leadership for advancing the practice of family-centered care in all settings.[7,10]

Patient- and family-centered care is supported by a growing body of research and by prestigious organizations, such as the Institute of Medicine (IOM), which in its 2001 report "Crossing the Quality Chasm: A New Health System for the 21st Century," emphasized the need to ensure the involvement of patients in their own health care decisions, to better inform patients of treatment options, and to improve patients' and families' access to information.[27] It specifies 6 domains for improving patient safety, one of which is patient centeredness. The IOM's recommendations are intrinsic to patient- and family-centered practice. In 2006, the Institute for Family-Centered Care and the Institute for Healthcare Improvement (IHI) brought together leadership organizations and patient and family advisors to advance the practice of patient- and family-centered care and ensure that there are sustained, effective partnerships with patients and families in all aspects of the health care system.[7,8]

The AAP has incorporated many of the principles of patient- and family-centered care into several policy statements and manuals.[25,28–37] In 2006, the AAP Board of Directors approved a Parent Advisory Group pilot program under the Section on Home Care.[38] Members of the Parent Advisory Group all share a special interest in patient- and family-centered care, have personal experience with children with special health care needs, and serve as advisors and leaders for patient- and family-centered pediatric care within their own communities and at the national level.

The IHI, founded in 1991, is an independent organization founded to improve health care throughout the world. Among its core values is patient and family centeredness.[39] The National Institute for Children's Healthcare Quality (NICHQ) was launched as an IHI program in 1999. The NICHQ is dedicated to improving the quality of health care provided to children. One component of its 4-part improvement agenda is promoting evidence-based patient- and family-centered care for children with chronic conditions. A strong focus of the NICHQ is the participation of family advisors.[40]

The value of patient- and family-centered care in health care quality is recognized by the American Hospital Association–McKesson Quest for Quality Prize, which raises awareness of patient- and family-centered care and rewards successful efforts to develop and promote improvements in the safety and quality of care.[41] As a result of improved outcomes when patient- and family-centered care is delivered in hospitals, the American Hospital Association partnered with the Institute for Patient- and Family-Centered Care to produce and distribute a toolkit, Strategies for Leadership: Patient- and Family-Centered Care, to the chief executive officer of every hospital in the United States to assist administration and medical leadership in advancing patient- and family-centered practice and to complement other

‡Among the legislation advancing the practice of family-centered care are such statutes as: the Education of the Handicapped Act Amendments of 1986 (Public Law 99-457), Part H—Early Intervention Programs for Handicapped Infants and Toddlers; Maternal and Child Health block grant amendments contained in the Omnibus Budget Reconciliation Act of 1989 (Public Law 101-239); Individuals With Disabilities Education Act of 1990 (Public Law 101-476); the Developmental Disabilities Assistance and Bill of Rights Act of 1990 (Public Law 101-496); Mental Health Amendments of 1990 (Public Law 101-639); and Families of Children With Disabilities Support Act of 1994 (Public Law 103-382).

efforts to improve patient safety and the quality of patient care.[8,42–44]

The National Patient Safety Foundation, with patients and families serving on its Board of Directors and on a Patient and Family Committee of the Board, is working to ensure that all health care organizations meaningfully involve patients and families in enhancing patient safety and redesigning health care systems and processes.[45] The Joint Commission, likewise, promotes patient- and family-centered care in their efforts to improve patient safety practices.[46]

The National Survey of Children with Special Health Care Needs in 2005 to 2006 demonstrated that, although most families of children with special health care needs feel they are partners in the care of their child, approximately one-third do not, particularly families with incomes below the poverty level, families without health care insurance, and Hispanic or black families.[47]

OUTCOMES OF PATIENT- AND FAMILY-CENTERED CARE: BRIEF SUMMARY OF RECENT LITERATURE

Patient- and family-centered care can improve patient and family outcomes, improve the patient's and family's experience, increase patient and family satisfaction, build on child and family strengths, increase professional satisfaction, decrease health care costs, and lead to more effective use of health care resources, as shown in the following examples from the literature.

Patient and Family Outcomes

High-quality, patient- and family-centered primary care is associated with a significant reduction in nonurgent emergency department visits in children.[48] Family presence during health care procedures decreases anxiety for the child and the parents. Research indicates that when parents are prepared, they do not prolong the procedure or make the provider more anxious.[49–53] Children whose mothers were involved in their posttonsillectomy care recovered faster and were discharged earlier than were children whose mothers did not participate in their care.[12]

A series of quality-improvement studies found that children who had undergone surgery cried less, were less restless, and required less medication when their parents were present and assisted in pain assessment and management.[54] Children and parents who received care from child life specialists[29] did significantly better than did control children and parents on measures of emotional distress, coping during procedures, and adjustment during hospitalization, posthospital adjustment, and recovery, including recovery from surgery.[55]

A multisite evaluation of the efficacy of parent-to-parent support found that 1-to-1 support increased parents' confidence and problem-solving capacity. Interviewees noted that this type of support could not be provided through any other means.[56,57] Family-to-family support can have beneficial effects on the mental health status of mothers of children with chronic illness.[58]

Since 1993, patient- and family-centered care has been a strategic priority at 1 children's hospital. Families participated in design planning for the new hospital, and they have been involved in program planning, staff education, and other key hospital committees and task forces. In recent years, this children's hospital has consistently received among the highest patient and family satisfaction scores in a nationwide survey of comparable pediatric facilities.[59] And more recently, it has demonstrated decreased length of stay, reduced medical errors, and improved staff satisfaction.[60,61] This children's hospital is part of a larger academic medical center and health system, recognized nationally for its commitment to patient- and family-centered practice. This health system is among the most cost-efficient organizations in the University Health System Consortium database and, for the past 5 years, has reported a decrease in malpractice claims and litigation, whereas many other academic medical centers, as measured by the University Health System Consortium, have reported annual increases in these expenditures.[8,62]

A different children's hospital has also been integrating patient- and family-centered care throughout its hospital and outpatient facilities since the late 1990s. In 2001, in response to the IOM report, "To Err is Human,"[63] and its outcome data, this hospital implemented an ambitious plan to improve safety and quality. Critical to its efforts and its subsequent success in improving safety and quality, improvement teams have consistently involved families as active members.[64] Because of the hospital's excellence in quality, safety, and patient experience, it has been the recipient of many honors, including the Leapfrog Group Top Hospital Award, the American Hospital Association's McKesson Quest for Quality Prize, and the Picker Award for Excellence in the Advancement of Patient-Centered Care.

In a federally funded medical home project using a quality-improvement model, families served by 13 community-based pediatric practices are collaborating with pediatricians and office staff to enhance the practices' capacity to provide care to children with special health care needs and to be more responsive to the priorities and needs of these children and their families. These practices have permanently integrated family input into decisions about their processes of care and have demonstrated a 34% improvement on a standardized measure of medical

home implementation.[65] A review of the emerging literature on medical homes reported that there are favorable outcomes associated with medical home including better health status, timeliness of care, family perception of family centeredness, and family functioning.[66] Clear communication between physicians, patients, and parents leads to improved satisfaction with acute inpatient pediatric and NICU care.[67] Patient and family satisfaction are linked to hospital safety and communication.[68]

Parents of infants who received more patient- and family-centered care while in the NICU and in discharge planning were more satisfied with the care they received, demonstrated increased competence and confidence in infant caregiving, and were more willing to seek help from health care providers.[69–72]

Use of a patient- and family-centered care map to identify opportunities for and implement patient- and family-centered practices resulted in significant improvement in growth parameters and earlier discharge of very low birth weight newborn infants.[73] This care map was designed for the NICU to promote family-centered care throughout daily interventions with infants and families to deliver care in a holistic fashion to meet the developmental, physical, and psychosocial needs of the infants and their families.

Staff Satisfaction

Staff members at another children's hospital who participate in education programs with families as teachers believe that these experiences are highly valuable.[74] A different program has shown that a family faculty program, combined with home visits, produces positive changes in medical students' perceptions of children and adolescents with cognitive disabilities.[75]

When patient- and family-centered care is the cornerstone of culture in a pediatric emergency department, staff members have more positive feelings about their work than do staff members in an emergency department that does not emphasize emotional support. This may lead to improved job performance, less staff turnover, and a decrease in costs.[76]

Cost-Effectiveness

Coordination of prenatal care in a manner consistent with patient- and family-centered principles for pregnant women at risk of poor birth outcomes at 1 medical center resulted in more prenatal visits, decreased rates of tobacco and alcohol use during pregnancy, higher infant birth weights and gestational ages, and fewer NICU days. All of these factors decrease health care costs and the need for additional services.[77]

After redesigning their transitional care center in a way supportive of families, creating 24-hour open visiting for families, and making a commitment to information sharing, another children's hospital experienced a 30% to 50% decrease in the infants' length of hospital stay. Other outcomes included fewer rehospitalizations, decreased use of the emergency department, greater parent satisfaction, and a decrease in maternal anxiety.[78]

In 1 community program a family support service for children with HIV infection hired family support workers whose backgrounds and life experiences were similar to those of families served by that program. This approach resulted in decreases in HIV-related hospital stays, missed clinic appointments, and foster care placements.[79]

One county program has a children's managed-care plan based on a family-participation service model. Families decide for themselves how dollars are spent for their children with special mental health needs, as long as the services are developed by a collaborative team created by the family. In the 5 years since the program's inception, the proportion of children living in community homes instead of institutions has increased from 24% to 91%; the number of children attending community schools has grown from 48% to 95%; and the average cost of care per child or family per month has decreased from ~$6000 to $4100.[80–82]

The risk-management literature indicates that patients and families are significantly less likely to initiate lawsuits, even when mistakes have been made, if there is open and effective communication and there are trusting relationships between the practitioner and patient and family. Communication problems that can lead to malpractice, by contrast, include the failure to understand patients' or families' perspectives, poor delivery of information, devaluation of patient or family views, and provider unavailability.[83–86]

The pediatrician who appropriately incorporates patient- and family-centered care concepts in patient encounters will, by necessity, spend additional time with the child and the supporting family. This time has value because it will eventually improve care and prevent unnecessary costs in the future. Consequently, payment for the time spent with a family should be adequate, and paid to the physician without undue administrative complexities.

BENEFITS OF PATIENT- AND FAMILY-CENTERED CARE FOR PEDIATRICIANS

Given the documented benefits, pediatricians who practice patient- and family-centered care may experience the following benefits:

- A stronger alliance with the family in promoting each child's health and development.[87]
- Improved clinical decision-making based on better information and collaborative processes.

- Improved follow-through when the plan of care is developed collaboratively with families.
- Greater understanding of the family's strengths and caregiving capacities.
- More efficient and effective use of professional time, including the use of patient- and family-centered rounds.
- More efficient use of health care resources (eg, more care managed at home, decrease in unnecessary hospitalizations and emergency department visits, more effective use of preventive care).
- Improved communication among members of the health care team.
- A more competitive position in the health care marketplace.
- An enhanced learning environment for future pediatricians and other professionals in training.[88]
- A practice environment that enhances professional satisfaction in both inpatient and outpatient practice.
- Greater child and family satisfaction with their health care.
- Improved patient safety from collaboration with informed and engaged patients and families.
- An opportunity to learn from families how care systems really work and not just how they are intended to work.
- A possible decrease in the number of legal claims, claim severity, and legal expenses.[62,85]

RECOMMENDATIONS

1. As leaders of the child's medical home, pediatricians should ensure that true collaborative relationships with patients and families as defined in the core concepts of patient- and family-centered care are incorporated into all aspects of their professional practice.[89] The patient and family are integral members of the health care team. They should participate in the development of the health care plan and have ownership of it.
2. Pediatricians should unequivocally convey respect for families' unique insights into and understanding of their child's behavior and needs, should actively seek out their observations, and should appropriately incorporate family preferences into the care plan.§
3. In hospitals, conducting attending physician rounds (ie, patient presentations and discussions) in the patients' rooms with nursing staff and the family present should be standard practice.[3–6]
4. Parents or guardians should be offered the option to be present with their child during medical procedures and offered support before, during, and after the procedure.
5. Families should be strongly encouraged to be present during hospitalization of their child, and pediatricians should advocate for improved employer recognition of the importance of family presence during a child's illness.
6. Pediatricians should share information with and promote the active participation of all children, including children with disabilities, if capable, in the management and direction of their own health care. The adolescent's and young adult's capacity for independent decision-making and right to privacy should be respected.
7. In collaboration with patients, families, and other health care professionals, pediatricians should modify systems of care, processes of care, and patient flow as needed to improve the patient's and family's experience of care.
8. Pediatricians should share medical information with children and families in ways that are useful and affirming. This information should be complete, honest, and unbiased.
9. Pediatricians should encourage and facilitate peer-to-peer support and networking, particularly with children and families of similar cultural and linguistic backgrounds or with the same type of medical condition.
10. Pediatricians should collaborate with patients and families and other health care providers to ensure a transition to good-quality, developmentally appropriate, patient- and family-centered adult health care services.
11. In developing job descriptions, hiring staff, and designing performance-appraisal processes, pediatricians should make explicit the expectation of collaboration with patients and families and other patient- and family-centered behaviors.
12. Pediatricians should create a variety of ways for children and families to serve as advisors for and leaders of office, clinic, hospital, institutional, and community organizations involved with pediatric health care.[7,8]

§It is the responsibility of the physician to make medical care decisions, but they should be made after such consultation has been made with the patient and the family. It is the patient's and family's responsibility to comply with the agreed upon medical care decisions. If there are major differences of opinion between physicians and families in the care of the child that cannot be resolved with consultation and further medical opinions, consultation with an ethics committee would be prudent. In rare and extreme circumstances, when the health and the life of the child is in jeopardy, appropriate legal action may need to be taken.

13. The design of health care facilities should promote the philosophy of patient- and family-centered care, such as including single-room care, family sleeping areas, and availability of kitchen and laundry areas and other areas supportive of families. Pediatricians should advocate for children and families to participate in design planning of health care facilities.[90–93]
14. Education and training in patient- and family-centered care should be provided to all trainees, students, and residents as well as staff members.
15. Patients and families should have a voice in shaping the research agenda, and they should be invited to collaborate in pediatric research programs. This should include determining how children and families participate in research and deciding how research findings will be shared with children and families.[9]
16. Pediatricians should advocate for and participate in research on outcomes and implementation of patient- and family-centered care in all venues of care.
17. Incorporating the patient- and family-centered care concepts described in this statement into patient encounters requires additional face-to-face and coordination time by pediatricians. This time has value and is an investment in improved care, leading to better outcomes and prevention of unnecessary costs in the future. Payment for time spent with the family should be appropriate and paid without undue administrative complexities.

CLINICAL REPORT

Pediatric Observation Units

abstract

FREE

Pediatric observation units (OUs) are hospital areas used to provide medical evaluation and/or management for health-related conditions in children, typically for a well-defined, brief period. Pediatric OUs represent an emerging alternative site of care for selected groups of children who historically may have received their treatment in an ambulatory setting, emergency department, or hospital-based inpatient unit. This clinical report provides an overview of pediatric OUs, including the definitions and operating characteristics of different types of OUs, quality considerations and coding for observation services, and the effect of OUs on inpatient hospital utilization. *Pediatrics* 2012;130:172–179

BACKGROUND INFORMATION

Across the United States, hospitals providing care for children are facing the challenges of limited inpatient and emergency department (ED) bed capacity and pressures to decrease health care costs and improve efficiencies, quality, and patient safety. One approach has been the establishment of pediatric observation units (OUs). OUs have become widely used in adult medicine to provide hospital-level patient care on a short-term basis, providing efficient care of adults with chest pain, asthma, congestive heart failure, overdose, and many other diagnoses.[1–4] Although the numbers of pediatric OUs and of children treated in them are not tracked or reported on a national basis, a growing body of literature and interest in these units accompanying health care reform support the notion that the number of OUs may increase in the near future. In this context, it is important that pediatricians be familiar with the clinical and operating characteristics of OUs.

DEFINITIONS

Efforts to categorize different OU models are hampered by a lack of universally accepted terminology and definitions. Nonetheless, OUs may be described on the basis of location, scope of clinical activity, or intended function. A recent Institute of Medicine report[5] described OUs as "separate areas that allow for observation of patients to determine whether admission is necessary"; this is a common perspective. OUs may also serve as an alternate site for treatment of selected conditions. And in some hospitals, the OU may serve both functions. In a recent study from a children's hospital with extensive OU experience,

the OU was described both as "dedicated areas where patients may be treated or observed for a defined time period to determine the need for inpatient admission" and as a "disposition option for children who are judged to be too ill for home management."[6] This range of descriptions demonstrates that there may be considerable overlap between different types and functions of OUs, even within a single institution.

The following are definitions related to OUs and observation care from recent literature, acknowledging that terminology varies widely. As the pediatric OU management and research literature evolves, it will be important to have standardized terminology for accurate comparison and referencing purposes.

- Traditional inpatient care: Admission of a patient to a hospital inpatient setting for management or diagnosis of a health-related condition, typically for more than 24 hours.
- Observation unit (OU): A hospital area used to manage and/or diagnose a health-related condition, typically for a well-defined, brief period (typically under 24 or 48 hours). Use of the word "observation" suggests that patients will be frequently reassessed to monitor progression of illness or response to therapy.
- Observation services: Services furnished by a hospital on its premises, including the use of a bed, periodic monitoring by nursing and other staff, and other reasonable and necessary services to evaluate a patient's condition or determine the need for a possible (inpatient) admission to the hospital.
- Observation status: Observation status is a level of care determination that is often assigned to patients who present to an ED (or a private office or clinic) and require a period of monitoring before a decision is made concerning admission or discharge. Observation status generally results in a decision to continue observation care (*Current Procedural Terminology* [CPT] codes 99224–99226 for subsequent observation care [Table 1]), admit the patient (ie, change them to inpatient status with the reporting of CPT codes 99221–99223 for initial hospital care), or discharge the patient (CPT code 99217 for observation care discharge). A patient need not be in a designated OU to be considered in observation status, and likewise, placing a patient in an OU does not constitute initiation of observation-status care.
- Clinical decision unit: Often used synonymously with OU, this is a more descriptive term for an area designated for assessment of patients for whom more time is needed to make a decision whether to admit for traditional inpatient care.[5]
- Rapid (or extended) treatment unit, short-stay unit, 23-hour unit: These and similar terms are sometimes used synonymously with OU. Their time-specific nature suggests a special emphasis on expeditious patient disposition as a key element of their operation, although observation stays can be longer than 24 hours.
- Hybrid OU: Hybrid OUs provide both the short-term diagnostic and management work performed in the typical OU and hospital-level care for scheduled, brief, elective admissions, typically for diagnostic or therapeutic procedures. The most common of these pediatric procedures is provision of sedation for a painful diagnostic procedure such as lumbar puncture or bone marrow aspirate,[6] admissions for infusions, pH probe studies, or recovery from anesthesia.[6,7] Hybrid units may enhance operating efficiencies in that they use a unit's resources for different activities at different times, leading to smoother bed and staffing demands.[6,8–10] The term "hybrid unit," as described here, is not consistently applied. The author of a 2001 review defined the dual mission of a "hybrid or combined unit" differently, calling it "an OU where both pediatric and adult patients can be treated or observed."[11]
- Holding unit, overflow unit, delayed admission unit: Because hospital overcrowding has led to significant numbers of admitted patients being kept in EDs and other areas of hospitals that have not previously provided traditional inpatient care, some hospitals have designated 1 or more specific areas to provide

TABLE 1 Observation-Related CPT Codes

Code	Description
99217	Hospital observation discharge
99218	Initial observation care, low complexity/severity
99219	Initial observation care, moderate complexity/severity
99220	Initial observation care, high complexity/severity
99224	Subsequent observation care, low complexity
99225	Subsequent observation care, moderate complexity
99226	Subsequent observation care, high complexity
99234	Hospital observation and discharge, same day, low complexity/severity
99235	Hospital observation and discharge, same day, moderate complexity/severity
99236	Hospital observation and discharge, same day, high complexity/severity

short-term care of these "overflow" inpatients. These may or may not overlap with the mission of an OU, depending on individual hospital requirements.[12] It is important to be aware that, just as is the case with EDs, holding inpatients in OUs that are designed for rapid patient turnover will impinge on their ability to perform their primary missions.

OPERATING CHARACTERISTICS OF PEDIATRIC OUs

Clinical Staffing

Optimal management of an OU requires a team approach, with all involved being focused on the goal of efficient yet safe patient management. Although management of OUs is typically led by physicians, including emergency physicians, hospitalists,[13,14] or a small-but growing group of dedicated "observationalists," nurse practitioners and/or physician assistants often play integral roles as well.[15,16] Using a hospital-based provider staff allows for the frequent rounding and decision-making usually associated with observation status. However, treatment of children in an OU or coding for such services is not limited to hospital-based physicians. The quality of pediatric OU care can be enhanced with dedicated, experienced nursing staff with specific pediatric experience. To enhance efficiency and decrease OU length of stay and waiting time, a well-organized system to schedule and interpret laboratory, imaging, and other test results is also important.

The role of residents and other trainees in the operation of OUs located in academic training centers is variable, and the literature on this topic is scant. A survey of interns during a rotation on a short-stay unit indicated that their educational experience was favorable.[17] The authors suggested that the unit's clustering of patients with symptoms suggestive of straightforward diagnoses enhanced the intern's educational experience. Exposing residents to patients in the OU also provides them with experience with lower-acuity patients than they would obtain in caring for those on hospital wards alone.

Clinical Care Provided in OUs

Studies describing the diagnoses of children cared for in OUs have revealed that these units may provide effective care for a wide range of common pediatric illnesses and conditions.[18] The most frequent pediatric observation diagnoses include the following: respiratory conditions, such as asthma, bronchiolitis, and croup; gastroenteritis/dehydration and abdominal pain; and prolonged observation of patients with head or other injuries, potential appendicitis, or toxic ingestions. OUs can also be used by day surgery or ambulatory procedure patients who have a delayed recovery time from sedation or anesthesia or whose postoperative/procedure pain is not well controlled. These conditions lend themselves to specific guidelines of care, and for this reason, diagnostic dilemmas are typically not well suited for the OU. Admission criteria to the OU are typically based on age, degree of illness, diagnosis, and the patient's then-current location (ED, clinic, primary care, etc). Although specific guidelines governing patient admission to OUs are universally recognized as critical to OU operations, it is also important to maintain flexibility in patient selection. Reconciling the intensity of expected OU care with available unit staffing is also important, because physician and nursing availability may vary with time of day or at time of peak volumes.

Location of Observation Care

Although traditional pediatric inpatient care is predominantly provided on a hospital floor setting, pediatric observation services may be provided in a variety of settings. This may include a geographic location (or locations) specifically designated as a pediatric OU or a mixed adult-pediatric OU. These units are most commonly found adjacent to or contiguous with an ED; however, others are distinct units in a hospital setting.[6,12,19,20] In either case, a patient is physically transferred to an OU, often after an initial period as an ED patient. Alternatively, observation services may be provided to patients who physically remain in an ED or who are on a hospital floor or other setting, such as a postanesthesia care unit. Observation services may be provided to patients who do not meet the specific admission criteria of a defined OU, who are at hospitals that have chosen not to dedicate space to a discrete OU,[21] or who may simply not fit in an already-full OU.

OUs, uniquely positioned at the interface of inpatient and outpatient care, present certain unique compliance, regulatory, and risk-management issues. In some states, OU beds may not count against a hospital's quota of licensed, inpatient beds and/or be subject to certificate of need determinations. An area of regulatory uncertainty relates to obligations created under the Emergency Medical Treatment and Labor Act for patients in observation status. In addition, OU care, with its unique billing codes and hospital requirements, requires careful attention to clinical protocols as well as documentation and management of medical records.

MEASURING AND ENSURING QUALITY OF CARE IN OUs

A well-functioning OU staff may commonly admit, manage, and discharge its entire census of patients in the course of a day. Safe and efficient operation of these high-volume, high-turnover units requires particular

attention to developing policies and procedures addressing administration, staffing, quality assurance, patient safety, equipment, clinical protocols for treatment, and quality measures. Macy et al[18] have suggested components of a performance metrics "dashboard" for pediatric OUs. Although some of the most commonly cited OU-specific quality measures include return visit rates, length of stay, and financial performance, consistent and comparative measures of operational and clinical performance have been hampered by a lack of standard definitions.[18]

As an example, return visit rates will vary depending on the follow-up time period, the type of return visits being tracked, and how closely the initial and subsequent medical conditions are related. Similarly, OU length of stay determination will vary depending on the definition of the starting and ending points of care. In addition, variability in accounting methods to report and allocate OU revenue and costs creates challenges in describing the economic outcomes of OU care.

The rate of admission for traditional inpatient care after observation services is also frequently tracked as a quality marker. Although sometimes characterized as "failed observation,"[18] progress to traditional hospital admission should be expected of a substantial portion of patients receiving observation services, especially those being observed to determine whether hospital admission will be required. The frequency of inpatient admission among children initially treated in OUs varies widely and may be impacted by medical condition or admission and discharge criteria for individual units. Reported admission rates range from 4% for diagnoses such as croup and seizures to, in some cases, more than 50% for respiratory conditions such as bronchiolitis.[6,16,18,20,22,23] An overall rate of 15% to 25% conversion from observation to full inpatient status is commonly reported.[18] Rates higher or lower than these suggest a need for reevaluation of admission criteria.

Attempts to identify the clinical features that differentiate which specific patients will go on to require an inpatient admission from those who will be discharged have had only marginal success. The clinical characteristics of patients more likely to require admission from an OU vary widely by diagnosis and care provided. Studies of children with asthma treated in an OU did not find meaningful differences in clinical characteristics of patients who were successfully discharged from the OU and those who required hospital admission, except for a persistent need for oxygen supplementation.[24,25] Hypoxia also predicts hospital admission for children with bronchiolitis.[23] Among children with dehydration caused by gastroenteritis and treated in an OU, unplanned admission was required in 19%, although there were no significant associations between specific historical, physical examination, or laboratory characteristics and the need for admission.[26] Young age (<30 days) has been shown to be associated with a risk of inpatient admission, along with diagnoses of hematochezia, viral pneumonia, and bronchiolitis.[18] Among patients with closed head injuries treated in an OU in a pediatric level 1 trauma center, patients with basilar skull fracture, head laceration, or the need for intravenous fluids were more likely to need inpatient admission after OU management.[27] A recent study at a major children's hospital revealed use of certain resources, including intravenous fluids and medications, cardiorespiratory monitoring, respiratory therapy, subspecialty consultation, and oxygen, were associated with hospitalization.[28] The diagnoses most commonly leading to hospitalization included asthma, adenitis, cellulitis, bronchiolitis, and the presence of esophageal foreign bodies.[28]

In addition to return visit and hospital admission rates, best practices in OUs generally include tracking other clinical quality metrics. Examples include the following: adverse events, patient outcomes, satisfaction (of patients, parents,[29] staff, and referring or primary care physicians[30]), and compliance with clinical protocols.[18]

The clinical characteristics of patients who are receiving observation services support the use of standardized clinical pathways for common diagnoses such as croup[31] and dehydration.[15] Although the quality effect of these pathways can be difficult to measure, standardized care has been shown to reduce the length of stay for patients in an OU compared with patients with equivalent conditions in an inpatient unit[32] by reducing unnecessary variations in care. The nature of OU care also requires clear indications as to when patients are moved out of observation status, either to inpatient hospital admission or discharge, providing additional opportunities to standardize care.

In addition to standard care protocols, safety and family-centered care may be enhanced through effective communication in the OU. Medical control responsibilities should be clearly delineated for all patients to ensure smooth transitions from the ED, operating room, or procedure area to inpatient or off-unit testing areas to reduce the risks associated with "handovers" or transfers of care from 1 site to another. After an episode of OU care, a discharge summary and follow-up plan provided to the family and primary provider is important to support the child's family and medical home.[33]

EFFECT OF OUs ON INPATIENT HOSPITAL UTILIZATION

A benefit of OUs is that they may reduce the rate of admissions to inpatient units. Although there are limited data to support this claim, OUs may have an especially important effect on pediatric inpatient admissions, in part because a significant number of inpatient admissions among children are of relatively short duration. An analysis of the Nationwide Inpatient Sample database, an all-payer nationally representative data set of hospital discharges compiled by the Agency for Healthcare Research and Quality, revealed that since 1999, nearly one-third of children hospitalized in the United States have stayed fewer than 2 nights.[34] Furthermore, the proportion of short-stay patients (0 or 1 night) increased from 25% to 30% between 1993 and 2003. Many of these patients are likely eligible for care in OUs.

Several studies support the notion that observation services can substitute for traditional inpatient admission. In a study of inpatient pediatric admissions for asthma in Rochester, NY, more than 70% of admissions could either have been avoided entirely or patients could have been treated in an observation setting.[35] In another study of emergency asthma care in a pediatric ED before and after implementation of an OU, the admission rate for asthma decreased 23%, although there was a modest increase in asthma-related return visits to the ED.[36] In a retrospective review of admissions for croup to a children's hospital after introduction of an OU, the rate of hospitalization among "nondischargeable" children with croup decreased from 9.5% to 4.2%, and median charges and length of stay were also decreased in the OU group.[37] A study of an ED-based OU in France revealed that among 509 admissions to an OU, the decision in the absence of the OU would have been hospital admission in nearly 80%.[15] The authors concluded that having an OU reduced patient hospitalizations while generating few inappropriate short-stay hospitalizations. A recent study of a British pediatric OU had similar findings.[12]

In published studies comparing observation care to inpatient care for selected diagnoses and cases, OU length of stay has been described as shorter than the inpatient alternative.[32,37–40] Because the care model in the OU may involve fewer handovers, more protocol-driven care, and more frequent patient assessment when compared with traditional inpatient care, reduction in length of stay in these units may be achieved by reducing the time from when the patient is clinically ready for discharge until actual departure from the unit. A chart review of 220 patients admitted to an Australian teaching hospital revealed that 65% of patients were medically ready for discharge within 12 hours.[41] The authors also found that the actual length of stay was closer to 17 hours, and they postulated that unnecessary delays caused by administrative aspects of hospital admission and the relatively infrequent evaluation of patients in inpatient settings may lengthen the period of admission. They suggested that many short-stay patients who are admitted to hospitals may be eligible for care in OUs. McConnochie et al[42] have shown similar results in a US study of pediatric patients admitted for gastroenteritis. Despite a growing body of evidence supporting the concept that observation services can substitute for inpatient admissions, however, there are insufficient data to assess the overall effect of OUs on pediatric inpatient use rates across the United States.[18]

Another potential effect of OUs is on the problem of ED overcrowding and patient flow. Patients in EDs may experience long delays when ED rooms are being used by patients needing ongoing treatment or awaiting an inpatient bed. A computer simulation study at the Children's Hospital in Vancouver British Columbia[43] revealed that an OU would reduce wait times in the pediatric ED by creating additional capacity and improving patient flow. Although it is plausible that establishing an OU could lead to increased hospitalization, because some patients who would previously have been discharged after ED evaluation might instead be admitted to the OU, this was not found in a recent, large, prospective pediatric study.[28]

CODING FOR OBSERVATION CARE

Historically, observation care has been clinically defined as care provided in less than 48 hours. However, for the purposes of coding and reporting of clinical services provided to observation patients, many payers, including Medicaid, have defined observation status by using clinical criteria that do not depend on time. Rather, observation status is more typically characterized as a set of clinically appropriate specific services that include ongoing short-term treatment, assessment, and reassessment before deciding whether a patient requires further treatment as a hospital inpatient or discharge from the outpatient hospital, independent of the time required for treatment.

Pediatricians who provide observation services for children need to be aware that there are specific, nuanced rules that govern the reporting and payment for professional services associated with observation care. The American Medical Association's CPT manual, the standard reference for coding medical encounters with patients, categorizes hospital observation services

under "evaluation and management" services.[44] The observation codes represent an unusual set of CPT codes. They represent physician services that lie between ambulatory and outpatient care and inpatient admission services. These codes may be reported by physicians practicing any specialty, including emergency physicians, hospitalists, and office, clinic, or hospital-based general pediatricians or pediatric medical subspecialists. The coding rules governing the reporting of professional fee codes for observation services are not the same as the reporting rules that health plans or state Medicaid agencies use to determine observation or inpatient status, which in turn determines facility payments. In general, the attending physician makes the determination as to whether the care provided is at the level of observation or inpatient. However, hospitals or payers including Medicaid frequently define observation care by using clinical characteristics developed by companies such as InterQual,[45] and these characteristics may vary depending on payer and geographic area.

The use of observation codes is based on the level, rather than the location, of care provided and, like all evaluation and management coding, requires careful documentation of the history, examination, and medical decision-making. Observation services may be reported by physicians for patients treated in an ED, OU, or an inpatient or other hospital unit. These codes are divided into those used when the child is both placed on observation status and discharged on the same date of service versus those used when the child is placed on observation status 1 day and sent home on another. When the child's observation services are begun and completed on the same date of service, the code set 99234–99236 is used. One or more physicians practicing the same specialty may not bill the same patient for the same complaint or illness on the same day. Thus, for example, an emergency physician or 2 emergency physicians may not submit professional bills for both emergency care and observation care on the same day. If the child is seen for the same complaint or illness in a number of different sites of service by a single physician (eg, office, ED, observation, and inpatient admission), only 1 code representing the final disposition of the patient is reported for that date. However, practitioners of different specialties, such as an emergency physician who first evaluates a patient and another physician practicing pediatrics in an OU, may submit separate professional bills on the first calendar day of admission, even if they are evaluating the same complaint or illness. When the child is placed on observation care on 1 date and discharged from the hospital on another calendar day, the 99218–99220 code set is used for the initial date of service, the code set 99226–99226 is used for subsequent days, and 99217 is used on the discharge day.[46] Children meeting clinical criteria may be transferred to inpatient status with the use of initial and subsequent inpatient care codes as determined by history, physical examination, and medical decision-making. An order reflecting the status change should be written. Code 99217 should not be used when a patient is transferred from observation to inpatient status.

CONCLUSIONS

With continued financial pressures to reduce costs of care as well as greater emphasis on efficiency and patient-centered care, it is likely that many hospitals providing care for children will offer observation services to children and that pediatricians will be increasingly likely to work in an OU or refer patients for OU care. Many children previously cared for in a traditional inpatient hospital setting may be safely and efficiently cared for in an OU. However, the operation of pediatric OUs presents distinct challenges, including a lack of uniform definitions for the types of OU care, the selection of patients for OU services, and the unique requirements to deliver care that may end with either admission or discharge. Pediatricians, managers, and other care providers should be aware of the unique coding and reporting requirements for observation services and ensure that the documentation provided supports the selection of specific observation care codes. Quality of care in OUs may be enhanced with defined criteria for admission and discharge, use of standardized clinical protocols, and clearly defined policies and procedures defining responsibility for the patient's care while in observation status. A growing research base, largely descriptive to date, suggests that OUs enhance the care of children; further research is necessary to better describe the contributions of OUs to overall pediatric health.

POLICY STATEMENT

Pediatric Sudden Cardiac Arrest

abstract

FREE

Pediatric sudden cardiac arrest (SCA), which can cause sudden cardiac death if not treated within minutes, has a profound effect on everyone: children, parents, family members, communities, and health care providers. Preventing the tragedy of pediatric SCA, defined as the abrupt and unexpected loss of heart function, remains a concern to all. The goal of this statement is to increase the knowledge of pediatricians (including primary care providers and specialists) of the incidence of pediatric SCA, the spectrum of causes of pediatric SCA, disease-specific presentations, the role of patient and family screening, the rapidly evolving role of genetic testing, and finally, important aspects of secondary SCA prevention. This statement is not intended to address sudden infant death syndrome or sudden unexplained death syndrome, nor will specific treatment of individual cardiac conditions be discussed. This statement has been endorsed by the American College of Cardiology, the American Heart Association, and the Heart Rhythm Society. *Pediatrics* 2012;129:e1094–e1102

INCIDENCE OF PEDIATRIC SUDDEN CARDIAC ARREST

In the United States, there is no centralized or mandatory registry for pediatric sudden cardiac arrest (SCA). Available data generally are collected through media reports, from lay SCA advocacy groups, or from peer-reviewed publications, often from major referral medical centers. Episodes of resuscitated cardiac arrest (aborted cardiac death) are even more difficult to document retrospectively. The Centers for Disease Control and Prevention has estimated that every year in the United States, approximately 2000 patients younger than 25 years will die of SCA.[1] Other older reports estimate the frequency of SCA in children and adolescents to be between 0.8 and 6.2 per 100 000 per year.[2–6] Two studies suggest that the frequency of SCA in adolescents and young adults actually may be increasing.[7,8] Although SCA occurs even at young ages and at rest, the likelihood of child and young adult SCA for those with underlying cardiovascular disease is increased by athletic participation.[9] Nonetheless, 2 studies from Maron et al[10,11] estimate fewer than 100 cases of SCA in young US competitive athletes each year. An Italian study reported a baseline incidence of SCA in young competitive athletes at 1:25 000 before implementing a national screening program.[12] Corrado et al identified a 2.5 times relative risk for SCA attributable to sports activity in adolescent and young adult athletes versus an age-matched nonathletic population,[13] related to underlying cardiac disorders.

Reporting and referral biases affect our knowledge of SCA incidence. The difficulty in determining cause of death in patients with primary cardiac electrical disorders (so-called "autopsy negative") must be acknowledged. Many of these now recognized electrical disorders have been described only recently, confounding older literature that details the cause of pediatric SCA identified at autopsy.

CARDIAC DISORDERS PREDISPOSING YOUTH TO SCA

Underlying cardiac disorders associated with pediatric and young adult SCA are listed in Table 1. In general, causes can be considered (1) structural or functional (expected to be identified with echocardiography or at autopsy); (2) primary electrical (most commonly associated with structurally and functionally normal hearts); or (3) other, including use of illicit drugs and stimulants (eg, cocaine, ephedra) or prescription medications (eg, erythromycin, ketoconazole, carbamazepine). The reader is directed to reference texts and previous publications for more detail about each of these individual conditions.[14,15]

GENETICS OF PEDIATRIC SCA

The identification of disease-causing genetic mutations is progressing rapidly in all areas of medicine. Evaluation of large cohorts of ostensibly healthy individuals has begun to catalog the common polymorphisms and the background rate of rare genetic variants of uncertain significance within the general population. For cardiac disease, the science of genotypic evaluation has not yet advanced to the point at which genotype alone (isolated from clinical phenotypic description) can routinely and accurately risk stratify for clinical outcome. Many cardiac disorders, including hypertrophic cardiomyopathy (HCM) and the cardiac ion channelopathies, are known to be genetic.[16,17] Several studies have documented the efficacy of genetic testing of first-degree relatives of persons who have died of SCA. A 2003 study[18] reported cardiac symptoms in 27% of surviving relatives, with a 22% incidence of unexpected premature sudden death in addition to the proband in any relative and a 6% incidence of sudden death in a first-degree relative. After evaluating 49 cases of young autopsy-negative SCA, Tester and Ackerman[19] reported 17 cases with genetic/molecular evidence for long QT syndrome (LQTS) or catecholaminergic polymorphic ventricular tachycardia (CPVT) disease–causing mutations; 9 (53%) of these cases had a family history of SCA or syncope documented by the medical examiner. A personal history of syncope, seizure, or previous cardiac arrest was detailed for 7 individuals whose deaths were attributable to SCA. In a 2005 report, genetic testing established a likely cause of death in 17 of 43 autopsy-negative persons (40%). Genetic testing of family members revealed an additional 151 presymptomatic and undiagnosed disease carriers (average of 8.9 per family).[20]

Recognizing the genetic nature of many of the disorders listed in Table 1, the role of a detailed, comprehensive family history (and considering consultation with an expert in cardiac genetics) is readily apparent. The primary goal is prospective identification of any family member, even if asymptomatic, who is genotypically or phenotypically affected by a disease entity predisposing a person to SCA. A 2008 publication discusses the role of family history for evaluating cardiomyopathy and ion channelopathies predisposing people to SCA.[21] A 3-generation pedigree as a family history tool is highly effective for clinical evaluation; a family history template suggested by the US Surgeon General's Family History Initiative is available free at www.hhs.gov/familyhistory.

WARNING SIGNS AND SYMPTOMS

Although SCA may be the sentinel event, symptoms in patients with structural-functional or primary electrical disorders may, in fact, be relatively common before SCA. Often, these warning signs or symptoms may be misinterpreted or disregarded by both family members and medical personnel. These points were emphasized in a 1996 publication[22] that summarized 9 previous studies. Preceding symptoms of dizziness, chest pain, syncope, palpitations, or dyspnea and a family history of premature, unexpected sudden death were noted in 25% to 61% of the study population. Deaths were exertion-related in 8% to 33% of cases. A study of 162 young persons (15–34 years of age)[23] undergoing autopsy evaluation after SCA found 92

cases with a history of syncope/presyncope, chest pain, palpitations, or dyspnea; 26 of these subjects had a family history of SCA. In a study of natural death in people 5 to 35 years of age,[24] the most common cause of sudden death was presumed arrhythmia in those with no or minimal heart disease (29%). Eleven percent of cases were exercise-associated. A history of SCA was reported in 4.5% of first-degree relatives of the descendents. Importantly, symptoms may be nonspecific and confusing in athletes, who may overexert until physical exhaustion.

In most cases, the immediate cause of SCA is a lethal ventricular tachyarrhythmia (ventricular fibrillation [VF] or pulseless ventricular tachycardia) causing cardiac collapse. Some of these arrhythmias (eg, torsades de pointes, the characteristic tachyarrhythmia associated with LQTS) may be short lived and self-terminating, causing episodes of syncope/presyncope or episodes of seizure-like activity.[19,22–25] These neurologic signs and symptoms may direct referral to a neurologist, inadvertently misdirecting the patient away from cardiac evaluation and, thus, delaying correct diagnosis and treatment. These tachyarrhythmia-associated SCA events must be distinguished from the well-recognized but poorly understood entity called sudden unexpected death in epilepsy.[26,27] In the latter, this primary neurologic event may cause a cardiac death, mediated through abnormalities of cardiovascular autonomic function.[28] Chest pain is almost never present in patients with primary electrical disorders but is more likely in patients with cardiomyopathies,[29,30] congenital coronary artery abnormalities,[31] or aortic disease (eg, dissection or rupture associated with Marfan syndrome[32]). Other nontypical cardiac presentations also may misdirect patients to other consulting medical subspecialties. Symptoms suggestive of exercise-induced bronchospasm may be present in patients with HCM and dilated or restrictive cardiomyopathy. Cardiomyopathy-associated wheezing is attributable to decreased left ventricular compliance, mitral insufficiency, or pulmonary venous hypertension with pulmonary edema. Failure of empirical exercise-induced bronchospasm medication or normal pulmonary function testing should prompt cardiovascular evaluation. Drowning or near-drowning has been associated with LQTS and CPVT.[33,34] Approximately 5% to 10% of sudden infant death syndrome (SIDS) cases may stem from channelopathic mutations in genes associated with LQTS, Brugada syndrome, and CPVT.[35–38] Congenital deafness has been noted in some types of LQTS.[39] Patients with congenital deafness should be evaluated for LQTS if the deafness is not otherwise associated with another recognized syndrome or anomaly. Febrile seizures may be a presenting sign of children affected with Brugada syndrome.[40]

SCREENING TECHNIQUES

The role of any screening effort is to identify individuals at risk; unaffected or low-risk individuals should be cleared, and conversely, those affected should be appropriately restricted counseled, and treated. Not all SCAs can be foreseen, even in the best of circumstances. No screening protocol has yet proven to be effective in this role or validated as highly effective.

Sports Preparticipation Evaluation and Cardiovascular Risk Assessment

As noted by aforementioned studies, it is estimated that as many as half of pediatric SCA cases exhibited a personal/familial sudden death warning sign or symptom (such as previous exercise-triggered faint or family history of premature unexplained sudden death). Thus, there is an opportunity to identify individuals at risk for pediatric SCA without technology-based screening programs, such as the 12-lead electrocardiography (ECG) and echocardiography; however, despite the aforementioned data supporting the fact that preceding warning signs and symptoms may be present in many patients and families at risk for SCA, most published studies have not substantiated the efficacy of current athletic preparticipation evaluation (PPE) processes. Only 3% of 158 athletes with SCA were suspected of having cardiovascular disease using a PPE screen, leading the authors of a 1996 study to conclude that "pre-participation screening appeared to be of limited value for identification of underlying cardiovascular abnormalities."[41] The 1996 study was retrospective, and the details of the PPE questionnaire used and the adequacy of PPE were not reported. This report also predated description of some of the disease entities now known to cause pediatric SCA. More recently, an investigation from the United Kingdom concluded that family history and personal symptom questionnaire alone were inadequate for identification of at-risk patients and families.[42] The 2008 UK study used a comprehensive PPE format and trained examiners, with little reported benefit, which reveals the potential failure of a single PPE at 1 point in time.

In contrast to a single PPE initiated only before athletic participation, a more thorough cardiovascular risk-assessment process, applied throughout childhood and adolescence (the continuum of well-child care), can be provided for any patient, of any age, by any care provider (Table 2). Patient and family histories can and do change over time, necessitating an update of information for the care provider. Families should be encouraged to provide complete and

TABLE 2 Pediatric Sudden Cardiac Death Risk Assessment Form

Patient history questions: Tell me about any of these in your child…	Yes	No
Has your child fainted or passed out during or after exercise, emotion, or startle?		
Has your child ever had extreme shortness of breath and/or discomfort, pain, or pressure in his or her chest during exercise?		
Has your child had extreme fatigue associated with exercise (different from other children)?		
Has a doctor ever ordered a test for your child's heart?		
Has your child ever been diagnosed with an unexplained seizure disorder? Or exercise-induced asthma not well controlled with medication?		
Family history questions: Tell me about any of these in your family…		
Are there any family members who had a sudden, unexpected, unexplained death before age 50 (including SIDS, car crash, drowning, others) or near-drowning?		
Are there any family members who died suddenly of "heart problems" before age 50?		
Are there any family members who have had unexplained fainting or seizures?		
Are there any relatives with certain conditions, such as:		
Enlarged heart: HCM		
Dilated cardiomyopathy		
Heart rhythm problems: LQTS		
Short QT syndrome		
Brugada syndrome		
Catecholaminergic ventricular tachycardia		
Arrhythmogenic right ventricular cardiomyopathy		
Marfan syndrome (aortic rupture)		
Heart attack, age 50 or younger		
Pacemaker or implanted defibrillator		
Deaf at birth (congenital deafness)		
Please explain more about any "yes" answers here:

Physician signature:		
Date:		

Ask these questions (or have parents complete for your review) at periodic times during well-child visits (neonatal, preschool, before or during middle school, and before or during high school).

accurate responses concerning history. PPE screening of athletes exclusively omits >25 million US schoolchildren who do not participate in sports. Postponing cardiovascular risk assessment until a more formal high school or collegiate athletic PPE screen also will delay detection of patients and families at risk for SCA before high school. For any PPE or cardiovascular risk assessment to succeed, medical providers must be aware of sudden death warning signs and symptoms and respond appropriately with comprehensive cardiovascular evaluation, referral, treatment, and activity restrictions as appropriate. The use of competent and qualified examiners is still a necessity, but recent data reveal that 35% of states allow nonphysicians with little cardiovascular training to perform the screening evaluations.[43]

The American Heart Association (AHA) has documented a 12-element recommendation for preparticipation screening of competitive athletes.[44] Another PPE, sponsored and endorsed by the American Academy of Pediatrics (AAP) and 5 other agencies, is now widely used throughout the United States for childhood and adolescent athletic PPE.[45] This document acknowledges the wide variation in physician competencies and documentation for PPE examinations. Many states have endorsed the use of this PPE to eliminate unnecessary variability and to more effectively screen for cardiovascular risk. The updated fourth edition of this PPE form became available in April 2010.

None of the aforementioned PPEs or cardiovascular risk-assessment tools have been validated but serve as standard templates for more comprehensive screening. Likewise, no true sensitivity or specificity data exist for prediction of risk of SCA by PPE. Among the many warning signs and symptoms, the following 4 appear to represent more ominous positive responses (based on expert opinion):

1. Have you ever fainted, passed out, or had a seizure suddenly and without warning, especially during exercise or in response to auditory triggers such as doorbells, alarm clocks, and ringing telephones?
2. Have you ever had exercise-induced chest pain or shortness of breath?
3. Are you related to anyone with sudden, unexplained, and unexpected death before the age of 50?
4. Are you related to anyone who has been diagnosed with a sudden death–predisposing heart condition such as HCM, LQTS, Brugada syndrome, and so forth? (See Table 1.)

Once a cardiovascular disorder listed on Table 1 is suspected or diagnosed, referral to and management by pediatric/adult cardiologists or heart rhythm specialists experienced with the particular sudden death–predisposing heart condition is crucial.

Another important time, resource, and cost-benefit issue centers around obtaining the detailed and accurate cardiovascular risk assessment or PPE forms in the primary care office setting. This time-consuming process is currently poorly reimbursed and difficult to prioritize and validate in a busy practice.

ECG Screening

Although some data suggest that SCA screening may be enhanced with the addition of ECG, broad-scale ECG screening has not been tested or implemented in the United States. Mandatory screening of Japanese schoolchildren since 1973[46,47] has demonstrated a greater sensitivity of ECG versus history and physical examination. Competitive Italian athletes undergo required PPE and ECG, with ECG reportedly demonstrating 77% greater power to detect HCM

than history and physical examination alone.[2] Italy also has reported a newborn ECG screening program to identify infants at risk for SIDS secondary to abnormal cardiac repolarization.[48] For Olympic athletes, the International Olympic Medical Committee issued a screening protocol including ECG in 2004.[49] A 2005 European Society of Cardiology consensus statement on cardiovascular preparticipation screening of young competitive athletes recommends 12-lead ECG in addition to focused history and physical examination.[50] Some US studies have suggested that ECG screening may be cost-effective on the basis of estimated cost per year of lives saved.[51,52]

The 2007 AHA scientific statement/screening guidelines[44] (coauthored by S.B. and M.J.A.) did not recommend standard ECG assessment, however, citing false-positive and false-negative results, cost-effectiveness, feasibility, and medicolegal concerns. Wide-scale ECG screening would require a major infrastructure enhancement not currently available in the United States. Recent reassessment of ECG "normal" values has helped to decrease false-positive findings.[53] Competitive athletes are known to have unusual but occasionally benign ECG findings, consistent with "athlete's heart," that must be differentiated from ECG findings attributable to pathologic conditions.[54]

The role of routine ECG screening in the United States to prevent SCA is not settled and will require more data and debate. Readers are referred to recently published debates of the subject for further details.[55,56]

Molecular Autopsy

The genetic nature of many cardiac ion channelopathies predisposing youth to pediatric SCA is being defined rapidly.[17] When children die suddenly, there may be no previous evaluation or diagnosis. Conventional autopsies often fail to identify a condition responsible for sudden death. These autopsy-negative cardiac conditions have previously defied complete definition. As already described, complete evaluation of a child who died of SCA through detailed clinical and targeted genetic testing of immediate family members may identify specifically the cause of SCA and direct appropriate care and genetic counseling to surviving family members. The cardiac channel postmortem genetic analysis (also known as "molecular autopsy")[57] remains a research test but soon may evolve into a standard clinical practice. Unfortunately, current standards of care for autopsy do not yet ensure that a postmortem sample suitable for DNA analysis is retained. Further, despite the evidence that approximately 25% to 35% of autopsy-negative sudden unexplained death is channelopathic, health insurance companies currently do not accept responsibility for molecular autopsy of the deceased in the United States. The cost would befall the medical examiner and, ultimately, the community; however, far more expensive testing of all first-degree surviving family members currently is used clinically and reimbursed. An important next step will be the development of guidelines at a public health level for postmortem genetic testing.

PRIMARY PREVENTION OF SCA

Primary prevention of SCA depends on patient diagnosis, specific etiology, and etiology-specific treatment. Treatment options include but are not limited to medical therapy, device therapy (eg, pacemakers, internal cardioverter defibrillators), activity-restriction guidelines, avoidance of certain classes of medications, and family emergency preparedness. The details of primary prevention, given that they are etiology specific and prescribed by a consulting cardiologist, are beyond the scope of this policy statement.

SECONDARY PREVENTION OF SCA

When SCA primary prevention strategies (ie, patient identification, treatment, activity restriction, and counseling) have failed, SCA still may occur, and secondary prevention (resuscitative) efforts are required. The AHA has proposed a "chain-of-survival"[58] beginning with early symptom recognition and 911 emergency medical services (EMS) contact, followed by effective bystander cardiopulmonary resuscitation (CPR), early defibrillation, and finally, advanced hospital care. The published outcomes for out-of-hospital pediatric cardiac arrest are dismal; survival to hospital discharge occurs in approximately <10% of children, and many have severe neurologic sequelae.[59–63] Poor outcomes may be related to prolonged periods of no cardiac output, in part because many out-of-hospital arrests are unwitnessed, and only approximately 30% of children received bystander CPR[61] (note also that bystander CPR more than doubles patient survival rates[64]).

Bystanders report that they do not perform CPR because of panic or fear of failure[65] and unwillingness to perform mouth-to-mouth rescue breathing. Recent studies suggest that "compression-only" CPR may be more effective than standard CPR with ventilation,[66,67] by using faster (approximately 100 per minute) and deeper compressions, in adults for witnessed nonasphyxial arrest (arrest not secondary to, for example, drowning, hanging, or carbon monoxide poisoning). To date, there are no pediatric studies with respect to compression-only CPR. Because pediatric patients are more likely to experience respiratory arrests, compression only may not be suitable. Two studies report VF as the initial rhythm in 19% to 24% of out-of-hospital pediatric cardiac arrests, excluding deaths attributable to SIDS.[68,69] VF and ventricular tachycardia generally have been considered more favorable initial SCA rhythms than

either asystole or pulseless electrical activity, with a higher rate of survival to hospital discharge, when prompt defibrillation (termination of VF) and return of an organized perfusing rhythm is achieved. As part of the chain of survival, public access defibrillation using automated external defibrillators (AEDs) has a prominent role.[70] Data from witnessed VF arrest in adults show that appropriate use of AEDs can lead to long-term survival rates >70%.[71,72] AEDs have now been recommended for children younger than 8 years,[73,74] with still insufficient scientific evidence to warrant official recommendation for or against AED use in children aged 1 year or younger. A 2007 AAP policy statement addressed current pathophysiology of VF and recommendations for AED use in children; readers are referred to this publication for further detail.[75]

SCHOOL AED PROGRAMS

The average school-aged child spends 28% of the day and 14% of his or her total annual hours in school.[76] In addition, adults (parents, grandparents, teachers, staff, and visitors) crowd our schools. As an area of higher traffic, schools have become sites for implementation of AED programs. In 1 report, 67% of schools activate EMS for an emergency involving a student, and 37% activate EMS for an emergency involving an adult.[76] A 2007 report detailed a 16-year history of SCA in Seattle city and King county schools, providing a framework for reasonable and rational school-based emergency programs.[77]

A growing number of states have mandated school AED programs. The cost-effectiveness of school AED programs has been reported by Berger et al.[78] Key components for a comprehensive school-preparedness program include education and all-staff awareness, knowledge and application of effective bystander CPR techniques, implementation of a lay-rescuer AED program, and written emergency action plans,[79] with all steps reinforced with effective communication throughout the school campus and periodic practice drills. Current principles guiding this recommendation for schools, primary clinicians, and school physicians have been detailed in the AAP policy statement "Medical Emergencies Occurring at School."[80] At this time, there are no published data to support the efficacy of home AEDs.[81]

RECOMMENDATIONS FOR PEDIATRIC CARE PROVIDERS

Evidence-based recommendations frequently are designated as class I, II, or III, indicating the supporting level of evidence. For pediatric SCA, the level of evidence does not permit a meaningful use of this terminology. This statement has been endorsed by the American College of Cardiology, the American Heart Association, and the Heart Rhythm Society.

All steps in the primary and secondary SCA-prevention strategies should be optimized if pediatric SCA is to be prevented.

RECOMMENDATIONS

Important steps for consideration include:

1. Recognize the warning signs and symptoms of SCA, including those that may "misdirect" initial evaluation to noncardiac specialties and, thus, delay correct diagnosis.
2. Understand the role of comprehensive and accurate family history and pedigree for preventing SCA stemming from inherited cardiac genetic disorders.
3. Use standardized PPE forms and processes to minimize unnecessary variation.
4. Ensure that identified patients and/or families with known or suspected cardiac disorders are referred to a pediatric cardiac center for further comprehensive evaluation and management. Appropriate secondary testing may include ECG, echocardiography, exercise testing, or genetic testing, as indicated.
5. Advocate for autopsy evaluation by a medical examiner familiar with rarely encountered heritable cardiac diseases causing SCA when pediatric SCA occurs. Procurement of and retention of DNA-bearing tissue for subsequent molecular autopsy should be encouraged for autopsy-negative cases.
6. Support education programs for effective bystander CPR and appropriate AED use.
7. Support development of effective school emergency response programs.
8. Consider participation in school emergency response programs as a medical director.
9. Support efforts to mandate a central registry for pediatric SCA as a reportable event.
10. Support recommendation for evidence-based evaluation of national screening processes and programs.

CLINICAL REPORT

The Pediatrician's Role in Supporting Adoptive Families

abstract

FREE

Each year, more children join families through adoption. Pediatricians have an important role in assisting adoptive families in the various challenges they may face with respect to adoption. The acceptance of the differences between families formed through birth and those formed through adoption is essential in promoting positive emotional growth within the family. It is important for pediatricians to be aware of the adoptive parents' need to be supported in their communication with their adopted children. *Pediatrics* 2012;130:e1040–e1049

CHANGING PICTURE OF ADOPTION

According to the 2007 National Survey of Adopted Children, approximately 2% of the child population in the United States was adopted, accounting for 1.8 million children.[1,2] Approximately 38% of these children were adopted from foster care, another 38% joined families through private domestic adoption, and 25% were adopted internationally. Furthermore, approximately 24% of adopted children were adopted by relatives, including 17% from foster care, and 37% of children were adopted privately in the United States.[1,2] Overall, 49% of adopted children were male; 39% of children adopted internationally and 57% adopted through the foster care system were male. Adopted children tended to be older than the general population, with only 14% younger than 5 years, compared with 27% in the general population. Adopted children were less likely to be white or Hispanic, but this varied by the type of adoption. Children adopted through the foster care system tended to have the highest percentage of black children, at 35%, whereas children adopted internationally had the least number of black children, at 3%. Children adopted privately in the United States were more likely to be white, at 50%, whereas children adopted internationally were least likely to be white, at 19%. The majority of children adopted internationally were of Asian descent (59%), with 33% originating from China. Adopted children were less likely to live in households with incomes below the poverty level than the general population (12% vs 18%, respectively). Conversely, 46% of adopted children live in households with incomes no higher than 2 times the poverty level. Similar to the general population, 69% of adopted children lived with 2 married parents. Eighty-five percent of adopted children were reported by parents to be in excellent or very good health, and 78% reportedly had adequate health insurance.[1] Knowing the current picture of adopted children, pediatricians can play a significant role in the adoption process by providing counseling

to parents during the preadoption phase and subsequently providing support for the adoptive family.[3] Additionally, by understanding the unique medical, developmental, mental health, and behavioral needs of the adopted child, pediatricians can provide optimal health care for these patients.

Adoption can be domestic or international. Domestic adoption involves adopting a child from within the United States. International adoption involves adopting a child who was born outside the country, with the intention of bringing the child to live in the United States. Regardless of the type of adoption, the biological family may have continued contact of varying degrees with the child for whom an adoption plan has been chosen, ranging from complete confidentiality to unlimited direct contact.[1,4,5] In fact, more than one-third of children in nonrelative adoptions have had some contact with their birth parents. Private domestic adoptions account for the majority of contact, with 68% of adoptive families reporting communication with birth parents, whereas 39% of families of children adopted from foster care and 6% of families of children adopted internationally acknowledge some degree of contact with birth parents.

Adoptive families are changing.[6–15] It is estimated that every year, approximately 120 000 children, representing 2% of the US population, are adopted.[1,7,8] The source of adoptees has undergone a transition. The number of adoptions from domestic sources, including foster care, has been increasing, and international adoptions have declined.[1,7] Blended families, families with gay or lesbian parents, and families with older parents are providing more homes to children through adoption, although exact numbers are difficult to obtain.[6] Single-parent adoptions have become increasingly more common.[9–11] Research from the 1970s found that an estimated 0.5% to 4% of people completing adoptions were single, compared with 8% to 34% of adopters in the 1980s. This percentage remained relatively stable in the 2000s.[9] Additionally, more children are being placed long-term with relatives, who may or may not formalize the relationship through adoption.[4,12–15] Twenty-three percent of children adopted from the foster care system were adopted by relatives, and an additional 22% were adopted by nonrelatives who knew the child before the adoptive process. In other domestic adoptions through the private sector, 41% were adopted by relatives, and an additional 7% were adopted by previously known nonrelatives.[1] Children may have had multiple sets of foster parents before their adoption, some of whom may maintain contact with the child after the adoption.[1,2] Others may be adopted by the only foster parent they have encountered. There were fewer newborn infants and more older children being placed for adoption. Sibling groups were often placed together. A child may be adopted into a family of the same ethnicity and/or race or into a family with members of different groups.[1,4,6,14] Four of 10 adopted children were in transracial adoptions.[1] Kinship care showed an increase.[1,12]

The number of adoptions of children with special needs has increased markedly in the past 2 decades.[11,16] Many adopted children have complex medical, developmental, behavioral, educational, and psychological challenges.[1,2,7,16,17] In fact, 39% of adopted children were classified as having special health care needs, compared with 19% in the general population.[1] Furthermore, more than half of children adopted from foster care (54%) were considered to have special health care needs.[1,7,17] Adopted children were more likely than nonadopted children to have asthma and to have moderate or severe health problems. Also, adoptive parents were more likely than nonadoptive parents to be told that their child had a learning disability, developmental delay, and/or physical impairment. Mental health issues, such as attention-deficit/hyperactivity disorder, autism, mental retardation, and emotional problems were more commonly reported in adopted children with special health care needs. These conditions may be the result of biological and/or environmental stressors experienced while the child was living with the biological family or may have been initiated or exacerbated while the child was in temporary care.[14] Despite the reported issues, most adoptive parents rated their children's health as "excellent" or "very good."[1]

Modern technology has contributed to the changing face of adoption. The Internet has led to wider dissemination of information about children waiting for permanent families and has established a new system of support among adoptive families. Information about adoption on the Internet may not always be reliable, however, and the broad and instant reach of the World Wide Web also allows great potential for unethical practices in adoption.[18]

PEDIATRIC ISSUES

Pediatricians may be asked to review preadoption health records to help families understand the current and potential future medical, developmental, and mental health needs of children they plan to adopt.[3,19] Pediatricians may be able to use health records to help parents determine additional questions that could clarify a particular health issue or diagnosis and help parents

elucidate what special needs they are prepared to accept. When reviewing medical records, the Privacy and Security Rules of the Health Insurance Portability and Accountability Act must be considered.[20] The Privacy and Security Rules define how covered entities use individually identifiable health information, or personal health information. If a covered entity is not involved, then adherence to Health Insurance Portability and Accountability Act rules may not be required, but other regulations may come into play.

Specific issues to address in the health records may include conditions related to complications of pregnancy, poor nutrition, preterm birth, lack of prenatal care, genetic diseases, alcohol use, substance abuse, early brain cognitive development, and growth trends of the child. In counseling families, all attempts should be made to obtain a complete medical and psychological history of the child, particularly in assessing potential special needs of a child. Through comprehensive preplacement assessment, parents should assess their resources and abilities to meet a particular child's needs. Pediatricians without expertise in this area may seek out and refer hopeful adoptive parents to pediatricians listed on the Council on Foster Care, Adoption, and Kinship Care Web page who have experience in preadoptive evaluations.[21]

Children who join their families through adoption must have a comprehensive medical evaluation to identify medical needs.[22–24] This should be completed soon after placement in an adoptive home to confirm and clarify existing medical diagnoses, assess for any previously unrecognized medical issues, discuss developmental and behavioral concerns, and make appropriate referrals. It is recommended that pediatricians review the standards for medical care of adopted children that have been published by the American Academy of Pediatrics (AAP).[22,25] For children adopted internationally, this evaluation includes but is not limited to screening tests and assessment of immunization status, as recommended in the *Red Book*.[22] Acute and chronic medical problems, vision and hearing loss, and developmental delays should be identified and addressed. Behavioral, emotional, learning, and developmental concerns need to be evaluated, with appropriate therapy initiated as needed.

The pediatrician can provide information to parents concerning issues of transition and adjustment of the child into the adoptive family.[25] For many, this may be an easy transition, but others may experience varying degrees of difficulty during this phase in their lives. The child may experience symptoms of anxiety, display signs of depression, or withdraw from his or her environment. The child may demonstrate misbehaviors that are atypical and may also experience school difficulties. Sleep and feeding problems may be prominent during this period. The following AAP resources are available to guide the pediatrician in management: *Addressing Mental Health Concerns in Primary Care: A Clinician's Toolkit*,[26] *AAP Developmental and Behavioral Pediatrics*,[27] and *Guide to Learning Disabilities for Primary Care: How to Screen, Identify, Manage, and Advocate for Children with Learning Disabilities*.[28]

After completion of the comprehensive evaluation, pediatricians can help families that have not finalized the adoption to be more prepared to negotiate adequate adoption subsidies. Adoption assistance may involve access to medical care, counseling or therapy, special equipment, tutoring programs, and other support services that may help children who have special needs. The type and amount of assistance vary by state.[29] Finally, providing information about available community services, such as early child intervention programs and support groups, may ease the transition for the expected family. The Child Welfare League of America also may be a valuable resource for pediatricians and adoptive families.[30]

DEVELOPMENTAL UNDERSTANDING OF ADOPTION

Just as a child's thinking and self-concept changes at various stages of development, so does a child's understanding of the meaning of adoption.[31–33] It is generally agreed that the child should be told of the adoption, but there is disagreement on when the information should be given. Until 3 years of age, most adopted children do not realize there is a difference between their family and families in which children are reared by their biological parents.[32] From the time a child is adopted, it is appropriate for families to use adoption language, as described later in this statement, on a routine basis. Using adoption language early helps to lay the groundwork for children to later understand these abstract concepts. It also provides the time that may be needed for the parents to become comfortable sharing their child's adoption with family and friends.[34] The pediatrician can facilitate the parents' comfort level by introducing the adoptive parents to available resources, such as support groups. The pediatrician can also suggest books on adoption for the parent and even young children.[29,35] Through the use of available resources, as well as any pictures that may help describe a child's own adoption story, parents should relate to children the story of how their family came to be. These

foundations are important in the later development of positive attitudes about adoption, a child's birth parents, and himself or herself.[34,36] It is also important for the pediatrician to remind parents that adoption issues come in and out of focus for children over time and may be dormant for periods. During nodal points in development, specific issues may become more relevant for the child. The pediatrician can counsel adoptive parents about the need to understand the child's questions surrounding the adoption in the context of the child's current development and answer questions in a way that promotes self-esteem.

By approximately 3 years of age, however, children become self-absorbed and may believe that they magically cause all things that have happened to them.[33–35] Three-year-old children often love to hear their adoption stories. At this age, most children begin to ask questions about what adoption means, yet children adopted at a very young age do not understand that they have another family besides the family with whom they live. Separation issues may be more pronounced than they are in peers, especially with children who remember the loss of biological or foster parents, siblings, or other relatives. Children at this age may feel responsible for the loss of their first family, as well as for the repeated losses through moves in and out of foster care. They may fear that their adoptive parents will abandon them in the same way once their hidden flaws are discovered. Some children may express yearnings to have been "in the belly" of their adoptive mother.[32] By the time children enter kindergarten, they realize that most of their peers are not adopted. They also may learn that some children may be living with biological parents in circumstances that are similar to those experienced by their own biological parents (eg, single-parent families or conditions of poverty). This, once again, may lead children to feel responsible for their biological parents' decision not to raise them.

School-aged children continue to face issues associated with adoption, although often they deal with them by going "underground." Although children in this stage may not ask questions or initiate discussion of issues related to adoption, they are most likely thinking about them.[33,36] When children are 6 to 12 years of age, they realize that, in gaining an adoptive family, they have also lost a biological family.[33,37] Realization of this loss may be one of the underlying issues in the emotional adjustment of adopted individuals giving rise to the appearance of increased adjustment difficulties during this period.[33] At the same time, school-aged children may identify with their imagined biological families, fantasizing about what life would have been like if an adoption plan had not been made for them. During middle childhood, children (particularly children adopted across racial and/or cultural lines) may become upset by the differences they notice in comparison with other children and other family members. They may experience denial of these differences as well as of the adoption itself.[36] Self-esteem issues may also complicate emotions and the thinking process during these years, because some children may wonder what flaw in them resulted in their biological parents making an adoption plan—particularly if the biological parent(s) chose to rear a sibling.

During preschool and elementary school years, peer and school problems may or may not be the manifestation for underlying adoption issues. Although internationally adopted children are more likely to have attention-deficit/hyperactivity disorder and learning concerns,[38] these do not exist in isolation and may be a result of posttraumatic stress disorder or reactive attachment disorder. When children well adapted to a high-threat environment, such as an institution, attempt to integrate into a new world, as at school or on the playground, they may find themselves ill prepared.[39] Some school assignments may be problematic for children who have joined their family through adoption. Children who have lived in foster care or in another country may not have pictures of themselves from birth or at an early age. Family tree assignments may be difficult, because children may be unsure of how to demonstrate their relationship to their biological family, adoptive family, or foster families. Information about biological ancestors also may be unavailable to the child for such a project. Tracing genetic traits through generations may be difficult even for children who have an ongoing relationship with their biological families. For children adopted by an extended family member, these simple learning assignments may create anxiety by highlighting family differences.[4,36] Communication with educators about adoption issues at this age, as at other ages, may be necessary to help children deal with some of these difficult school assignments and insensitive comments about adoption, family circumstances, culture, race, and ethnicity.

As adolescence approaches, physical and mental changes are rapidly occurring.[40] Teenagers are developing the ability to do abstract thinking. Concepts like adoption may be internalized and could have gray areas instead of black or white. Adolescents might go through an intense period of self-reflection in an attempt to define

their identities, but as adolescents develop and begin the task of separation and individuation, adoption issues commonly become very important. This may widen the gap between the adoptee and the adoptive family. It is important for pediatricians to recognize that the consolidation of identity is not the same as an identity crisis, and pediatricians should neither over- nor underpathologize children and adolescents. Also, it is important to remember that identity development is not unique to adopted children, but it can add to its complexity. At 12 to 16 years of age, many adolescents become angry over the differences between their own life experiences and society's norm of an intact family. Adolescents may continue to fantasize about their "perfect" biological family and may look to identify with their perceived biological families even more. The teenager may try identities similar to those of their biological families, whether known or imagined, which may include changes in physical appearance, religion, and customs.[36] The adolescent may question parental views and authority of the adoptive parents and may partake in behaviors that may be out of character, such as engaging in risk-taking activities similar to those that may have led to their conception, including participating in unprotected sex. The adolescent may also take on other activities that played a part in the biological parent's (or parents') decision to make an adoption plan, such as substance abuse. These actions may be the teen's way of connecting to his perceived birth family; however, the adolescent may wish to avoid making similar mistakes as the biological parents. Although the adolescent may be fully committed to the adoptive family, he or she may have a heightened curiosity about the past and his or her biological family, creating a feeling of ambivalence. The teenager may feel a sense of betrayal to his or her adoptive family if this avenue is explored, but he or she needs to develop his or her own sense of belonging as well as a sense of autonomy. The adoptive family may fear the loss of the teen to the biological family, ultimately resulting in increased conflict. The conflicting emotions may be exacerbated as adolescents head toward emancipation from their family and as separation comes to the forefront. Both the child and the family may experience increased emotional uncertainty at the thought of moving away from the adoptive family and home.[36] The pediatrician can play a role in helping the adolescent and family by stressing the need to keep the lines of communication open. The pediatrician should be aware of available community resources, such as support groups and counselors, to help the family explore their feelings in a safe environment.

LOSSES IN ADOPTION

Although parents and children gain so much in becoming a part of an adoptive family, children who join their families through adoption often experience issues of loss relevant to adoption.[41] Although these feelings of loss may be more rooted in societal expectations of genetically based attachments rather than in any inherent biological loss, they nonetheless are experienced by many adopted people.[42]

All members of the adoption triad—the child, the adoptive family, and the biological family—are affected by the losses. Children in closed adoptions may lose the sense of their own original identity as well as ties to those with whom they share genetic links. Even children in open and kinship adoptions are aware of the way in which their families are different and will process their knowledge in different ways at different ages. Adoption may also represent loss to adoptive parents. Some adoptive parents have faced infertility, so they too may grieve the loss of genetic links to their child. In confidential adoptions, biological parents have an obvious loss of a relationship with the child they have conceived. Through understanding and acknowledgment of these losses, adoptive families, children, and biological families are able to adapt better and build healthier families.[43]

COMMUNICATING ABOUT ADOPTION WITH CHILDREN

Even before a child understands the words "adoption," "adopted," and "biological family" or "birth family," it is important that these words be a part of a family's natural conversation, whether the adoption is open or confidential, kinship, or foster-adoptive placement.[35,44] Families should be discouraged from "waiting until just the right minute" to tell children that they were adopted, because this may leave children feeling betrayed and wondering what else their parents may have hidden from them.[36] Children may also learn information from peers or neighbors, which may impair the trust between parent(s) and child. It is important to share with even young children their adoption story, starting with their birth, not the adoptive family's initiation of the adoption process.[36] An honest approach in the discussion of a child's biological family and the adoption process will give a child permission to ask questions or to make statements about adoption and, at the same time, will take away the veil of secrecy that often implies that being adopted is a negative condition.[32]

Some information in a child's past may be private or difficult for the parent to share with the child. The pediatrician,

potentially with the collaboration of a mental health specialist, may help the family decide how and when to disclose this information. Open discussion with a child is essential in building bridges of trust and security within a family, but it is also important that the discussion be framed with developmentally appropriate language. The family can be encouraged to present the information without judgmental comments or criticism. Even the most difficult information, such as previous sexual or physical abuse or having been conceived in the context of rape or incest, eventually may be shared with a child at a developmentally appropriate age.[36]

Some parents who have dealt with infertility may be uncomfortable with the reality that their child has another family—another set of parents.[37] Thus, issues of loss in the adoptive family may continue after the child is adopted into the family.[32] Avoidance of discussion about the biological family will deprive children of the opportunity to ask questions, openly fantasize, or understand having a family outside the one in which they live and may give children the perception that their thoughts and questions about adoption are bad.[36] It is important to tell a child that he or she was not "given up" but rather that the biological parents made an adoption plan in the best interest of the child's future and to the best of their abilities at the time. As children grow in their understanding of the relationship with their biological family, they may become concerned that just as they were "rejected" by their biological family, their adoptive family may also reject them.[32,36] Adoptive parents may need to verbalize their commitment to their child frequently. A "life book," a compilation of all (difficult and happy) that is known about a child's history, can be an effective tool for parents to use in helping a child to process all the thoughts and feelings about his or her adoption story. There may be an opportunity for the pediatrician to encourage families to develop rituals with their child to honor the birth parents, which may take the form of a celebration during holidays or the designation of a particular ornament or saying a special prayer to commensurate the birth family. Rituals like these allow adoptive children to acknowledge and remember their past but also to honor their adoption.

RACIAL, ETHNIC, AND CULTURAL DIFFERENCES

Children adopted by parents of a different race, ethnicity, or cultural background may have other concerns specific to their identities. Even children as young as 3 or 4 years of age will be aware of the physical differences between themselves and members of other racial groups.[45] When adopted children live in communities where they are members of an ethnic minority, the differences in racial identity will be easily apparent to classmates, other parents, and strangers. As these children enter preschool and elementary school, peers may ask questions about their biological and cultural heritage. As children reach the developmental stage of wanting to be just like their peers, these questions may provoke a variety of responses. Some of these responses might seem to the casual observer to be out of proportion for the information requested. Some remarks may be taunting or intrusive.[36] Children may encounter racist remarks for the first time, particularly in situations in which they are not physically or emotionally safeguarded by their parents.

Families need to acknowledge openly the racial differences that exist between their child and themselves. Relationships with others of the same race or ethnic group, including adults and children, may be very helpful to a child.[45] Whenever possible, an adopted child should be given the opportunity to learn more about the heritage of the country of his or her birth or of his or her ethnic group.[36,45] Role-playing with children with respect to stereotypes and racist statements may help them to feel in control when they encounter inevitable comments from strangers, friends, or extended family members.[43] Parents who have not experienced racism personally may need to pay extra attention to teaching their children effective ways to respond to racism.

ADOPTION BY SAME-SEX PARENTS

Although accurate statistics are unavailable, it is estimated that gay and lesbian parents are raising approximately 4% of all adopted children in the United States, accounting for approximately 65 500 adopted children.[46] Demographically, same-sex couples raising adopted children are typically older, more educated, and have more economic resources compared with other adoptive parents. Adopted children in this family composition are generally younger and more likely to be born outside the United States. Research on the subject of children raised by same-sex couples continues, primarily focusing on developmental outcomes, such as psychological adjustment, peer relationships, family relationships, and progress through school.[47] The AAP published a policy statement[48] and technical report[49] supporting coparent or second-parent adoption in 2002 and reaffirmed the policy statement in May 2009. The basis for the policy statement was to ensure the best interest of children living in this family structure, allowing legal stability for the child. The statement pointed out that children fare

better in a home in which parents, regardless of sexual identity, provided a caring, supportive, and secure home environment. After review of the literature, the AAP concluded that children who grow up with gay or lesbian parents do as well in emotional, cognitive, social, and sexual functioning as children who grow up with heterosexual parents. The pediatrician should be familiar with the existing professional literature and support families in their desire to parent children.

OPEN ADOPTION

Open adoption describes a continuum of communication between birth parents and the adoptive family. It may be restricted to the birth parents providing input into the selection of the adoptive parents, or it may describe regular communication between or face-to-face meetings with the adoptive parents, adopted child, or both.[5] Pediatricians should discuss with families the extent of communication between the adoptive family and the biological family and provide needed support by identifying potential and real benefits and drawbacks to the relationship. The adoptive parents may fear birth parents will interfere in the adoptive family's life. They may have concerns of their child's ability to bond within the adoptive family. Anxiety may arise about the parental authority for the child. These and other issues should be part of the routine visit, allowing parents an opportunity to express their concerns. Pediatricians should be knowledgeable about resources, including support groups, available within the community.

SPECIAL ISSUES IN KINSHIP ADOPTION

For children who are placed for adoption within their biological family, separation issues are lessened. At the same time, these relationships present particular challenges for a family. There may be a reluctance of other family members to confirm the adoptive parents as the child's actual parents, and reference may be made within the family setting to the child's "real" parents. Boundaries must be set regarding the type of contact, timing, and granting of parental responsibility to the biological parents. All family members may need to be reminded that the adoptive parent is the responsible parent. Family gatherings may provide particular challenges, especially in cases in which the biological parents' rights have been involuntarily terminated. Many kinship adopters have limited contact with support groups, and there may be a tendency to "keep it in the family," especially with respect to the open discussion of family secrets that led to the placement of the child with a family member. Grandparents who become adoptive parents may grieve the loss of the vision of their own children as parents, coping with the stresses of raising children again and dealing with the circumstances of the reason the child was placed with them.

It is important that pediatricians provide support to these families, particularly in the area of validating the adoptive parents' rights to make decisions for the child. Kinship adoptive parents may be reluctant to share with the child painful information involved in the circumstances leading to the separation from the biological parents. Failing to share the truth may increase the anxiety for the child. The biological parents and kinship adoptive parents must communicate about the sharing of information and what language will be used, keeping in mind the child's developmental stage. Support services and resources for families with a kinship adoptive placement, whether formal or informal, may be available, including local child welfare agencies, the Department on Aging's "Grandparents Raising Grandchildren," and other community resources, financial assistance, respite care, and services.[35]

DIFFICULT TIMES

"Anniversary reactions" often occur in adopted children at certain times of the year.[36] On Mother's Day, children may think about the many mothers they have had, including their adoptive mother, biological mother, and foster mothers. On birthdays and adoption days, children may seem depressed and withdrawn instead of joyful. These anniversaries may trigger thoughts of the biological family, and children may wonder whether their biological parents still love them or even think about them. Sensitivity, particularly at these significant times, may help a child in dealing with difficult adoption issues.

SEARCHING FOR BIOLOGICAL FAMILY AND CULTURAL TIES

As adopted children age into adolescence and adulthood, they may wish to seek out more information about their biological families.[41] Individuals who joined their families through international adoption may choose to make a trip to the country of their birth. Domestic adoptees may pursue reunification with biological relatives through a reunion registry, may choose to reestablish ties in a lapsed open adoption, or may develop a stronger interest in understanding kinship ties. Although some adoptive parents may view their child's searching for his or her biological family as a sign of rejection, it is actually a sign of healthy emotional growth in the search for an identity.[37] The experience of a reunion

with the biological family may be rewarding, but there may also be some pitfalls. In preparing for contact and reunion, adopted people (and birth parents) should prepare for a whole range of realities, including rejection by the biological parent(s) and family members. Pediatricians need to be aware of the feelings the adopted child may have after meeting a sibling—either one who is older and remained with the biological parent(s) or one who was born after the adopted child was placed. All members of the adoption triad may need the help of mental health professionals to work through these situations. Pediatricians are encouraged to become aware of local community resources for adoptive families, including resources for locating information about biological families, support groups, adoption conferences and services, and mental health professionals.

MODELING POSITIVE ADOPTION LANGUAGE

Pediatricians are encouraged to model positive adoption language for all families.[44] Adoptive families are "real" families; siblings who joined a family through adoption are "real siblings." Biological parents do not "give up a child for adoption," which might imply to the child that he or she was of less worth and was given away. Rather, they "make an adoption plan for a child." A biological mother should not be identified as a "natural parent," because this implies that adoptive families are "unnatural." A child's racial identity, adoption, or birth in another country should never be the identifying characteristics for any child. It is never appropriate to ask how much a child "cost." In modeling positive adoption language, pediatricians can use vocabulary that reflects respect and permanency about children and their families.[36]

As more children each year become part of permanent families through adoption, it is becoming increasingly important for pediatricians to be aware of and knowledgeable about adoption. Pediatricians play an important role in helping families deal with the differences, the losses, and the many other issues surrounding the adoption of a child. Pediatricians are encouraged to have a greater understanding about adoption to be able to advise and support parents as they communicate about adoption with their children. It is also important for pediatricians to remind families of the importance of forthright communication about adoption. Open acknowledgment of the adoptive relationship helps to nurture a child's self-esteem as he or she grows in the understanding of what it means to join a family through adoption. Effective communication about adoption is important for the long-term mental and physical health and well-being of each child and family.

abstract

FREE

This statement presents the position of the American Academy of Pediatrics on pesticides. Pesticides are a collective term for chemicals intended to kill unwanted insects, plants, molds, and rodents. Children encounter pesticides daily and have unique susceptibilities to their potential toxicity. Acute poisoning risks are clear, and understanding of chronic health implications from both acute and chronic exposure are emerging. Epidemiologic evidence demonstrates associations between early life exposure to pesticides and pediatric cancers, decreased cognitive function, and behavioral problems. Related animal toxicology studies provide supportive biological plausibility for these findings. Recognizing and reducing problematic exposures will require attention to current inadequacies in medical training, public health tracking, and regulatory action on pesticides. Ongoing research describing toxicologic vulnerabilities and exposure factors across the life span are needed to inform regulatory needs and appropriate interventions. Policies that promote integrated pest management, comprehensive pesticide labeling, and marketing practices that incorporate child health considerations will enhance safe use. *Pediatrics* 2012;130:e1757–e1763

INTRODUCTION

Pesticides represent a large group of products designed to kill or harm living organisms from insects to rodents to unwanted plants or animals (eg, rodents), making them inherently toxic (Table 1). Beyond acute poisoning, the influences of low-level exposures on child health are of increasing concern. This policy statement presents the position of the American Academy of Pediatrics on exposure to these products. It was developed in conjunction with a technical report that provides a thorough review of topics presented here: steps that pediatricians should take to identify pesticide poisoning, evaluate patients for pesticide-related illness, provide appropriate treatment, and prevent unnecessary exposure and poisoning.[1] Recommendations for a regulatory agenda are provided as well, recognizing the role of federal agencies in ensuring the safety of children while balancing the positive attributes of pesticides. Repellents reviewed previously (eg, N,N-diethyl-meta-toluamide, commonly known as DEET; picaridin) are not discussed.[2]

SOURCES AND MECHANISMS OF EXPOSURE

Children encounter pesticides daily in air, food, dust, and soil and on surfaces through home and public lawn or garden application, household insecticide use, application to pets, and agricultural product

TABLE 1 Categories of Pesticides and Major Classes

Pesticide category	Major Classes	Examples
Insecticides	Organophosphates	Malathion, methyl parathion, acephate
	Carbamates	Aldicarb, carbaryl, methomyl, propoxur
	Pyrethroids/pyrethrins	Cypermethrin, fenvalerate, permethrin
	Organochlorines	Lindane
	Neonicotinoids	Imidacloprid
	N-phenylpyrazoles	Fipronil
Herbicides	Phosphonates	Glyphosate
	Chlorophenoxy herbicides	2,4-D, mecoprop
	Dipyridyl herbicides	Diquat, paraquat
	Nonselective	Sodium chlorate
Rodenticides	Anticoagulants	Warfarin, brodifacoum
	Convulsants	Strychnine
	Metabolic poison	Sodium fluoroacetate
	Inorganic compounds	Aluminum phosphide
Fungicides	Thiocarbamates	Metam-sodium
	Triazoles	Fluconazole, myclobutanil, triadimefon
	Strobilurins	Pyraclostrobin, picoxystrobin
Fumigants	Halogenated organic	Methyl bromide, Chloropicrin
	Organic	Carbon disulfide, Hydrogen cyanide, Naphthalene
	Inorganic	Phosphine
Miscellaneous	Arsenicals	Lead arsenate, chromated copper arsenate, arsenic trioxide
	Pyridine	4-aminopyridine

residues.[3–9] For many children, diet may be the most influential source, as illustrated by an intervention study that placed children on an organic diet (produced without pesticide) and observed drastic and immediate decrease in urinary excretion of pesticide metabolites.[10] In agricultural settings, pesticide spray drift is important for residences near treated crops or by take-home exposure on clothing and footwear of agricultural workers.[9,11,12] Teen workers may have occupational exposures on the farm or in lawn care.[13–15] Heavy use of pesticides may also occur in urban pest control.[16]

Most serious acute poisoning occurs after unintentional ingestion, although poisoning may also follow inhalational exposure (particularly from fumigants) or significant dermal exposure.[17]

ACUTE PESTICIDE TOXICITY

Clinical Signs and Symptoms

High-dose pesticide exposure may result in immediate, devastating, even lethal consequences. Table 2 summarizes features of clinical toxicity for the major pesticides classes. It highlights the similarities of common classes of pesticides (eg, organophosphates, carbamates, and pyrethroids) and underscores the importance of discriminating among them because treatment modalities differ. Having an index of suspicion based on familiarity with toxic mechanisms and taking an environmental history provides the opportunity for discerning a pesticide's role in clinical decision-making.[18] Pediatric care providers have a poor track record for recognition of acute pesticide poisoning.[19–21] This reflects their self-reported lack of medical education and self-efficacy on the topic.[22–26] More in-depth review of acute toxicity and management can be found in the accompanying technical report or recommended resources in Table 3.

The local or regional poison control center plays an important role as a resource for any suspected pesticide poisoning.

There is no current reliable way to determine the incidence of pesticide exposure and illness in US children. Existing data systems, such as the American Association of Poison Control Centers' National Poison Data System or the National Institute for Occupational Safety and Health's Sentinel Event Notification System for Occupational Risks,[27,28] capture limited information about acute poisoning and trends over time.

There is also no national systematic reporting on the use of pesticides by consumers or licensed professionals. The last national survey of consumer pesticide use in homes and gardens was in 1993 (Research Triangle Institute study).[29]

Improved physician education, accessible and reliable biomarkers, and better diagnostic testing methods to readily identify suspected pesticide illness would significantly improve reporting and surveillance. Such tools would be equally important in improving clinical decision-making and reassuring families if pesticides can be eliminated from the differential diagnosis.

The Pesticide Label

The pesticide label contains information for understanding and preventing acute health consequences: the active ingredient; signal words identifying acute toxicity potential; US Environmental Protection Agency (EPA) registration number; directions for use, including protective equipment recommendations, storage, and disposal; and manufacturer's contact information.[30] Basic first aid advice is provided, and some labels contain a "note for physicians" with specific relevant medical information. The label does not specify the pesticide class or "other"/"inert" ingredients that may have significant toxicity and can account for up to 99% of the product.

Chronic toxicity information is not included, and labels are predominantly available in English. There is significant use of illegal pesticides (especially in immigrant communities), off-label use, and overuse, underscoring the importance of education, monitoring, and enforcement.[31]

TABLE 2 Common Pesticides: Signs, Symptoms, and Management Considerations[a]

Class	Acute Signs and Symptoms	Clinical Considerations
Organophosphate and N-methyl carbamate insecticides	• Headache, nausea, vomiting, abdominal pain, and dizziness • Hypersecretion: sweating, salivation, lacrimation, rhinorrhea, diarrhea, and bronchorrhea • Muscle fasciculation and weakness, and respiratory symptoms (bronchospasm, cough, wheezing, and respiratory depression) • Bradycardia, although early on, tachycardia may be present • Miosis • Central nervous system: respiratory depression, lethargy, coma, and seizures	• Obtain red blood cell and plasma cholinesterase levels • Atropine is primary antidote • Pralidoxime is also an antidote for organophosphate and acts as a cholinesterase reactivator • Because carbamates generally produce a reversible cholinesterase inhibition, pralidoxime is not indicated in these poisonings
Pyrethroid insecticides	• Similar findings found in organophosphates including the hypersecretion, muscle fasciculation, respiratory symptoms, and seizures • Headache, fatigue, vomiting, diarrhea, and irritability • Dermal: skin irritation and paresthesia	• At times have been mistaken for acute organophosphate or carbamate poisoning • Symptomatic treatment • Treatment with high doses of atropine may yield significant adverse results • Vitamin E oil for dermal symptoms
Neonicotinoid insecticides	• Disorientation, severe agitation, drowsiness, dizziness, weakness, and in some situations, loss of consciousness • Vomiting, sore throat, abdominal pain • Ulcerations in upper gastrointestinal tract	• Supportive care • Consider sedation for severe agitation • No available antidote • No available diagnostic test
Fipronil (N-phenylpyrazole insecticides)	• Nausea and vomiting • Aphthous ulcers • Altered mental status and coma • Seizures	• Supportive care • No available antidote • No available diagnostic test
Lindane (organochlorine insecticide)	• Central nervous system: mental status changes and seizures • Paresthesia, tremor, ataxia and hyperreflexia	• Control acute seizures with lorazepam • Lindane blood level available as send out
Glyphosate (phosphonate herbicides)	• Nausea and vomiting • Aspiration pneumonia type syndrome • Hypotension, altered mental status, and oliguria in severe cases • Pulmonary effects may in fact be secondary to organic solvent	• Supportive care • Pulmonary effects may be secondary to organic solvent
Chlorophenoxy herbicides	• Skin and mucous membrane irritation • Vomiting, diarrhea, headache, confusion • Metabolic acidosis is the hallmark • Renal failure, hyperkalemia, and hypocalcemia • Probable carcinogen	• Consider urine alkalinization with sodium bicarbonate in IV fluids
Rodenticides (long-acting anticoagulants)	• Bleeding: gums, nose, and other mucous membrane sites • Bruising	• Consider PT (international normalized ratio) • Observation may be appropriate for some clinical scenarios in which it is not clear a child even ingested the agent • Vitamin K indicated for active bleeding (IV vitamin K) or for elevated PT (oral vitamin K)

IV, intravenous; PT, prothrombin time.

[a] Expanded version of this table is available in the accompanying technical report.[1]

CHRONIC EFFECTS

Dosing experiments in animals clearly demonstrate the acute and chronic toxicity potential of multiple pesticides. Many pesticide chemicals are classified by the US EPA as carcinogens. The past decade has seen an expansion of the epidemiologic evidence base supporting adverse effects after acute and chronic pesticide exposure in children. This includes increasingly sophisticated studies addressing combined exposures and genetic susceptibility.[1]

Chronic toxicity end points identified in epidemiologic studies include adverse birth outcomes including preterm birth, low birth weight, and congenital

anomalies, pediatric cancers, neurobehavioral and cognitive deficits, and asthma. These are reviewed in the accompanying technical report. The evidence base is most robust for associations to pediatric cancer and adverse neurodevelopment. Multiple case-control studies and evidence reviews support a role for insecticides in risk of brain tumors and acute lymphocytic leukemia. Prospective contemporary birth cohort studies in the United States link early-life exposure to organophosphate insecticides with reductions in IQ and abnormal behaviors associated with attention-deficit/hyperactivity disorder and autism. The need to better understand the health implications of ongoing pesticide use practices on child health has benefited from these observational epidemiologic data.[32]

EXPOSURE PREVENTION APPROACHES

The concerning and expanding evidence base of chronic health consequences of pesticide exposure underscores the importance of efforts aimed at decreasing exposure.

Integrated pest management (IPM) is an established but undersupported approach to pest control designed to minimize and, in some cases, replace the use of pesticide chemicals while achieving acceptable control of pest populations.[33] IPM programs and knowledge have been implemented in agriculture and to address weeds and pest control in residential settings and schools, commercial structures, lawn and turf, and community gardens. Reliable resources are available from the US EPA and University of California—Davis (Table 3). Other local policy approaches in use are posting warning signs of pesticide use, restricting spray zone buffers at schools, or restricting specific types of pesticide products in schools. Pediatricians can

play a role in promotion of development of model programs and practices in the communities and schools of their patients.

RECOMMENDATIONS

Three overarching principles can be identified: (1) pesticide exposures are common and cause both acute and chronic effects; (2) pediatricians need to be knowledgeable in pesticide identification, counseling, and management; and (3) governmental actions to improve pesticide safety are needed. Whenever new public policy is developed or existing policy is revised, the wide range of consequences of pesticide use on children and their families should be considered. The American Academy of Pediatrics, through its chapters, committees, councils, sections, and staff, can provide information and support for public policy advocacy efforts. See http://www.aap.org/advocacy.html for additional information or contact chapter leadership.

Recommendations to Pediatricians

1. Acute exposures: become familiar with the clinical signs and symptoms of acute intoxication from the major types of pesticides. Be able to translate clinical knowledge about pesticide hazards into an appropriate exposure history for pesticide poisoning.
2. Chronic exposures: become familiar with the subclinical effects of chronic exposures and routes of exposures from the major types of pesticides.
3. Resource identification: know locally available resources for acute toxicity management and chronic low-dose exposure (see Table 3).
4. Pesticide labeling knowledge: Understand the usefulness and limitations of pesticide chemical information on pesticide product labels.
5. Counseling: Ask parents about pesticide use in or around the home to help determine the need for providing targeted anticipatory guidance. Recommend use of minimal-risk products, safe storage practices, and application of IPM (least toxic methods), whenever possible.
6. Advocacy: work with schools and governmental agencies to advocate for application of least toxic pesticides by using IPM principles. Promote community right-to-know procedures when pesticide spraying occurs in public areas.

Recommendations to Government

1. Marketing: ensure that pesticide products as marketed are not attractive to children.
2. Labeling: include chemical ingredient identity on the label and/or the manufacturer's Web site for all product constituents, including inert ingredients, carriers, and solvents. Include a label section specific to "Risks to children," which informs users whether there is evidence that the active or inert ingredients have any known chronic or developmental health concerns for children. Enforce labeling practices that ensure users have adequate information on product contents, acute and chronic toxicity potential, and emergency information. Consider printing or making available labels in Spanish in addition to English.
3. Exposure reduction: set goal to reduce exposure overall. Promote application methods and practices that minimize children's exposure, such as using bait stations and gels, advising against overuse of pediculicides. Promote education regarding proper storage of product.
4. Reporting: make pesticide-related suspected poisoning universally reportable and support a systematic central repository of such incidents to optimize national surveillance.
5. Exportation: aid in identification of least toxic alternatives to pesticide use internationally, and unless safer alternatives are not available or are impossible to implement, ban export of products that are banned or restricted for toxicity concerns in the United States.
6. Safety: continue to evaluate pesticide safety. Enforce community right-to-know procedures when pesticide spraying occurs in public areas. Develop, strengthen, and enforce standards of removal of concerning products for home or child product use. Require development of a human biomarker, such as a urinary or blood measure, that can be used to identify exposure and/or early health implications with new pesticide chemical registration or reregistration of existing products. Developmental toxicity, including endocrine disruption, should be a priority when evaluating new chemicals for licensing or reregistration of existing products.
7. Advance less toxic pesticide alternatives: increase economic incentives for growers who adopt IPM, including less toxic pesticides. Support research to expand and improve IPM in agriculture and nonagricultural pest control.
8. Research: support toxicologic and epidemiologic research to better identify and understand health risks associated with children's exposure to pesticides. Consider supporting another national study of pesticide use in the home and garden setting of US households as a targeted initiative or through cooperation with existing research opportunities (eg, National Children's Study, NHANES).
9. Health provider education and support: support educational efforts to increase the capacity of pediatric health care providers to diagnose and manage acute pesticide

poisoning and reduce pesticide exposure and potential chronic pesticide effects in children. Provide support to systems such as Poison Control Centers to provide timely, expert advice on exposures. Require the development of diagnostic tests to assist providers with diagnosing (and ruling out) pesticide poisoning.

abstract

FREE

Pesticides are a collective term for a wide array of chemicals intended to kill unwanted insects, plants, molds, and rodents. Food, water, and treatment in the home, yard, and school are all potential sources of children's exposure. Exposures to pesticides may be overt or subacute, and effects range from acute to chronic toxicity. In 2008, pesticides were the ninth most common substance reported to poison control centers, and approximately 45% of all reports of pesticide poisoning were for children. Organophosphate and carbamate poisoning are perhaps the most widely known acute poisoning syndromes, can be diagnosed by depressed red blood cell cholinesterase levels, and have available antidotal therapy. However, numerous other pesticides that may cause acute toxicity, such as pyrethroid and neonicotinoid insecticides, herbicides, fungicides, and rodenticides, also have specific toxic effects; recognition of these effects may help identify acute exposures. Evidence is increasingly emerging about chronic health implications from both acute and chronic exposure. A growing body of epidemiological evidence demonstrates associations between parental use of pesticides, particularly insecticides, with acute lymphocytic leukemia and brain tumors. Prenatal, household, and occupational exposures (maternal and paternal) appear to be the largest risks. Prospective cohort studies link early-life exposure to organophosphates and organochlorine pesticides (primarily DDT) with adverse effects on neurodevelopment and behavior. Among the findings associated with increased pesticide levels are poorer mental development by using the Bayley index and increased scores on measures assessing pervasive developmental disorder, inattention, and attention-deficit/hyperactivity disorder. Related animal toxicology studies provide supportive biological plausibility for these findings. Additional data suggest that there may also be an association between parental pesticide use and adverse birth outcomes including physical birth defects, low birth weight, and fetal death, although the data are less robust than for cancer and neurodevelopmental effects. Children's exposures to pesticides should be limited as much as possible. *Pediatrics* 2012;130:e1765–e1788

INTRODUCTION

Pesticides represent a broad classification of chemicals that are applied to kill or control insects, unwanted plants, molds, or unwanted animals (eg, rodents). "Pesticide" is a collective term for a wide array of products but is often inappropriately used in reference to only insecticides. The universe of pesticide types and products is broad, and

a comprehensive review of all active ingredients is beyond the scope of this report. This review focuses on select insecticides, herbicides, and rodenticides and specific chemical classes within these groups that have the greatest acute and chronic toxicity for children on the basis of historical experience and/or emerging evidence (Table 1).

Several types of pesticides are not discussed in this report. Fumigants and fungicides, although potentially toxic, are less commonly involved in acute childhood exposure and poisoning, in general, so these are not included. Wood preservatives containing arsenic are also not included in this report. The specific compound containing arsenic, copper chromium arsenate, has been removed from the market since January 2004. Older wood structures treated with copper chromium arsenate may still be found in homes, on playgrounds, and in yards and should be treated yearly with a waterproof sealant.[1] Insect repellents, including *N, N*-diethyl-meta-toluamide and picaridin, are different from most pesticides in that they are a product purposefully applied to human skin to prevent insect bites and are, in fact, not insecticides. These compounds are unique and have been reviewed recently.[2]

Although the severity of pesticide exposures and toxicity may be greater in developing countries where regulatory oversight and information is limited, the content of this technical report is oriented toward exposures most relevant to children residing in the United States. Commonly used insecticides, including the organophosphates (OPs), carbamate, and pyrethroid classes, are discussed, as are the relatively new neonicotinoids. Other pesticides that will be discussed in some detail include the phosphonate herbicides (eg, glyphosate), chlorophenoxy herbicides, and long-acting anticoagulants (rodenticides). For a more comprehensive survey of the acute toxicity from the spectrum of pesticide active ingredients and products, see other sources.[1,3]

CHILDREN'S EXPOSURE: VULNERABILITY, MECHANISMS, AND SOURCES OF EXPOSURE

Children's Unique Vulnerabilities

Children are uniquely vulnerable to uptake and adverse effects of pesticides because of developmental, dietary, and physiologic factors. Exposure occurs through ingestion, inhalation, or dermal contact. Unintentional ingestion by children may be at a considerably higher dose than an adult because of the greater intake of food or fluids per pound of body weight. Children exhibit frequent hand-to-mouth activity, and this is an important source of increased exposure in comparison with adults.[4,5]

Residential Factors

Fortunately, acute toxicity attributable to pesticide poisoning is relatively uncommon in US children, and a pediatrician in general practice may not encounter such an event. However, subacute and chronic low-level exposure is common. Residential factors that influence chronic exposure include the use of insecticides and rodenticides in the home, and herbicide and fungicide use on lawns, as well. Indoors, broadcast applications including sprays, "flea bombs," and foggers can leave lingering residues in the air, carpet, toys, and house dust.[6–9] Typical exploratory behavior, including playing on and crawling across the floor, increases the risk of dermal, inhalation, and oral exposure to residues on surfaces or the air as it settles.[10] Repeated and cumulative incidental exposure can also occur. Pesticides can be measured in indoor air samples and persist in dust vacuumed from carpeted areas, upholstered objects, and children's toys, such as stuffed animals, and can also be brought home from the workplace.[11–14] Herbicides applied on the lawn or garden can be tracked into the home, with residues building up over time.[15] Applications of diazinon to lawns have been demonstrated to be carried indoors via the paws of pet dogs.[16] Residential pesticide residue levels also vary geographically according to the specific pesticide needs in the area. In Los Angeles, high levels of chlorpyrifos and other insecticides were found because of the large numbers of crawling insects, fleas, and termites. Conversely, in Iowa, there were high levels of the herbicides 2,4-dichlorophenoxyacetic acid (2,4-D) and dicamba because of weed-control applications.[17]

Residentially related sources may be relevant in other settings where children spend time, including school, child care, a relative's home, etc, depending on indoor and outdoor pesticide use patterns and proximity to pesticide use. In a North Carolina study of 142 urban homes and preschools, chlorpyrifos was detected in all indoor air and dust samples.[18]

Biomonitoring Data for Exposure Assessment

The Centers for Disease Control and Prevention (CDC) conducts a population-based biomonitoring program associated with the NHANES.[19] The most recent report includes biomarker data for many organochlorine, OP, and carbamate insecticides; herbicides; pyrethroid insecticides; and some other pesticides. Testing of 44 pesticide metabolites revealed that 29 were detectable in most people from whom samples were analyzed (ages 6–59 years), with OP and organochlorine insecticides reported to be most prevalent in the US population.[19] Although the health implications of these "snapshot" sampling data are largely unknown, they do

TABLE 1 Major Pesticide Classes and Selected Examples

Pesticide Class	Examples	Toxicity	Comment, Uses
Organochlorines	DDT, endrin, aldrin, chlordane, lindane	• High toxicity	• Many organochlorines now banned in the United States • Lindane has been banned in California, elsewhere used for control of lice and scabies • DDT and other organochlorines have long metabolic disposition and are stored in fatty tissues and can persist in the environment
Organophosphates	Parathion, chlorpyrifos, dichlorvos, acephate, methyl-parathion, malathion, phorate	• Most OPs are highly toxic • Malathion is considered relatively less toxic than other OPs	• Parathion is banned for use in the United States • Chlorpyrifos is no longer approved for residential use • Most others are used for insect control in both agricultural and home settings • Malathion is an approved treatment of head lice
N-Methyl carbamates	Aldicarb, carbaryl, carbofuran, pirimicarb, propoxur	• Aldicarb and carbaryl are both highly toxic • Other carbamates have a relatively moderate toxicity	• Insect control in agricultural and home settings
Pyrethrins and pyrethroids	Permethrin, cyano-pyrethroids: deltamethrin, cypermethrin, fenvalerate	• Permethrin has relatively low toxicity • Other pyrethroids have moderate toxicity	• Permethrin is a common pediculicide • Most other pyrethroids are commonly used to control insects, often used in home and garden
Neonicotinoids	Imidacloprid	• Relatively newer class of insecticides	• Selective affinity toward insect nicotinic acetylcholine receptors compared with mammalian nicotinic acetylcholine receptors
		• Have relatively lower toxicity than OPs and carbamates	• Often used as spot-on flea control for domestic animals
N-Phenylpyrazole insecticides	Fipronil	• Relatively newer class of insecticides	• Often used as spot-on flea control for domestic animals • Yard treatments for insect control
Phosphonate herbicides	Glyphosate	• Because of primary mechanism of action, has relatively low toxicity from active ingredient. • Toxicity often due to the accompanying organic solvent	• Acts on plant cell wall • Commercially available in many products
Chlorophenoxy herbicides	2,4-D, 2,4,5-T	• Moderate toxicity	• Weed control
Dipyridyl herbicides	Paraquat, diquat	• Highly toxic	• Infrequently used • Paraquat toxicity often requires lung transplant
Long-acting anticoagulants	Brodifacoum (superwarfarins)		• Rodenticides • Longer-acting than warfarin • Recently eliminated packaging as loose pellets

2,4,5-T, 2,4,5-trichlorophenoxy acetic acid.

provide a reference point on pesticide metabolite distributions. Periodic reassessment also allows for evaluations of population-level exposure trends.

As noted previously, children's unique behaviors and metabolic rate often place them at risk for absorption of higher doses from contaminated environments in comparison with adults. One example evident from the biomonitoring data is chlorpyrifos, a nonpersistent OP insecticide. Although banned in 2000 for use inside the home, it continues to be used in agriculture, including orchard fruits, such as apples and pears, and other dietary staples of children. In the CDC biomonitoring data, chlorpyrifos-specific urinary metabolites were highest for the youngest age group assessed (6–11 years) compared with older children and adults.[19] In contrast, biomonitoring of serum markers of organochlorine insecticides and their metabolites, such as DDT, dieldrin, and chlordane, many of which were banned from use in the United States in the 1970s and 1980s, revealed lower concentrations in the youngest age group monitored (12–19 years). Despite relatively lower concentrations, the ongoing detection and the higher levels with increasing age likely reflect the influence of the accumulation of these fat-soluble, persistent compounds over a lifetime.

Exposures From the Food Supply

In the general population, the food supply represents the most important source of exposure for organochlorines and OPs. For pyrethroids, both food residues and household pest control products are important sources.[20] The US Environmental Protection Agency (EPA) regulates exposure to pesticides in food by setting "tolerances," which are the maximum amount of pesticides that may legally remain in or on food

and animal feed. The US Food and Drug Administration is responsible for enforcement of these tolerances, which includes a modest monitoring program, which analyzed 7234 total samples in 2003. Among the domestically produced samples, 49% of fruit, 29% of vegetables, 26% of grain products, 24% of fish/shellfish, and 0% of milk/dairy tested had detectable but legally allowable pesticide residues. Only fruit and vegetables had residues above the legal tolerance (approximately 2% each). Overall, the detection of residues in the samples from imported fruits and vegetables tested were less, but the exceedances of legal tolerances were greater (5%–7% of imported fruits/vegetables sampled).[21] Consumption of organic food may lower pesticide exposure, as demonstrated by a study in which children were placed on an organic diet for a period of 5 consecutive days. A rapid and dramatic drop in their urinary excretion of metabolites of malathion and chlorpyrifos OP insecticides during the organic diet phase was observed.[22]

Agriculturally Related Exposures

Proximity to pesticide-treated agricultural areas or household members that work with pesticides presents another opportunity for contamination of the residential environment for some children. In a Washington State study of children of agricultural workers and nonagricultural workers in an agricultural setting, pesticide levels in carpet dust and pesticide metabolites in urine of residents increased with self-reported proximity of homes to orchard fields and during the pesticide application season.[9,23] Similarly, in an agriculture center in California, pesticide residues of 3 chemicals used recently on crops were significantly correlated with house dust samples in nearby homes and urine samples among their inhabitants. The findings were noted in both farmworkers and nonfarmworkers.[24] The presence of an agricultural worker in the home also increases pesticide levels through "take-home" exposures.[23] Children living on a farm had higher urinary pesticide metabolite levels than children not living on a farm.[25] Children themselves may participate in agricultural work that involves the use of pesticides or contact with pesticide-treated foliage.[26–28]

Exposures From Drinking Water

Contamination of drinking water presents another potential source of exposure, particularly for herbicides. A 10-year study (1992–2001) by the US Geological Survey's National Water-Quality Assessment program provided a national-scale view of pesticide occurrence in streams and groundwater. Overall, pesticides were detected in more than 50% of sampled wells from shallow groundwater tapped beneath agricultural and urban areas as well as in 33% of the deeper wells that tap major aquifers used for water supply. The concentrations associated with these detections rarely exceeded water quality health reference levels (approximately 1% of the 2356 domestic and 364 public-supply wells that were sampled). Herbicides, particularly the triazine class, were the most frequently detected pesticide group in agricultural areas. (It should be noted that atrazine and other triazine herbicides were monitored from surface water.) In urban areas, both herbicides and insecticides (particularly diazinon and carbaryl) were frequently detected. The greatest proportion of wells exceeding a health reference level was for those tapping shallow groundwater beneath urban areas. It is noteworthy that the detection of pesticides usually occurred as mixtures, and health reference levels reflected exposure to a single agent.[29]

NATIONAL DATA ON ACUTE EXPOSURE, MORBIDITY, AND MORTALITY

Although some states (eg, California and Washington) mandate the reporting of pesticide-related illness, there is no national surveillance system for pesticide exposure and poisoning. The American Association of Poison Control Centers' National Poison Data System (NPDS [formerly known as the Toxic Exposure Surveillance System]) compiles annual data on pesticide exposures. Incidents reported by the NPDS are categorized by age (<6 years, 6–19 years, and >19 years), reason (unintentional, intentional, other, adverse reaction), and outcome (none [no morbidity], minor, moderate, major, or death). However, these data represent self-reports from patients and/or family members and calls from medical treatment facilities. Although they are useful to describe trends, they do not indicate true prevalence or incidence. Data are reported annually and, since 2005, have been published in *Clinical Toxicology*.[30]

In 2009, pesticides were the tenth most frequently involved substance in human exposure (3.9% of all NPDS reports) and the ninth most common substance encountered in children (3.3% of pediatric NPDS reports). Nearly 55.8% of all single-substance pesticide exposures involved children ≤19 years of age, and 94% of all pesticide ingestions were unintentional. Twenty-one of the reports from pesticide exposure resulted in death; however, these were not categorized by age.[30] Rates (calculated by using US census data for the catchment area served by the poison control center as the denominator) of reported pesticide poisonings described as moderate, major, and fatal declined from 1995 to 2004 by approximately 42%. The sharpest declines in poisonings were from OP and carbamate insecticides,

likely reflecting EPA regulatory action to discontinue residential use of several previously widely available OP and carbamate insecticides on the basis of child health concerns.[31]

ACUTE TOXICITY MECHANISMS AND CLINICAL MANIFESTATIONS

OP and Carbamate Insecticides

OP and carbamates insecticides have been widely used for insect control in the home and in agriculture since the 1960s. During this period, OP and carbamates usage largely replaced the use of organochlorines because of environmental and human health concerns of the latter class. In the past 10 years, chemical products in the OP and carbamate group have come under scrutiny, with subsequent regulatory action based on human health concerns. Examples include 2 commonly used OPs with high acute toxicity: parathion (banned) and chlorpyrifos (no longer allowed for residential use). Other OPs that remain widely used include dichlorvos, acephate, methyl-parathion, and malathion. Malathion has relatively lower acute toxicity among the OPs and is registered for the treatment of head lice (Ovide). A well-known example of a carbamate is aldicarb, although use has largely been curtailed by regulatory action because of its high toxicity. Commonly used carbamates include carbaryl and pirimicarb.[1,3]

Toxicity, Clinical Signs, and Symptoms

OPs and carbamates exert a common mechanism of action by inhibiting the acetylcholinesterase enzyme, thereby producing accumulation of acetylcholine at the synapses, neuromuscular junction, and end organs, which results in excessive stimulation at those sites. The reaction is generally an irreversible binding by OPs and a reversible binding by carbamates, and it influences treatment approaches for each class of insecticides. Consequently, acute poisoning by OPs tends to be more severe and refractory than that of carbamates; however, variations are observed in each class. There are some notable carbamates (such as aldicarb) that have equal if not greater toxicity than some OPs.[1,3]

Acute clinical manifestations reflect the development of cholinergic crisis and can arise from stimulation of muscarinic, nicotinic, and/or central nervous system receptors (Table 2). Early findings can often mimic a flu-like illness and include hypersecretion. Miosis is a helpful diagnostic sign. The classic cardiovascular sign is bradycardia, although early on, tachycardia may be present initially because of nicotinic stimulation. Progressive symptoms lead to muscle and respiratory problems. The central nervous system may also be affected, signifying severe poisoning, particularly in children.[1,3,32–34] Reviews of case series indicate that between 20% and 30% will have seizures, and between 50% and 100% of children will have lethargy, stupor, or coma.[32–34] A high clinical suspicion plus directed and persistent environmental history taking to identify potential exposures are necessary to identify these poisonings. Reviews of pediatric poisonings note that, historically, most children were transferred to a referral center with the wrong preliminary diagnosis and parents initially denied any exposure history.[33,34]

Laboratory Evaluation and Treatment

Poisoning with OPs and carbamates can be detected on the basis of clinical findings and history of exposure. Laboratory confirmation can assist in the diagnosis by using red blood cell and plasma cholinesterase levels; both are typically depressed with acute poisoning, although there is some variation among active ingredients as well as variation in levels by severity of poisoning.[35] Measurement techniques and resultant levels vary among laboratories; therefore, clinicians will need to check with their own laboratory for reference values. Red blood cell cholinesterase levels typically are more specific for acute poisoning and will be depressed longer than plasma cholinesterase levels (often 1–3 months) until enzyme is replaced.[3] Interpretation of results can be discussed with a pediatric environmental health specialist or clinical toxicologist.

The parent active ingredient cannot typically be measured in biological specimens. These compounds undergo metabolic transformation in the liver and are excreted in the urine mostly in their metabolized form, most of which are nonspecific metabolites for all OPs.[19] Exceptions include parathion, methyl-parathion, and chlorpyrifos, all of which have their own specific metabolite in addition to the nonspecific metabolites. Urinary metabolites can be measured, and human data are available from the CDC on a nationally representative sample.[19] However, an evidence base to support clinical interpretation of urinary concentrations is lacking.

Treatment of OP poisoning (and this applies to the acute treatment of any other pesticide as well) begins with the basics of advanced life support, with any necessary airway or breathing support as needed. Gastrointestinal (GI) decontamination is controversial. The American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists issued a joint statement on the use of single-dose charcoal for poisoned patients (inclusive of all types of poisonings). They stated that activated charcoal is most effective when given within 1 hour after the ingestion of a poison, but routine administration in all poisonings is not recommended.

TABLE 2 Clinical Signs and Symptoms

Class of Compounds	Signs and Symptoms	Special Notes, Laboratory Evaluations, Specific Treatments, or Antidote
Organophosphate and carbamate insecticides	• Nonspecific early symptoms: headache, nausea, vomiting, abdominal pain, and dizziness	• Red blood cell and plasma cholinesterase levels
	• Sometimes hypersecretion: sweating, salivation, lacrimation, rhinorrhea, diarrhea, and bronchorrhea	• Measure nonspecific metabolites for most OPs
	• Progressive symptoms: muscle fasciculation, muscle weakness, and respiratory symptoms (bronchospasm, cough, wheezing, and respiratory depression)	• Specific metabolites can be measured for chlorpyrifos and parathion
	• Bradycardia is typical, although early in acute poisoning, tachycardia may be present	• Atropine is primary antidote
	• Miosis	• Pralidoxime is also an antidote for OP and acts as a cholinesterase reactivator
	• Central nervous system: respiratory depression, lethargy, coma, and seizures	• Because carbamates generally produce a reversible cholinesterase inhibition, pralidoxime is not indicated in these poisonings
Pyrethroids	• Dermal: skin irritation and paresthesia	• At times have been mistaken for acute OP or carbamate poisoning and treated with atropine with potentially adverse or disastrous results
	• Nonspecific symptoms including headache, fatigue, vomiting, diarrhea, and irritability	• Symptomatic treatment
	• Similar findings found in OPs, including hypersecretion, muscle fasciculation, pulmonary symptoms and seizures	• Vitamin E oil for dermal symptoms
Neonicotinoids	• Disorientation, agitation—severe enough to require sedation, drowsiness, dizziness, weakness, and, in some situations, loss of consciousness	• Supportive care
	• Vomiting, sore throat, abdominal pain	• No available antidote
	• Ulcerations in upper GI tract	• No available diagnostic test
Fipronil (*N*-phenylpyrazole insecticides)	• Nausea and vomiting	• Supportive care
	• Aphthous ulcers	• No available antidote
	• Altered mental status and coma	• No available diagnostic test
	• Seizures	
Organochlorines	• Central nervous system: mental status changes and seizures	• Control acute seizures with lorazepam
	• Paresthesia, tremor, ataxia, and hyperreflexia	
Glyphosate (phosphonate herbicides)	• Nausea and vomiting	• Supportive care
	• Aspiration pneumonia type syndrome	
	• Hypotension, altered mental status, and oliguria in severe cases	
	• Aspiration pneumonia type syndrome	
	• Pulmonary effects may in fact be secondary to organic solvent	
Chlorophenoxy herbicides	• Skin and mucous membrane irritation	• Consider forced alkaline diuresis with sodium bicarbonate in IV fluids
	• Vomiting, diarrhea, headache, confusion	
	• Metabolic acidosis is the hallmark	
	• Renal failure, hyperkalemia, and hypocalcemia	
Long-acting anticoagulants (rodenticides)	• Bleeding: gums, nose, and other mucous membrane sites	• Consider PT (INR) or observation
	• Bruising	• Vitamin K indicated for bleeding (IV vitamin K) or for elevated PT (INR) (oral vitamin K)

IV, intravenous.

Activated charcoal is contraindicated if the patient does not have a protected or intact airway.[36] A randomized controlled trial evaluating the effect of multiple-dose charcoal for pesticide-poisoned patients in Asia found no benefit, as measured by a reduction in mortality.[37] Skin decontamination also is critically important, and clothing should be removed. Medical personnel should take measures to protect themselves from contaminated skin and clothing, because numerous cases of hospital-acquired OP poisoning have been documented.[38] Parents or other family caregivers may also be at risk for skin contamination. Seizures should be controlled with intravenous lorazepam.[3]

Atropine can be given as a nonspecific antidote in both OP and carbamate poisoning. It will reverse the muscarinic effects of the poisoning; however, it is less effective on central nervous system effects. It is given as a dose of

0.05 to 0.1 mg/kg per dose and may be given as often as every 15 minutes until respiratory secretions are controlled.[3] Notably, this dose is 10 times the usual dose given during a resuscitation situation, because the purpose is to overcome complete blockade of the muscarinic channel. Pralidoxime is also given as a specific antidote to reverse the acetylcholinesterase inhibitor complex. The use of pralidoxime continues to be of interest, particularly in developing countries, although most studies have been performed with adult patients.[39,40] The World Health Organization recommends its use for all patients who require atropine.[41] Its use is indicated for OP poisoning, because cholinesterase inhibition usually is permanent in OP poisoning. Use of pralidoxime usually is not necessary or recommended for carbamate poisoning, because this inhibition is reversible.[3]

Pyrethrins and Pyrethroid Insecticides

Pyrethrins and pyrethroids are a relatively more recent class of insecticides that have been largely replacing the use of cholinesterase-inhibiting insecticides, especially in the consumer market. These insecticides are used for structural pest control in urban areas, in gardening or agriculture for row crops and orchards, and in the home for pet sprays and shampoo.

The pyrethrins are botanically derived from pyrethrum, an extract of the chrysanthemum plant. For these consumer products, pyrethrins are usually combined with another active ingredient: either a longer-acting synthetically derived pyrethroid or one of the cholinesterase inhibitors. Pyrethrins are not stable in heat or sunlight and, therefore, are usually used more for indoor application. Permethrin is the most widely known example of a pyrethrin and is one of the few products licensed for use to apply to human skin, because it is commonly used as a pediculicide.[3,42,43]

Pyrethroids are synthetically derived compounds that have been modified to be more stable in sunlight and heat and are, therefore, used more widely for insect control, especially outdoors. Toxicity varies widely among pyrethrins and pyrethroids, and, although they are less acutely toxic as a class than the cholinesterase insecticides, there is a subgroup of these compounds that has been modified with a cyano side chain. This modification creates a compound that is significantly more resistant to degradation and potentially more acutely toxic than other pyrethroids. Commonly used chemicals in this subgroup include deltamethrin, cypermethrin, and fenvalerate—these are the insecticides to which the majority of toxic signs and symptoms in the next section apply.[43]

Toxicology, Clinical Signs, and Symptoms

Pyrethroids exert their toxic effect by blocking the sodium channel at the level of the cell membrane. Most clinical reports of poisoning occur either through excessive skin contact or through ingestion or inhalation. The result is continued hyperpolarization, effectively inhibiting cell function. Some types of pyrethroids also work at other sites, including voltage-dependent chloride channels and γ-aminobutyric acid–gated chloride channels. This appears to be one of the reasons for a variety of toxicity found among pyrethroid insecticides.[42,43] Pyrethroids with a cyano group, also known as type II pyrethroids, constitute most cases of human poisoning.[42,43] Pyrethroids are well absorbed across the GI tract, but limited penetration occurs across the skin barrier, which can limit acute toxicity.[42,44] Some pyrethroids have a high acute toxicity, usually after ingestion.[42,45] Pyrethroids are metabolized by the liver and excreted in their metabolic forms.

Pyrethroids have adverse effects on the nervous system, GI tract, and skin. Specific signs and symptoms are found in Table 2. Similar to OPs, muscle fasciculation, weakness, an altered level of consciousness, and seizures can develop after exposures to some pyrethroids.[42–45] Of note, paresthesias, including burning, tingling, stinging, and eventually numbness, are characteristic of pyrethroid exposure.[46,47] The paresthesias appear to be dose-dependent and occur at pyrethroid dosages lower than what would cause systemic toxicity, thereby acting as a warning of exposure. The paresthesias are self-limiting once exposure is eliminated.[48]

Laboratory Evaluation and Treatment

Pyrethroid toxicity is identified through clinical history and knowledge of exposure to the agent. There are no rapidly available diagnostic laboratory tests. Most pyrethroids are metabolized to 3-phenoxybenzoic acid, which can be recovered in the urine. CDC national surveys provide biomonitoring information on pyrethroid urinary metabolites and can act as comparison for background measures of exposure in the general population. However, in the clinical setting, results of metabolite levels are usually obtained from specialty laboratories and are not immediately available; therefore, these results not useful in acute clinical management.

Paresthesias are generally self-limiting and resolve within 24 hours.[46,48] If exposure is interrupted after the onset of paresthesias and other dermal findings, no additional treatment is necessary. Vitamin E oil or cream has been shown to improve the

symptoms associated with the paresthesias.[47] The mechanism is not completely clear; however, in experimental studies, vitamin E (α-tocopherol) blocked tetramethrin-modified sodium channels.[49]

Treatment of systemic pyrethroid poisoning is supportive, in general, and there are no specific antidotes. Because of the similar features of cholinesterase inhibitor poisoning, some patients have been treated erroneously with high atropine, sometimes with disastrous results.[45] Efforts have been aimed at antagonizing the sodium current resulting from the pyrethroid blockade. Several medications have been tested in the animal model, but, to date, none have been considered effective antidotes for systemic pyrethroid poisoning in humans. For significant neurologic effects, patients should have standard decontamination, including GI tract decontamination, supportive respiratory care, seizure control with diazepam or lorazepam, and careful dosing of atropine for excessive salivation.[42] Proper identification of the offending agent is imperative to distinguish these poisonings from OPs and often requires a high index of suspicion and a thorough exposure history.

Organochlorine Insecticide (Lindane)

The discussion of acute toxicity for organochlorines is focused on lindane, because most other organochlorine compounds have been banned for use in the United States. Other organochlorines, including DDT and some of the cyclodienes, including chlordane and dieldrin, are important compounds, because they can still persist in human and environmental samples. These chronic exposures are of continuing concern for developmental health effects, including immunotoxicity, endocrine disruption, and neurodevelopmental insults (see Chronic Health Effects of Pesticide Exposure).

Lindane, also known technically as the γ-isomer of hexachlorocyclohexane, is still approved in some states for control of lice and scabies. However, in a comparison of in vitro activity against lice with other pediculicides, it was the least effective.[50] It is efficiently absorbed across the skin (approximately 9%) and even more so across abraded skin, such as with severe excoriations from scabies.[51,52] Signs and symptoms are noted in Table 2. Treatment is supportive and includes decontamination and the control of seizures with lorazepam. There is no specific antidote. Lindane has been banned in California because of high levels found in the water supply.[53]

Neonicotinoids

Neonicotinoids are a new class of insecticides based on metabolic alterations of nicotine. They are used primarily in agriculture and are gaining widespread use for flea control on domestic animals. They act on the nicotinic *N*-acetylcholine receptors and selectively displace acetylcholine. They do have a relatively selective affinity for insects as opposed to mammals, although there have been a few reports of human poisoning.[54–56] The most commonly used neonicotinoid in the United States is imidacloprid. Information about toxicity and signs and symptoms can be found in Tables 1 and 2.

N-Phenylpyrazoles

Fipronil is the primary representative of this class and was developed in the mid-1990s. It is widely used in flea control on domestic pets. It is also used in ant and roach bait stations, agriculture crops, and lawn treatments. It acts by inhibiting γ-aminobutyric acid–gated chlorine channels. The inhibition will block chloride passage and result in hyperexcitability of the cell.[57–59] Signs and symptoms are reported in Table 2.

HERBICIDES

Chlorophenoxy Herbicides

Chlorophenoxy herbicide compounds are often mixed with fertilizers and are used both in agriculture and on residential lawns. These compounds are well absorbed from the GI tract but are not well absorbed after inhalational or dermal exposure.[60] Examples of commonly used chlorophenoxy herbicides are 2,4-D and 2,4,5-trichlorophenoxy acetic acid. The half-lives of these compounds range between 13 and 39 hours. They are mostly excreted unchanged in the urine; excretion can be greatly enhanced in an alkaline environment.[3,61,62] More toxic substances that can be produced during the manufacture of these herbicides include dioxins, which were contaminants of the herbicide Agent Orange and were found in the Love Canal chemical dump site.[63]

Primary initial effects are on the skin and mucous membranes. Severe poisoning will result in metabolic acidosis and possibly renal failure.[3,61,64] Specific symptoms are discussed in Tables 1 and 2. The compounds can be measured in the urine, although similar to pyrethroid insecticides, analyses are generally performed at specialty laboratories, so results are usually not immediately available to clinicians. Treatment is primarily supportive and may also include forced alkaline diuresis by adding sodium bicarbonate to the fluids and establishing a high urine pH and high urine flow.[3,61,65]

Phosphonate Herbicides (Glyphosate)

Glyphosate is a commonly used herbicide and is commercially available in

many products. Glyphosate acts on the cell wall of plants, so, theoretically, it should have no effect on human cells, at least by way of its primary mechanism of action. Despite this, there are numerous reports in the medical literature of adverse events after human exposure, particularly unintentional ingestions. Patients have presented with signs and symptoms consistent with an aspiration pneumonia–like syndrome, and the offending agent may be the hydrocarbon solvent with which the glyphosate is mixed. Treatment is primarily supportive, and providers should be vigilant for aspiration pneumonia.

RODENTICIDES (LONG-ACTING ANTICOAGULANTS)

Most currently used rodenticides belong to the class of warfarin-type anticoagulants. Unlike warfarin, the superwarfarin agents, such as brodifacoum, have a much longer half-life. Although they have traditionally been available as pellets that can be spread around or in a box that the rat can consume, the EPA has recently changed the type of products that are available to consumers. Since 2008, superwarfarins can only be sold as a child-resistant bait station instead of loose pellets.[66]

The mechanism of action is inhibition of the synthesis of vitamin K–dependent clotting factors. As such, the primary manifestations of toxicity are bleeding and easy bruisability. In severe cases, bleeding may be life-threatening. Clinicians who suspect that their patients may have ingested a superwarfarin should consider obtaining a prothrombin time (PT; also known as the international normalized ratio [INR]).[3] However, several studies that have analyzed cohorts of exposed children have found very few subjects with an elevated PT (INR) or active bleeding. Therefore, in situations in which it is unclear whether a child ingested more than a few pellets, it is reasonable to simply observe the child.[67–70] Most patients can be managed in the outpatient setting as long as the ingestion has been recognized early.[71]

Treatment is vitamin K and should be reserved for patients with elevated PT (INR) levels or active bleeding. With severe bleeding or shock, a transfusion of blood or plasma is indicated as well.[3]

CHRONIC HEALTH EFFECTS OF PESTICIDE EXPOSURE

The health implications of the nonacute, relatively low, but often repetitive and combined exposures encountered routinely by children are an ongoing focus of concern and inquiry for scientists, regulators, and parents.[72,73] Pediatricians are well placed to provide guidance to parents about potential long-term or subtle health effects from pesticide residues on food, in water, or used in homes or schools and on exposure-reduction strategies. However, surveys suggest pediatricians often feel ill-prepared with training in this topic, underscoring the importance of improving educational opportunities for clinical providers.[74–76]

The associated health effects of chronic pesticide exposure in children vary, reflecting the diversity of toxicological properties of this broad group of differing chemicals. Some of the important end points of concern include an increased risk of cancer, abnormal neurodevelopment, asthma, perturbation of gestational growth, and endocrine-mimicking effects. Health effects of pesticides and the current relative strength of the evidence base are reviewed in subsequent sections for each of these health outcomes.

Childhood Cancer

All pesticides undergo in vitro and animal testing to determine their likelihood of causing cancer. The EPA maintains a list and classification of all active ingredients in pesticides and their potential for carcinogenicity. The method of identifying potential carcinogenicity has changed. Before 1996, pesticides were assigned a letter classification (eg, pesticides with the "C" classification were considered "possibly carcinogenic"). Subsequently, pesticides have been assigned a category such as "likely to be carcinogenic to humans," "suggestive evidence of carcinogenic potential," "inadequate evidence," and "not likely." These categories are not directly comparable, so both classifications (before 1996) and categories (after 1996) continue to exist.

The pesticides that are categorized as "possibly carcinogenic" or "likely to be carcinogenic to humans" are available from the EPA via an e-mailed report.[77] Included in this report are some well-known and widely used OPs, carbamates, pyrethroids, and fungicides. Within classes of pesticides, variation in carcinogenicity potential exists. Note that a pesticide, such as cypermethrin, that has "replaced" use of cancer-causing OPs has cancer-causing potential.

A substantial amount of observational epidemiological data demonstrate a link between pesticide exposure and childhood cancers.[78–87] However, the evidence base includes studies that found no association between childhood cancers and pesticides or few associations that cannot be ruled out as a chance finding.[88,89] Overall, the most comprehensive reviews of the existing literature implicate an association of pesticides with leukemia and brain tumors.[78,79]

Leukemia

In 1998, Zahm and Ward[79] reviewed 18 studies assessing the relationship between pesticide exposure and leukemia; 13 studies found an elevated risk, and,

for 6 of those studies, the association was statistically significant. The most frequently occurring associations among the studies were between pesticide exposure and acute lymphocytic leukemia.

A 2007 review by Infante-Rivard and Weichenthal[78] summarized the 1998 review of Zahm and Ward and updated findings from recent studies. Although it was previously postulated that childhood exposure to agricultural products or proximity to an agricultural setting would present the highest risks, the most commonly associated pesticide exposure in childhood acute lymphocytic leukemia studies was household insecticide use. Cases were more likely to have had preconception exposure and/or exposures in utero in most studies. The main limitations with the studies in the 1998 review included crude exposure assessment, concern for recall bias, small numbers of exposed cases, and mixing of different leukemia types.[78]

In the updated review, 5 of 6 recent case-control studies found a statistically significant relationship between pesticide exposure and leukemia.[84,85,90–92] In particular, 2 studies included the most detailed exposure assessment to date and reported findings related to a dose/exposure–response gradient.[84,85] The primary risk factors were maternal exposure to pesticide between the periods of preconception through pregnancy. The largest of the 2 studies had 491 cases and an equal number of controls, focused only on acute lymphocytic leukemia, included a measure of frequency of use, and considered genetic susceptibility. For maternal use of herbicides, plant insecticides, and pesticides for trees during pregnancy, the odds ratio (OR) was 1.84 (95% confidence interval [CI], 1.32–2.57), 1.97 (95% CI, 1.32–2.94), and 1.70 (95% CI, 1.12–3.59), respectively. For parental use during the child's postnatal life, OR was 1.41 (95% CI, 1.06–1.86), 1.82 (95% CI, 1.31–2.52), and 1.41 (95% CI, 1.01–1.97) after exposure to herbicides, plant insecticides, and pesticides for trees, respectively.[84]

To further explore associations between pesticides and leukemia, a group of authors conducted 2 meta-analyses. They provided similar and additional support to the associations described previously. One examined studies that included parental occupational exposure (prenatally and in early childhood) and leukemia in their offspring. Maternal occupational exposure, but not paternal occupational exposure, was found to be associated with leukemia. The reported OR was 2.09 (95% CI, 1.51–2.88) for overall pesticide exposure, 2.38 (95% CI, 1.56–3.62) for insecticide exposure, and 3.62 (95% CI, 1.28–10.3) for herbicide exposure.[93] The second meta-analysis assessed pesticide exposure in the home and garden setting. In this meta-analysis, 15 studies were included, and exposures during pregnancy to unspecified pesticides, insecticides, and herbicides were all associated with leukemia (OR, 1.54 [95% CI, 1.13–2.11], 2.05 [95% CI, 1.80–2.32], and 1.61 [95% CI, 1.2–2.16], respectively).[94]

Brain Tumors

Zahm and Ward's 1998 review included 16 case-control studies examining associations between brain tumors and pesticide exposures. Of these, 12 found an increased risk estimate of brain tumors after pesticide exposure; 7 of these findings reached statistical significance. Associated exposures were most often from parental use of pesticides in the home, in the garden, and on pets. Interpretation of these studies is difficult given the inadequate exposure assessments, small numbers because of a relatively rare childhood outcome, and a mixture of brain tumor types among cases.[79]

Since 1998, 10 additional studies have been published, all but one of which demonstrated an increased risk estimate of cancer with maternal and/or paternal exposure, although not all studies demonstrated statistical significance. Some of the more robust findings come from a case-control study with 321 cases of astrocytomas. The risk estimate from maternal occupational exposure to insecticides before or during pregnancy was 1.9 (95% CI, 1.1–3.3). The risk estimates for paternal exposure for insecticides, herbicides, and fungicides were 1.5, 1.6, and 1.6, respectively. These risk estimates were just short of reaching statistical significance.[87] In a cohort study of more than 200 000 patients, paternal exposure in any occupation and in agricultural/forestry preceding conception was associated with an increased risk of central nervous system tumors (relative risk [RR], 2.36 [95% CI, 1.27–4.39] and RR, 2.12 [95% CI, 1.08–4.39], respectively).[83] For all studies, it appears that prenatal exposure to insecticides, particularly in the household, as well as both maternal and paternal occupational exposure before conception through birth represent the most consistent risk factors.[83,86,87,95–100]

Ewing Sarcoma

Two case-control studies were performed to evaluate potential parental occupational exposures and the development of Ewing sarcoma (ES). One study of 196 cases and matched controls found an association between ES in boys age 15 years or younger and household pesticide extermination (OR, 3.0; 95% CI, 1.1–9.2). There was no association between parental occupational exposure to pesticides and ES.[101] A study in Australia compared 106 cases of either ES or peripheral primitive neuroectodermal tumor with 344 population-based controls. Exposures

included prenatal exposure from conception through pregnancy and also included parental exposures through the time of the child's diagnosis. Notable elevated risks were observed for mothers who worked on farms (OR, 2.3; 95% CI, 0.5–12.0), mothers who handled pesticides (OR, 2.3; 95% CI, 0.6–8.5), patients who ever lived on a farm (OR, 2.0; 95% CI, 1.0–3.9), and farming fathers at the time of conception and/or pregnancy (OR, 3.5; 95% CI, 1.0–11.9).[102] Of note in this study, all 95% CIs include 1.0, so they did not reach statistical significance, although some ORs approached it.

In summary, there is some evidence of increased risk of developing several childhood cancers after preconception and/or prenatal exposure to pesticides. The strongest evidence appears to be for leukemia, which is a relatively more common type of childhood cancer than brain tumors. Maternal exposure to insecticides and paternal occupational exposure appear to carry the greatest risk.

Neurodevelopment/ Neurobehavioral Effects

Many pesticides have well-described acute neurotoxicant properties that have been described previously in this report in relation to human poisoning episodes and acute toxic mechanisms. However, information on the potential neurodevelopmental toxicity arising from chronic, low-level exposure in gestational or postnatal life is inadequate or lacking for most pesticides in use. There is a growing available evidence base supporting an adverse effect on neurodevelopment from 2 classes of insecticides, the organochlorines (specifically DDT and its metabolite *p,p'*-dichlorodiphenyldichloroethylene [DDE]) and, most recently, OPs. Several recent reviews of the evidence base are now available.[103–105]

Although chronic neurologic sequelae after acute OP poisoning have been observed in multiple adult studies, the epidemiological data on children are limited.[106,107] A recent neuropsychological evaluation of healthy school-aged children who had experienced hospitalization for acute OP poisoning before the age of 3 years found subtle but significant deficits in their ability to restrain and control their motor behaviors compared with both children who had no history of poisoning and children who had a history of early life poisoning with kerosene.[108]

Of greater public health concern is the potential neurotoxicity from routinely encountered chronic exposures. This is the subject of study in ongoing, large National Institutes of Health/EPA-sponsored prospective birth cohorts. Studies in 2 urban settings and a rural farmworker community have enrolled women during pregnancy with an objective assessment of exposure by the use of environmental measurements and biological monitoring.[104,109,110] Follow-up assessment of neurodevelopment and neurobehavior in their children with the use of validated tools such as the Brazelton Neonatal Assessment Scales, the Bayley Scales of Infant Development, the Child Behavior Checklist, and IQ testing at comparable intervals is being conducted. To date, remarkably similar findings relating adverse neurodevelopmental and neurobehavioral outcomes associated with prenatal OP exposure have been made in these distinct cohort studies. For example, in 2 cohorts, the Brazelton Neonatal Behavioral Assessment Scale was administered in the first weeks of life. In both, deficits in the primitive reflex domain were noted with the other 6 of 7 Brazelton Neonatal Behavioral Assessment Scale domains not associated with prenatal OP exposure.[111,112] Two of the cohorts have published their Bayley Mental and Psychomotor Developmental Index results conducted during the toddler years (ages 2–3).[113,114] Significantly poorer mental development was associated with higher OP exposure in both, whereas one of the cohorts also observed OP-associated deficits in the motor scale at 3 years of age. Results of Child Behavior Checklist assessments are also available for 2 cohorts, conducted at 2 years of age in one and 3 to 4 years of age in the other. Significantly increased scores representative of pervasive developmental disorder were associated with higher OP exposure in both.[113,114] One cohort also had increased scores for inattention and attention-deficit/hyperactivity disorder subscales.[114] All 3 cohorts have found decrements in IQ testing associated with higher prenatal exposures at the time of follow-up at 7 years of age.[115–117]

In one of the cohorts, postnatal exposure effects in the child have been investigated and reported. Interestingly, improved mental development based on Bayley's Index at 12 and 24 months of age is associated with higher contemporary child excretion of OP urinary metabolites. Explanations for this are debated but include theories that children with higher cognitive abilities may explore their environments more thoroughly and, as such, experience higher exposure.

Recently, a US-based cross-sectional analysis demonstrated that children with high urinary concentrations of OP metabolites were more likely to have a diagnosis of attention-deficit/hyperactivity disorder. This study used data from a representative sample of 8- to 15-year-old children collected as part of the NHANES conducted by the CDC.[118]

One study based in Ecuador has examined the relationship of OP exposure on neurodevelopment in school-aged children.[119] Prenatal exposure (based

on mother occupational history questionnaire) was associated with a decrease on the Stanford-Binet copying test among the study subjects at 7 years of age. Their concurrent exposure (on the basis of OP urinary metabolites) was associated with an increase in simple reaction time.

The toxicological mechanisms that underlie the adverse neurodevelopmental observations are also under investigation. Interestingly, noncholinergic mechanisms are being deciphered in animal models and in vitro studies, distinct from the well-described mechanism of acute OP toxicity (cholinesterase inhibition) and occurring at doses much lower than required to inhibit cholinesterase.[120]

Well-designed recent cohort studies and previous work including animal models suggest that OP exposures that are being experienced by US children may have adverse neurodevelopmental consequences. The plasticity of these effects and clinical implications are as yet unclear, although continued assessments as these cohorts age and enter school age are planned and may add clarity. The potential modification of these effects on the basis of genetic factors, specifically metabolic enzymes involved in pesticide detoxification pathways, are also being explored in these cohorts. For example, preliminary analyses indicate that children with a particular variant of the paraoxonase I gene, which is associated with lower levels of this OP-metabolizing enzyme, may be at higher risk of health consequences from OP exposure.[121,122]

Although DDT has not been used since the early 1970s, its persistence in the environment and fat solubility results in ongoing detection of the parent compound and breakdown product (DDE) in contemporary US populations.[19] The potential adverse neurodevelopmental consequences of prenatal DDT (2 studies) and DDE (several studies) was studied in one of the recent cohorts described previously in this report, which was a predominately Mexican American farmworker population. In this cohort, maternal serum DDT levels were negatively associated with mental development and psychomotor development at 12 and 24 months.[123] Maternal serum DDE was associated with reduced psychomotor development at 6 months and mental development at 24 months. A review of the overall evidence base reveals that studies of in utero DDE exposure and neurodevelopment are mixed, with at least 2 studies showing decrements in psychomotor function. Both of the 2 studies that have evaluated effects of DDT exposure observed cognitive deficits.[103]

In summary, the existing and recently emerging evidence base suggests that organochlorine and OP exposure in early life, particularly prenatally, may have adverse consequences on child neurodevelopment.

Physical Developmental Effects

In addition to neurodevelopmental toxicity, there is also considerable concern of physical developmental toxicity to the embryo and fetus from pesticide exposure. These concerns arise from multiple epidemiological studies that have investigated their relationship to adverse pregnancy outcomes including intrauterine growth retardation, preterm birth, fetal death, and congenital anomalies. The available studies are heterogeneous in design, are conflicting in results, and often have an insufficient exposure assessment. Nonetheless, pesticides remain one of the most common environmental exposures of concern cited in relation to adverse pregnancy outcomes and have been the focus of recent reviews on the topic, which include weight of the evidence evaluations.[124–126]

Among studies that are able to address specific types of pesticide exposures, there are more data focused on the organochlorine and OP insecticides or phenoxy or triazine herbicides. These represent the currently or historically (eg, organochlorine) most heavily used pesticides. This review summarizes the highlights of the existing evidence base with a focus on studies that incorporate direct measures of exposure for individual study subjects.

Fetal Death and Birth Defects

A California-based case-control study found an increased risk of fetal death attributable to congenital anomalies when OP application occurred in the residential area of the mother during weeks 3 through 8 of pregnancy—consistent with organogenesis.[127] One other study found an elevated risk of spontaneous abortion associated with chlorophenoxy herbicides. However, as with some studies of birth defects discussed previously, this study also relied on self-report and less reliable means of exposure assessment.[128] Results are not consistent, because other studies have not found association of parental exposure to OPs with spontaneous abortion or stillbirth.[129–131]

Birth defects will be discussed first, followed by other adverse birth outcomes. The more common birth defects include orofacial clefts, limb defects, and neural tube defects, which are generally the defects studied in relationship to pesticide exposures. Although several studies have found associations of maternal or paternal exposures with a wide variety of birth defect categories, all of the studies used indirect measures of exposure and most were ecological study designs, making interpretation of the adverse birth outcome evidence base inadequate and unreliable.[125]

A 1995 review article discussed the available evidence for associations between birth defects and potential

pesticide exposure.[132] Five studies were included that assessed various birth defects (central nervous system, oral cleft, limb defects) compared with maternal agricultural occupation. Four of those 5 reported an elevated RR or an OR ranging from 1.6 to 5.0; however, only 2 were statistically significant.[133–137] Of note, in these studies, there was not an assessment to any single pesticide; rather, the "exposure" was maternal occupation.

Six additional studies from this period evaluated maternal pesticide exposure at work and the development of birth defects. Of the 5 studies with an elevated OR or RR, ranging from 1.3 to 7.5,[138–142] 3 were statistically significant. Unfortunately, some of these studies included small numbers of cases, and others were likely to have significant exposure misclassification. The conclusion of this review was that there are some indications of elevated risk but no clearly convincing evidence.[143]

Two studies from Minnesota have reported a relationship between physical defects in children and paternal occupation of pesticide applicator. The first study compared data from a birth registry between 1989 and 1992. A geographic section of Minnesota that had the highest agriculture activity and highest frequency of use of chlorophenoxy herbicides and fungicides was also found to have the highest rate of birth defects (30.0/1000). By comparison, the general population in this same region had a birth defect rate of 26.9/1000. Interestingly, there was a seasonal effect, with the highest frequency occurring in infants who were conceived in the spring, the same time as most herbicide and some fungicide application (OR, 1.36; CI, 1.10–1.69).[144] The second study is a cross-sectional study that used a survey of licensed applicators and subsequently more in-depth interviews of either/both the applicator and female partners of licensed applicators when possible. The study eventually included live births fathered by 536 applicators. The birth defect rate in this study was 31.3/1000, which is statistically significantly higher than what the previous study found for the general population. Again, there was a significant difference in season of conception (7.6% in spring versus 3.7% in other seasons).[145]

Studies of birth defects often include all types within the analysis because of insufficient numbers of individual defects to allow adequate power of statistical analyses. A meta-analysis used 19 studies that had sufficient data to be included to estimate the effects of pesticides on orofacial clefting. Maternal occupational exposure to pesticides was associated with orofacial clefts (OR, 1.37; 95% CI, 1.04–1.81). There was a weaker association for paternal occupation (OR, 1.16; 95% CI, 0.94–1.44).[146] Studies on 3 other birth defects—cryptorchidism, hypospadias, and polythelia—will be discussed in the section on endocrine effects.

In summary, a small risk elevation is noted for birth defects and pesticide exposure, but the findings are not robust, and the data specific to pesticide subtypes are not adequate.

Adverse Birth Outcomes (Low Birth Weight, Decreased Gestational Age)

DDT (and its major metabolite DDE) is the organochlorine that has been most extensively examined in relation to birth defects, fetal death, and fetal growth, with mixed findings. Fetal exposures, as determined by maternal serum or umbilical cord blood levels, have been associated with preterm birth, decreased birth weight, and intrauterine growth retardation.[147–151] However, not all studies reported significant associations between exposure with infant birth weight or preterm birth, including a relatively recent study of Mexican American farmworking women in the United States with higher exposures in comparison with a similar group of a national sample of nonfarmworking Mexican American women.[142,152] In the largest cohort study to date (a US cohort of births between 1959 and 1966), DDE concentrations in maternal serum during pregnancy demonstrated a dose–response relationship to risk of preterm delivery and delivering small for gestational age (SGA) infants.[147]

Exposure to pesticides is associated with risk of decreased birth weight. In a study conducted before recent regulatory actions that reduced their residential use, exposure to the OPs chlorpyrifos and diazinon were associated with decreased birth weight in a New York City cohort.[110] In another New York City cohort, birth weight was reduced among mothers with higher OP exposure levels in pregnancy, but only among those with a genetic polymorphism of an OP detoxification enzyme (paraoxonase 1 or PON1).[150] In a similar longitudinal pregnancy cohort conducted among Latina farmworkers in agricultural California, no association of maternal pregnancy exposure to OPs and birth weight was determined, but a reduction in gestational age was associated.[153]

An ecological study determined that women in a rural region of Iowa with increased levels of triazine, metolachlor, and cyanazine herbicides in the drinking water had an elevated risk of delivering an infant with intrauterine growth retardation compared with women in other parts of the state.[154] A study based in France reported that atrazine levels in municipal drinking water throughout pregnancy were not associated with increased risk of delivering an SGA infant but that the

risk of delivering an SGA infant increased when the third trimester occurred in whole or in part during the period of May through September, when atrazine levels typically peak.[155]

Summary: Physical Developmental Defects

In summary, the true extent and nature of pesticide exposure on adverse fetal growth and birth outcomes is unknown despite suggestive epidemiological studies that link some of the most widely used pesticides to reduced intrauterine growth, fetal death, preterm birth, and congenital anomalies. Very little is known about many pesticide types in current use, including synthetic pyrethroids and carbamate insecticides, rodenticides, and fungicides. Studies that examine the timing and extent of exposure to pesticides and exposure to pesticide mixtures with validated exposure assessment techniques including biological markers are needed. The potential for differential vulnerabilities because of genetic polymorphisms that influence the toxicological properties of these exposures must also be explored.

ENDOCRINE EFFECTS

An emerging concern, although less well studied in humans, is the potential effects that some chemicals including pesticides may have on the endocrine system. Some of the most notable pesticides thought to have such effects are the organochlorine pesticides, such as DDT, endosulfan, methoxychlor, chlordecone, chlordane, and dieldrin. Other herbicides (atrazine, 2,4-D, and glyphosate) and fungicides (vinclozolin) also have some endocrine activity.[156–159] The associations are very complex and are primarily based on in vitro and animal studies. Estrogen-mimicking properties tend to be the most commonly reported, although effects on androgen and thyroid hormones, among others, are also reported. Feminization has been noted in alligators found in lakes highly contaminated by organochlorine pesticides.[160] Hayes et al[161] have studied the effects of atrazine on amphibians and have noted a 10-fold decrease in testosterone from exposure to 25 ppb of atrazine in mature male frogs. The mechanism of the latter appears to be activation of the enzyme aromatase, which promotes conversion of testosterone to estrogen.[162]

The human epidemiology literature is limited on endocrine effects from pesticides. One report from Macedonia noted some degree of early pubertal findings, primarily premature thelarche, which was hypothesized to be related to organochlorine pesticide exposure.[163] A study in 2000 with 48 patients, 18 of which had cryptorchidism, first raised the hypothesis about an association with organochlorine pesticides. An association between cryptorchidism and organochlorine pesticide levels has been hypothesized.[164] Since then, additional case-control studies have been conducted to examine the effects of organochlorines on endocrine-related birth outcomes, cryptorchidism, hypospadias, and/or polythelia. Two focused on fetal exposures from maternal levels of DDE alone and development of cryptorchidism and hypospadias.[165,166] Bhatia et al[165] calculated an OR of 1.34 (95% CI, 0.51–3.48) for the association of cryptorchidism and DDE and 1.18 (95% CI, 0.46–3.02) for the association of hypospadias and DDE. Longnecker et al[166] estimated an OR of 1.3 (95% CI, 0.6–2.4) for the association between DDE and cryptorchidism and an OR of 1.2 (95% CI, 0.6–2.4) the association between DDE and hypospadias. The modest association is felt to be inconclusive with the imprecision in risk estimates and suggests that a larger sample size may be needed. A third case-control study found inconclusive results on the effect of heptachlor and β-hexachlorocyclohexane levels in pregnant women on cryptorchidism. For heptachlor, the OR was 1.2 (95% CI, 0.6–2.6), and for β-hexachlorocyclohexane, the OR was 1.6 (95% CI, 0.7–3.6). The sample size in this study was 219 cases, compared with 564 controls.[167]

Two nested case-control studies have examined the possibility that multiple organochlorine compounds will have a cumulative effect on the development of urogenital abnormalities in boys.[168,169] Fernandez et al[168] reported that total xenoestrogens as well as detectable pesticide levels were associated with cryptorchidism and/or hypospadias. They found elevated ORs in the range of 2.19 for endosulfan to 3.38 for lindane. All 95% CIs were noted to be statistically significant. The study in Finland and Denmark reported a significant relationship between chlordane and cryptorchidism but no other relationships between 7 other individual organochlorines. However, combined analysis of the 8 persistent pesticides did demonstrate a statistically significant increase in cryptorchidism in exposed boys.[169]

Testing chemicals is an important and necessary step for the EPA to determine potential long-term risks from pesticide during the registration or re-registration process. There has been progress in the development of appropriate biomarkers to evaluate chemicals for the presence of endocrine-disruption qualities. The ability to measure DDE and dioxins from human milk has been developed.[170] More recently, a biomarker for xenoestrogen mixtures was developed in Spain.[171]

In summary, there is compelling basic science evidence for endocrine-mimicking effects of several pesticide chemicals that is sound and scientifically plausible. Human data

are slowly emerging but not yet conclusive.[172]

Asthma

Given the widespread use of pesticides and the high morbidity of asthma in children, questions have been raised regarding pesticides as triggers as well as risk factors for incident disease. Concern is raised by a mounting adult occupational literature associating pesticides with asthma or other measures of respiratory health. In addition, preliminary toxicological data provide mechanisms that link pesticides and asthma. An important limitation of most epidemiological studies to date is the lack of exposure specificity regarding pesticide chemicals or chemical classes. In addition, studies regarding children are few.

There is indirect evidence that pesticides skew the immune response toward the T helper 2 (Th2) phenotype associated with atopic disease. The National Institutes of Health/EPA-sponsored rural birth cohort described above regarding evaluation of neurodevelopmental effects has also observed that maternal agricultural work was associated with a 26% increase in proportion of Th2 cells in their 24-month-old infants' blood samples.[173] The percentage of Th2 cells was associated with both physician-diagnosed asthma and maternal report of wheeze in these infants. This population of largely Mexican American farmworkers was selected for study on the basis of the relatively high use of OP pesticides in this agricultural area.

Animal-based toxicological mechanistic models include OP-induced airway hyperreactivity via alteration in muscarinic receptor function in airway smooth muscle and oxidative stress induced by OP-related lipid peroxidation.[174–177]

The few epidemiological data on pesticides and respiratory health in children have mixed results. In a cohort of rural Iowan children, any pesticide use indoors or any outdoor use in the previous year was not significantly associated with asthma symptoms and prevalence.[178] Contrarily, a cross-sectional analysis of Lebanese children identified increased risk of chronic respiratory symptoms, including wheeze, among those with any pesticide exposure in the home, exposure related to parent's occupation, and use outside the home. The highest risk was observed for children whose parents had occupational exposure to pesticides (OR, 4.61; 95% CI, 2.06–10.29).[179] However, given this study's cross-sectional design, it is not possible to discern whether the pesticide exposure preceded the diagnosis of asthma.

Among exposures in the first year of life explored in a nested case-control study of the Southern California Children's Health Study, both herbicides and pesticides/insecticides had a strong association with asthma diagnosis before 5 years of age (OR, 4.58 [95% CI, 1.36–15.43] and OR, 2.39 [95% CI, 1.17–4.89], respectively).[180]

More published data are available regarding adult farmers and adult rural residents. These studies more consistently support a link between pesticides and respiratory symptoms or chronic respiratory disease, such as asthma.[181,182] For example, use of multiple individual pesticides was evaluated in relation to self-reported episodes of wheeze in the previous year in a large cohort of commercial pesticide applicators (adults) and farmers enrolled in the Agricultural Health Study.[182] Among the pesticides classes, several OPs showed associations with wheeze, including several that demonstrated a dose–response trend. Chlorpyrifos, malathion, and parathion were positively associated with wheeze among the farmers; for the commercial applicators, the OPs chlorpyrifos, dichlorvos, and phorate were positively associated with wheeze. Among commercial applicators, the strongest OR was for applying chlorpyrifos on more than 40 days per year (OR, 2.40; 95% CI, 1.24–4.65). Elevated risk for wheeze related to herbicide use was almost exclusively associated with chlorimuron-ethyl (urea-derivative class).

Similar studies addressing the respiratory health implications for children for specific pesticide chemical types or groups are rare. However, for DDT, there is some emerging evidence for a link between metabolites of DDT and asthma risk.[183,184] In a prospective cohort study of children in Spain, wheezing at 4 years of age increased with increasing levels of DDE at birth. The adjusted RR for the children with exposure in the highest quartile was 2.63 (95% CI, 1.19–4.69). The use of physician-diagnosed asthma (occurring in 1.9% of children) instead of wheezing as the outcome variable also resulted in a positive association, although it was not statistically significant.[184]

In summary, the available data regarding chronic exposure to pesticides and children's respiratory health remain limited. Studies that incorporate pesticide-specific exposure assessment and markers of biological mechanisms and consider the influence of timing of exposure across the life span are needed.

THE PESTICIDE LABEL

Pesticides for sale or use in the United States must be registered with the EPA, and this includes approval of the product label, which contains the EPA registration number. The pesticide label contains several types of information that may be important in understanding and preventing acute health consequences associated with their use.[185]

The product label identifies the active ingredient and provides the manufacturer's

contact information. The label does not specify the particular class of pesticide for the active ingredient, which may make it difficult for a physician to identify potential toxic effects. Information about "other" or "inert" ingredients, which may account for up to 99% of the product, is not required to be disclosed on the label. These constituents include chemicals with known toxicity. The physician treating a patient may request this from the manufacturer; however, delay in information may compromise optimal clinical care. The local or regional poison control center plays an important role as a resource for any suspected pesticide poisoning. The EPA is currently considering rulemaking changes that would expand the disclosure of information on inert ingredients. One of the options under consideration includes labeling 100% of the ingredients.[186]

The "directions for use" section on the label explains when, how, and where the pesticide may be applied. The label is considered the law; therefore, any use of the product in a manner inconsistent with the label is a violation of the Federal Insecticide, Fungicide, and Rodenticide Act (Pub L No. 80-104).[187] Information on recommended storage of the product and disposal of the container is also printed on the label.

The label will contain a signal word and symbol to identify acute toxicity potential: "danger" along with the word poison and the skull and crossbones symbol signifies high acute toxicity; "warning" signifies moderate acute toxicity; and "caution" represents slight acute toxicity. There is a section for precautionary statements regarding the potential hazards to people or pets and the actions that can be taken to reduce these hazards, such as wearing gloves or other protective equipment. Basic first aid advice for responding to dermal, inhalational, and/or oral exposure is provided. Some labels contain a "note for physicians" that includes specific medical information. The label does not provide any information or warnings about the potential for chronic toxicity arising from normal use or misuse of the pesticide. An example of an interactive pesticide label can be found at the EPA Web site.[188] It includes "pop-up" features that define each of the components on the pesticide label.

STATE OF PESTICIDE KNOWLEDGE AMONG PEDIATRICIANS

Self-reported medical education and self-efficacy suggests pediatricians are not well prepared to identify pesticide exposure and illness, including taking a relevant environmental history or discussing pesticide risks with their patients.[189–191] Even in agricultural areas of the Pacific Northwest, where pesticide use is heavy, a survey of health care providers who serve high volumes of agricultural farmworkers and their families found that 61% did not feel comfortable responding to patient/client questions regarding pesticides on the basis of their training, background, and experience.[75] Among academic pediatricians with an interest in pediatric environmental health, pesticides were among the topics they felt least prepared to teach to their trainees.[192] Given the widespread use of pesticides and concerns for child health, opportunities to increase pesticide competency in pediatric medical education are likely to prevent missed diagnoses and reduce exposure because of improved anticipatory guidance.

Clinicians must have a high index of suspicion to identify pesticide poisoning. Identification and treatment of acute pesticide poisoning requires familiarity with the toxic mechanisms and related signs and symptoms of the pesticide classes. For example, when evaluating a patient with status epilepticus or mental status changes, certain insecticides belong in the differential among the numerous and more common etiologies. Eliciting an environmental history will help decipher the relative importance of pesticides in further clinical decision-making. The environmental history is a general tool for addressing potentially hazardous environmental exposures and is discussed in detail in the Pediatric Environmental Health manual from the AAP.[193]

EFFORTS TO REDUCE PESTICIDE EXPOSURE

Dietary Considerations

Dietary modifications can help reduce pesticide exposure. As mentioned previously, consuming organic produce has shown a reduced amount of urinary pesticide levels in comparison with a conventional diet.[22] Because many food-based pesticide residues occur on the surface of food crops, other practical approaches may be used to reduce exposures by washing produce, peeling off outer layers of leafy vegetables, and removing peels from fruits and vegetables. Trimming fat from meat and fat and skin from poultry and fish may reduce residues of persistent pesticides, such as the organochlorines, that concentrate in animal fat.

Efforts to address and reduce chronic pesticide exposure via the food supply in children have included regulatory approaches that consider the unique vulnerability of the developing child in policy decision-making. For example, the 1996 Food Quality Protection Act (Pub L No. 104-170, Section 405) required that the EPA use an additional 10-fold margin of safety regarding limits of pesticide residues on food (unless there are data that show a less stringent residue level is safe for

prenatal and postnatal development; for description, see http://www.epa.gov/opp00001/factsheets/riskassess.htm).

Integrated Pest Management

In addition to food residues, use of pesticides in and around the home and other settings where children spend time (child care, school, and playgrounds and sports fields) is an important influence on the chronic and cumulative exposure to pesticides among US children. Most of the pest problems that occur indoors as well as control of lawn and garden pests can be addressed with least toxic approaches, including integrated pest management (IPM) techniques. IPM focuses on nontoxic and least toxic control methods to address pest problems have been promoted and adopted for residential, school, and agricultural settings (fact sheets available at http://www.epa.gov/opp00001/factsheets/ipm.htm).

"Integrated" refers to employment of complementary strategies of pest control, which may include mechanical devices; physical devices; genetic, biological, and cultural management; and chemical management. For example, to control cockroaches, a family could be counseled to keep garbage and trash in containers with well-fitted lids, eliminate plumbing leaks or other sources of moisture, store food in insect-proof containers, vacuum cracks and crevices, clean up spills immediately, and use the least-toxic insecticides, such as boric acid, in cracks and crevices or bait stations. The goal is to target the pest and limit the effect on other organisms and the environment. Although developed with a focus on agricultural insect pests, IPM programs and knowledge have extended to address weeds and pest control in residential settings and schools, commercial structures, lawn and turf, and community gardens.

Within agriculture, IPM has been recognized and promoted for decades; however, inadequate leadership, coordination, and management of US Department of Agriculture IPM programs were identified as impediments to adequate progress in a 2001 report.[194] The report provided the basis for an ongoing national roadmap effort to improve ongoing development of increased IPM in agriculture.

To protect children, IPM in schools has been recommended by the US Department of Agriculture, EPA, American Public Health Association, and National Parent Teacher Association. Many states and local municipalities have adopted programs and resources to encourage IPM in public places, in addition to homes and schools (see Table 3). IPM strategies seek to minimize insecticide use by applying strategies such as cleaning up food and water, sealing cracks and crevices, and using pesticides that are contained in baits or traps, which are far less likely to pose a health concern compared with any type of broadcast spray application. Avoiding combination products with pesticides and fertilizers (ie, "weed and feed" preparations) is advised for lawn maintenance, because these tend to result in overapplication of pesticides. Hand weeding is always a reasonable alternative to herbicides. However, if an herbicide is to be used, some (such as glyphosate) have better acute human toxicity profiles than others (such as 2,4-D). Even so, glyphosate is not without its risks. Most cases of moderate to severe toxicity have occurred after intentional (suicidal) ingestion.[195] Using safe storage practices (in a locked cabinet or building) and not reusing pesticide containers are important components toward the prevention of acute poisonings after unintentional ingestion by small children. Reliable resources for useful information on pest-control alternatives and safe use of pesticides are available from the EPA and University of California-Davis (Table 3).

Spraying in the Community: Right to Know

Although there is no federal mandate for notification of pesticide use in communities, many states, locales, or schools have implemented requirements for posting warning signs or developing registries to alert individuals of planned pesticide application (see Table 3). These are designed to allow the public to make decisions to avoid exposures during application or soon after from residues. Other local policies that have been developed include restricting spray zones that create buffers from schools or other areas or restrict specific types of pesticide products in schools. Pediatricians can play a role in the promotion of development of model programs and practices in the communities and schools of their patients. For example, in some communities, pediatricians have participated in local organizations that have successfully advocated for no pesticide application in schools.

SUMMARY

Pesticides are a complex group of chemicals with a wide range of acute and chronic toxicity. Poison control centers report lower rates of more severe poisonings but continue to report similar total numbers of acute exposures among children. There is a growing body of literature that suggests that pesticides may induce chronic health complications in children, including neurodevelopmental or behavioral problems, birth defects, asthma, and cancer. Pediatricians are a trusted source of information for families and communities, although current training focused on pesticide toxicity and environmental health, in

general, is limited. Pediatricians should be familiar with the common pesticide types, signs and symptoms of acute toxicity, and chronic health implications. Efforts should be made to limit children's exposure as much as possible and to ensure that products released to the marketplace have been appropriately tested for safety to protect fetuses, infants, and children from adverse effects.

CLINICAL REPORT

Psychological Maltreatment

abstract

FREE

Psychological or emotional maltreatment of children may be the most challenging and prevalent form of child abuse and neglect. Caregiver behaviors include acts of omission (ignoring need for social interactions) or commission (spurning, terrorizing); may be verbal or nonverbal, active or passive, and with or without intent to harm; and negatively affect the child's cognitive, social, emotional, and/or physical development. Psychological maltreatment has been linked with disorders of attachment, developmental and educational problems, socialization problems, disruptive behavior, and later psychopathology. Although no evidence-based interventions that can prevent psychological maltreatment have been identified to date, it is possible that interventions shown to be effective in reducing overall types of child maltreatment, such as the Nurse Family Partnership, may have a role to play. Furthermore, prevention before occurrence will require both the use of universal interventions aimed at promoting the type of parenting that is now recognized to be necessary for optimal child development, alongside the use of targeted interventions directed at improving parental sensitivity to a child's cues during infancy and later parent-child interactions. Intervention should, first and foremost, focus on a thorough assessment and ensuring the child's safety. Potentially effective treatments include cognitive behavioral parenting programs and other psychotherapeutic interventions. The high prevalence of psychological abuse in advanced Western societies, along with the serious consequences, point to the importance of effective management. Pediatricians should be alert to the occurrence of psychological maltreatment and identify ways to support families who have risk indicators for, or evidence of, this problem. *Pediatrics* 2012;130:372–378

INTRODUCTION

Psychological or emotional maltreatment of children and adolescents may be the most challenging and prevalent form of child abuse and neglect, but until recently, it has received relatively little attention. The American Academy of Pediatrics (AAP) reviewed the topic in a technical report in 2002.[1] This clinical report updates the pediatrician on current knowledge and approaches to psychological maltreatment, with guidance on its identification and effective methods of prevention and treatments/intervention.

DEFINITION

There is no universally agreed definition of psychological maltreatment or emotional maltreatment, terms that are often used interchangeably. Psychological maltreatment encompasses both the cognitive and affective components of maltreatment.[2] One of the difficulties in clearly defining what such maltreatment comprises involves the absence of a strong societal consensus on the distinction between psychological maltreatment and suboptimal parenting.[3] Exposure to psychological maltreatment is considered when acts of omission or commission inflict harm on the child's well-being, which may then be manifested as emotional distress or maladaptive behavior in the child. Psychological maltreatment is difficult to identify, in part because such maltreatment involves "a relationship between the parent and the child rather than an event or a series of repeated events occurring within the parent-child relationship."[4] Isolated incidents of behaviors identified in Table 1 do not necessarily constitute psychological abuse. Psychological maltreatment refers to a repeated pattern of parental behavior that is likely to be interpreted by a child that he or she is unloved, unwanted, or serves only instrumental purposes and/or that severely undermines the child's development and socialization.[4] Recent conceptualization[5] of psychological maltreatment focuses on the caregiver's behaviors as opposed to the disturbed behaviors in the child. Such behaviors of the caregiver include acts of omission (ignoring the need for social interaction) or commission (spurning, terrorizing); may be verbal or nonverbal, active or passive, and with or without intent to harm; and negatively affect the child's cognitive, social, emotional, and/or physical development. Table 1 summarizes the different types of psychologically abusive caregivers' behaviors across 6 main categories.[2,5]

Although the psychological components of any form of child maltreatment are key to understanding its effects, psychological maltreatment is often not recognized when other forms of maltreatment coexist.[3] When psychological maltreatment occurs alone, it can be even harder to identify, and opportunities for intervention may be missed. This form of child maltreatment is possibly the most underreported to authorities.[3,6]

TABLE 1 Types of Psychologically Abusive Behaviors by Caregivers

Spurning	• Belittling, denigrating, or other rejecting • Ridiculing for showing normal emotions • Singling out or humiliating in public
Terrorizing	• Placing in unpredictable/chaotic circumstances • Placing in recognizably dangerous situations • Having rigid/unrealistic expectations accompanied by threats if not met • Threatening/perpetrating violence against child or child's loved ones/objects
Isolating	• Confining within environment • Restricting social interactions in community
Exploiting/Corrupting	• Modeling, permitting, or encouraging antisocial or developmentally inappropriate behavior • Restricting/undermining psychological autonomy • Restricting/interfering with cognitive development
Denying emotional responsiveness	• Being detached or uninvolved; interacting only when necessary • Providing little or no warmth, nurturing, praise during any developmental period in childhood
Mental health/medical/educational neglect	• Limiting a child's access to necessary health care because of reasons other than inadequate resources • Refusing to provide for serious emotional/behavioral, physical health, or educational needs

Adapted from Hart et al[2] and Brassard et al.[5]

DISTRIBUTION OF PSYCHOLOGICAL MALTREATMENT

A recent review of the burden and consequences of psychological abuse concluded that, although there were few studies reporting its prevalence, a number of large population-based, self-report studies in the United Kingdom and United States found that approximately 8% to 9% of women and 4% of men reported exposure to severe psychological abuse during childhood.[7] This review found even higher rates reported in Eastern Europe. A number of US surveys found that psychological and emotional maltreatment were the most frequently self-reported forms of victimization.[8]

DETERMINANTS OF PSYCHOLOGICAL MALTREATMENT

Although it is recognized that psychological maltreatment occurs in a wide range of families, it is more often associated with multiple family stresses[9] and, in particular, with factors such as family conflict, adult mental health problems, and parental substance abuse[10] that may be co-occurring.[11] For example, some parental mental health problems are associated with unpredictable and frightening behaviors, and others (particularly depression) are linked with parental withdrawal and neglect.[12,13] Similarly, in terms of family conflict, attacks on a parent almost always frighten a child, even if the child is not the direct target. Threats or actual violence as part of a pattern of aggression against one parent will sometimes exploit the other parent's or child's fears.[14,15] Children exposed to violence in the home are at disproportionate risk of injury,

eating disorders, and self-harm,[16] even when they are not themselves victims of physical violence. The AAP statement "Intimate Partner Violence: The Role of the Pediatrician" deals with how such issues should be addressed.[17] Although there is a paucity of literature specifically addressing the issue of parental substance abuse and psychological maltreatment,[18] substance abuse on the part of one or both parents is associated with high rates of child maltreatment.[19,20]

ASSOCIATED IMPAIRMENT

Precisely because it interferes with a child's developmental trajectory, psychological maltreatment has been linked with disorders of attachment, developmental and educational problems, socialization problems, and disruptive behavior.[21,22] Research involving institutionalized Romanian orphans demonstrated the effects of severe emotional and sensory deprivation on later IQ, executive function and memory, psychological processing, attachment, and psychiatric disorders.[23,24] The effects of psychological maltreatment during the first 3 years of life can be particularly profound, because rapid and extensive growth of the brain and biological systems takes place during this period, and this growth is significantly influenced by the young child's environment and, in particular, the early parenting that he or she receives.[25] Psychological maltreatment also negatively affects the organization of the child's attachment to important adults in his or her life.[26,27] Longitudinal studies have shown that impairment in security of attachment is associated with a range of later problems,[27] because early parenting plays a significant role in influencing children's beliefs about themselves (ie, in terms of the extent to which they are lovable) and about themselves in relation to other people (ie, when they have needs, people will respond appropriately to them). The research suggests that these internalized beliefs can affect children's later cognitive schemas and, thereby, their psychological adjustment.[28]

Psychological maltreatment in early childhood is also associated with insecure attachment in adulthood.[29] A recent overview of the evidence found that as the child grows older, such attachment problems interfere with a number of aspects of later functioning, including peer relations, intimacy, caregiving and caretaking, sexual functioning, conflict resolution, and relational aggression.[29] The findings from longitudinal[30] and retrospective[28] studies also suggest a strong association with psychiatric morbidity. For example, one longitudinal study found that psychological unavailability and neglect in early childhood were associated with increased social problems, delinquency, aggression, and attempted suicide in adolescents and also that most psychologically abused children received at least 1 diagnosis of mental illness, with three-quarters having comorbid conditions for 2 or more disorders. Factors that may influence the effects of the abuse include early caregiving experiences; frequency, intensity, and duration of the abuse; factors intrinsic to the child, such as behavioral and coping strategies, self-esteem, and disposition; and the availability of supportive relationships.[31] For example, although the evidence does not relate specifically to psychological maltreatment, 1 study found that boys who experienced abuse that started before 12 years of age had more serious problems (eg, arrests and severity of delinquency) compared with boys who were abused after 12 years of age.[32] Without intervention, the cycle of abuse is often repeated in the next generation.[29]

Psychological maltreatment carries a significant burden for society, as can be seen in its effects on the health and social care systems,[33] such as the costs of educational failure, crime, and health services as a result of poor mental health.

ASSESSMENT

Psychological maltreatment poses a real challenge to pediatricians dedicated to ensuring the health and well-being of children. Pediatricians need to be alert to the possibility of psychological maltreatment and consider such exposure in any assessment of psychological and behavioral conditions in childhood. Just as history about a psychological or behavioral problem should be obtained from multiple informants whenever possible, this is also the case when considering whether a child is being exposed to psychological maltreatment. Much emphasis has been placed on appropriate skills for interviewing children about sexual abuse, but it is also important to develop approaches for asking children about their relationships with caregivers, experiences of discipline (some psychological maltreatment occurs in this context), and feelings of self-worth, safety, and being loved. Once it is possible to interview a child from a developmental standpoint and the pediatrician is comfortable doing so, an individual interview with the child becomes important for assessment of any concerns of major psychological or behavioral problems. Even very young children, once they are speaking in sentences, can often provide this information. It is important to interview children alone, away from their caregivers, because they may be experiencing maltreatment from the very caregivers who accompanied them to an appointment. The AAP resources, Bright Futures[34] and Addressing Mental Health Concerns in Primary Care, A Clinician's Toolkit[35] provide guidance

that may be helpful in approaching these issues. The pediatrician needs to be aware of risk indicators for psychological maltreatment, such as parental psychiatric illness, including depression and substance abuse, among others. It is also important to be aware of the psychological maltreatment that can accompany exposure to intimate partner violence, although this is considered a separate type of maltreatment and is the focus of a previous AAP report as outlined above.[17] For children of all ages, major caregivers need to be interviewed (this should be performed individually to ensure the parent's safety when asking about such issues as intimate partner violence), and information should be gathered from teachers or child care personnel. Even brief telephone contact with school or child care personnel can be helpful in assessing a child's exposure to psychological maltreatment. Because this can be time consuming, ideally, the task of obtaining this information can be shared with another member of the pediatrician's office staff. Consultation with a pediatrician who has expertise in assessing child maltreatment or a mental health professional may assist the pediatrician in completing an assessment and plan.

Although there are no specific physical indicators for psychological maltreatment, it is essential to assess a child's growth and development, because these can be impaired in association with exposure to psychological maltreatment. The extent of impairment can vary; severe forms of psychological deprivation can be associated with psychosocial short stature, a condition of short stature or growth failure formerly known as psychosocial dwarfism.[36] Observing a child and parent(s) together can provide valuable information about the quality of their relationship and ability of a parent to respond to a child, although appropriate behavior by a parent in the context of a brief office visit does not rule out the possibility that a child is experiencing psychological maltreatment. Conversely, a single interaction that is of concern between a parent and child is generally not diagnostic of psychological maltreatment. Close clinical follow-up may be needed to clarify any issues of concern.

As outlined in the earlier technical report on this topic,[1] reporting of psychological maltreatment can be difficult. In some jurisdictions, clear indication of impairment in growth and/or development may be necessary for a child protective services agency to accept a report; detailed documentation is essential in such situations. It is important that the pediatrician record specific statements from the child, the family, and other sources and that the pediatrician is systematic in assessing the child's behavioral, psychological, and physical status in relation to the baseline assessment. For example, the pediatrician who has been providing general pediatric care to a child whose parents become involved in an extremely contentious custody/access dispute can alert the parents to the potential for the child to experience psychological trauma and can be aware of early indicators of impairment in the child. If identification for the parents of a child being exposed to potential psychological maltreatment does not lead to improvement in parenting behavior, the pediatrician can then make referrals to such services as mediation, mental health services, or child protective services. Careful follow-up is very important, because parents who are psychologically abusive may not be reliable in providing information about their child's functioning or their own response to intervention.

PREVENTION

The potential for major impairment associated with psychological maltreatment during the early years of life underscores the importance of identifying approach to intervention in infancy and toddlerhood. Prevention before occurrence involves both the use of universal interventions aimed at promoting the type of parenting that is now recognized to be necessary for optimal child development, alongside the use of targeted interventions directed at improving parental sensitivity to infant cues. This would include, for example, the recommendation that all routine contact between professionals and parents be used as an opportunity to promote sensitive and attuned parenting using a range of approaches (including media-based strategies, such as leaflets, books, and videos, among others) and to observe and identify parent-child interactions that require further intervention using targeted approaches. Although it is unknown whether these strategies actually prevent psychological maltreatment, there is preliminary evidence to suggest that the use of population strategies of this nature show promise in the prevention of child maltreatment generally.[37]

Targeted programs aimed at preventing early indicators of psychological abuse often focus on infants and younger children.[38] Much less is known about approaches to preventing psychological maltreatment in the older age groups. Specifically, maternal insensitivity to infant cues,[39] which is associated with insecure attachment, is a significant predictor of socioemotional maladaptation.[27] A meta-analysis of attachment-based interventions that ranged from home-visiting programs to parent-infant psychotherapy, found significant improvements in maternal sensitivity ($d = 0.33$) and infant attachment insecurity ($d = 0.22$).[40]

Greater effectiveness was associated with programs that included several sessions and had a clear behavioral focus. Maternal insensitivity is an important element of psychologically harmful parent-child relationships; brief focused interventions, such as those involving video feedback and attachment discussion, might improve insensitive parenting, but there is no direct evidence at this time that these interventions prevent psychological maltreatment. Furthermore, interventions to date have focused on maternal-child interactions; it is important to address paternal-child interactions as well as other significant caregiving relationships.

One targeted program that has been shown effective in preventing child maltreatment generally is the Nurse Family Partnership (NFP), an intensive home-visitation program provided by nurses to low-income first-time mothers beginning prenatally and during infancy.[41] Because the goals of the NFP include assisting women to promote healthy prenatal behaviors and parents' competent care of their children, it is possible that the NFP could prevent psychological maltreatment as part of the overall reduction in maltreatment, but its effectiveness in preventing this specific type of maltreatment has not been assessed.

TREATMENT

Despite ongoing debate about the role of formal child protection processes for dealing with psychological maltreatment,[42] there is agreement about the need to intervene early to minimize poor outcomes. It is important to consider what is known about approaches to prevent recurrence of psychological maltreatment and treat associated impairment, once it has been identified. There is a paucity of studies evaluating the effectiveness of approaches specifically designed for parents or caregivers who psychologically abuse their children. One randomized trial compared 2 group-based cognitive-behavioral therapy parenting programs (standard and enhanced models of the Triple-P Program) aimed at psychologically abusive parents.[43] The standard program focused on child-management strategies, and the enhanced model included components to alter parental anger and misattributions. Both groups made gains, there was no actual control group, and many parents had self-referred, reducing the generalizability of the results. Parents who are psychologically abusive may not be able to recognize their own behavior and self-refer.[44] Results of another trial suggest that a preschool child-parent psychotherapy program may be beneficial in improving specific aspects of the mother-child relationship, but further research is necessary.[45] A number of innovative methods of working with parents with mental health[46] and substance misuse problems have recently been developed and evaluated.[47]

There is major need for research to develop and test effective treatments for children who have experienced psychological maltreatment, either alone or in combination with other forms of maltreatment.

GUIDANCE FOR THE PEDIATRICIAN

Psychological maltreatment is just as harmful as other types of maltreatment. Although little is known about approaches to its prevention or treatment, it is important for pediatricians to be alert to its occurrence and consider ways to support families who have risk indicators for this problem. Pediatricians should develop approaches for asking children about their relationships with caregivers, experiences of discipline and feelings of self-worth, safety, and being loved. Bright Futures[34] and the Addressing Mental Health Concerns in Primary Care toolkit[35] are resources that can assist the pediatrician in the evaluation; however, they are not specific to psychological maltreatment.

The pediatrician should encourage parents who are experiencing mental health problems, intimate partner violence, or substance misuse to consider the effects of such conditions on their parenting and assist them in accessing appropriate resources, such as referrals to mental health professionals and substance misuse treatment programs. With respect to identification of psychological maltreatment, Rees[48] suggests that pediatricians need to be "as confident in assessing inadequate emotional care as physical and sexual abuse." This might include an assessment of parent-child interactions through the use of interviews or consultation with other clinicians, such as mental health providers, to assess the child's feelings and understanding about the situation. As with other types of child maltreatment, children showing signs of behavioral and psychological problems should be assessed to identify specific conditions, such as depression or posttraumatic stress disorder, for which there are evidence-based treatments, such as cognitive-behavioral therapy. Several trauma-specific interviews have been developed to determine whether children and adolescents presenting with mental health problems have been exposed to maltreatment.[49] To date, such instruments have been used mainly in research settings, but studies are increasingly examining their clinical applicability.

Although the evidence is limited with regard to interventions for psychological maltreatment, it is important for pediatricians to refer families for additional assessment and treatment if psychological abuse or neglect is

suspected, in addition to referring to child protective services in accordance with individual state laws, and follow-up appointments should be made so that the progress of the situation can be monitored.

Another equally important aspect of responding to psychological maltreatment is professional communication; collaboration among pediatric, psychiatric, and child protective services professionals is essential in formulating a management plan for a child at risk for or experiencing psychological maltreatment. Specific goals need to be put in place, and in cases where exposure to psychological maltreatment persists, the pediatrician should advocate for the needs of the child to remain paramount. Although efforts should focus on ways to assist the family with the child remaining in the home, it is important for the pediatrician to be alert to situations in which a child's needs are better met outside the home, either on a temporary or permanent basis. Consideration of out-of-home care interventions should not be restricted to cases of physical or sexual abuse; children exposed to psychological maltreatment may also require a level of protection that necessitates removal from the parental home.

Pediatricians are uniquely positioned to educate those working in child welfare, child health care, and the judicial system about the complex needs of children exposed to psychological maltreatment. Because determination of and response to psychological maltreatment by child protective services can vary considerably across regions, pediatricians can assist child protective services workers in understanding the effects of exposure to maltreatment on the child as well as possible resources for intervention. Because less is known about psychological maltreatment and it has been recognized relatively recently compared with other subtypes of abuse and neglect, there is even less standardization of approaches to investigation and intervention by child protective services agencies. The pediatrician is well situated to advocate on behalf of the child and can take on an important liaison role with professionals in the child welfare system.

abstract

FREE

Control of pain and stress for children is a vital component of emergency medical care. Timely administration of analgesia affects the entire emergency medical experience and can have a lasting effect on a child's and family's reaction to current and future medical care. A systematic approach to pain management and anxiolysis, including staff education and protocol development, can provide comfort to children in the emergency setting and improve staff and family satisfaction. *Pediatrics* 2012;130:e1391–e1405

BACKGROUND

A systematic approach to pain management is required to ensure relief of pain and anxiety for children who enter into the emergency medical system, which includes all emergency medical services (EMS) agencies, interfacility critical care transport teams, and the emergency department (ED).[1] The administration of appropriate analgesia in children varies by age as well as by training of the ED team (which includes physicians, nurses, physician assistants, and nurse practitioners), however, and still lags behind analgesia provided for adults in similar situations.[2] Furthermore, neonates are at highest risk of receiving inadequate analgesia.[3,4]

Encouragingly, improvements in the recognition and treatment of pain in children have led to changes in the approach to pain management for acutely ill and injured pediatric patients.[5] Studies have shown an increase in opiate use in children with fractures.[6–8] Recent advances in the approach and support for pediatric analgesia and sedation, as well as new products and devices, have improved the overall climate of the ED for patients and families in search of the "ouchless" ED.[5,9] Increased parental education regarding pain and sedation, physician comfort and desire to enhance patient satisfaction, and a quest to satisfy accreditation regulations have appropriately driven this effort. System-wide approaches for pain management awareness and strategies work best if they are woven into the fabric of the emergency medical system through education and protocol development. The purpose of this report was to provide information to optimize the comfort and minimize the distress of children and families as they are cared for in the emergency setting.

STATEMENT OF THE PROBLEM

Barriers to adequate pain control for children in the ED and in out-of-hospital emergency care settings include difficulty in assessing pain in

young patients, unfamiliarity with new products and techniques, fear of medication adverse effects, staffing limitations, and time constraints.[10–15] Children's pain is underestimated because of the underuse of appropriate assessment tools and the failure to account for the wide range of children's developmental stages. Analgesic agents typically used for pain in other settings might not be used in the ED because of concerns regarding masking of symptoms and prevention of appropriate diagnoses as well as misconceptions or personal biases by physicians or parents against using stigmatized medications like opiates. Topical anesthetics may be underused because of concerns regarding delay in definitive treatment, cost, or lack of availability. In addition to the child's developmental level, culture, ethnicity, and race affect pain management from both a patient and physician perspective. It is clear that cultural differences can contribute to how an individual or family manifests behavioral distress and anxiety[16–19]; however, no predictable patterns have emerged with regard to a consistent pain experience within ethnic groups.[20] Studies have noted that Hispanic and black individuals with long-bone fractures were less likely to receive analgesics than were non-Hispanic white individuals.[21–23] A review of the National Hospital Ambulatory Medical Care Survey from 1992 to 1997 demonstrated that among patients with fractures, black children covered by Medicaid were least likely to receive parenteral sedation and analgesia.[24] Opioid prescribing for painful conditions has increased for all patients, but white patients continue to be more likely to receive an opioid prescription than black, Hispanic, or Asian patients.[25]

Although few physicians still believe that children do not feel pain the same way adults do and that pain has no untoward consequences,[15] there is a growing recognition of how even minor painful procedures, such as needle sticks, can affect a child's longer-term emotional well-being.[26] Inadequate sedation and pain control can worsen a child's reaction to subsequent, possibly even nonpainful procedures. Neonates who undergo procedures with inadequate analgesia have long-standing alterations in their response to and perceptions of painful experiences.[27–32] Inadequate pain control as well as invalidation of the child's pain during oncology procedures leads to significantly increased pain scores for subsequent painful procedures.[33,34] Posttraumatic stress symptoms can occur after procedures or stressful medical experiences that are not accompanied by appropriate pain control or sedation, and this can lead to adverse reactions to subsequent procedures.[35–37]

In the ED, children often present with a constellation of symptoms but no final diagnosis; they are usually unknown to the treating physician, have a wide range of medical or surgical problems, and are unlikely to be fasting on arrival.[11] These factors make their assessment and the selection of appropriate analgesic intervention more complicated. As well, the emergency setting can be a busy, fast-paced environment in which heightened patient and parental anxiety increases the perception of pain and makes its treatment more difficult.[12]

Optimal pain management requires a thorough understanding of pain assessment and management strategies.[12,13] Education in pain management is a recent emphasis for hospitals as well as regulatory agencies, such as The Joint Commission: "Each and every patient has a right to the assessment and management of pain."[38,39]

NEW INFORMATION

Setting the Stage for Relief of Pain and Anxiety

Physicians can begin to address pain and anxiety as soon as a child comes in contact with the EMS system. Prehospital EMS providers typically receive relatively little pain management instruction.[40,41] The development of pain assessment and management protocols specifically for prehospital EMS providers, along with educational initiatives, can improve pain management in the field.[40,42–44] Several adult studies and 1 pediatric trial show that analgesics, such as opiates and tramadol hydrochloride, can be used in prehospital protocols to decrease pain scores without causing respiratory depression.[45–48] Alternative delivery systems, such as transmucosal medications or inhaled nitrous oxide, could offer pain control without requiring intravenous (IV) access, providing advantages in the field as well as in the hospital setting.[49–53] Some EMS systems have implemented a "toolbox" of distraction equipment on units as an adjunct to providing pain relief in the anxious, uncomfortable child.

Assessment and Management of Pain, Stress, and Anxiety in the ED

The Environment

It is clear that there is a relationship between anxiety and perceived pain in children and adults.[54] The creation of an appropriate environment is essential to minimize the pain and distress of a child's ED visit.[12] Ideally, each child should be placed in a private room. Even in a general ED, there can be a dedicated pediatric area that provides a child-friendly, calming environment.[11] Colorful walls, pictures on the ceiling, and a collection of toys and games will minimize fear induced by this strange setting.[12]

Stress management and emotional support are essential to providing a comfortable environment for the child and have been shown to reduce anxiety in older children as well as parental perception of pain in younger children.[55] Adequate preparation has been shown to decrease anxiety and increase a child's coping before a minor procedure or surgery.[56–58] Distraction can range from simple techniques, such as a bubble blower or pinwheel used by the child during a painful injection, to techniques that require more time and training, such as hypnosis.[59–61] Structural changes, such as outfitting each procedure room with equipment that can provide videos and music, and distraction stations equipped with bubble columns, light wands, and imagery projectors, can be helpful in engendering a feeling of safety and comfort in young children.[62–67] A child life specialist based in the ED has the ability to (1) decrease anxiety and pain perception using developmentally appropriate education and preparation to patients and families; (2) teach the child and staff simple distraction techniques, deep breathing, progressive relaxation, or guided imagery; (3) help the child to develop and execute coping plans during difficult events in the ED; (4) educate the child about the ED environment and his or her diagnosis; and (5) support family involvement in the child's care.[68–70] The child life specialist has an important role. He or she is one of a few professionals in the emergency setting who is not in a position to cause emotional or physical pain to the child[71,72]; however, nurses, physicians, and ancillary staff also share in this responsibility and can learn from and teach each other these techniques. Optimally, the treatment plan for each child should be communicated to the entire medical care team with specific regard to the environmental and behavioral management of anxiety in the emergency medical setting. This includes teaching children what to expect during a procedure or during their visit, showing them specific medical supplies they will be using, offering them choices when appropriate, giving them a role or a job during a procedure or hospital visit, and using distractions. Creating a relaxing environment can help a child to feel more comfortable and less stressed.

Allowing (but not requiring) family presence during painful procedures also may be of benefit. Although there is no evidence that family presence decreases pain, their presence for procedures can decrease child distress.[73–76] Family presence does not usually increase anxiety of the child or decrease the procedure success rate of experienced physicians; however, it is important to monitor parental responses to limit the adverse effects on all parties.[73,74,77] In addition, involving the parent as a coach for the child during the procedure is useful in reducing anxiety and distress.[78–82]

Pain Assessment in the ED

The Joint Commission standards include mandatory pain assessments for all hospital patients.[39] Pain is, by nature, a subjective experience and is influenced by social, psychological, and experiential factors. For example, patients who experience chronic pain may not report the same pain level or exhibit the same facial cues and vocalizations as those who are new to the pain experience. Pain assessment, which is obviously the first step toward appropriate treatment, can, therefore, be more complex than just obtaining a single pain score; it is also essential to pay attention to changes in pain scores in response to treatment. The current clinical standard for pain assessment is a self-report scale. Simple numerical scales, such as verbally grading pain from 0 to 10, are often used in adults; although there is evidence that this technique may be accurate in older children with moderate to severe pain, it may be less accurate for those with abdominal pain.[83,84] Several well-validated scales exist for children as young as 3 years to report their own pain level.[85–88] The revised FACES pain scale, the Wong-Baker Faces scale, and the 10-cm Visual Analog Scale have been used successfully in many EDs caring for children.[86,88–92] Other dimensions can be added to the visual analog scale, such as height, width, and color, and are valid methods for assessment of acute pain in children.[93] For those who are unable to use self-report scales, behavioral scales can be combined with an evaluation of the patient's history and physical findings to assess the level of a child's pain.[94–96] Pain in a neonate can be evaluated using the Neonatal Infant Pain Scale,[97] and pain in infants, young children, and those with cognitive impairment can be assessed using the FLACC (face, legs, activity, crying and consolability) scale.[98–104] It must be noted that few, if any, scales have been validated in the prehospital setting.

Pain Management in the ED

Pain assessment should occur routinely at the triage desk along with vital signs; however, reassessment during the ED stay is imperative to determine treatment effect.[12,13,105] In addition, physicians should take into account the possibility that combining multiple minor procedures may produce as much stress and discomfort as a single major procedure.[106]

Controlling Pain Related to Needle Sticks and Other Minor Procedures

Patients with less acute conditions also may require analgesia.[107] Protocols should be developed to facilitate the delivery of appropriate medications, such as acetaminophen, ibuprofen, or oral opiates, to these patients (Table 1).

TABLE 1 Triage Oral Analgesic Administration Guidelines

Purpose
To provide analgesic therapy to patients presenting to triage with a complaint of pain
Procedure
1. Assess pain score using a validated tool
2. Immediately triage to a treatment room all patients with severe pain as assessed by triage nurse and consideration of pain score
3. For those not requiring immediate evaluation with pain score >3 (0–10 scale) or chief complaint consistent with pain, consider administration of oral analgesic
4. Assess recent analgesic use
Contraindications
1. Allergy to analgesic (consider alternative)
Medications
1. Ibuprofen (avoid if the patient has aspirin allergy, anticipated surgery, bleeding disorder, hemorrhage, or renal disease)
2. Acetaminophen (avoid if the patient has hepatic disease or dysfunction)
3. Oral oxycodone

TABLE 2 Guidelines for Use of Topical Lidocaine in the ED

Topical anesthetics should be considered in any patient who has a high likelihood of undergoing a non-emergent invasive procedure on intact skin in the ED. These include the following:
• Intravenous line placement or venipuncture
• Lumbar puncture
• Abscess drainage
• Joint aspiration
Discussion with parents should bring up the following issues:
• Topical lidocaine does not provide complete pain relief
• Some patients may require a procedure before topical lidocaine reaches its full effectiveness (see below)
• Discuss with the parents how they feel the patient will tolerate the topical lidocaine application, in terms of anticipation of the procedure as well as sensory integration disorders
Contraindications:
• Emergent need for IV access
• Allergy to amide anesthetics
• Nonintact skin
• EMLA only: Recent sulfonamide antibiotic use (trimethoprim-sulfamethoxazole, erythromycin-sulfisoxazole); congenital or idiopathic methemoglobinemia
The topical anesthetic dose should be lower for patients <12 mo old or weighing <10 kg
Placement of topical lidocaine:
• Intravenous line placement
Topical lidocaine should be placed in at least 2 sites over veins amenable to placement of an IV line, preferably judged by the nurse placing the IV line.
Care should be taken to avoid mucous membrane contact or ingestion
• Lumbar puncture
Placement of topical lidocaine for lumbar puncture should be considered as soon as the decision is made to perform a lumbar puncture; accurate placement may require consultation with the clinician performing the procedure
Liposomal topical lidocaine reaches full effectiveness in 30 min, heated topical lidocaine in 20 min, EMLA reaches full effectiveness in 60 min.

Topical anesthetics can be placed proactively to control the pain associated with placement of IV catheters and other minor procedures. For example, in 1 inner-city pediatric ED, 90% of patients requiring IV access did not undergo this procedure until at least 60 minutes after triage.[108] A prediction model was developed whereby the patient's chief complaint and medical history, combined with an experienced triage nurse assessment, determined with some accuracy which patients had a high probability of requiring IV access.[109] These findings could be adapted to develop topical anesthetic protocols for painful procedures in other EDs, taking into account their patient volume, acuity, and flow characteristics (Table 2). Some topical anesthetics have been developed that produce anesthesia more rapidly than eutectic mixture of local anesthetics (EMLA; AstraZeneca, Wilmington, DE). A topical liposomal 4% lidocaine cream (LMX_4; Ferndale Laboratories, Ferndale, MI) provides anesthesia in approximately 30 minutes.[110,111] Heat-activated systems have shortened the time required to as low as 10 to 20 minutes for IV insertion pain relief.[112] Topical anesthetics also have been reported to improve procedural success rates, likely because of decreased movement leading to better accuracy.[113,114] When the procedure cannot be delayed or needs to take place in the prehospital setting, other techniques can be used; intradermal lidocaine injection as well as intradermal saline with benzyl alcohol preservative decreases the pain of venous cannulation without affecting procedural success rate.[115–119] Needle-free injection systems using either powder or liquid jet injection reduce the onset time even more.[106,120–123] Vapocoolant sprays that have immediate onset of action have been found to be effective in reducing venipuncture pain in adults; however, they are less effective in children, likely because of their intolerance of the unpleasant cold feeling resulting from the required administration time.[124,125] Recent innovations include a vibrating device that, when applied to the proximal extremity over a cold pack, may decrease the pain of venipuncture and immunizations by taking advantage of the "gate" theory of pain. However, further study is required to determine the comparative efficacy of this technique.

Similar protocols should be developed for topical anesthetic placement for laceration repair at triage (Table 3). Laceration repair should be completed with an emphasis on minimizing pain and anxiety. Several topical anesthetic/vasoconstrictor combinations, such as lidocaine, epinephrine, and tetracaine, which can be made by the in-hospital pharmacy as a liquid or gel preparation, provide excellent wound anesthesia in 20 to 30 minutes.[126,127] EMLA cream also provides topical anesthesia for laceration repair, although it is not approved by the US Food and Drug Administration for this purpose.[128,129] Tissue adhesives, such as octyl cyanoacrylate, provide essentially painless closure for low-tension wounds.[130,131] Steri-Strips (3M, St Paul, MN) provide similar painless closure and are less expensive than currently available tissue adhesives.[132] Absorbable sutures should be considered for facial wounds that must be sutured to avoid the pain and anxiety produced by suture removal.[133,134]

TABLE 3 Guidelines for Use of LET (a Topical Anesthetic for Open Wounds)

Eligibility
- LET can be applied to simple lacerations and may be applied to complex or deeper lacerations that may require supplemental subcutaneous anesthetic administration.

Contraindications
- Allergy to amide anesthetics
- Gross contamination of wound

Procedure
- LET should be placed according to standard ED procedure; time of placement should be documented on triage sheet
- Dose: 3 mL for children >17 kg; 0.175 mL/kg in children <17 kg[a]
  (1) Place LET on open wound and cover with occlusive dressing or place cotton ball soaked with LET solution into wound
  (2) Allow LET to soak into wound for 10–20 min or until wound edges appear blanched.

LET, lidocaine, epinephrine, and tetracaine.
[a] Based on maximum dose of 5 mg/kg of lidocaine.

Lidocaine can be used alone in urgent situations or after topical anesthetics have been applied. Lidocaine can be injected in an almost painless manner.[115] This technique includes buffering the anesthetic with bicarbonate, warming the lidocaine before injection, and injecting slowly with a small-gauge needle.[135–139] Lidocaine buffered with bicarbonate made in advance can be stocked in the ED and will remain stable for up to 30 days.[140,141]

The pain of intramuscular injection can be reduced using the shortest needle length possible to reach the intramuscular tissue, and applying concurrent manual pressure to the injection site.[142–145]

Neonatal Pain Management in the ED

Simple changes in practice can minimize painful stimuli for infants. Protocols for topical anesthetic placement should include neonates. Topical anesthetics for procedures ranging from circumcision to venipuncture are safe in newborn infants and even preterm infants, with appropriate dosing and short administration times.[146–148]

Recent studies have suggested methods by which neonatal distress during painful procedures can be minimized. Sucrose has been found to decrease the response to noxious stimuli, such as heel sticks and injections, in neonates and has even been demonstrated to reduce subsequent crying episodes during routine care, such as diaper changes.[149–161] This effect seems to be strongest in the newborn infant and decreases gradually over the first 6 months of life. Nursing protocols that allow for the use of sucrose before painful procedures are in place at many hospitals (Table 4). A 12% to 25% sucrose solution that is made by the pharmacy or is available commercially can be used (Sweet-Ease, Children's Medical Ventures, Norwell, MA). The use of a pacifier alone or in conjunction with sucrose also has been shown to have analgesic effects in neonates undergoing routine venipuncture.[162] Skin-to-skin contact of an infant with his or her mother and breastfeeding during a procedure decrease pain behaviors associated with painful stimuli.[163,164]

Available evidence supports the use of local and topical anesthetic for lumbar puncture in neonates.[165,166] Protocols can allow for the timely placement of topical anesthetic, or injected buffered lidocaine can be used at the site of needle insertion before the procedure. Concerns over the increased difficulty of lumbar puncture after local anesthetic use have proved to be unfounded, and one study even demonstrated improved success with the use of topical anesthetic.[113,165,167]

Pain can be decreased in neonates by the elimination of heel sticks and intramuscular injections. Venipuncture seems to be less painful than heel lancing for obtaining blood for diagnostic testing.[168] When the intramuscular route is necessary, topical anesthetic should be used.[169] Use of distraction techniques discussed previously,

TABLE 4 Guidelines for Use of Sucrose in the ED

Indications
- Use as an adjunct for limiting the pain associated with procedures such as heel sticks, venipuncture, IV line insertion, arterial puncture, insertion of a Foley catheter, and lumbar puncture in neonates and infants younger than 6 mo

Procedure
1. Administer 2 mL of 25% sucrose solution by syringe into the infant's mouth (1 mL in each cheek) or allow infant to suck solution from a nipple (pacifier) no more than 2 min before the start of the painful procedure
2. Sucrose seems to be more effective when given in combination with a pacifier; nonnutritive suck also contributes to calming the infant and decreasing pain-elicited distress

Contraindications: None

ice, and less painful injection techniques can also be efficacious.[170–173] The use of lidocaine as the diluent for ceftriaxone can decrease the pain of intramuscular injection.[174]

Does the Appropriate Use of Analgesics Make Evaluation More Difficult?

There is no evidence that pain management masks symptoms or clouds mental status, preventing adequate assessment and diagnosis. For patients with abdominal pain, several adult studies have shown that pain medications such as morphine can be used without affecting diagnostic accuracy.[175–179] Pediatric studies have demonstrated similar findings.[179,180] Clinical experience suggests that the use of pain medication makes children more comfortable and makes the examination of the patient's abdomen and diagnostic testing (such as ultrasonography) easier, thus aiding in diagnosis. In the child who has suffered multisystem trauma, small titrated doses of opiates can be used to provide pain relief without affecting the clinical examination or the ability to perform neurologic assessments.[181,182] The development of pain protocols can improve the management of children

who suffer major trauma.[183] Regional anesthesia should also be considered for patients who have injuries that are amenable to these techniques.[184,185] Additional studies evaluating these practices in pediatric patients are necessary but should not delay the development of protocols for the use of analgesics in patients with acute abdominal pain and multisystem trauma in the ED and even the prehospital setting.

Analgesia in the ED and EMS Setting

Optimal pain management requires expeditious pain assessment and rapid administration of systemic opioid pain medication to patients in severe pain. This may occur through various routes of administration, including transmucosal or IV routes. The IV route allows for rapid relief of pain and drug titration; the intramuscular route is less preferred, because it does not allow for medication titration and is painful at the time of delivery and for days afterward. Adjunctive pain medications, such as nonsteroidal antiinflammatory drugs, can be used judiciously in children with pain; antiplatelet activity and gastrointestinal tract and renal toxicity are rare but recognized adverse effects. Oral opiates and nonsteroidal antiinflammatory drugs are appropriate for mild to moderate pain if the patient has no contraindications to receiving oral medications. Alternative routes of medication administration, including oral, intranasal, transdermal, and inhaled routes, should be used when appropriate and may offer rapid relief of pain.[186] Studies of transmucosal, aerosolized, and inhaled fentanyl show analgesic action commensurate with IV opioids.[187–189] Transmucosal administration may be appropriate and useful in the prehospital setting as well.[190] Intranasal delivery, despite demonstrating more rapid onset of action, also may be less tolerated because of burning of the nasal mucosa during administration.[54,191] Drug delivery into the central nervous system is greatly enhanced with the use of an atomizer that distributes the medication more evenly to the mucous membranes.[192–194] Because adverse events are still possible when this mode of opiate administration is used, care should be taken when using adjunctive medications, such as benzodiazepines. In addition, if there is no IV access, it is prudent to prepare for alternative methods of administration for reversal agents. Pain medication should be provided in the ED as well as on discharge, even for those with mild to moderate pain. Patients and families should get specific instructions regarding dose and duration of use. Clear, written instructions should be provided for families regarding the after care of children who have received procedural sedation. Pain medication should be recommended on an around-the-clock basis for anyone in whom moderate pain is anticipated.

The use of sedative hypnotic medication may be required to reduce pain and distress for children undergoing procedures in the ED. Unfortunately, pain and anxiety are often difficult to differentiate in infants and toddlers and even in school-aged children. Although many procedures can be performed relatively painlessly with the use of a topical or local anesthetic, this does not obviate the use of pharmacologic agents to decrease the anxiety and stress in children undergoing procedures in the ED, especially when the child needs to remain still to ensure the success of the procedure. When the procedure is expected to be painful, the agents used should have analgesic properties as well. Emergency physicians are increasingly using short-acting medications such as propofol, alone or in combination with ketamine, for procedural sedation in children.[195,196] Published reports involving adult patients and recently published experiences with children demonstrate that, when applied using careful protocols and in a setting of experienced sedation teams, propofol, either alone or in combination with ketamine, can be used safely and effectively for sedation in children.[195,197–205] Benzodiazepines, particularly rapidly effective but relatively short-acting ones, such as midazolam, are also helpful in the prehospital and ED settings. Nitrous oxide is a potent analgesic that does not require venous access and is available in some EDs.[49–53] Nitrous oxide should be used in conjunction with appropriate sedation guidelines and avoided in patients with pneumothorax, bowel obstruction, intracranial injury, and cardiovascular compromise.[52,53] Nitrous oxide has many potential applications, including anxiolysis for procedures such as IV catheter insertion and laceration repair, pain control for burn débridement, and fracture and dislocation reduction; care should be taken if opiates are used concurrently so as not to reduce respiratory drive.[206] The most important part of providing safe sedation for children is the establishment of appropriate sedation systems and sedation training programs with credentialing guidelines for sedation providers that specifically address the core competencies required for the care of pediatric patients.[207,208]

Pain Considerations for Children With Developmental Disabilities

Children with developmental disabilities, particularly those with severe neurologic involvement, provide additional challenges to parents and EMS and ED personnel in management of acute pain and its associated anxiety. For many children, previous painful experiences in similar settings add to stress of the acute incident. Learning about the child's anticipated response

and previous experiences from parents, primary care physicians, and specialists informs the emergency physician and staff of useful supportive technique.[209–211] Parental understanding and awareness of subtle indirect behaviors or emotional shifts are often critical adjuncts in the assessment process of the child's sense of comfort and well-being. Child life specialists, as previously mentioned, are knowledgeable of distinct coping strategies to assist children with developmental disabilities and children who are more sensitive to sights and sounds. Myths of pain insensitivity or indifference must be actively avoided.[212–214] Pain modulation can vary widely, related to neurotransmitter function differences within the brain or along the injured spinal cord, thereby altering the perception and response to pain in children with previous injuries.[213–215] Cognitive impairments can affect both understanding and coping mechanisms, making self-report particularly challenging in young people with motor and/or cognitive differences. Maladaptive behaviors, heightened anxiety, and uncommon coping styles can add further complexity to the assessment process. The Non-communicating Children's Pain Checklist–Revised offers a validated visual method for staff members to assess and reassess children 3 to 18 years of age.[216–218] In addition, the Individual Numeric Rating Scale has been shown to be effective in children with developmental disabilities. In general, the approaches to medication use for pain and anxiety should hold true for children with developmental disabilities; some children, however, show altered sensitivity to medications and may be taking medications that interact with common pain medications.[219]

Sedation Policies and Protocols in the ED

Physicians, physician assistants, and nurse practitioners who administer sedation and analgesia should have proven training and skills and ongoing education in the management of pediatric airways and resuscitation, especially in the use of face mask ventilation and laryngeal mask airways. Emergency physicians and other nonanesthesiologist physicians with appropriate training have demonstrated the ability to safely and effectively provide moderate and deep sedation and dissociative anesthesia, allowing for the timely performance of procedures and rapid relief of pain and anxiety.[202,207,208,220,221] A recent large prospective study of 131 751 elective pediatric sedation encounters demonstrated no differences in serious adverse outcomes (ie, death, ICU admissions, aspiration events) between those performed by anesthesiologists and those performed by other pediatric medical subspecialists practicing in highly organized sedation systems.[222] Although the reported incidence of serious complications is low, it is imperative to develop ongoing policies that establish informed consent and close monitoring of these patients. A critical component of any sedation protocol is to require a trained observer to be solely responsible for monitoring the patient while the procedure is being performed.[223,224] Techniques such as noninvasive end-tidal carbon dioxide monitoring allow for more consistent detection of bradypnea, hypopnea, and apnea in sedated children and are being recognized increasingly as an essential part of the sedation armamentarium[225,226]; however, this is not a replacement for direct visualization of respiratory effort. Current guidelines from the American Academy of Pediatrics, American Society of Anesthesiologists, and American College of Emergency Physicians recommend a structured evaluation of children that allows risk stratification before beginning sedation, thereby reducing the risk of complications in the pediatric age group.[223,227–235] This evaluation should include issues such as preexisting medical conditions, focused airway examination, and consideration of nil per os (NPO) status. NPO guidelines for children receiving sedation in the ED are controversial. Many children who have received procedural sedation for emergencies have not fasted in accordance with published guidelines for elective procedures, and this variation was not associated with adverse outcomes.[236–239] Current data are insufficient to determine the length of time that constitutes safety with regard to NPO status.[237–243] Recently published guidelines recommend that the physician consider the urgency of the procedure, targeted depth of sedation, risk level of the patient, and timing of most recent solid food intake to determine the safety profile for each patient.[244]

Discharge criteria also are critically important for children undergoing sedation in the ED. Patients who receive sedatives with long half-lives, such as chloral hydrate or pentobarbital, are at particular risk of adverse events after discharge, either during transportation or in their homes after the procedure.[224] Strict adherence to criteria that require a child to be "back to baseline" in terms of consciousness, or adaptation of newer "maintenance of wakefulness" criteria, are critical to optimize safety surrounding the sedation process.[245]

Quality Improvement Programs

Any ED that provides treatment of children should have a quality improvement program that reviews, at regular intervals, sedation and pain management practices in pediatric patients. Transport team and prehospital EMS providers are essential partners in this ongoing review and should consider establishing internal review policies as well. Many hospitals use a multidisciplinary committee to

help interpret the data emanating from these reviews and then suggest system-wide protocol and educational initiatives. Indicators that should be evaluated include the use of validated pain scores; appropriate analgesics for specific disease states (whether severe or mild to moderate pain); topical anesthetics and other non-noxious routes of analgesia and sedation; monitoring for adverse outcomes; and the use of discharge instructions that outline the indications, dose, and duration of analgesic to be used.[246–248] Discharge instruction also should include any possible adverse effects of sedative/analgesic medications used in the ED. Adverse events that lead to respiratory depression or other life-threatening conditions should be fully reviewed by a committee charged with understanding if systemic care issues or provider-specific issues were root causes of these outcomes.

Implementation

A systematic approach to pain management in the EMS requires an implementation strategy, promoted and advocated by leadership, that includes the following: (1) a comprehensive evaluation of current pain and distress management practices; (2) an educational and credentialing program regarding pain assessment and management techniques for all clinical staff, preferably overseen by a hospital-wide sedation committee[249]; (3) development of protocols to allow the universal and efficient application of pain management strategies and medications; and (4) a quality improvement process to evaluate the ongoing success of the program.[11,13] EMS agencies should establish policies and protocols that make available pertinent provider education and ensure quality improvement processes are in place for pediatric pain management protocols appropriate for their practice setting.

CONCLUSIONS

Management of a child's distress during illness or after an injury is an important yet complex aspect of emergency medical care for children. Physicians and prehospital EMS providers should be aware of all the available analgesic and sedative options. Adequate pain assessment is essential for pain relief and should begin on entry into the EMS and continue through discharge of the child from the ED. Multiple modalities are now available that allow pain and anxiety control for all age groups. Future research should concentrate on pharmacologic, nonpharmacologic, and device-related technology that can assist in reducing the pain and distress associated with medical procedures.

SUMMARY OF KEY POINTS

1. Training and education in pediatric pain assessment and management should be provided to all participants in the EMS for children; EMS medical directors should formally include pediatric pain management measures within the protocols provided to EMS providers.
2. Incorporation of child life specialists and others trained in nonpharmacologic stress reduction can alleviate the anxiety and perceived pain related to pediatric procedures.
3. Family presence during painful procedures can be a viable and useful practice in the acute care setting.
4. Pain assessment for children should begin at admission to EMS, including prehospital management, and continue until discharge from the ED. When discharged, patients should receive detailed instructions regarding analgesic administration.
5. Administration of analgesics and anesthetics should be painless or as pain free as possible.
6. Neonates and young infants should receive adequate pain prophylaxis for procedures and pain relief as appropriate.
7. Administration of pain medication has been demonstrated to preserve the ability to assess patients with abdominal pain and should not be withheld.
8. Sedation or dissociative anesthesia should be provided appropriately for patients undergoing painful or stressful procedures in the ED.
9. Pain management and sedation, including deep sedation and dissociative anesthesia, are fully within the monitoring and management capabilities of appropriately trained emergency medicine and pediatric emergency medicine physicians. Each emergency department that provides sedation and analgesia to children should include sedation competencies in recredentialing procedures and develop protocols, policies, and quality improvement programs as part of the systematic approach to pain management in the EMS.

POLICY STATEMENT

The Role of the Pediatrician in Rural Emergency Medical Services for Children

abstract

FREE

In rural America, pediatricians can play a key role in the development, implementation, and ongoing supervision of emergency medical services for children (EMSC). Pediatricians may represent the only source of pediatric expertise for a large region and are a vital resource for rural physicians (eg, general and family practice, emergency medicine) and other rural health care professionals (physician assistants, nurse practitioners, and emergency medical technicians), providing education about management and prevention of pediatric illness and injury; appropriate equipment for the acutely ill or injured child; and acute, chronic, and rehabilitative care. In addition to providing clinical expertise, the pediatrician may be involved in quality assurance, clinical protocol development, and advocacy, and may serve as a liaison between emergency medical services and other entities working with children (eg, school nurses, child care centers, athletic programs, and programs for children with special health care needs). *Pediatrics* 2012;130:978–982

COMMITTEE ON PEDIATRIC EMERGENCY MEDICINE

EMSC—emergency medical services for children
IOM—Institute of Medicine

INTRODUCTION

Ten percent of prehospital emergency responses[1] and 37% of emergency department (ED) visits are for patients 24 years and younger.[2] Children, in general, have been shown to use emergency medical services (EMS) less frequently than adults. When children younger than 5 years are cared for in the EMS system, they are less likely to receive appropriate interventions, such as splinting or cervical spine immobilization.[3]

According to the 2000 US Census,* 42% of the population lives in nonmetropolitan areas, 25% of which are rural[4]; 41% of community hospitals are considered rural by the *American Hospital Guide*.[5] Additionally, certain populations such as Native Americans disproportionately live in rural areas. Depending on the state, one-fourth to one-third of the population resides in rural or frontier areas[6]; rural is defined as fewer than 1000 people per square mile, and frontier is defined as 6 to 8 people per square mile. Rural areas vary widely, however, by environment, terrain, resources, and needs. Additionally, rural and frontier areas are common vacation destinations, with

*US Census data on urban and rural populations for 2010 are scheduled to be released in October 2012.

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

seasonal increases in population. A study of rural EMS reported the following: (1) 70% of prehospital health care professionals practice in rural areas; (2) rural EMS medical directors are more likely to be nonpediatric primary care physicians; and (3) 20% of states cross-train prehospital health care professionals in an expanded hospital role to address the national nursing shortage.[7]

Because of occupational and lifestyle exposure to work- and play-related vehicles, hazardous structures, and animals (eg, farm machinery, pickup trucks, all-terrain vehicles, grain silos, and horses) and environmental threats (eg, weather, terrain, and toxins), children in rural areas have unique medical and surgical emergency needs. Children in rural areas have increased risk of disability and death from injury, trauma and medical diseases largely because of long transport times to definitive care.[7] It has also been reported that the quality of care rendered to children in rural EDs is not of a level equal to the quality of care in urban facilities.[8] Additionally, there may be a higher risk of medication errors for children treated in rural EDs.[9,10] Finally, in a survey study, remote and rural EDs were not as well prepared as urban EDs were to care for children.[11] Because definitive pediatric emergency and critical care usually are located far from rural children, any inadequacy of EMS education and intervention or lack of appropriate pediatric equipment may be even more detrimental in a rural setting.

Lack of access to all levels of care, with particular effects on vulnerable populations, is a major difference between emergency medical services for children (EMSC) systems in rural and urban areas. Decreased access to medical care increases the morbidity and mortality of rural children.[12,13] Vital access issues include:

- Communication (eg, 911 access [especially enhanced 911 access], the use of telemedicine in EMS consultation, and limited availability of cellular wireless telephone systems and high-speed and wireless Internet access)
- Transport method and availability (ground versus air; fixed wing versus rotor wing; weather, terrain, and distance)
- Appropriate emergency care equipment for children from infancy through adolescence
- Level of responding prehospital personnel (emergency medical technicians—basic versus paramedic, paid versus volunteer EMS services)
- Pediatric skills of prehospital health care professionals
- Pediatric expertise at the immediate receiving facility (general, community hospitals)
- Rural-to-urban hospital pediatric transport
- Referral center care
- Rehabilitation
- Local follow-up care
- Repatriation to local facilities
- Pediatric-specific primary and subspecialty care
- Preparation for emergencies involving children with special health care needs—specifically, technology-assisted children, including awareness and utilization of the Emergency Information Form [14]
- Public health emergency, disaster, and terrorism response plans applicable to rural settings (recognition of risk and familiarity with rural systems in preparation)

Pediatricians can play valuable roles in ensuring access to high-quality and comprehensive care for children in rural communities. Their leadership and advocacy, often organized through state American Academy of Pediatrics (AAP) chapters and state/territorial EMSC programs, can aid local and regional EMS organizations in the establishment of pediatric-specific protocols and policies, data collection, and pediatric-specific quality management and support for the development of enhanced pediatric capabilities via the legislative and regulatory process. They can also advocate for addressing the unique needs of children, including children with special health care needs, in local preparedness efforts around public health emergency and disaster planning. Through their expertise in the care of children, pediatricians can support efforts in pediatric emergency care education.

Local health care professional training (prehospital, emergency, and school nurses) in pediatrics would be enhanced by rural pediatricians' input and participation. Because skill retention is an issue in rural settings, periodic updates for rural health care professionals is necessary. Many pediatric-specific enhanced training courses (eg, Pediatric Advanced Life Support, Pediatric Education for Prehospital Professionals, Neonatal Resuscitation Program, Emergency Nursing Pediatric Course, Advanced Pediatric Life Support) are applicable. Promoting telehealth initiatives and Web-based education could also help increase access to training in the rural setting.[15–21] In fact, a study of rural education reports that rural prehospital providers accessed pediatric Web-based training more commonly than did urban providers.[21] In addition to health care professional education, pediatricians can provide patient and parent education about injury prevention, recognition of childhood emergencies, and accessing 911 and

poison control centers. Anticipatory guidance should also include first aid and preparation of the home for public health emergencies and disasters.

Office preparation for emergency response is crucial in rural areas and builds confidence in providers.[22] Pediatricians must recognize that rural areas, like urban areas, are subject to terrorist attacks, and it is prudent to address the needs of children in rural areas in preparation plans. Pediatric offices should be prepared to care for the acutely ill or injured child, arrange for definitive care, and participate in a community public health emergency or disaster response. The AAP provides information on office preparation in *Childhood Emergencies in the Office, Hospital, and Community*.[23] Additionally, a policy statement on the role of the pediatrician in disasters and bioterrorism preparedness has been published by the Committee on Pediatric Emergency Medicine and Committee on Medical Liability of the AAP.[24]

Finally, involvement in legislator and public education about children's health care by collecting and reporting EMSC data may improve the system locally and statewide. Data collection and research are particularly needed for EMSC in rural areas, where certain problems are more prevalent than in urban settings (eg, skills retention, transport mechanisms, volunteer responder's education and responsibilities, and delayed access issues). Interested pediatricians can find many opportunities to promote studies generating outcome-based information to improve local and national EMSC, with support from sources such as the Community Access to Child Health program, the Practice Research in Office Settings network, other AAP programs and support staff, and the Centers for Disease Control and Prevention and other federal agencies. Legislative input can be presented by pediatricians knowledgeable about statewide EMSC issues. Building local, statewide, and regional coalitions is a sound approach to generating legislative responsiveness and awakening the community to the importance of a sophisticated and competent EMSC program. In many rural areas, limited resources have led to the development of interstate coalitions to pursue EMSC agendas (eg, Intermountain Regional EMS for Children Coordinating Council).

In the 2006 Institute of Medicine (IOM) Future of Emergency Care Series entitled *Emergency Care for Children: Growing Pains*, regionalization, accountability, and coordination are the 3 goals set by the IOM Committee on the Future of Emergency Care in the United States Health System for developing an emergency and trauma care system of the future.[25] According to the IOM report, "critically ill and injured children should not be directed simply to the closest facility, but to the nearest facility with the pediatric expertise and resources needed to deliver high level care. The goal of regionalization is to improve patient outcomes by directing patients to facilities with the optimal capabilities and best outcomes for any given type of illness or injury."[25] To aid in regionalization efforts, rural issues that may need distinct legislative assistance include establishment of universal 911 (preferably "enhanced") service, communications technology, educational processes, advisory councils, coding standards, and data collection resources to assess areas for improvement in EMSC. Guidelines[26,27] are available to provide a framework for continued development of state EMSC; amendments specific to the rural locales may be necessary.

RECOMMENDATIONS

Development of quality EMSC in rural America requires motivated pediatric advocates to commit their expertise to prevention, education, legislation, and facilitation of these services. As highly trained child health professionals and leaders of the child health care team, rural pediatricians are encouraged to be aware of activities that would benefit from their involvement.

1. Advocate for legislative initiatives supportive of EMSC that meet the needs of children and pediatricians, including equity in funding for EMSC, especially trauma services. This will be a step toward ensuring that all children—whether they live in a rural or urban area; or are insured, underinsured, or uninsured—have unhindered access to care.
2. Participate in and work cooperatively with local EMS agencies responsible for local system design and development, including educational programs, simulations, structured protocols, communication (from dispatchers to ED physicians), hospital care and transport (with special focus on long transport time and distance issues), and quality improvement. This system should address children's needs, including those of children with special health care needs, and integrate well with the state EMS system. Key participants in this system include representatives from the state office of rural health, department of health, state EMSC programs, and AAP chapters.
3. Provide guidance in recruiting and retaining community EMS providers (prehospital and ED) and primary health care professionals (family practitioners, nurse practitioners, and physician assistants) who have pediatric training. This

includes helping them maintain skills and comfort with pediatric emergencies by providing continuing medical education, pediatric office rotations, and sensitive quality assurance review.

4. Develop a personal awareness of rural EMSC issues for American Indian/Alaska Native communities. For information, contact the Indian Health Services EMSC liaison or the Health Resources and Services Administration.

Pediatricians can develop strategies for community-sensitive outreach to rural areas and assist in the organization of regionalized pediatric emergency care, using available rural expertise and assets to optimize outcomes of seriously ill or injured rural children. Several resources are available for implementation and continuation of such an EMSC agenda.

POLICY STATEMENT

Role of the School Physician

abstract

FREE

The American Academy of Pediatrics recognizes the important role physicians play in promoting the optimal biopsychosocial well-being of children in the school setting. Although the concept of a school physician has existed for more than a century, uniformity among states and school districts regarding physicians in schools and the laws governing it are lacking. By understanding the roles and contributions physicians can make to schools, pediatricians can support and promote school physicians in their communities and improve health and safety for children. *Pediatrics* 2013;131:178–182

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

HISTORY OF PHYSICIANS IN THE SCHOOL SETTING

Physicians associated with schools have held a variety of titles over the years. For the purpose of this article, a school physician is any physician who serves in any capacity for a school district, such as, but not limited to, an advisor, consultant, medical director, volunteer, team physician, medical inspector, or district physician.[1] This statement does not address the role of physicians in school-based health centers[2] or the role of community pediatricians as private providers to school-aged children. Information on these topics is available on the American Academy of Pediatrics (AAP) Council on School Health Web site (http://www.aap.org/sections/schoolhealth/).

The tradition of a school physician dates back to the late 1800s, as parents and public officials recognized that public school facilities needed national systematic medical inspection.[3] Over time, the role of the school medical inspector expanded to include containment of prevalent infectious diseases of childhood[3,4] and eventually as an important vehicle to manage universal immunization.[5] Modern school physicians focus on the needs of individual children as well as the public health of the school community.[3,6,7] They often assist schools in accommodating students who have special health care needs, manage acute and chronic illness, and oversee emergency response, environmental health and safety, health promotion, and education.[8,9]

Millions of children spend roughly 7 hours per day, 180 days per year, in school[10] and may only visit their medical home once annually. In 1999, Dr Joycelyn Elders acknowledged the interdependence of health and education when she said, "You cannot educate a child who is not healthy, and you cannot keep a child healthy who is not educated."[11] In addition, Bright Futures, a national health care promotion initiative, encourages public schools and public health communities to become partners in prevention efforts.[12] Despite the value of coordinating

health and education, physicians are not effectively and consistently involved in schools across the nation. As a result, US children have varying levels of medical support and safety, depending on the community in which they live. Well-placed school physician expertise can contribute to the creation of policies and practices that provide sound, evidence-based structure to coordinated school health teams.

CURRENT LAWS PERTAINING TO THE PHYSICIAN IN SCHOOLS

Currently, there is no single national set of school health laws. School health services are primarily regulated by state or local governments or individual school districts, and these regulations vary.[13–15] Some states mandate school physicians; most do not.[16,17] However, "no one has systematically identified the full range of relevant legal authorities pertinent to schools that may help shape the health of children and adolescents."[15]

Federal law guarantees antidiscrimination and equal protection to individuals who have disabilities.[18–20] These laws require federally funded states to provide "related services," such as school nursing, as part of a child's Individualized Education Plan. However, the US Supreme Court ruled that school districts are not required to provide physician services for individual students, except for diagnostic or evaluative purposes for special education services.[13–15] This ruling's broad interpretation has limited funding to schools for physician services, despite the fact that many states, and the AAP, established basic minimal health services schools should provide without established guidance for pediatrician involvement.[21,22]

The AAP recommends that all schools have a registered professional school nurse, hereafter referred to as school nurse, to provide health services in schools.[23] The American Medical Association not only recommends that school health be provided by "a professionally prepared school nurse" but also that "health services in schools must be supervised by a physician, preferably one who is experienced in the care of children and adolescents. Additionally, a physician should be accessible to administer care on a regular basis."[24]

Despite a scarcity of laws addressing school physicians, pediatricians remain leaders in child health care and are integral members of the school health team.[22,25–29] Certainly, pediatricians need to know the laws that apply to their patients and themselves and will benefit from collaboration with their AAP chapter, state and local health departments, and school district to understand the laws specific to their role in the schools. However, the lack of uniformity of laws or standards of best practice for school physicians complicates the role physicians have in schools and results in a difference of health care for children based on the schools they attend.

CRITICAL KNOWLEDGE BASE FOR PHYSICIANS WORKING IN THE SCHOOL SETTING

Ideally, school physicians should be board-certified pediatricians or physicians with expertise in pediatrics.[24] In addition to basic training in child growth and development, disease processes, and well-child maintenance including adolescent and reproductive health and sports medicine, physicians who work with schools need additional expertise in key school health topics.[30–32] The degree of mastery required depends on the extent of the physician's role with the schools. Overall, a school physician can become a positive liaison between the medical home, the family, and the school.[8] Table 1 contains a nonexclusive list of essential areas of expertise required of a school physician.

TABLE 1 Critical Knowledge Base for School Physicians

Infectious diseases (eg, outbreak control)
Public health (eg, risk assessment and management, resources)
Immunizations (eg, school requirements and medical contraindications)
Medical-legal issues
State and district school and public health laws, regulations, and policies
IDEA, Section 504, and ADA
FERPA and HIPAA and how they intersect in the school setting
Adolescent health (eg, brain development and reproductive health)
Sports medicine[a]
The value of physical education and physical activity at school
Injury prevention
Conditioning
Disqualifying conditions
Hydration
The effects of climate extremes on athletes
Concussion management
Adaptive physical education
Emergency preparedness (eg, children with special health care needs)
Environmental and occupational health (eg, indoor air quality)
Health and learning (eg, medical, emotional, attentional, and learning problems that affect learning)
Social services resources (eg, access to health insurance and assistance programs)
A coordinated school health model (eg, health services, health education, healthy and safe environment, physical education and activity, nutrition services, counseling/psychology/social services, staff health promotion and family/community involvement)

ADA, Americans With Disabilities Act; FERPA, Family Education Rights and Privacy Act; HIPAA, Health Insurance Portability and Accountability Act; IDEA, Individuals With Disabilities Act.

[a] Unless there is a separate team physician.

CURRENT ROLES AND RELATIONSHIPS FOR SCHOOL PHYSICIANS

The roles and types of relationships for physicians working in schools are broad. Involvement can range from fulfilling mandated services, serving as an advisor to a school health advisory group, or being the leader of a coordinated school health program. School physicians function based on the medical and social needs or demands of the community, the school district's priorities, and state laws. School physicians not only bring value to the quality of health services but also may provide a cost savings to districts, with decreased liability from physician oversight of sound school health programs. For example, school physician–coordinated concussion management programs, established climate standards for outdoor activity, or guided anaphylaxis management protocols can potentially save lives, reduce morbidity, improve outcomes, and prevent potential costly litigation against school districts.[33–36] Because states fund schools on the basis of student attendance, a school physician can potentially save schools money by decreasing absenteeism through advocacy and education, such as in improved asthma or diabetes management.[37–40] The Council on School Health Web site (http://www.aap.org/sections/schoolhealth/) provides guidance on these activities and how pediatricians can work with schools (Table 2).

TABLE 2 Roles for School Physicians

- Mandated Services
  - Physical exams (grade mandated, special education, work permits, sports participation)
  - Oversight of return to sports (eg, concussion management programs)
  - Active member on teams/committees (eg, special education, wellness, health education)
- Consultation
  - Write standing nursing orders/protocols
  - Athletic advisor/team physician
    - Oversee health aspects of athletic programs and best practice standards
      - Infectious diseases esp. for close contact sports
      - Participation of athletes with serious medical conditions
    - Adaptive physical education for acutely injured or chronically disabled youngsters
    - Mixed gender competition
  - Develop policies
    - Contagious diseases/pandemics
    - Restraint, suspension, expulsion
    - Bullying
    - Reproductive health
    - Chronic school absenteeism
  - Develop protocols
    - Delivery of medications
    - Seizure management
    - Diabetes care
    - Anaphylaxis management
    - Asthma education and management
  - Assist in the management of specific medical emergencies or immediacies
  - Participate at the building level in comprehensive, multidisciplinary teams and wellness councils
- Programmatic leadership
  - Health program evaluation and quality improvement
    - Health education
    - Mental health promotion programs
    - Nutrition and food services
    - Physical activity and education
    - Staff wellness
    - Family and community education
  - Liaison with primary care physicians regarding specific concerns
  - Professional performance development
  - Evaluation and collaborative oversight of nursing staff and other health service providers, including one-on-one nurses and door-to-door transportation
  - Reviews of emergency care plans for children with life-threatening conditions.
  - Classroom observations of children with special needs
  - Health education curriculum development
- Direct consultation with principals or the superintendent
  - Medical-legal issues
  - Parent attorneys or advocates in accommodation disputes and hearings
  - Building and playground health and safety
  - Bloodborne pathogen incidents
  - School closure related to illness or weather extremes, or infections that affect public health

Physicians can have a professional relationship with schools in many ways, such as a full- or part-time employee, an independent contractor, or a volunteer on a school health advisory group. Where feasible, a school physician does not serve as a private physician for a child in that school district, however, because it can create a potential conflict of interest between the physician as representative/advocate for a patient versus the school.

Whatever the relationship, once a school district asks a physician to participate in hands-on medical practice for compensation in exchange for services, a clear definition of district expectations of the physician is essential. An agreement, accounting for laws governing the relationship of the physician to the public school district, should define indemnification and liability. It is critical that physicians understand the specifics of their relationship and that the legal implications are articulated clearly in a written agreement renewed periodically. Although community volunteerism is attractive, physicians should take some precautions before volunteering to serve as a school or team physician. It is essential that he or she knows and understands state laws that address whether a district has an obligation to

hire a medical director. Regardless of the type of relationship, the physician should notify his or her professional liability insurance company of involvement in school health activities and determine whether the insurance covers such activities. If covered, this decision should be noted in writing. If a district has an obligation to provide compensation for physician services, this will allow the physician to schedule time for the school district and to improve the quality and consistency of service.

RECOMMENDATIONS

Given the contribution a school physician can make to the overall well-being of a child within the context of the school setting, the AAP recommends the following:

1. Pediatricians should advocate that all school districts have a school physician to oversee health services. The school physician's roles and responsibilities should be well defined, fairly compensated, and outlined within a written contract.
2. Pediatricians should support their patients and local school health programs by working closely with the school health services team. In districts without school physicians, pediatricians should educate these districts about the benefits of having a school physician and work to foster private-public partnerships for school physicians.
3. School physicians should be experts in key school health topics and be educated about the medical-legal environment in which they practice. They need to provide proper notification of their role and responsibility to their medical liability insurer and should collaborate with their AAP chapter, state and local health departments, and school district to understand the laws specific to their role in the schools.
4. Community pediatricians should be knowledgeable about key school health topics and how to work effectively with schools their patients attend.
5. Pediatricians should consider becoming a school physician or serving on school boards or school health advisory groups to develop sound school health policies and community programs.
6. All physicians who work with school-aged children should recognize the value to the child when there is a comprehensive, coordinated team effort among the child's medical home, the school, and family.
7. Pediatric medical investigators should consider further research to determine how comprehensive coordinated school health programs under the direction of a school physician can improve health care in schools and enhance the goals of the medical home without attempting to replace it.
8. AAP districts and chapters should support school health and school physicians and use the school physician's expertise to advocate for important changes to state and local school health policy. In addition, AAP districts and chapters should advocate to develop and promote school health policies that benefit children by advocating for additional research on the benefits of school physicians in school health services.

abstract

FREE

School-based health centers (SBHCs) have become an important method of health care delivery for the youth of our nation. Although they only represent 1 aspect of a coordinated school health program approach, SBHCs have provided access to health care services for youth confronted with age, financial, cultural, and geographic barriers. A fundamental principle of SBHCs is to create an environment of service coordination and collaboration that addresses the health needs and well-being of youth with health disparities or poor access to health care services. Some pediatricians have concerns that these centers are in conflict with the primary care provider's medical home. This policy provides an overview of SBHCs and some of their documented benefits, addresses the issue of potential conflict with the medical home, and provides recommendations that support the integration and coordination of SBHCs and the pediatric medical home practice. *Pediatrics* 2012;129:387–393

BACKGROUND

According to the most recent national census of school-based health centers (SBHCs) conducted by the National Assembly on School-Based Health Care,[1] almost 2000 SBHCs are operating in 48 states and territories of the United States, with 57% located in urban communities, 16% in suburban communities, and 27% in rural communities. Approximately 33% of SBHCs are located in high schools, 24% are located in elementary or middle schools, and 43% are located in alternative schools or schools with a combination of grade levels. As SBHCs become more prevalent, pediatricians and other health care providers should be familiar with the role of SBHCs in providing primary care and preventive services to school-aged youth. In addition, it is critical that health care providers working in SBHCs are aware of the importance of supporting the medical home and coordinating care with other primary care providers in the community.

The provision of health services in schools is not a new concept; rather, it was pioneered by pediatric and nursing health professionals to address common pediatric health challenges.[2,3] Schools already provide several critical health services, including triage and management of medical emergencies; medication delivery; services for youth with special health care needs; referral of common health problems, such as injury, asthma, and behavioral and emotional difficulties; and health screenings (such as vision and hearing screenings).[4–7] SBHCs are an expansion of these school health services. SBHCs evolved during the 1970s and 1980s and were promoted by the Robert Wood Johnson Foundation, which continues its support by funding The Center for

Health and Health Care in Schools.[8,9] Over time, guidelines regarding best practices for SBHCs have been developed. These include performing a community needs assessment; coordinating care with the medical community, hospitals, and public health providers; and documenting the effect of SBHC services on students' health and educational outcomes.[10–14] Another best practice of SBHCs is to establish a business plan to generate grants, contracts, and billings to match SBHC expenses. Although state funding of SBHCs has almost quadrupled over the past 20 years, finding adequate resources and income remains a challenge for most SBHCs.[15]

By the early 1990s, some pediatricians expressed concern that SBHCs might fragment children's health care because schools are closed on the afternoons and during weekends and holidays.[4] Although this concern was warranted, most SBHCs have avoided fragmentation of health care delivery by conducting needs assessments and finding a health care "sponsor" to address the community's documented needs. Sponsors can include pediatricians who provide care to underserved children in their communities by establishing SBHCs as satellites of their practices with financial support from grants and contracts. In addition, local hospitals often provide after-hours and school vacation coverage and financial support for SBHCs. Local hospitals benefit from this arrangement because SBHCs can reduce hospitals' costs by preventing unnecessary emergency or urgent care visits and hospitalizations and enrolling students in public health insurance. As the medical home concept has evolved, SBHCs fit into the model just as satellite offices and practice networks do for private practice.[12] A recent national survey of SBHCs revealed that 35% of managed care organizations recognize SBHCs as reimbursable primary care providers.[1]

THE ROLE OF THE SBHC IN INCREASING ACCESS TO HEALTH CARE

SBHCs address many of the barriers to health care access for school-aged children.[16–21] Because SBHCs are located where children spend a significant amount of their time, scheduling and transportation barriers are minimized. SBHCs address financial barriers by helping enroll eligible students in Medicaid or the Children's Health Insurance Program and offering free services for uninsured students. Many adolescents, especially boys, are reluctant to use traditional medical care.[22] SBHCs increase adolescents' health care use, particularly for sexual health issues, drug or alcohol problems, and mental health problems, by providing convenient and confidential care in a familiar setting.[23–27]

Surveys of students, parents, and pediatricians indicate that the majority are supportive of SBHCs and believe SBHCs can increase access to health care for underserved children.[18,27–30] In addition, the authors of several studies have documented that children and adolescents who use SBHCs have more primary care visits and fewer emergency department visits when compared with those who do not use SBHCs.[18,31–35] A national multisite study by the Robert Wood Johnson Foundation revealed that 71% of students enrolled in SBHCs reported having a health care visit compared with 59% who were not enrolled.[20] Studies conducted in Denver revealed that adolescents who used SBHCs, the majority of whom were uninsured, had higher visit rates and a higher proportion of visits for preventive care or screening for high-risk behaviors compared with those who did not use SBHCs.[24,35] Although colocation and integration of medical with oral health services are not common in pediatric practices, SBHCs can offer integration along with improved access for oral health services.[36] Three reports have documented improved access to dental care, which is a particularly difficult access issue for uninsured and publicly insured adolescents with many dental health needs.[37–39]

SERVICES PROVIDED BY SBHCs

SBHCs can deliver a variety of services, including medical, oral, nutritional, case management, and mental health services. Because the types of providers and range of services offered by SBHCs vary, pediatricians should be knowledgeable about what their local SBHCs offer. SBHCs usually use 1 of 3 primary staffing models. The primary care model, used by 25% of SBHCs, comprises a nurse practitioner or physician assistant who provides basic health services, with supervision by a physician. The primary care–mental health model (40%) also includes a mental health professional, such as a licensed clinical social worker or psychologist. Finally, the primary care–mental health plus model (35%) comprises primary care and mental health providers and other professionals, such as health educators, case managers, and nutritionists.[1,36] According to the recent census of SBHCs, the most common services provided are comprehensive health assessments (offered by 97% of SBHCs), treatment of acute illness (96%), prescriptions for medications (96%), vision and hearing screenings (92%), sports participation examinations (92%), nutrition counseling (91%), and anticipatory guidance (90%).[1]

The provision of reproductive health services in SBHCs has resulted in community controversy, despite the fact that parents have been found to support these services.[40,41] Currently, ~68% of SBHCs provide screening and treatment of sexually transmitted infections, 70% provide counseling about

birth control methods, 39% dispense contraception, and 59% provide follow-up regarding contraception use.[1] Many SBHCs are prohibited from dispensing contraception by school district policy (57%), health center policy (13%), and state law (10%).[1]

In addition to providing services for individual students, SBHCs can provide prevention, early intervention, and harm-reduction services for the entire school community by following the 8 components of the Coordinated School Health Program model, as described by the Division of Adolescent and School Health of the Centers for Disease Control and Prevention.[42] These 8 components are as follows: (1) health education; (2) physical education; (3) health services; (4) mental health and social services; (5) nutrition services; (6) healthy and safe environment; (7) family and community involvement; and (8) staff wellness. A literature review conducted by the Division of Adolescent and School Health of the Centers for Disease Control and Prevention identified school-based health promotional interventions that not only improved health attitudes and behaviors but also improved academic performance.[43] A New York comparison study revealed that students in schools with SBHCs had greater satisfaction with their learning environment, compared with students in schools without SBHCs.[44] Thus, in addition to addressing health promotion by using *Bright Futures* guidelines for health examinations, SBHCs are increasingly using small group, classroom, and schoolwide evidence-based curricula and interventions to better reach *Bright Futures* goals for health.

EFFECTIVENESS OF SBHCs IN IMPROVING HEALTH OUTCOMES

SBHCs have been shown to improve children and adolescents' health for several outcomes while also reducing health care costs.[32,33,45–48] Students who use SBHCs are more likely to have received recommended vaccines and screening for high-risk behaviors, compared with those who do not use SBHCs.[24,35,49] Students who use SBHCs have also been shown to have higher satisfaction with their health status and have healthier behaviors, such as more physical activity and greater consumption of healthier foods.[47] Two studies using Medicaid claims data to compare health care costs for students who did and did not use SBHCs revealed that those who used SBHCs had lower Medicaid expenses.[32,48]

Asthma is 1 chronic disease for which SBHCs have improved outcomes. Children with asthma have better outcomes with management and coordination by the SBHC with the children's medical homes and pediatric subspecialists. A study by Webber et al[46] revealed that access to SBHCs was associated with a reduction in the rate of hospitalization and a gain of 3 days of school for school children who have asthma. Another study revealed that students with asthma who accessed SBHCs had lower hospitalization rates and improved self-care, such as use of peak flow meters and metered-dose inhalers.[45] Guo et al[50] investigated rates of hospitalization and emergency department visits for school-aged children with asthma and found that children with asthma attending a school with an SBHC had fewer hospitalizations and emergency department visits compared with children without SBHC access. They estimated the potential cost savings to be $970 per child.

Integration of medical health and mental health screening and services in SBHCs benefit school performance.[27,51–53] When mental health services are offered in SBHCs, students' access to mental health services is improved and communication is facilitated between students, school personnel, SBHC staff, and parents.[24,54,55] In Dallas, medical services decreased school absences by 50% among students who had 3 or more absences in a 6-week period, and students who received mental health services had an 85% decline in school discipline referrals.[55] In North Carolina, students who used SBHCs were significantly more likely to stay in school and to graduate or be promoted than did students who did not use SBHC services. This was especially true for African American male students, who were 3 times more likely to stay in school.[51] Another study conducted in a northeastern city revealed that SBHC users had a 50% decrease in absenteeism and a 25% decrease in tardiness 2 months after receiving SBHC services.[52]

SBHCS AND THE MEDICAL HOME

The American Academy of Pediatrics defines the medical home as a model of delivering primary care that is accessible, continuous, comprehensive, family centered, coordinated, compassionate, and culturally effective to all children and youth.[56,57] Some pediatricians are concerned that SBHCs might not support the medical home model because they do not provide access to care when schools are closed or may provide duplicative services to children outside of their medical homes without communicating with the medical homes.[10] Most SBHCs are able to avoid these concerns by conducting needs assessments and coordinating or collaborating with the community's local health care providers to address their community's documented needs.[11] SBHCs can meet the definition of the medical home for their patients in collaboration with their sponsoring agencies by (1) ensuring linkage so that services are available 24 hours per day, 7 days a week, and 52 weeks per year, even when schools are closed; (2) encouraging parental

participation and providing education about the health care needs of the youth they serve; (3) working collaboratively with primary care practices, school districts, and community agencies; and (4) coordinating all specialty and subspecialty consultations, referrals, and collaborations.

For families who do not have access to a medical home, SBHCs can assist in linking them to a medical home. For example, SBHCs can:

- Provide families with onsite insurance eligibility and enrollment and connect them to health insurance plans (private or public) that will provide financial access to primary care practices.
- Connect families to primary care practices/medical homes that are accepting new patients and families.
- Provide satellite primary care services in collaboration with existing pediatric medical homes (eg, private practices, community health centers) that are not otherwise able to enroll these patients into their practice.
- Become the medical home for school youth who are in need of a provider if the SBHCs meet the criteria for a medical home described in the preceding paragraph.

OPPORTUNITIES

1. SBHCs can provide families with onsite insurance eligibility and enrollment and connect them to health insurance plans (private or public) that will provide financial access to primary care practices and can connect families to primary care practices that are accepting new patients and families.
2. Community primary care providers can collaborate with SBHCs to expand both the SBHCs' and the practices' enrollment, particularly for populations such as adolescent boys, which may not readily access traditional health services. Basic preventive services could be provided in the SBHC and consultative services, specialty referral, and follow-up could be provided in the community practice for patients enrolled at both sites.
3. SBHCs can provide assistance in the day-to-day monitoring and case management of children with chronic disease and disabilities.
4. SBHCs can help reinforce *Bright Futures* health examination goals by implementing health–promoting, evidence-based curricula, and interventions in the school setting.
5. Large SBHCs may provide health and health-related services, including dental services, mental health services, and nutrition counseling, as well as confidential reproductive health services that pediatric offices do not or cannot supply, especially for families with limited financial resources.

CHALLENGES

1. The health and education systems do not always share the same priorities. SBHC providers and community pediatricians can bring the health and education communities together with a common goal of better outcomes for children. They can help educate the school community about prioritizing children's health because children do not learn well if they are not healthy.[58]
2. Communication among schools, SBHCs, and community primary care providers should be facilitated. SBHCs should be planned and executed with primary care providers' input to result in a collaborative and integrated model that supports the medical home.[4,10] In addition, SBHCs should develop systems to regularly communicate with community providers about shared patients.
3. Pediatricians interested in starting a new SBHC may be unable to do so because of the time required to involve appropriate stakeholders, conduct a needs assessment, develop a business plan, and identify funding sources. However, school health advisory councils, which already exist in the majority of schools or districts, can assist in these activities and reduce the burden.[12,59,60]
4. SBHCs require multiple funding sources to stay financially solvent. Most SBHCs serve uninsured or underinsured patients or patients who may require additional case management or social support that is poorly reimbursed by insurance. Therefore, initial and ongoing funding in addition to insurance billing is required.[12,15]
5. Concerns about confidentiality and privacy can be a barrier to communication. Confidentiality for adolescents and health information transfer are challenges regulated by the Health Insurance Portability and Accountability Act and the Family Educational Rights and Privacy Act, laws that are implemented differently from state to state. However, model forms and approaches have been developed by the National Association for School-Based Health Centers and American School Health Association.[61,62]

RECOMMENDATIONS

1. Advocate for SBHCs as 1 model of a system of health care delivery that provides a health care "safety net" for children and adolescents who are uninsured or underinsured or represent special populations who do not regularly access health care.

2. Learn about SBHCs and the services they provide in the community. Pediatricians should become familiar with current or planned school health initiatives in their communities and assess their practices' capabilities to work with such efforts. SBHCs should conduct outreach activities to ensure that pediatricians and other health care providers in the community know about what SBHCs have to offer.
3. Ensure that all patients served by SBHCs have access to a medical home, either in the SBHC itself or with a practice in the community. Community pediatricians with experience in implementing the medical home model in their practices can educate and assist SBHCs in doing the same. SBHCs should work with their sponsoring agency to ensure that all patients they serve have access to a medical home by meeting the requirements of a medical home in the SBHC itself and/or collaborating with other community providers.
4. Facilitate coordination of care between SBHCs and community primary care providers. Community pediatricians can determine whether youth and families in their practices may be utilizing services at SBHCs and contact the SBHCs to facilitate coordination of care. In turn, SBHCs should identify enrollees that have a medical home and perform outreach to community pediatricians to facilitate a model of collaboration and communication.
5. Support access to services provided by SBHCs that are limited, not affordable, or not available in private practice or other community settings for children and adolescents. These services may include: mental health, substance use or nutritional counseling, oral health services, or confidential reproductive health services. In addition, students with chronic conditions may benefit from school-based monitoring that is reported back to the medical home.
6. Consider SBHCs as sites to provide volunteer pediatric services and supervised educational opportunities for health services professionals in training.[63] Pediatricians can support community schools and families by volunteering or working part time at SBHCs, supervising trainees at SBHCs, or serving as the SBHC's consultant or medical director.
7. Encourage the development of school health advisory councils to establish a setting for planning, monitoring, and developing SBHCs and coordinated school health services.[12,59,60]

abstract

FREE

This statement revises a previous statement on screening of preterm infants for retinopathy of prematurity (ROP) that was published in 2006. ROP is a pathologic process that occurs only in immature retinal tissue and can progress to a tractional retinal detachment, which can result in functional or complete blindness. Use of peripheral retinal ablative therapy by using laser photocoagulation for nearly 2 decades has resulted in a high probability of markedly decreasing the incidence of this poor visual outcome, but the sequential nature of ROP creates a requirement that at-risk preterm infants be examined at proper times and intervals to detect the changes of ROP before they become permanently destructive. This statement presents the attributes on which an effective program for detecting and treating ROP could be based, including the timing of initial examination and subsequent reexamination intervals. *Pediatrics* 2013;131:189–195

INTRODUCTION

Retinopathy of prematurity (ROP) is a disorder of the developing retina of low birth weight preterm infants that potentially leads to blindness in a small but significant percentage of those infants. In almost all term infants, the retina and retinal vasculature is fully developed, and ROP cannot occur; however, in preterm infants, the development of the retina, which proceeds from the optic nerve head anteriorly during the course of gestation, is incomplete, with the extent of the immaturity of the retina depending mainly on the degree of prematurity at birth.

The Multicenter Trial of Cryotherapy for Retinopathy of Prematurity demonstrated the efficacy of peripheral retinal cryotherapy (ie, cryoablation of the immature, avascular peripheral retina) in reducing unfavorable outcomes for threshold ROP, defined as morphologic changes beyond which the incidence of unfavorable outcome was >50%.[1] The study's 15-year follow-up report[2] confirmed the following lasting benefits: unfavorable structural outcomes were reduced from 48% to 27%, and unfavorable visual outcomes (ie, best corrected visual acuity worse than 20/200) were reduced from 62% to 44%. Subsequently, laser photocoagulation has been used for peripheral retinal ablation with at least equal success and is now the preferred method of ablation.[3–6] More recently, the Early Treatment for Retinopathy of Prematurity Randomized Trial confirmed the efficacy of

treatment of high-risk prethreshold ROP and redefined the indications for treatment.[7]

Because of the sequential nature of ROP progression and the proven benefits of timely treatment in reducing the risk of visual loss, effective care now requires that at-risk infants receive carefully timed retinal examinations by an ophthalmologist who is experienced in the examination of preterm infants for ROP using a binocular indirect ophthalmoscope on a scheduled basis according to their gestational age at birth and their subsequent disease severity and that all pediatricians or any other primary care providers who care for these at-risk preterm infants be aware of this schedule.

This statement outlines the principles on which a program to detect ROP in infants at risk might be based. The goal of an effective ROP screening program is to identify the infants who could benefit from treatment and make appropriate recommendations on the timing of future screening and treatment interventions. Because unchecked ROP can lead to permanent blindness, it is important that all at-risk infants be screened in a timely fashion, recognizing that not all infants require treatment. On the basis of information published thus far, the sponsoring organizations of this statement suggest the following guidelines for the United States. It is important to recognize that other world locations could have different screening parameters.[8,9] It is also important to note that despite appropriate timing of examinations and treatment, a small number of infants at risk progress to poor outcomes.[3–6]

RECOMMENDATIONS

1. Infants with a birth weight of ≤1500 g or gestational age of 30 weeks or less (as defined by the attending neonatologist) and selected infants with a birth weight between 1500 and 2000 g or gestational age of >30 weeks with an unstable clinical course, including those requiring cardiorespiratory support and who are believed by their attending pediatrician or neonatologist to be at high risk for ROP, should have retinal screening examinations performed after pupillary dilation by using binocular indirect ophthalmoscopy with a lid speculum and scleral depression (as needed) to detect ROP. Dilating drops should be sufficient to allow adequate examination of the fundi, but care should be used in using multiple drops if the pupil fails to dilate, because poor pupillary dilation can occur in advanced ROP, and administering multiple doses of dilating drops can adversely affect the systemic status of the infant. Sterile instruments should be used to examine each infant to avoid possible cross-contamination of infectious agents. One examination is sufficient only if it unequivocally shows the retina to be fully vascularized in both eyes. Effort may be made to minimize the discomfort and systemic effect of this examination by pretreatment of the eyes with a topical anesthetic agent such as proparacaine; consideration also may be given to the use of pacifiers, oral sucrose, and so forth.
2. Retinal examinations in preterm infants should be performed by an ophthalmologist who has sufficient knowledge and experience to identify accurately the location and sequential retinal changes of ROP. The International Classification of Retinopathy of Prematurity Revisited[10] should be used to classify, diagram, and record these retinal findings at the time of examination.
3. The initiation of acute-phase ROP screening should be based on the infant's postmenstrual age. The onset of serious ROP correlates better with postmenstrual age (gestational age at birth plus chronologic age) than with postnatal age.[11] That is, the more preterm an infant is at birth, the longer the time to develop serious ROP. This knowledge has been used previously in developing a screening schedule.[12,13] Table 1 was developed from an evidence-based analysis of the Multicenter Trial of Cryotherapy for Retinopathy of Prematurity natural history data and confirmed by the Light Reduction in ROP Study, which was conducted a decade later.[14] It represents a suggested schedule for the timing of the initial eye examinations based on postmenstrual age and chronologic (postnatal) age to detect ROP before it becomes severe enough to result in retinal detachment while minimizing the number of potentially traumatic examinations.[15] Although Table 1 provides a schedule for detecting ROP potentially damaging to the retina with 99% confidence, it should be

TABLE 1 Timing of First Eye Examination Based on Gestational Age at Birth

Gestational Age at Birth, wk	Age at Initial Examination, wk	
	Postmenstrual	Chronologic
22[a]	31	9
23[a]	31	8
24	31	7
25	31	6
26	31	5
27	31	4
28	32	4
29	33	4
30	34	4
Older gestational age, high-risk factors[b]		4

Shown is a schedule for detecting prethreshold ROP with 99% confidence, usually before any required treatment.
[a] This guideline should be considered tentative rather than evidence-based for infants with a gestational age of 22 to 23 wk because of the small number of survivors in these postmenstrual-age categories.
[b] Consider timing based on severity of comorbidities.

appreciated that infants born before 25 weeks' gestational age should be considered for earlier screening on the basis of severity of comorbidities (6 weeks' chronologic age, even if before 31 weeks' postmenstrual age to enable earlier identification and treatment of aggressive posterior ROP [a severe form of ROP that is characterized by rapid progression to advanced stages in posterior ROP] that is more likely to occur in this extremely high-risk population).

4. Follow-up examinations should be recommended by the examining ophthalmologist on the basis of retinal findings classified according to the international classification (see Fig 1).[8] The following schedule is suggested:

1-Week or Less Follow-up

- immature vascularization: zone I—no ROP
- immature retina extends into posterior zone II, near the boundary of zone I
- stage 1 or 2 ROP: zone I
- stage 3 ROP: zone II
- the presence or suspected presence of aggressive posterior ROP

1- to 2-Week Follow-up

- immature vascularization; posterior zone II
- stage 2 ROP: zone II
- unequivocally regressing ROP: zone I

2-Week Follow-up

- stage 1 ROP: zone II
- immature vascularization: zone II—no ROP
- unequivocally regressing ROP: zone II

2- to 3-Week Follow-up

- stage 1 or 2 ROP: zone III
- regressing ROP: zone III

5. The conclusion of acute retinal screening examinations should be based on age and retinal ophthalmoscopic findings.[13] Findings that suggest that examinations can be terminated include the following:
   - zone III retinal vascularization attained without previous zone I or II ROP (if there is examiner doubt about the zone or if the postmenstrual age is less than 35 weeks, confirmatory examinations may be warranted);
   - full retinal vascularization in close proximity to the ora serrata for 360°—that is, the normal distance found in mature retina between the end of vascularization and the ora serrata. This criterion should be used for all cases treated for ROP solely with bevacizumab;
   - postmenstrual age of 50 weeks and no prethreshold disease (defined as stage 3 ROP in zone II, any ROP in zone I) or worse ROP is present; or
   - regression of ROP[16] (care must be taken to be sure that there is no abnormal vascular tissue present that is capable of reactivation and progression in zone II or III).
6. The use of digital photographic retinal images that are captured and sent for remote interpretation is a developing approach to ROP screening[17,18]; however, outcomes comparison between large-scale operational digital-imaging systems with remote interpretation versus binocular indirect ophthalmoscopy have not been published. Nevertheless, some neonatal centers are conducting remote ROP screening for infants still in the hospital.[17] At a minimum, programs that employ this method should comply with the timing and other recommendations outlined in the preceding guidelines. Protocol modifications may be required to allow for additional time for communication, processing, transportation, or other

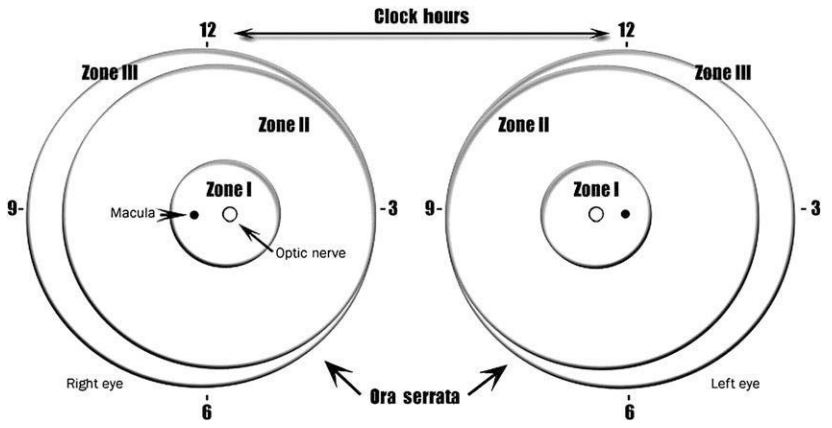

FIGURE 1

Scheme of retina of the right and left eyes showing zone borders and clock hours used to describe the location and extent of ROP. Diagrammatic representation of the potential total area of the premature retina, with zone I (the most posterior) symmetrically surrounding the optic nerve head (the earliest to develop). A larger retinal area is present temporally (laterally) rather than nasally (medially) (zone III). Only zones I and II are present nasally. The retinal changes discussed in recommendation 4 are usually recorded on a diagram such as this one.

logistical issues.[19] Captured images and their interpretation should be incorporated into the permanent medical record. It is also recommended that indirect ophthalmoscopy be performed at least once by a qualified ophthalmologist before treatment or termination of acute phase screening of ROP for infants at risk for ROP.

Digital image capture (taking of photographs) requires skill, experience, practice, a broad understanding of the infant eye, and ideally, a knowledge of the pathophysiology of ROP (zone, stage, and plus). Remote ROP graders should have the same training requirements as bedside examiners and a mentored experience in interpretation of digital images for ROP. Interpretation requires not only expert knowledge about ROP but also understanding of the limitations of interpreting static images and the special care that must be taken to schedule more frequent imaging sessions that may be required because of those limitations. Remote interpreters must provide clinical input on the timing of follow-up imaging sessions and ophthalmoscopic examinations and appropriate methodology, and these findings need to be communicated in a manner that is compliant with rules of the Health Insurance Portability and Accountability Act (HIPAA).

Digital retinal imaging may also be a useful tool for objective documentation of retinal findings and for teaching NICU staff and parents about examination results, even if it is not the primary method used for ROP screening in the NICU.[20]

ROP care that includes off-site photographic interpretation requires close collaboration among neonatologists, imaging staff, and ophthalmologists. As with all ROP screening programs, specific responsibilities of each individual must be carefully delineated in a written protocol in advance so that repeat imaging and/or confirmatory examinations and required treatments can be performed without delay.

Treatment

7. The presence of plus disease (defined as abnormal dilation and tortuosity of the posterior retinal blood vessels in 2 or more quadrants of the retina meeting or exceeding the degree of abnormality represented in reference photographs[1,8]; see below) in zones I or II suggests that peripheral ablation, rather than observation, is appropriate.[13]

   Treatment should be initiated for the following retinal findings:

   - zone I ROP: any stage with plus disease
   - zone I ROP: stage 3—no plus disease
   - zone II: stage 2 or 3 with plus disease

8. Practitioners involved in the ophthalmologic care of preterm infants should be aware that the retinal findings that require strong consideration of ablative treatment were revised according to the Early Treatment of Retinopathy of Prematurity Randomized Trial study.[7] This recommendation is based on the findings of improved visual outcomes with earlier treatment recommended by the Final Visual Acuity Results in the Early Treatment of Retinopathy of Prematurity Study.[21] "Threshold ROP," a term that refers to specific morphologic features defined in the Multicenter Trial of Cryotherapy for Retinopathy of Prematurity, is no longer the least severe ROP for which intervention should be considered. Threshold ROP, as defined in the Multicenter Trial of Cryotherapy for Retinopathy of Prematurity study, is now included in type 1 ROP.

   Certain levels of high-risk prethreshold disease also respond better to ablative treatment than observation. Special care must be used in determining the zone of disease. The revised International Classification of Retinopathy of Prematurity Revisited classification gives specific examples on how to identify zone I and zone II disease by using a 28-diopter lens with binocular indirect ophthalmoscopy. As noted previously, the presence of plus disease rather than the number of clock hours of disease may be the determining factor in recommending ablative treatment. Treatment should generally be accomplished, when possible, within 72 hours of determination of treatable disease to minimize the risk of retinal detachment. Follow-up is recommended in 3 to 7 days after treatment to ensure that there is no need for additional treatment in areas where ablative treatment was not complete.

9. Recently published data[22] indicate that intravitreal bevacizumab monotherapy, as compared with conventional laser therapy, in infants with stage 3+ ROP showed a significant benefit for zone I but not zone II disease. Development of normal-appearing peripheral retinal vessels continued after treatment with intravitreal bevacizumab, but conventional laser therapy led to apparent permanent destruction of the peripheral retina,

although published studies indicate that this apparent destruction was associated with only a modest visual field loss. This trial was too small to assess safety and effects on future development of brain and other tissues. Consideration may be given to treatment of infants with zone I, stage 3+ ROP with intravitreal injection of bevacizumab; however, bevacizumab is not approved by the US Food and Drug Administration for the treatment of ROP. If intravitreal injection of bevacizumab for zone I stage 3+ ROP is contemplated, it is essential that treatment be administered only after obtaining a detailed informed consent, because there remain unanswered questions involving dosage, timing, safety, visual outcomes, and other long-term effects. Infants treated with bevacizumab injection should be monitored weekly after injection by using techniques in accord with these published ROP examination guidelines until retinal vascularization is completed. Because in the BEAT-ROP study,[22] recurrence of ROP after bevacizumab injection tended to occur considerably later than that after conventional laser peripheral retinal ablative treatment (16 $\pm$ 4.6 weeks vs 6.2 $\pm$ 5.7 weeks), longer follow-up is required for infants treated with bevacizumab to ensure that ROP requiring treatment does not recur.

10. Communication with parents by members of the care team is very important, as is documentation of those communications. Parents should be aware of ROP examinations and should be informed if their child has ROP, with subsequent updates on ROP progression. The possible consequences of serious ROP should be discussed at the time that a significant risk of poor visual outcome develops. Documentation of such conversations with parents in the nurse or physician notes is highly recommended, along with the use of standardized parental educational materials.
11. Responsibility for examination and follow-up of infants at risk for ROP must be carefully defined by the staff and consultants of each NICU. Unit-specific criteria with respect to birth weight and gestational age for examination for ROP should be established for each NICU by consultation and agreement between neonatology and ophthalmology services. These criteria should be recorded and should automatically trigger ophthalmologic examinations. If hospital discharge or transfer to another neonatal unit or hospital is contemplated before retinal development into anterior zone III has taken place or if the infant has been treated by ablation for ROP and there is either incomplete regression or incomplete retinal healing, the availability of appropriate follow-up ophthalmologic examination must be ensured, and specific arrangement for that examination must be made before such discharge or transfer occurs. The transferring primary care physician, after communication with the examining ophthalmologist, should have the responsibility for communicating to the infant's new primary care physician what eye examinations are needed and their required timing. The new primary care physician should ascertain the current ocular examination status of the infant by reviewing the record and communicating with the transferring physician so that any necessary examinations by an ophthalmologist with ongoing experience and expertise in examination of preterm infants for ROP can be arranged at the appropriate time at the receiving facility or on an outpatient basis if discharge is contemplated before the need for continued examination has ceased, as outlined in Diagnosis Recommendation 6. If responsibility for arranging follow-up ophthalmologic care after discharge is delegated to the parents, they must be made to understand the potential for severe visual loss, including blindness; that there is a critical examination time schedule to be met if treatment is to be successful; and that timely follow-up examination is essential to successful treatment. This information should be communicated both verbally and in writing and should be carefully documented in the infant's medical record. If such arrangements for communication and follow-up after transfer or discharge cannot be made, the infant should not be transferred or discharged until appropriate follow-up examination can be arranged by the unit staff who are discharging the infant.

Regardless of whether infants at risk develop ROP requiring treatment, pediatricians and other physicians who care for infants who have had ROP should be aware that these infants are at risk for other seemingly unrelated visual disorders, such as strabismus, amblyopia, high refractive errors, cataract, and so forth. Ophthalmologic follow-up for these potential problems after discharge from the NICU is indicated within 4 to 6 months after discharge.

This statement replaces the previous statement on ROP from the American Academy of Pediatrics, American Academy of Ophthalmology, and American Association for Pediatric

Ophthalmology and Strabismus[23]; ROP care is evolving, and recommendations may be modified as additional data about ROP risk factors, treatments, and long-term outcomes are published.

Sensory Integration Therapies for Children With Developmental and Behavioral Disorders

abstract

FREE

Sensory-based therapies are increasingly used by occupational therapists and sometimes by other types of therapists in treatment of children with developmental and behavioral disorders. Sensory-based therapies involve activities that are believed to organize the sensory system by providing vestibular, proprioceptive, auditory, and tactile inputs. Brushes, swings, balls, and other specially designed therapeutic or recreational equipment are used to provide these inputs. However, it is unclear whether children who present with sensory-based problems have an actual "disorder" of the sensory pathways of the brain or whether these deficits are characteristics associated with other developmental and behavioral disorders. Because there is no universally accepted framework for diagnosis, sensory processing disorder generally should not be diagnosed. Other developmental and behavioral disorders must always be considered, and a thorough evaluation should be completed. Difficulty tolerating or processing sensory information is a characteristic that may be seen in many developmental behavioral disorders, including autism spectrum disorders, attention-deficit/hyperactivity disorder, developmental coordination disorders, and childhood anxiety disorders.

Occupational therapy with the use of sensory-based therapies may be acceptable as one of the components of a comprehensive treatment plan. However, parents should be informed that the amount of research regarding the effectiveness of sensory integration therapy is limited and inconclusive. Important roles for pediatricians and other clinicians may include discussing these limitations with parents, talking with families about a trial period of sensory integration therapy, and teaching families how to evaluate the effectiveness of a therapy. *Pediatrics* 2012;129:1186–1189

BACKGROUND: DEVELOPMENT OF THE SENSORY SYSTEM

Sensory integration is a framework first described by occupational therapist A. Jean Ayres, PhD, in the 1970s. It refers to the body's way of handling and processing sensory inputs from the environment.[1] Ayres felt that the sensory system develops over time, much like other aspects of development (language, motor, etc), and that deficits can occur in the process of developing a well-organized sensory system. A well-organized sensory system can integrate input from multiple sources (visual, auditory, proprioceptive, or vestibular). Ayres postulated that sensory integration dysfunction occurs when sensory neurons are not signaling or functioning efficiently, leading to deficits in development, learning, and/or emotional regulation.

The ability of the brain to process sensory information from the environment has been an expanding area of basic neuroscience research. Hubel and Wiesel were among the first to document the important effects of early experience (eg, deprivation) on the way visual sensory input is processed in the brain.[2–5] Animal and human research is beginning to explore how other senses are processed and integrated[6–10] and how those processes are disrupted in specific syndromes (eg, autism,[11,12] schizophrenia[13,14]) and by specific experiences (eg, institutionalization, international adoption[15,16]).

STATEMENT OF THE PROBLEM

Since Ayres[1] described sensory integration dysfunction in the 1970s, sensory-based therapies have been used increasingly, mainly by occupational therapists (but sometimes other health professionals) to treat a range of symptoms seen in children presenting from across a variety of settings, including the home, community organizations, clinics, and schools. Sensory integration, sensory "diets," and other sensory-based therapies typically are based on classic sensory integration theory but often do not use all of the originally described sensory integration protocols. Sensory-based therapies involve activities that are believed to organize the sensory system, by providing vestibular, proprioceptive, auditory, and tactile inputs, by using brushes, swings, balls, and other specially designed equipment to provide these inputs. Occupational therapists and other health professionals may also use a sensory processing approach when identifying and modifying barriers that limit the individual's ability to participate in everyday activities or occupations.

Proponents of sensory integration theory believe that inappropriate or deficient sensory processing is a developmental disorder amenable to therapy and that treatment can improve developmental outcomes.[17] A definition of sensory processing disorder has been proposed but has not been universally accepted.[18] Standardized measures, such as the Sensory Profile,[19] have been developed to classify a child's sensory deficits. The Sensory Profile provides a standard method for professionals to measure a child's sensory processing abilities and to provide a profile of the effect of sensory processing on functional performance in the daily life of a child.[20] Such standardized measures are commonly used by occupational therapists to quantify how much these developmental and behavioral differences affect the child's functional performance of the daily activities of childhood.

The possible diagnosis of sensory processing disorders remains a challenging clinical issue. In the sensory processing disorder classification system proposed by Miller et al,[18] sensory processing disorders are subdivided into 3 specific patterns: sensory modulation disorder, sensory discrimination disorder, and sensory-based motor disability. These patterns are then categorized into subtypes. Sensory modulation disorder is subdivided into overresponsive, underresponsive, and sensory seeking/craving subtypes. Sensory discrimination disorder has no subtypes. Sensory-based motor disability is subdivided into postural disorder and dyspraxia.

Sensory processing disorder or a similar diagnosis has been included in Zero to Three's *Diagnostic Classification of Mental Health and Developmental Disorders of Infancy and Early Childhood Revised*[21] and the *Diagnostic Manual for Infancy and Early Childhood of the Interdisciplinary Council on Developmental and Learning Disorders*,[22] where "regulatory-sensory processing disorder" in infants has also been classified as a developmental difference for this group. For older children and adolescents, no commonly accepted definition of sensory processing disorder exists. Some experts have proposed that the definition of autism spectrum disorders in the forthcoming *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* be expanded to include definitions of associated sensory issues, such as under- and overresponsiveness; however, the committee that is preparing the textbook has requested that more studies be performed before sensory processing disorder can be officially recognized.[23]

It remains unclear whether children who present with findings described as sensory processing difficulties have an actual "disorder" of the sensory pathways of the brain or whether these deficits represent differences associated with other developmental and behavioral disorders. Specifically, the behavioral differences seen in children with autism spectrum disorders,[24] attention-deficit/hyperactivity disorder,[25] and developmental coordination disorders[26] overlap symptoms described in children with sensory processing disorders. Studies to date have not demonstrated that sensory integration dysfunction exists as a separate disorder distinct from these other developmental disabilities. Furthermore, numerous challenges exist for evaluating the effectiveness of sensory integration therapy, including the wide spectrum of symptom severity and presentation, lack of consistent outcome measures, and family factors, which make response to therapy variable.[27–29]

Despite the challenges of defining and studying the effectiveness of sensory integration therapy, it is possible that the treatment of sensory processing difficulties is helpful to children who have problems identified in sensory processing measures. Some published case series and observational studies

have reported positive outcomes of sensory integration therapy for children with sensory processing disorders.[27,29] Older meta-analyses[30,31] and at least 2 more recent reviews[32,33] have been published that suggested a positive trend in meeting occupational goals with the use of sensory integration therapy. However, the authors of the 1999 meta-analysis cautioned that most studies in the field were of insufficient scientific rigor to be included in a meta-analysis, studies varied in the use of outcome measures, and the ability to draw conclusions and detect a treatment effect was limited.[31] Many of the more recent studies, unfortunately, share some of these traits.

One recent small study cautions health care practitioners about the possible negative behavioral effects of sensory integration therapy in certain populations. Devlin et al[34] reported on the comparative effects of sensory integration therapy and behavioral interventions on rates of challenging or self-injurious behavior in 4 children in whom autism spectrum disorder was diagnosed. A functional assessment was conducted to identify the variables maintaining the challenging behaviors. The sensory integration therapy was designed by an occupational therapist who was trained in sensory integration therapy. The sensory integration therapy and a behavioral intervention were compared within an alternating treatments design. Results from this study clearly demonstrated that the behavioral intervention was more effective in reducing challenging behavior and self-injurious behavior than was the sensory integration therapy. Finally, in the best treatment phase, only the behavioral intervention was implemented, and further reduction was observed in the frequency of challenging behavior and self-injurious behavior.

RECOMMENDATIONS

1. At this time, pediatricians should not use sensory processing disorder as a diagnosis. When these sensory symptoms are present, other developmental disorders—specifically, autism spectrum disorders, attention-deficit/hyperactivity disorder, developmental coordination disorder, and anxiety disorder—must be considered and thoroughly evaluated, usually by appropriate referral(s) to a developmental and behavioral pediatrician, child psychiatrist, or child psychologist. The American Academy of Pediatrics clinical report on the management of children with autism spectrum disorders is a useful resource to help with these referrals.[35]
2. Pediatricians should recognize and communicate with families about the limited data on the use of sensory-based therapies for childhood developmental and behavioral problems.
3. If the pediatrician is managing a child whose therapist is using sensory-based therapies, the pediatrician can play an important role in teaching families how to determine whether a therapy is effective.
    a. Help families design simple ways to monitor effects of treatment (eg, behavior diaries, pre-post behavior rating scales). Help the family be specific and create explicit treatment goals, designed at the onset of therapy, focused on improving the individual's ability to engage and participate in everyday activities (eg, ability to focus, tolerate foods, and be in a room with loud noises).
    b. Set a time limit for seeing the family back to discuss whether the therapy is working to achieve the stated goals.
4. Pediatricians should inform families that occupational therapy is a limited resource, particularly the number of sessions available through schools and through insurance coverage. The family, pediatrician, and other clinicians should work together to prioritize treatment on the basis of the effects the sensory problems have on a child's ability to perform daily functions of childhood.

With input from the following committees/councils: COCWD, ASC, SOAI, COPACFH, SOAH, SODBP, SON, SOEH, and COCHF.

abstract

FREE

Privacy and security of health information is a basic expectation of patients. Despite the existence of federal and state laws safeguarding the privacy of health information, health information systems currently lack the capability to allow for protection of this information for minors. This policy statement reviews the challenges to privacy for adolescents posed by commercial health information technology systems and recommends basic principles for ideal electronic health record systems. This policy statement has been endorsed by the Society for Adolescent Health and Medicine. *Pediatrics* 2012;130:987–990

BACKGROUND

State laws allow minors to consent for their health care on the basis of their status (eg, as an emancipated or mature minor or a pregnant or parenting teenager) and on the basis of the services they seek (eg, sexually transmitted infection [STI] diagnosis and treatment, contraception, pregnancy care, substance abuse counseling/treatment, or mental health care). If adolescents cannot trust that their health information will be both private and secure, they may not seek these services.[1–6] State and federal laws provide protection of privacy when minors consent for their own health care; laws pertaining to such care vary depending on where the teenager resides.[7] The American Academy of Pediatrics (AAP), along with other medical societies, encourages adolescents to discuss health issues with parents but has supported the right to adolescent privacy.[8]

Privacy control of protected information specific to adolescent health has not been adequately addressed in the development of electronic health records (EHRs). Current federal rules related to the Health Information Technology for Economic and Clinical Health Act limit the discussion of privacy as it relates to the Health Insurance Portability and Accountability Act (HIPAA) and, thus, related criteria for certification of EHRs. Such criteria have no specific references to issues of adolescent privacy.[9,10] Because electronic systems currently are unable to filter or compartmentalize health information consistent with current laws, states have been left to identify individual barriers to appropriate exchange of adolescent health information and to identify interim solutions.[11]

A policy statement regarding use of personal health records (PHRs) published in 2009 by the AAP addressed the importance of protection of privacy. The AAP policy statement "Using Personal Health Records to Improve the Quality of Health Care for Children" stresses the importance of the development of the PHR as an extension of the EHR but also addresses the lack of privacy controls, which are necessary for adolescents to access care protected by state and federal laws.[12]

STATEMENT OF THE PROBLEM

Current health information technologies, including EHRs, PHRs, personally controlled health records, health information exchanges (HIEs), or other patient portals generally do not have the flexibility or the technical capacity to maintain or support policies that address the ability of minors to give their own consent for health care or to protect minors' sensitive health care data.[13] Privacy and trust between the adolescent and provider during the health care visit is complicated by requirements to document care in the record, bill for services, and communicate with the parent/guardian within the boundaries of applicable state laws.[14–16] PHRs can improve access to health information, but to realize the benefits for teenagers, standards for developing and accessing the information within PHRs must include the ability to protect privacy and security issues for adolescents. The PHR must have the flexibility to meet the variation in the legal mandates of the state in which the teenager resides. These standards must also grant adolescents the ability to exclude parents or guardians from their PHRs when state law allows that they may consent for their own health care without parental consent on the basis of status (eg, as an emancipated or mature minor or as a parent) and on the basis of the services they seek (eg, diagnosis and treatment of STIs, contraception, substance abuse counseling and treatment, and mental health care).[7,13,16]

Currently, most systems are not capable of allowing dual (or plural) consent to allow or restrict access to different portions of a patient's electronic health information. Thus, adolescents who are minors cannot record legal consent to allow or disqualify their health information to be included in PHRs, PCRHs, and HIEs, because current technologies allow parents as the only parties who can provide informed consent. Specific challenges include:

- Lack of standards for electronic medical technology regarding privacy issues and care for the adolescent patient where rights of minors are protected by state law or precedent court cases.
- Lack of standards for electronic medical technology when states remain silent on the issue of care around sensitive area issues for the adolescent, and care is routinely provided to teenagers as mature minors.
- Lack of standards for electronic medical technology regarding who has access to the medical record—that is, parent or legal guardian, adolescent, pediatrician, or other health care providers.
- Lack of standards for electronic medical technology regarding protection of sensitive information, including laboratory test results, prescriptions, and other health data.
- Lack of standards for electronic billing to prevent disclosure of protected information through the act of generating a bill. These standards might include making it possible to suppress the laboratory test name (eg, HIV test name, pregnancy test name) while still generating a bill. Without this ability, pediatricians and health care facilities may choose to forego billing to protect the adolescent's privacy. This places the burden of care on the pediatrician or facility.
- Lack of standards for protecting sensitive information when used for public health, research, or other uses separate from the care episode.

RECOMMENDATIONS

Basic Principles for Ideal EHRs, PHRs, Personally Controlled Health Records, and HIEs (Collectively EHR Systems) for Adolescents

The AAP recommends the following basic principles for ideal EHR systems:

1. The creation and implementation of criteria for EHR systems that meet privacy standards for adolescents, particularly in areas of care that are protected by federal and state laws.
2. The creation and implementation of criteria for EHR systems that allow determination of who has access to, or who has the ability to control access to, the medical record either in total or in part. The "who" would need to accommodate any legally authorized physician, health care provider, guardian, or patient, including an adolescent or minor, and must be adaptable to change on the basis of the age and health care activity of the patient. Controlling access should also take into account the specific issues related to release of information (to other providers or secondary to subpoena) such that only the minimum necessary information pertinent to the request is released to protect the privacy of the adolescent.

3. The creation and implementation of criteria for EHR systems that allow adolescents to record their consents and authorizations for care or treatment according to privacy rules and laws (by using the HL-7 Child Health Profile DC.1.3.3 standard).[17]
4. The creation and implementation of criteria for EHR systems to allow the explicit and specific consent of the adolescent for release of specific protected health information. Authorization to access the most sensitive parts of an EHR is most definitive if made by this explicit consent.
5. Flexibility of these standards that allow for protection of privacy for diagnoses and associated laboratory test results, prescriptions, problem lists, and ultimately, any documentation/note that contains confidential data. This requirement is the most difficult to attain and control. These standards must also allow an entire visit to be marked as private and not viewable by anyone but those to whom the adolescent has given appropriate permission.
6. Certified EHR systems that meet privacy standards that are consistent with state laws.
7. EHR systems that are able to flag data that are being imported or exchanged between health entities (hospitals, clinics, emergency departments, other physician offices, health networks or exchanges) so that the information can be reviewed and placed in a confidential area of the EHR if appropriate.
8. EHR systems that are able to apply local (state) and federal privacy and confidentially rules when assembling aggregate data to prevent identification of individuals by unauthorized parties (HL-7 Child Health Profile DC.2.6.1).[17]
9. Billing systems associated with EHR systems that have the ability to suppress billing to the parent, guardian, or other legally authorized representative when an adolescent or minor seeks care for health issues that are delivered within the context of general visits and protected under state or federal statutes.

SUMMARY/CONCLUSIONS

Privacy and security of health information is a basic expectation of patients. The HIPAA Privacy Rule provides federal protections for personal health information held by covered entities and gives patients an array of rights with respect to that information. The HIPAA Security Rule specifies a series of administrative, physical, and technical safeguards for covered entities to use to ensure the protection of privacy, integrity, and availability of electronic protected health information. These protections focus on breaches of security and rarely address the needs of minors or adolescents, who routinely have health care provided under their parent's supervision. These issues apply equally to other populations including young adults who still live with their parent or guardian as well as for adult populations, and we believe that the recommendations have broader applicability beyond adolescents.

Although HIPAA rules defer to state law regarding minors with "exceptional circumstances" (eg, adolescents seeking care for STIs) and gives the minor and not the parent the right to this protected health information, the rules have not led to commercial health information technology systems having the capability to protect this information.

This policy addresses the basic needs related to privacy issues that must be protected within commercial health information technology systems. Protection must include the ability to consent for care, consent for release of information associated with care, and prevent inadvertent disclosure through billing activities or electronic aggregation of data for quality improvement, research, public health reporting, or other use. Continued lack of privacy protection in EHRs risks diminishing adolescent access to care, potentially resulting in higher adolescent pregnancy and STI (including HIV) rates, and unraveling significant gains that have been achieved. Even if these technical capacities exist in software, the privacy and security of the adolescent's health care will require educating pediatricians and staff to the specific issues outlined in this policy. This policy statement has been endorsed by the Society for Adolescent Health and Medicine.

Health care–associated infections in the NICU result in increased morbidity and mortality, prolonged lengths of stay, and increased medical costs. Neonates are at high risk of acquiring health care–associated infections because of impaired host-defense mechanisms, limited amounts of protective endogenous flora on skin and mucosal surfaces at time of birth, reduced barrier function of their skin, use of invasive procedures and devices, and frequent exposure to broad-spectrum antibiotic agents. This clinical report reviews management and prevention of health care–associated infections in newborn infants. *Pediatrics* 2012;129:e1085–e1093

INTRODUCTION

Health care–associated infections in the NICU are infections acquired in the hospital while receiving treatment of other conditions. Although they are less likely to cause mortality than early-onset infections, they have considerable health and economic consequences. Most health care–associated infections in the NICU result from the instrumentation and procedures required to preserve an infant's life. Thus, it is not possible to lower the rate of health care–associated infections merely by limiting the use of procedures. Furthermore, it is no longer acceptable to consider health care–associated infections as a consequence of neonatal intensive care. Rather, it is incumbent on clinicians to minimize risks of infection by performing invasive procedures only when needed and in the safest manner possible. There is evidence to support the concept that proactive strategies to prevent health care–associated infections in the NICU are possible,[1–5] although data supporting specific infection-control interventions in neonates are lacking. Although neonates clearly have unique vulnerabilities, there is no reason to believe that interventions shown to be effective in the pediatric ICU or adult ICU would not be equally effective in the NICU. Because of unique issues confronting the vulnerable neonate, however, these interventions may require some accommodations and further study.

STRATEGIES FOR THE PREVENTION OF HEALTH CARE–ASSOCIATED INFECTIONS

Hand Hygiene

Hand hygiene remains the most effective method for reducing health care–associated infections.[6] Hospitals with higher rates of hand hygiene

compliance have lower rates of central line bloodstream infection; however, compliance with hand hygiene practices is less than optimal.[7] A recent meta-analysis concluded that educational programs and multidisciplinary quality-improvement teams can be effective in increasing compliance with hand hygiene procedures[8]; however, each of the 33 studies included more than 1 intervention, and it was difficult to determine which was most efficacious. The Centers for Disease Control and Prevention (CDC) published guidelines for hand hygiene in health care settings in 2002.[9] Although the guidelines were widely accepted and disseminated by members of the National Nosocomial Infection Surveillance System, a recent analysis demonstrated that implementation of these guidelines had no effect on hand hygiene compliance rates (mean, 56.6%).[10]

The sixth edition of the *Guidelines for Perinatal Care*[11] recommends use of an antiseptic soap or an alcohol-based gel or foam for routine hand sanitizing if hands are not visibly soiled. When hands are visibly contaminated, they should first be washed with soap and water. Larson et al[12] compared the effectiveness of a traditional antiseptic hand wash with an alcohol hand sanitizer in reducing bacterial colonization. There were no differences in mean microbial counts on nurses' hands or infection rates among patients in the NICU; however, nurses' skin condition improved during the alcohol phase. Other studies have demonstrated the effectiveness of alcohol-based products, but there are no data to suggest they are superior. Compliance with hand hygiene may be enhanced if alcohol-based products are available at each infant's bedside.

In May 2009, the World Health Organization published new consensus recommendations for hand hygiene.[13] The guidelines provide a comprehensive overview of hand hygiene in health care and evidence- and consensus-based recommendations for successful implementation. Consensus recommendations were categorized according to the CDC/Healthcare Infection Control Practice Advisory Committee grading system (Tables 1 and 2). A partial list of recommendations relevant to the NICU is shown in Table 3.

Prevention of Central Line–Associated Bloodstream Infections

Catheter-related bloodstream infections are the most common hospital-acquired infections in the NICU. Central line–related infections are in large part a result of poor technique at the time of placement and ongoing care of the catheter site. Attempts to reduce the incidence of central line–associated bloodstream infections primarily fall into 1 of 5 categories: (1) clinical practice guidelines for the insertion and maintenance of indwelling lines[14]; (2) prophylactic administration of antibiotic agents (including antibiotic lock therapy); (3) topical emollients to reduce skin penetrance of bacteria; (4) promotion of breastfeeding; and (5) gowning for visitors and attendants. The goal of all infection-control programs should be to reduce the rate of central line–associated bloodstream infections to zero.

Both chlorhexidine (2%) and povidone-iodine are recommended for skin antisepsis in infants 2 months or older[15,16]; however, chlorhexidine is not approved by the US Food and Drug Administration for infants younger than 2 months. In a randomized trial, use of a chlorhexidine-impregnated gauze dressing (0.5% chlorhexidine gluconate in a 70% alcohol solution) in infants of very low birth weight reduced central venous catheter colonization when compared with use of a 10% povidone-iodine scrub but did not reduce the incidence of central line–associated bloodstream infections.[17] Notably, in the chlorhexidine group, contact dermatitis occurred in

TABLE 1 Evidence Grading System

Ranking System for Evidence According to the CDC/Healthcare Infection Control Practice Advisory Committee System
Category IA: Strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies.
Category IB: Strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies and a strong theoretical rational.
Category IC: Required for implementation, as mandated by federal and/or state regulation or standard.
Category II: Suggested for implementation and supported by suggestive clinical or epidemiologic studies or a theoretical rationale or a consensus by a panel of experts.

TABLE 2 Infectious Diseases Society of America/US Public Health Service Grading System for Ranking Recommendations for Clinical Guidelines

Category, Grade	Definition
Strength of recommendation	
A	Good evidence to support a recommendation for use
B	Moderate evidence to support a recommendation for use
C	Poor evidence to support a recommendation for use
Quality of evidence	
I	Evidence from ≥1 properly randomized controlled trial
II	Evidence from ≥1 well-designed clinical trial, without randomization; from cohort or case-controlled analytic studies (preferably from >1 center); from multiple time series; or from dramatic results from uncontrolled experiments
III	Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports from expert committees

TABLE 3 World Health Organization Recommendations for Hand Hygiene

- Wash hands with soap and water when visibly dirty or soiled with blood or other body fluids (IB) or after using the toilet (II).
- Use of an alcohol-based hand rub for all routine antisepsis is recommended for all clinical settings if the hands are not soiled (IA). If an alcohol-based hand rub is not obtainable, wash hands with soap and water (IB). Brushes are no longer recommended (even for surgical scrubs) (IB).
- Perform hand hygiene:
  - Before and after touching the patient (IB).
  - Before handling an invasive device for patient care, regardless of whether gloves are worn (IB).
  - After contact with body fluids or excretions, mucous membranes, nonintact skin, or wound dressings (IA).
  - If moving from a contaminated body site to another body site during care of the same patient (IB).
  - After contact with inanimate surfaces and objects (including medical equipment) in the immediate vicinity of the patient (IB).
  - After removing sterile (II) or nonsterile gloves (IB).
- Selection and handling of hand hygiene agents:
  - Provide products with a low irritancy potential (IB).
  - To maximize acceptance of hand hygiene products by health care workers, solicit input regarding the skin tolerance, feel, and fragrance of any products under consideration (IB).
  - Determine any known interaction between products used to clean hands, skin care products, and the types of gloves used in the institution (II).
  - Ensure that dispensers are accessible at point of care (IB).
  - Provide alternative hand hygiene products for health care workers with confirmed allergies or adverse reactions to standard products (II).
  - When alcohol-based hand rub is available in the health care facility, use of antimicrobial soap is not recommended (II).
  - Soap and alcohol-based hand rub should not be used concomitantly (II).
- Use of gloves:
  - The use of gloves does not replace the need for hand hygiene (IB).
  - Wear gloves when it can be reasonably anticipated that contact with blood or other potentially infectious materials, mucous membranes, or nonintact skin will occur (IC).
  - Remove gloves after caring for a patient. Do not wear the same pair of gloves for more than 1 patient (IB).
  - Change or remove gloves during patient care if moving from a contaminated body site to either another body site (including nonintact skin, mucous membrane, or medical device) within the same patient or the environment (II).
- Other aspects of hand hygiene:
  - Do not wear artificial fingernails or extenders when having direct contact with the patient (IA).
  - Keep natural nails short.
- Hand hygiene promotion programs:
  - In hand hygiene–promotion programs for health care workers, focus specifically on factors currently found to have a significant influence on behavior and not solely on the type of hand hygiene product. The strategy should be multifaceted and multimodal and include education and senior executive support for implementation (IA).
  - Educate health care workers about the type of patient-care activities that can result in hand contamination and about the advantages and disadvantages of various methods used to clean their hands (II).
  - Monitor health care workers' adherence to recommended hand hygiene practices and provide them with performance feedback (IA).
  - Encourage partnerships between patients, their families, and health care workers to promote hand hygiene in the health care setting (II).

15% of neonates weighing less than 1000 g. In a meta-analysis of studies comparing chlorhexidine gluconate solution with a povidone-iodine solution, the overall risk reduction (for central line–associated bloodstream infections) with chlorhexidine gluconate compared with a povidone-iodine solution was approximately 50%.[18]

Extraluminal contamination of the intracutaneous tract is believed to be responsible for catheter-related infections that happen in the week after placement.[19] Catheters are more mobile during the first week after insertion and can slide in and out of the insertion site, drawing organisms down into the catheter tract. Techniques to reduce the likelihood of extraluminal contamination include proper hand hygiene, aseptic catheter insertion (including use of a maximal sterile barrier for catheter insertion and care [IA]), use of a topical antiseptic (IA), and use of sterile dressing (IA). Although transparent dressings permit easier inspection of the catheter site, they have no proven benefit in reducing infection.[20] Catheter sites must be monitored visually or by palpation on a daily basis (IB) and should be redressed and cleaned on a weekly basis (IA). In neonates, there are no data indicating that tunneled catheters have a lower risk of infection than nontunneled catheters.[21]

After the first week of placement, intraluminal colonization after hub manipulation and contamination is responsible for most central line–associated bloodstream infections.[19] Mahieu et al[22] demonstrated that the frequency of catheter manipulations was directly related to the frequency of central line–associated bloodstream infections. Tubing used to administer blood products or lipid emulsions should be changed daily (IB). Tubing used to infuse dextrose and amino acids should be replaced every 4 to 7 days. It is important to remove all central venous catheters when they are no longer essential (1A). Many NICUs remove central catheters when the volume of enteral feedings reaches 80 to 100 mL/kg per day. Topical antibiotic agents or creams should not be used at the insertion site for catheters (1B).

Guidelines for the prevention of intravascular catheter-related infections have been published.[23] These guidelines make specific recommendations for umbilical catheters. Levels of evidence are indicated in parentheses (Table 4).

Recently, there has been a focus on implementing "NICU care bundles" to reduce the incidence of hospital-acquired infections. Care bundles are groups of interventions (extrapolated from studies in adults or recommendations from professional organizations) that are likely to be effective. This multifaceted approach has reduced the incidence of health care–associated sepsis in each center or groups of centers where it has been implemented.[24–27]

Coagulase-negative staphylococci are the most common cause of central line–associated bloodstream infections in the United States. Therefore, the use of low-dose vancomycin in parenteral alimentation solutions (at concentrations above the minimal inhibitory concentration) has been suggested as a way to decrease the incidence of bacteremia attributable to coagulase-negative staphylococci. Five randomized clinical trials of low-dose vancomycin in preterm neonates have been conducted, all of which date from the late 1990s. In 4 of the studies, there was a statistically significant reduction in the incidence of coagulase-negative staphylococcal sepsis (relative risk [RR], 0.11; 95% confidence interval [CI], 0.05–0.24)[28]; however, there were no significant differences in mortality or length of stay. The use of antibiotic lock therapy has also been investigated. Lock solutions containing vancomycin are instilled into the catheter lumen to reduce intraluminal colonization. Most randomized clinical trials of antibiotic lock therapy have been completed in adults and older children.[29] A meta-analysis of these trials demonstrated a significant reduction in bloodstream infections (RR, 0.49; 95% CI, 0.26–0.95). Use of vancomycin as a true lock solution (instilling it for a defined period rather than flushing it through the catheter) conferred greater benefit. The single study of antibiotic lock therapy in the neonatal population[30] demonstrated a statistically significant reduction in central line–associated bloodstream infections (RR, 0.13; 95% CI, 0.01–0.57). No increase in vancomycin resistance occurred in this study; however, the study was not sufficiently powered to address that question. Because of the concern for development of vancomycin-resistant organisms and the lack of long-term efficacy data, neither continuous infusions of vancomycin nor antibiotic lock therapy can be recommended.

Invasive fungal infections are responsible for 9% to 12% of health care–associated infections in infants weighing less than 1500 g.[31] In a prospective study from the National Institute for Child Health and Human Development research network, 9% of infants weighing less than 1000 g developed candidiasis.[32] Death or neurodevelopment impairment occurred in 73% of these infants. Prophylactic fluconazole has been suggested as a way to decrease the incidence of invasive fungal disease. The rationale is that prevention of fungal colonization in high-risk infants will lower the risk of invasive disease. A meta-analysis of 5 trials comparing systemic fluconazole with placebo, demonstrated a statistically significant reduction in the incidence of invasive fungal infections (RR, 0.48; 95% CI, 0.31–0.73)[33]; however, there was no significant difference in the incidence of death before discharge from the hospital and insufficient data to assess neurodevelopmental outcomes. There is a concern that the use of azoles to prevent fungal infections will lead to an increase in fluconazole resistance or will result in toxicity, especially among the most immature infants for whom there are limited pharmacokinetic data.

In many NICUs, it is policy that care providers and visitors wear gowns on entering the nursery. Eight trials have evaluated the benefit of gowning.[34] A meta-analysis demonstrated that there was no significant effect of a gowning policy on reducing the incidence of systemic nosocomial infection (RR, 1.24; 95% CI, 0.90–1.71). For that reason,

TABLE 4 Guidelines for the Prevention of Intravascular Catheter-related Infections

1. Remove and do not replace umbilical artery catheters if any signs of central line–associated bloodstream infection, vascular insufficiency in the lower extremities, or thrombosis are present (Category II).
2. Remove and do not replace umbilical venous catheters if any signs of central line–associated bloodstream infection or thrombosis are present (Category II).
3. Cleanse the umbilical insertion site with an antiseptic before catheter insertion. Avoid tincture of iodine because of the potential effect on the neonatal thyroid. Other iodine-containing products (eg, povidone-iodine) can be used (Category IB).
4. Do not use topical antibiotic ointment or creams on catheter insertion sites because of the potential to promote fungal infections and antimicrobial resistance (Category IA).
5. Add low doses of heparin (0.25–1.0 U/mL) to the fluid infused through umbilical arterial catheter (Category IB).
6. Remove umbilical catheters as soon as possible when no longer needed or when any sign of vascular insufficiency to the lower extremities is observed. Optimally, umbilical artery catheters should not be left in place for more than 5 d (Category II).
7. Umbilical venous catheters should be removed as soon as possible when no longer needed but can be used up to 14 d if managed aseptically (Category II).
8. An umbilical catheter may be replaced if it is malfunctioning and there is no other indication for catheter removal and the total duration of catheterization has not exceeded 5 d for an umbilical artery catheter or 14 d for an umbilical vein catheter (Category II).

gowns should not be required for routine admission to the NICU by health care workers or visitors. Despite the lack of overall benefit, gowns and gloves should be worn when an infant is colonized with a resistant or invasive pathogen, consistent with appropriate isolation requirements. Additional personal protective equipment may be required on the basis of isolation requirements of the specific pathogen or clinical condition and the activity or procedure to be performed.

Prevention of Health Care–Associated Pneumonia

The CDC published guidelines for preventing health care–associated pneumonia in 2003.[35] These guidelines were not specifically designed to address the unique issues facing the mechanically ventilated patient in the NICU; however, many of the recommendations are relevant to all patient populations.

General concepts discussed in the CDC document include the following:

1. Staff Education and Involvement in Infection Prevention. All providers should receive appropriate information relating to the epidemiology of and infection control procedures for preventing health care–associated pneumonia. There should be procedures in place to ensure worker competency, including performance of appropriate infection-control activities. Staff should be involved with implementation of interventions to prevent health care–associated pneumonia using performance-improvement tools and techniques (IA).
2. Infection and Microbiologic Surveillance. Surveillance for health care–associated pneumonia in patients in the NICU should be performed to determine trends and help identify outbreaks or other problems (IB). Routine surveillance cultures of patients or equipment should not be performed (II).
3. Prevention of Transmission of Microorganisms. Within the NICU, risks for acquisition of microorganisms that could result in health care–associated pneumonia can be reduced by (1) proper sterilization or disinfection and maintenance of equipment and devices (IA), and (2) prevention of person-to-person transmission of bacteria by use of Standard Precautions as well as other isolation practices when appropriate (IA).
4. Modifying Host Risk for Infection. Aspiration is a major risk for the development of health care–associated pneumonia. Devices such as endotracheal tubes, tracheostomy tubes, or enteral tubes should be removed from patients as soon as appropriate and clinically indicated (IB). In the absence of medical contraindication(s), the head of the bed should be elevated at an angle of 30 to 45 degrees for mechanically ventilated patients (II). A comprehensive oral-hygiene program should be followed for the infant (II).

Suctioning practices and position of the infant in the bed may influence tracheal colonization. The use of closed-suctioning systems allows endotracheal suctioning without disconnecting patients from the ventilator. Closed-suctioning methods reduce physiologic disruptions (hypoxia and decrease in heart rate), and NICU nurses judged them to be easier to use than an open system.[36,37] Closed-suctioning systems provide an opportunity for bacterial contamination when pooled secretions in the lumen are reintroduced into the lower respiratory tract with repeat suctioning. On the other hand, closed-suctioning systems could potentially reduce environmental contamination of the endotracheal tube. In studies evaluating mechanically ventilated adults, airway colonization was more common when closed-suctioning systems were used,[38,39] but ventilator-associated pneumonia rates were equal to or slightly less than the rates among patients managed with open systems.[38–40] CDC recommendations[35] do not endorse one system over the other, and there is no recommendation addressing the frequency at which closed-suctioning systems should be changed.

Tracheal colonization from oropharyngeal contamination is less common among neonates on mechanical ventilation when the neonates are placed in a lateral position on the bed as compared with the supine position (30% for lateral versus 87% for supine; $P < .01$).[41] Keeping the endotracheal tube and the ventilator circuit in a horizontal position might reduce tracking of oropharyngeal sections down into the lower respiratory tract.[42] The lateral position also is associated with reduced aspiration of gastric secretions into the trachea.[41] Using a nonsupine position may reduce the risk of ventilator-associated pneumonia.[43]

Other Strategies to Reduce Health Care–Associated Infections in the NICU

The skin of the preterm newborn infant has compromised barrier and immune function. In addition, the skin of the extremely preterm infant can be easily damaged and serve as a portal for the entry of organisms into the bloodstream. Topical emollients have been used to decrease transepidermal water losses and have been suggested as a method to decrease health care–associated infections. In a meta-analysis of 4 trials completed in industrialized countries, a significantly increased risk of coagulase-negative staphylococcal infection was found in infants treated with prophylactic topical ointment.[44] In contrast, infants born at <33 weeks' gestation in Bangladesh treated topically with sunflower oil were 41% less likely to

develop health care–associated infections than were control infants.[45] The lack of effectiveness of topical emollients in industrialized countries may be attributable to different mechanisms of transcutaneous sepsis. In industrialized countries, instrumentation is used more commonly, and sites of insertion can serve as a portal for bacterial invasion. In developing countries, environmental contamination and malnutrition play a greater role, and invasive devices are used less frequently. Therefore, bacterial invasion is likely attributable to microscopic sites of skin barrier compromise, which might be protected by the use of an emollient.

The use of human milk feedings has been associated with a lower risk of sepsis and necrotizing enterocolitis in preterm infants.[46] Human milk contains a large number of immunoprotective substances, prebiotics, and probiotics and has been shown to decrease the incidence of gastrointestinal and respiratory infections in infancy.[47] Although a number of randomized clinical trials and cohort studies have concluded that human milk feedings had a protective effect on infection in preterm infants, a meta-analysis of 9 studies (6 cohort and 3 randomized clinical trials from India) failed to show an advantage of human milk feedings.[48] The authors believed there were serious methodologic flaws in all of the cohort studies, "including poor study design, inadequate sample sizes, neglecting to account for some confounders, failure to eliminate the effects associated with maternal choice of feeding method and other sociodemographic variables." In addition, the definition of human milk feedings was not consistent among studies. It is important to note that necrotizing enterocolitis was excluded from this systematic review.

A number of other practices may provide opportunities to reduce colonization of the critically ill neonate with health care–associated pathogens or to modify the risk of developing disease if colonized. Specific practices that may provide benefit include (1) appropriate vaccination of health care workers (eg, influenza vaccine and tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis, adsorbed); (2) cohorting in selected outbreak situations; and (3) visitation guidelines to identify ill/infected visitors.

Antibiotic Use and Misuse

The use and misuse of antibiotics can be associated with alteration in neonates' microflora and the development of antibiotic resistance. This is a particular concern within the confines of a NICU, where there is a population of vulnerable children who have medical conditions that may require frequent and/or prolonged antibiotic use, long hospitalizations, crowded conditions, and frequent contact and interventions.

Antimicrobial resistance can be intrinsic (ie, present without exposure to antimicrobial agents) or acquired. An example of intrinsic resistance is the resistance of Gram-negative organisms to vancomycin. Acquired antimicrobial resistance is driven by antimicrobial exposure, as is seen in methicillin-resistant *Staphylococcus aureus* and the extended-spectrum β-lactamase (ESBL)-producing organisms. These patterns of resistance represent adaptations of bacteria to antibiotic exposure.

Judicious use of antibiotic agents is commonly recommended as appropriate in the NICU, but it is not commonly practiced. The critically ill nature of patients in the NICU prompts frequent and prolonged use of antimicrobial agents. Judicious use of antibiotic agents in the NICU would include limiting use to only those situations in which a bacterial infection is likely, discontinuing empirical treatment when a bacterial infection has not been identified, changing the antibiotic agents administered to those with the narrowest spectrum on the basis of susceptibility testing, and treating for the appropriate duration. Although clinical situations will vary, these principles remain consistent. It is also relevant to consider the potential for different antibiotic agents to drive the development of resistance. ESBL-producing organisms (primarily Gram-negative enteric agents) are present in many NICUs because of the frequent use of third-generation cephalosporins and other broad-spectrum β-lactam antibiotic agents. Curtailing the use of third-generation cephalosporins and using other antibiotic agents, such as aminoglycosides for empirical therapy, has been associated with less antibiotic resistance, including ESBL-producing organisms. Good infection-control practices also play a significant role in reducing horizontal transmission of antibiotic-resistant bacteria.

The Infectious Diseases Society of America and the Society for Healthcare Epidemiology of America have developed guidelines for "Antimicrobial Stewardship" to reduce antimicrobial resistance.[49] These guidelines are designed to address programmatic changes that improve control of antibiotic resistance (see Table 1 for levels of evidence). Strategies that might be helpful in the NICU setting include the following: (1) auditing antimicrobial use of practitioners and providing feedback (IA); (2) formulary restriction and preauthorization requirements for selected antimicrobial agents (IB); (3) education of prescribers and nurses concerning the role of antimicrobial use and the development of resistance (IB); (4) development of clinical guidelines/pathways for selected conditions (IA); (5) antimicrobial order forms (IB); (6) specific plans for streamlining (broad- to narrow-spectrum antibiotic agents) or deescalating (elimination of redundant or unnecessary) antimicrobial

agents (IB); (7) dose optimization on the basis of individual characteristics (eg, weight, renal status, drug-drug interactions) (IB); and (8) switching from parenteral to oral antibiotic agents when appropriate and feasible (IB). Data are not sufficient to recommend antimicrobial cycling or routine use of combination therapy merely to prevent the development of resistance; however, antimicrobial combinations may be valuable for preventing development of resistance in specific circumstances.

CONCLUSIONS

Health care–associated infections are an important medical morbidity facing an already vulnerable group of infants. The epidemiology and strategies that can reduce these infections are well known; however, implementation of strategies that can influence the occurrence of health care–associated infections within the NICU requires a concerted team effort by all individuals who participate in the care of these infants. Each care provider must understand his or her role in preventing health care–associated infections and have a willingness to modify behaviors such that they comply with recognized infection-control practices. All too frequently, the health of a tiny infant whose life is being saved through the use of the best in 21st-century technology is jeopardized by the smallest of acts—such as a care provider neglecting to wash his or her hands. Recognition of the importance of even the most basic care practices can result in behavior modification within the NICU and improve compliance with established infection-control practices.

CLINICAL REPORT

Supporting the Family After the Death of a Child

abstract

FREE

The death of a child can have a devastating effect on the family. The pediatrician has an important role to play in supporting the parents and any siblings still in his or her practice after such a death. Pediatricians may be poorly prepared to provide this support. Also, because of the pain of confronting the grief of family members, they may be reluctant to become involved. This statement gives guidelines to help the pediatrician provide such support. It describes the grief reactions that can be expected in family members after the death of a child. Ways of supporting family members are suggested, and other helpful resources in the community are described. The goal of this guidance is to prevent outcomes that may impair the health and development of affected parents and children. *Pediatrics* 2012;130:1164–1169

KEY WORDS

child death, family support, grief, pediatrician, parents, siblings

INTRODUCTION

The death of an infant, child, or adolescent, from any cause, has a devastating effect on the family. For parents, the loss of a child defies the natural order. In our era, parents do not expect to bury their children. The death of a child or adolescent also often means there is a sibling or siblings who experience their own significant loss. The pediatrician is in a position to help family members cope, both with the immediate loss and then the ongoing effect of the child's death. Because of the general good health of children in our society, pediatricians are often unfamiliar with how to deal with the death of a child, however. Or they may feel that addressing this event is too emotionally painful. This report identifies the most important issues to be considered and suggests ways the pediatrician can and should help.

PARENTAL GRIEF

The death of a child of any age is extremely painful for parents. Parents have an obligation and a strong emotional need to protect their children from harm. Most parents experience a profound sense of guilt when harm comes to their child, even if through no fault of their own. Parents invest much of their hopes and wishes for the future in their children. All of these factors lead to a devastating grief that is much longer lasting than most people realize.[1] The depth of parental grief often shocks and surprises others. It is common for grieving parents to be unable to function for varying times after their child's death. They may spend days in bed, away from work, and unable to carry out

household tasks. It is common for parents to have great difficulty eating and sleeping. The thought that life is not worth living is frequent, as are thoughts that one might be "going crazy."

ISSUES RELATED TO THE CIRCUMSTANCES OF THE DEATH

Death as the Result of Chronic Illness or Disability

When a child or adolescent's death results from chronic illness or disability, it is likely that the pediatrician has been involved in the patient's care and may have a long-standing relationship with the family. Although the family may have anticipated the death, the grief will still likely be profound. Even when the child has had severe disability or has suffered, the parents' sense of grief and loss is not usually diminished. When there has been a long-standing relationship with the family surrounding the child's illness or disability, the family also may suffer from the loss of the relationship with the pediatrician. Under these circumstances, the pediatrician's continuing involvement with the family may be especially important.

Sudden, Unexpected Death

Injuries are the single most common reason for death in children and adolescents. In adolescents, suicide and homicide are also a common cause of death. Pediatricians may not immediately be aware of the death in such circumstances. If there is a brief period of survival after the event, the pediatrician may be involved; however, these deaths often occur in the emergency department. If this situation is the case, the emergency physician should inform the pediatrician of the death, including the details of the last hours of care.[2,3] If not actually witnessed by the parents, these details will often be what haunts the parents' thoughts in the months after the death. Pediatricians may hear about the death of a child or adolescent who was one of their patients from the news or from their office staff or other parents in their practice. Although the pediatrician was not involved at the time of the death, if there has been a relationship with the family and if there are surviving siblings who are still patients in the practice, the pediatrician has an important role in supporting the family.

Infant Death

In the case of infant death, many physicians fail to appreciate the intense attachment to the fetus and infant and the extent to which parents and other family members invest in that infant's imagined future. The grief at this loss is intense, and the surviving siblings also may be deeply affected. The physician should recognize the depth of these feelings and be prepared to provide the kind of support outlined in this statement.

Helpful Responses and Those That Hurt

The most helpful response after a child or adolescent death is to provide an opportunity to meet with the parents, face to face, and to just listen, responding in ways that encourage the parents to talk. Frequently, in the context of an unexpected death, physicians fail to respond at all. This failure to respond may contribute to the family's pain. Many physicians find the thought of losing a child so terrible that they avoid contact with the grieving parents rather than confront their own fears. Others find it difficult to be with parents who are crying or showing their grief in other ways. Physicians often hold the mistaken belief that talking about the death will be harmful because such talk will reawaken and prolong the parents' grief.[4] Quite the contrary, grieving parents report that acknowledging their grief is important, and they seldom forget the pain of a friend, family member, or physician who fails to make contact after such a loss.[5] If pediatricians have a relationship with a family, they should always contact the parents when they learn of the death of a child in that family, including the pediatrician who hears about the death from the news or from others in the community. Such contact should be more than attendance at a viewing or a funeral. At such formal times of grieving, personal contact is not possible, and parents are usually in shock and unable to ask the questions that may be on their minds. The most helpful response is a face-to-face visit.[6] The purpose of such an encounter is to acknowledge the death and allow the parents to talk. The pediatrician might say, simply, "I'm so sorry to hear about _____'s death. What a terrible loss for you and your family." Attempts to alleviate the grief by providing advice are usually ineffective and may be hurtful. Expressions of religious interpretation may or may not be appropriate and should be tailored to what the pediatrician knows of the family's beliefs. Comments made to parents of children with disabilities, such as "he/she is better off now," are often perceived as diminishing the value of the child. Some parents, however, may voice this thought themselves.

Duration of Grieving

Many people are surprised at how long parents may grieve the loss of a child. The period of a year of grieving is acknowledged by many religions and cultural practices, but commonly, parents experience significant grief for much longer. Parents frequently report waves of grief that include reliving the traumatic details of the injury or visions of the person suffering the final stages of a fatal illness.

Anniversaries of the death and important dates, such as the child's birthday, bring recurring waves of grief, often for several years. Family events, such as graduations, marriages, and births, reawaken grief. These events are reminders of the hopes and dreams shattered by the child's death. Eventually, and the period of time varies greatly, parents describe a gradual pattern of change. They no longer relive the experiences at the time of death, and they are able to remember common and happy events in the child's life with less pain and even with pleasure. This change is, however, usually measured in years. Parents frequently report that their greatest fear is that the child will be forgotten, so failing to mention or talk about the child who has died confirms these fears.

Helping During Prolonged Grief

Every parent grieves in his or her own way, and the pediatrician should not expect a prescribed timetable of grieving. Parents find it painful to hear a statement such as, "You should get over it and get on with your life." Yet such statements are frequently made. Self-help support groups, such as The Compassionate Friends and Bereaved Parents USA (see Resources section), are specifically designed for parents whose children have died and provide some of the best help for this prolonged grieving process.[7] These peer-led support groups provide an atmosphere in which it is possible to talk about the loss without the pressure to "get over it." Also, most parents are comforted by an environment in which others have been through a similar experience and in which they meet those who have survived this devastating loss. Descriptive studies confirm that many parents resolve their grief by talking about their loss in an accepting environment.[4] Family members who are discouraged from expressing their grief may find it more difficult to get past the most painful part of their grieving and function effectively. Pediatricians are encouraged to learn about the support groups in their community and how they function. They can then refer parents who might benefit from such groups (see Resources).

Special Circumstances

The death of a child, no matter what the cause, is devastating. But there are some circumstances that make this loss particularly difficult. When the death occurs by suicide or through the child's use of alcohol or drugs, the guilt experienced by parents can be particularly strong. Homicide or injuries that are caused by negligence, such as by drunk driving, produce intense anger. The grief also may be especially intense if the parent's actions may have contributed to the death, such as in situations in which supervision was lacking or if the parent was driving when an injury occurred. Parents in these circumstances may require special help through counseling or therapy. If the cause of a child's death might be filicide, special circumstances beyond the scope of this statement must be addressed.

Complicated Grief, Medication, and Grief Counseling

In this report, the term "complicated grief" refers to the situation when grief is so intense and/or prolonged that the pediatrician believes that professional mental health evaluation or treatment is required. It is difficult to specify either the symptoms or the circumstances when this point is reached, but a few general guidelines can be given. Complicated grief occurs most frequently when the parent is already experiencing a psychiatric problem, or the parent may have had a psychiatric disorder in the past. Most obviously, when a parent is already experiencing depression, the death of his or her child is likely to exacerbate that problem. Other psychiatric disorders also may worsen with such a death. Another situation that is known to result in a more serious grief reaction is the death of a child when the parent-child relationship has been a troubled one[8]; however, grief (including intense and prolonged grief, as described previously) is a normal reaction to the loss of a child. In most situations, medication is not needed and can be counterproductive. If, however, the pediatrician judges the grief to be especially intense and debilitating, medication may be needed, and a referral to a mental health specialist should be considered.

Grief counseling is available and/or provided under a variety of circumstances. In situations of injury death in which a number of people have been killed, such as in an airplane crash, grief counselors may provide help in the immediate aftermath. Also, in most communities and at most hospitals, grief counseling groups meet, usually for a prescribed period of time, typically lasting from 6 to 8 weeks. Such groups usually are not designed just for parents who have lost children. Although these groups are helpful to many parents, they do not address the long-term issues mentioned previously. Grief counselors can be especially helpful when they are trained to recognize the complicated grief described previously and can make appropriate referrals.

SIBLINGS

Siblings in a family in which an infant, child, or adolescent has died are sometimes called "the forgotten mourners."[9] This phrase acknowledges that the grief of siblings is often neglected because parents are the focus of grieving within the family. The pediatrician is in a unique position to provide support to siblings

who are in their practice, both at the time of death of their brother or sister and in the context of the sibling's ongoing health care. What follows are suggestions on how to provide this type of care.

Initially, particularly in the case of sudden, unexpected death, the problem may be that parents may not be able to provide ongoing support to their surviving children in the midst of their own grief. For very young siblings for whom the need for parental support is great, this problem may be acute. Members of the extended family may be in the position to help once the need is identified. When not available, however, other social services may need to be recruited to provide support. Older siblings often experience an ongoing lack of emotional support and feel abandoned by their grieving parents. The pediatrician may be in the best position to assess these issues and identify other resources if needed.

The way siblings respond to the death of a brother or a sister of any age varies depending on the developmental age of the sibling, and this response changes as the sibling matures. The reactions to death in the family and the changes that occur during development are discussed elsewhere in the pediatric literature[10]; however, there are special issues associated with sibling loss that are less well known and are reviewed here.

Survivor Guilt

Survivor guilt in siblings is common, especially in situations of unexpected death. Guilty feelings may be especially strong in siblings who have experienced intense sibling rivalry. Before the death, the sibling may have had negative feelings about the deceased, or there may have been harsh words spoken during angry arguments. The sibling may have harbored thoughts wishing that harm would come to his or her brother or sister. These thoughts and words may haunt the surviving sibling. Such thoughts and memories may be emotionally crippling unless talked about in counseling or dealt with in therapy.

Overprotection

Parents commonly fear that their surviving child or children will also die. These fears may lead to serious overprotection of surviving siblings, such as restricting age-appropriate activities. Behavior problems in these siblings may stem from the need to break free from stifling overprotection. Pediatricians should be sensitive to this possibility and should counsel parents under such circumstances.

Idealization and the Replacement Child

Parents and other family members frequently idealize the deceased child. Parents often create shrines to memorialize the child, which may reinforce this idealization. Siblings, especially younger ones, may be jealous and resent this picture of the idealized child. The surviving sibling may feel he or she cannot live up to that ideal and may respond with rebellious behavior. Parents also may come to view a surviving sibling, particularly a younger one, as a replacement for the child who died.[11] In this situation, the family member projects on to the surviving sibling his or her hopes and wishes for the child who died. The sibling may sense the parents' feelings and rebel against these wishes and hopes, especially if they are unrealistic. If pediatricians recognize these dynamics, they can be discussed with the parents, and suggestions can be made to address the sibling's feelings.[12] A referral for therapy may be needed if the problem persists.

Assuming the Parental Role

It is especially common for older siblings to assume a parental role when parents are absorbed with their own grief. Although this reaction may be adaptive in the early months of the parents' grief journey, it may become maladaptive as the sibling matures. The pediatrician should look for this situation and help the parent and surviving sibling to relinquish this distortion of family roles.

General Issues of Sibling Grief

One's siblings play a special role in a child's growth and development. Siblings share family secrets, and no one else in a child's life may share that experience. Siblings also have a special role to play in protecting each other in the wider environment of school and playground. Surviving siblings may experience a profound sadness at the loss of this special relationship and may find it helpful to talk about this aspect of their loss.

Providing Sibling Support

If a surviving sibling is in the pediatrician's practice, the clinician should find a way to follow that sibling's emotional development and intervene when problems are detected. One suggestion is to place a picture of the deceased child in the sibling's chart as a reminder whenever that sibling is seen in ongoing health care. A helpful approach is to raise the issue of the brother's or sister's death at well-child visits. The surviving sibling's feelings and thoughts will change with time. The pediatrician should be aware that siblings may refuse to talk about their deceased brother or sister at first. The pediatrician should honor this resistance but be persistent in raising the issue, because this reaction often changes over time.

Some self-help support groups provide support for siblings who are old enough

to benefit from talking to other young people who have suffered a similar loss. Support for siblings may also be provided by schools, religious organizations, and groups such as scouts or other organizations. Knowledge of these and other such services in one's community allows the pediatrician to tap other sources of support (see Resources).

SUMMARY

The death of an infant, child, or adolescent is a devastating experience for the family. The pediatrician is in a special position to help families through their grief experience. The ultimate goal of such support is the prevention of problems that may result from such trauma. The following are suggestions for pediatricians regarding this support.

1. Expect that grief after the loss of a child is intense and long lasting.
2. Recognize that failing to acknowledge the death of an infant, child, or adolescent who was a patient can contribute to the family's pain. A telephone call or a face-to-face visit with the parent(s) of a patient who has died is encouraged.
3. Follow up with and provide guidance to surviving siblings who are still patients. Providing guidance to siblings requires recognition of the special issues experienced by grieving siblings.
4. Understand that the duration of grieving within a family after the loss of a child is longer than many expect and is usually measured in years.
5. Recognize the power of self-help support groups in helping parents get through the prolonged grief after their child's death. Be aware of the presence of such groups in the community and make referrals when indicated.
6. Be aware that when the death of a child or adolescent is by suicide, through the use of alcohol or drugs, or through homicide, the grief is especially intense and is accompanied by intense guilt and/or anger. Consider referral for counseling or therapy in these cases.
7. Be aware that complicated grief is more likely when the parent has a preexisting psychiatric problem or when there was a troubled parent-child relationship before death. In such cases, referral to a mental health specialist may be indicated. Most intense and prolonged grief is normal, however, and the use of medication is usually not helpful.

POLICY STATEMENT

Trampoline Safety in Childhood and Adolescence

abstract

FREE

Despite previous recommendations from the American Academy of Pediatrics discouraging home use of trampolines, recreational use of trampolines in the home setting continues to be a popular activity among children and adolescents. This policy statement is an update to previous statements, reflecting the current literature on prevalence, patterns, and mechanisms of trampoline-related injuries. Most trampoline injuries occur with multiple simultaneous users on the mat. Cervical spine injuries often occur with falls off the trampoline or with attempts at somersaults or flips. Studies on the efficacy of trampoline safety measures are reviewed, and although there is a paucity of data, current implementation of safety measures have not appeared to mitigate risk substantially. Therefore, the home use of trampolines is strongly discouraged. The role of trampoline as a competitive sport and in structured training settings is reviewed, and recommendations for enhancing safety in these environments are made. *Pediatrics* 2012;130:774–779

George Nissen, a competitive gymnast, patented the modern trampoline as a "tumbling device" in 1945. Nissen initially designed the trampoline as a training tool for acrobats and gymnasts and subsequently promoted it for military aviator training. Recreational use of trampolines is a more recent phenomenon, driven primarily by the increased availability of relatively inexpensive trampolines marketed for home use.

The evolving pattern of trampoline use and injury resulted in a series of published policy statements from the American Academy of Pediatrics (AAP) in 1977, 1981, and 1999.[1–3] The American Academy of Orthopedic Surgeons issued trampoline safety position statements in 2005 and 2010.[4] The Canadian Pediatric Society and the Canadian Academy of Sports Medicine issued a joint statement on trampoline use in 2007.[5] These statements all discouraged recreational and playground use of trampolines and urged caution with and further study of trampoline use in supervised training and physical education settings.

The recent growth of trampoline as a competitive sport, the emergence of commercial indoor trampoline parks, research on the efficacy of safety measures, and more recently recognized patterns of catastrophic injury with recreational trampoline use have prompted a review of the current literature and an update of previous AAP policy statements regarding trampolines.

EPIDEMIOLOGY

Over the past several decades, national estimates of trampoline injury numbers have been generated annually by using the US Consumer Product Safety Commission's (USCPSC) National Electronic Injury Surveillance System (NEISS).[6] Trampoline injuries increased throughout the 1990s, with case numbers more than doubling between 1991 and 1996 (from approx 39 000 to >83 000 injuries per year). Injury rates and trampoline sales both peaked in 2004 and have been decreasing since then (Table 1).[6,7] As home trampoline use appears to be waning, commercial trampoline parks and other trampoline installations have been emerging over the past several years. Although indoor commercial parks typically consist of multiple contiguous trampoline mats with padded borders, other setups are highly variable. Any effect of these facilities on trampoline injury trends should be monitored but is not yet evident.

A comparison of trampoline injury prevalence with those from other sports and recreational activities provides a sense of the societal burden of injury; however, it does not reflect the true risk of trampoline use by an individual. Risk takes into account the exposure or frequency of a given activity, and unfortunately, exposure data for many recreational activities, including trampoline use, are difficult to define and measure. Trampoline injury rates for 2009 were 70 per 100 000 for 0- to 4-year-olds[6] and increased to 160 per 100 000 for 5- to 14-year-olds. Injury rates attributable to bicycling and use of playground equipment were higher in these age groups, but population exposure was likely significantly greater in these 2 activities as well.

In children younger than 14 years, rates of swimming injuries were similar to those for trampoline.[6] Once again, exposure comparisons are difficult, but home swimming pools and home trampolines do share some features in terms of injury risk. Home trampolines and home swimming pools are both considered by many insurance companies to be "attractive nuisances" capable of enticing children into potentially dangerous situations. As such, many homeowner insurance policies have trampoline exclusions or mandate that trampolines are within enclosed areas with restricted access, similar to rules for swimming pools and spas. A key difference between swimming pools and trampolines is that evidence-based safety recommendations for home swimming pools (ie, 4-sided fencing that completely isolates the pool from the house and yard) are a broadly publicized focus for many groups concerned with public safety, but trampoline safety information has not been as well studied or as widely disseminated. Many parents and supervising adults do not appear to be aware of key components of trampoline safety, such as limiting the trampoline to 1 user at a time, and this may contribute significantly to current injury rates.[8]

Although the prevalence of trampoline injuries is decreasing, concern persists regarding the severity of injuries sustained on the trampoline. Studies over the past decade in other countries revealed hospitalization rates between 3% and 14%.[8,9] Hospitalization rates in the United States have been approximately 3% from 2005 to 2009.[6]

TABLE 1 Trampoline-Related Injuries

Year	Actual Number of Cases[a]	Estimated Number of Injuries[b]	Rate of Injury per 100 000	Estimated Number of Hospitalizations/DOA
2004	3277	111 851	38.1	—
2005	3330	108 029	36.4	3537
2006	3277	109 522	36.6	4793
2007	3226	107 435	35.6	3188
2008	3130	104 752	34.5	2843
2009	3041	97 908	31.9	3164

[b] Calculated national estimate of trampoline injuries treated in US emergency departments.

TRAMPOLINE SAFETY CONCERNS

Unfortunately, the very forces that make trampoline use fun for many children also lead to unique injury mechanisms and patterns of injury. The trampoline industry has attempted to address the safety concerns with implementation of voluntary safety standards. In response to the 1999 AAP policy statement recommendation against consumer trampoline use, the USCPSC, the International Trampoline Industry Association, and the American Society of Testing and Materials Trampoline Subcommittee issued a revision of performance and safety standards. Equipment recommendations included the following: (1) extending padding to the frame and springs; (2) improving the quality of the padding; and (3) prohibiting inclusion of ladders in the packaging to help prevent young children from accessing the trampoline. Printed warnings were included with new trampoline equipment that recommended avoiding somersaulting, restricting multiple jumpers, and limiting trampoline use to children 6 years or older. Concerns have been raised as to whether these recommendations, in addition to other measures proposed in previous policy statements, have substantially affected the rate or severity of injuries.[9,10]

Another area of concern included reports of decreased quality of recreational trampoline equipment sold over the

past several decades. According to the International Trampoline Industry Association, trampolines sold in 1989 had an expected life of 10 years; the expectation for trampolines sold in 2004 was only 5 years.[10] Warranty coverage has also decreased since 2004, but the warranty for the frame and mat is consistently found to be greater than for the padding and enclosure nets. This reflects the manufacturers' expectation that the padding and enclosure net will need replacement during the lifetime of the trampoline.[10]

MECHANISMS OF TRAMPOLINE-RELATED INJURY AND THE EFFICACY OF CURRENT SAFETY MEASURES

Multiple Simultaneous Users

Several studies have revealed that approximately three-quarters of injuries occurred when multiple people were using the trampoline at the same time.[11–13] The smallest participants were up to 14 times more likely to sustain injury relative to their heavier playmates.[14] Heavier users create more recoil of the mat and springs and greater upward impaction forces than smaller users can generate on their own. These forces must be absorbed by the falling body and can be larger than landing on solid ground.[15] The risk associated with weight differences in the participants, in combination with less developed motor skills, likely contributes to the increased risk of fractures and dislocations in younger children.

Falls From the Trampoline

The most obvious risk of trampoline use is the ability to propel oneself to greater heights off a trampoline than from a jump on the ground. Falls from the trampoline can be severe and accounted for 27% to 39% of all trampoline-associated injuries.[10,16,17] Risk of falling is increased by the "off-balance" bounce that occurs when the trampoline is placed on an uneven surface, and children who fall off the mat are more likely to be injured if they make contact with nearby trees or other ground obstacles.

Netting and other perimeter enclosures to prevent falls from the trampoline were first commercially available in 1997, and the American Society for Testing and Materials produced a safety standard for enclosures in 2003. There is a paucity of literature on the effects of netting and other safety measures on injury risk. However, current evidence suggests that the availability of enclosures on the market has not significantly affected the proportions of injuries attributable to falls off the trampoline,[10] and there does not appear to be an inverse correlation between presence of safety equipment and rates of injury.[8] Proposed reasons for lack of efficacy of safety enclosures include positioning of enclosures on the outside of the frame[8] and inappropriate installation and maintenance.[10] Children are often tempted to climb or grasp the netting, which may be an additional source of injury.

Impact With Trampoline Frame and Springs

Approximately 20% of trampoline injuries have been attributable to direct contact with the springs and frame. However, similar to concerns regarding enclosure use, current literature on the effects of padding use on injury is sparse. Available data suggest that the availability and use of padding does not seem to correlate with decreased rates of injury.[8,10] Rapid deterioration of padding has been cited as 1 potential reason for the lack of safety efficacy.[8,10]

Trampoline Shape

No data exist regarding the difference in injury rates between rectangular and round trampolines. However, rectangular trampoline mats have a larger "sweet spot" that may provide a straighter and more consistent bounce across a broader area of the mat. This may translate into lower injury risk with rectangular trampolines as compared with round.

Recommendation for Adult Supervision

Trampoline safety recommendations have consistently advised adult supervision when children are on the trampoline. However, multiple studies reveal that approximately one-third to one-half of injuries[8,12,17–19] occurred despite reported adult supervision. These authors have raised concerns regarding supervision complacency, particularly when safety measures are in place, as well as lack of adult knowledge and intervention regarding risk behavior with trampoline use.

PATTERNS OF INJURY WITH TRAMPOLINE USE

Most trampoline injuries are manifestations of routine musculoskeletal injury mechanisms, but several unique patterns of injury are attributed to trampoline use and may warrant additional attention. Although the most common trampoline-related injury is an ankle sprain,[12] more serious injuries are not uncommon.

By Age

Patterns of injury vary by patient age. In retrospective reviews, individuals younger than 6 years accounted for 22% to 37% of individuals with a trampoline-related injury presenting to emergency departments for evaluation.[8,16] Although most trampoline injuries are sprains, strains, contusions, or other soft tissue injury, younger children seem to be more prone to bony injury.[11,18] According to an analysis of data from the NEISS,

29% of injuries in the 6- to 17-year age group resulted in fractures or dislocations, as compared with 48% in children 5 years and younger.[18] Data from the Canadian Hospitals Injury Reporting and Prevention Program revealed higher rates of hospitalization for trampoline injuries in children younger than 4 years as compared with their older counterparts.[9]

Extremity Injuries

The lower extremity is the most common site of trampoline injury, accounting for 34% to 50% of injuries.[11,20] Of these injuries, 1 study revealed that >60% involved the ankle,[20] and approximately three-quarters of ankle injuries were sprains.[6] The upper extremities were injured in 24% to 36% of cases. Of these, approximately 60% were fractures.[3,11] Upper extremity injuries were more common in participants who fell off the trampoline.[12]

Head and Neck Injuries

Although rates of extremity injuries are high, often the most frightening and alarming trampoline injuries are those to the head and neck. Many reports have revealed that head and/or neck injuries accounted for 10% to 17% of all trampoline-related injuries,[3,11,12,20] and 0.5% of all trampoline injuries resulted in permanent neurologic damage.[21] Head injuries occurred most commonly with falls from the trampoline.[20] Cervical spine injuries can happen with falls but also commonly occur on the trampoline mat when failed somersaults or flips cause hyperflexion or hyperextension of the cervical spine. These injuries can be the most catastrophic of all trampoline injuries suffered.

UNIQUE INJURIES ATTRIBUTED TO TRAMPOLINE USE

Proximal Tibial Fractures

Trampoline-related fractures of the proximal tibia have been described in children 6 years and younger.[15,22] These injuries have included transverse fractures as well as more subtle torus-types injuries. These injuries occurred when young children were sharing the trampoline with larger individuals, resulting in greater impact forces, as discussed previously.

Manubriosternal Dislocations/ Sternal Injuries

Sternal injuries have traditionally been described as a result of major trauma. However, several case reports[23] have been published of children between 10 and 11 years old suffering from isolated trampoline-related sternal fracture or manubriosternal dislocation. These occur after thoracic hyperflexion injuries on the trampoline.[23,24] They typically heal uneventfully; however, surgical stabilization may be necessary if pain persists.[24]

Vertebral Artery Dissection

Several cases of vertebral artery dissection presenting 12 to 24 hours after a neck injury on the trampoline have been reported. Vertebral artery dissections are the result of abrupt cervical hyperextension and rotation. Trauma to the artery may result in an intramural thrombus, which can cause a subsequent dissection of the vessel and possible intracranial emboli. These are often devastating injuries and may produce lasting neurologic complications.[25,26] Any neck pain associated with trampoline use requires prompt medical evaluation and diagnostic assessment.

Atlanto-axial Subluxation

Although patients with known atlanto-axial instability are often advised against the use of trampolines, there have been 2 reported cases of trampoline-related atlanto-axial subluxation in previously normal children.[27] Torticollis or neck pain after a trampoline-related neck injury warrants prompt medical evaluation and diagnostic assessment.

TRAMPOLINE USE IN A STRUCTURED TRAINING PROGRAM

Trampoline was accepted as an Olympic sport in 2000. In addition, trampolines are part of structured training programs in sports such as gymnastics, diving, figure skating, and freestyle skiing. USA Gymnastics and US Trampoline and Tumbling Association both administer competitive training and development programs in the sport of trampoline. USA Gymnastics oversees Olympic competition in single trampoline. The US Trampoline and Tumbling Association sponsors competition in single trampoline, synchronized trampoline, and double mini-trampoline. Some competitions accept athletes as young as 3 years old, although the majority of competitors are older than 8 years.

Competitive trampoline programs use a rectangular trampoline that is significantly different in size, quality, and cost than a recreational trampoline. Competition-style trampolines have center mats that are 7 ft by 14 ft. They are surrounded by a rim of padding over the springs and the 10-ft by 17-ft frame. These trampolines are raised off the ground and have 6 ft of end-deck padding. They do not have enclosure netting present. Within the competition setting, these trampolines have an additional 5- to 6-ft radius of padding present on the floor. In the training setting, competitive trampolines may be either raised off the ground, or "pit" trampolines, which are located at ground level. Either a bungee system or a rope and pulley system with a harness is used as athletes master tumbling skills.

No research documents the injury patterns or rates that occur specifically

in the structured training environment or with competitive trampoline events. Given the significant differences between the recreational and the structured training settings, extrapolation of data from the recreational setting to a formal training program is not appropriate. This is an area in which more research is warranted.

CONCLUSIONS

1. Although trampoline injury rates have been decreasing since 2004, the potential for severe injury remains relatively high. More prospective data are needed on this topic.
2. Enclosures and padding are not expected to prevent the large numbers of injuries that occur on the trampoline mat itself and may provide a false sense of security.
3. Many injuries occur even with reported adult supervision.
4. Multiple jumpers increase injury risk, particularly to the smallest participants.
5. Current trampoline equipment has shorter warranties than in the past, and protective equipment may require earlier replacement.
6. Individuals 5 years and younger appear to be at increased risk of fractures and dislocations from trampoline-related injuries.
7. Somersaulting, flipping, and falls put jumpers at increased risk of head and cervical spine injury with potentially permanent and devastating consequences.
8. Equipment, safety measures, and supervision within structured training programs are significantly different than those used in the recreational environment.

RECOMMENDATIONS FOR TRAMPOLINE USE

1. Pediatricians should counsel their patients and families against recreational trampoline use and explain that current data indicate safety measures have not significantly reduced injury rates and that catastrophic injuries do occur. For families who persist in home trampoline use despite this recommendation, pediatricians should advise parents and their children on the following guidelines until better information becomes available:

   a. Homeowners should verify that their insurance policies cover trampoline-related claims. Coverage is highly variable and a rider may need to be obtained.
   b. Trampoline use should be restricted to a single jumper on the mat at any given time.
   c. Trampolines should have adequate protective padding that is in good condition and appropriately placed.
   d. Trampolines should be set at ground level whenever possible or on a level surface and in an area cleared of any surrounding hazards.
   e. Frequent inspection and appropriate replacement of protective padding, net enclosure, and any other damaged parts should occur.
   f. Trampolines should be discarded if replacement parts are unavailable and the product is worn or damaged.
   g. Somersaults and flips are among the most common causes of permanent and devastating cervical spine injuries and should not be performed in the recreational setting.
   h. Active supervision by adults familiar with the above recommendations should occur at all times. Supervising adults should be willing and able to enforce these guidelines. Mere presence of an adult is not sufficient.
   i. Parents should confirm that these guidelines are in place anytime their child is likely to use a trampoline.

2. Data are insufficient regarding the safety of trampoline parks and similar installations. Until further safety information is available, the cautions outlined here regarding home trampolines are also applicable to recreational trampoline use in any setting.
   a. Pediatricians should advocate for all commercial jump parks to inform jumpers of the risk associated with trampoline use and the AAP guidelines for use.
   b. Parents should be aware that the rules and regulations of jump parks may not be consistent with the AAP guidelines for trampoline use and that the jumpers may be at increased risk for suffering an injury, potentially catastrophic.
   c. Injury rates at these facilities should be monitored.
3. The trampoline was designed as a piece of specialized training equipment for specific sports. Pediatricians should only endorse use of trampolines as part of a structured training program with appropriate coaching, supervision, and safety measures in place. In addition to the aforementioned recommendations, the following apply to trampolines used in the training setting:
   a. Any attempts at new skills, particularly somersaults or flips, should only follow an appropriate skill progression and include appropriate coaching and spotting measures.
   b. Use of safety belts/harnesses is encouraged when skill development is being taught.

Summary

Group B streptococcus (GBS) remains a leading cause of serious neonatal infection despite great progress in perinatal GBS disease prevention in the 1990s. In 1996, CDC, in collaboration with other agencies, published guidelines for the prevention of perinatal group B streptococcal disease (CDC. Prevention of perinatal group B streptococcal disease: a public health perspective. MMWR 1996;45[RR-7]:1–24). *Data collected after the issuance of the 1996 guidelines prompted reevaluation of prevention strategies at a meeting of clinical and public health representatives in November 2001. This report replaces CDC's 1996 guidelines. The recommendations are based on available evidence and expert opinion where sufficient evidence was lacking. Although many of the recommendations in the 2002 guidelines are the same as those in 1996, they include some key changes:*

- *Recommendation of universal prenatal screening for vaginal and rectal GBS colonization of all pregnant women at 35–37 weeks' gestation, based on recent documentation in a large retrospective cohort study of a strong protective effect of this culture-based screening strategy relative to the risk-based strategy*
- *Updated prophylaxis regimens for women with penicillin allergy*
- *Detailed instruction on prenatal specimen collection and expanded methods of GBS culture processing, including instructions on antimicrobial susceptibility testing*
- *Recommendation against routine intrapartum antibiotic prophylaxis for GBS-colonized women undergoing planned cesarean deliveries who have not begun labor or had rupture of membranes*
- *A suggested algorithm for management of patients with threatened preterm delivery*
- *An updated algorithm for management of newborns exposed to intrapartum antibiotic prophylaxis*

Although universal screening for GBS colonization is anticipated to result in further reductions in the burden of GBS disease, the need to monitor for potential adverse consequences of intrapartum antibiotic use, such as emergence of bacterial antimicrobial resistance or increased incidence or severity of non-GBS neonatal pathogens, continues, and intrapartum antibiotics are still viewed as an interim strategy until GBS vaccines achieve licensure.

Introduction

Group B streptococcus (GBS) emerged as the leading infectious cause of neonatal morbidity and mortality in the United States in the 1970s (*1–4*). Initial case series reported case-fatality ratios as high as 50%. In the early 1980s, clinical trials demonstrated that administering antibiotics during labor to women at risk of transmitting GBS to their newborns could prevent invasive disease in the first week of life (i.e., early-onset disease) (*5*). As a result of the collaborative efforts of clinicians, researchers, professional organizations, parent advocacy groups, and the public health community in the 1990s, recommendations for intrapartum prophylaxis to prevent perinatal GBS disease were issued in 1996 by the American College of Obstetricians and Gynecologists (ACOG) (*6*) and CDC (*7*), and in 1997 by the American Academy of Pediatrics (*8*).

Those guidelines recommended the use of one of two prevention methods, a risk-based approach or a culture-based screening approach. Providers using the risk-based method identify candidates for intrapartum chemoprophylaxis according to the presence of any of the following intrapartum risk factors associated with early-onset disease: delivering at <37 weeks' gestation, having an intrapartum temperature ≥100.4°F (≥38.0°C), or rupture of membranes for ≥18 hours. The screening-based method recommends screening of all pregnant women for vaginal and rectal GBS colonization between 35 and 37 weeks' gestation. Colonized women are then offered intrapartum antibiotics at the time of labor. Under both strategies, women with GBS bacteriuria during their current

The material in this report was prepared by the National Center for Infectious Diseases, James M. Hughes, M.D., Director; Division of Bacterial and Mycotic Diseases, Mitchell L. Cohen, M.D., Director.

pregnancy, or who previously gave birth to an infant with early-onset GBS disease are candidates for intrapartum antibiotic prophylaxis.

Before active prevention was initiated, an estimated 7,500 cases of neonatal GBS disease occurred annually (*9*). Despite striking declines in disease incidence coinciding with increased prevention activities in the 1990s, GBS disease remains a leading infectious cause of morbidity and mortality among newborns in the United States (*10,11*). Moreover, since the release of the 1996 guidelines, new data are available to evaluate the effectiveness of the screening approach relative to the risk-based approach and to resolve some of the clinical challenges of implementing prevention.

In light of these new data, in November 2001, CDC consulted with multiple partners to revise the 1996 guidelines for the prevention of perinatal group B streptococcal disease, using an evidence-based approach where possible and scientific opinion when sufficient data were lacking (Table 1). These updated guidelines replace CDC's 1996 guidelines. They are intended for the following groups: providers of prenatal, obstetric, and pediatric care; supporting microbiology laboratories, hospital administrators and managed care organizations; childbirth educators; public health authorities; and expectant parents and their advocates.

Differences and similarities between current and previous guidelines

Following are major differences in the new guidelines:

- Recommendation of universal prenatal culture-based screening for vaginal and rectal GBS colonization of all pregnant women at 35–37 weeks' gestation
- Updated prophylaxis regimens for women with penicillin allergy
- Detailed instruction on prenatal specimen collection and expanded methods of GBS culture processing, including instructions on susceptibility testing
- Recommendation against routine intrapartum antibiotic prophylaxis for GBS-colonized women undergoing planned cesarean deliveries who have not begun labor or had rupture of membranes
- A suggested algorithm for management of patients with threatened preterm delivery
- An updated algorithm for management of newborns exposed to intrapartum antibiotic prophylaxis

Although important changes have been instituted, many recommendations remain the same:

- Penicillin remains the first-line agent for intrapartum antibiotic prophylaxis, with ampicillin an acceptable alternative.
- Women whose culture results are unknown at the time of delivery should be managed according to the risk-based approach; the obstetric risk factors remain unchanged (i.e., delivery at <37 weeks' gestation, duration of membrane rupture ≥18 hours, or temperature ≥100.4°F [≥38.0°C]).
- Women with negative vaginal and rectal GBS screening cultures within 5 weeks of delivery do not require intrapartum antimicrobial prophylaxis for GBS even if obstetric risk factors develop (i.e., delivery at <37 weeks' gestation, duration of membrane rupture ≥18 hours, or temperature ≥100.4°F [≥38.0°C]).
- Women with GBS bacteriuria in any concentration during their current pregnancy or who previously gave birth to an infant with GBS disease should receive intrapartum antimicrobial prophylaxis.
- In the absence of GBS urinary tract infection, antimicrobial agents should not be used before the intrapartum period to treat asymptomatic GBS colonization.

TABLE 1. Evidence-based rating system used to determine strength of recommendations

Category	Definition	Recommendation
Strength of recommendation		
A	Strong evidence for efficacy and substantial clinical benefit	Strongly recommended
B	Strong or moderate evidence for efficacy, but only limited clinical benefit	Generally recommended
C	Insufficient evidence for efficacy; or efficacy does not outweigh possible adverse consequences	Optional
D	Moderate evidence against efficacy or for adverse outcome	Generally not recommended
E	Strong evidence against efficacy or for adverse outcome	Never recommended
Quality of evidence supporting recommendation		
I	Evidence from at least one well-executed randomized, controlled trial or one rigorously designed laboratory-based experimental study that has been replicated by an independent investigator	
II	Evidence from at least one well-designed clinical trial without randomization; cohort or case-controlled analytic studies (preferably from more than one center); multiple time-series studies; dramatic results from uncontrolled studies; or some evidence from laboratory experiments	
III	Evidence from opinions of respected authorities based on clinical or laboratory experience, descriptive studies, or reports of expert committees

Background

Early Infancy and Pregnancy-Related Infections

GBS causes severe invasive disease in young infants. The majority of infections in newborns occur within the first week of life and are designated early-onset disease. Late-onset infections occur in infants aged >1 week, with most infections evident in the first 3 months of life. Young infants with invasive GBS disease usually present with sepsis or pneumonia, and less often contract meningitis, osteomyelitis, or septic arthritis. The proportion of infants with meningitis is higher among those with late-onset infections. When neonatal infections caused by GBS appeared in the 1970s, as many as 50% of patients died. During the 1990s, the case-fatality ratio of early- and late-onset disease was 4% (*10*) because of advances in neonatal care.

Intrauterine infection of the fetus results from ascending spread of GBS from the vagina of a colonized woman who is typically asymptomatic. Fetal aspiration of infected amniotic fluid can lead to stillbirth, neonatal pneumonia, or sepsis. Infants can also become infected with GBS during passage through the birth canal, although the majority of infants who are exposed to the organism through this route become colonized on skin or mucous membranes but remain asymptomatic.

In pregnant women, GBS can cause clinical infections, but most women have no symptoms associated with genital tract colonization. Urinary tract infections caused by GBS complicate 2%–4% of pregnancies (*12,13*). During pregnancy or the postpartum period, women can contract amnionitis, endometritis, sepsis, or rarely, meningitis caused by GBS (*14–19*). Fatalities among women with pregnancy-associated GBS disease are extremely rare.

GBS Colonization

The gastrointestinal tract serves as the natural reservoir for GBS and is the likely source of vaginal colonization. Vaginal colonization is unusual in childhood but becomes more common in late adolescence (*20*). Approximately 10% to 30% of pregnant women are colonized with GBS in the vagina or rectum (*21*). GBS colonization can be transient, chronic, or intermittent. Maternal intrapartum GBS colonization is a major risk factor for early-onset disease in infants, and vertical transmission of GBS from mother to fetus primarily occurs after the onset of labor or membrane rupture. However, colonization early in pregnancy is not predictive of neonatal sepsis (*22*). Culture screening of both the vagina and rectum for GBS late in gestation during prenatal care can detect women who are likely to be colonized with GBS at the time of delivery and are thus at higher risk of perinatal transmission of the organism (*23*).

Classic epidemiologic studies conducted during the 1980s revealed that women with prenatal GBS colonization were >25 times more likely than women with negative prenatal cultures to deliver infants with early-onset GBS disease (*24*). Researchers used prenatal cultures as the basis for identifying candidates for intrapartum antimicrobial chemoprophylaxis; clinical trials identified reductions in vertical transmission of the organism, as measured by infant colonization (*25,26*) or by protection against early-onset disease (*5,27*). Heavy colonization, defined as culture of GBS from direct plating rather than only from selective broth, is associated with higher risk for early-onset disease. GBS identified in clean-catch urine specimens is considered a surrogate for heavy maternal colonization and also is associated with a higher risk for early-onset GBS disease (*12,13*); it has been included among indications for intrapartum antibiotic prophylaxis.

GBS Culture-Based Screening Methods

Numerous studies have documented that the accuracy of prenatal screening cultures in identifying intrapartum colonization status can be enhanced by careful attention to the timing of cultures, the anatomic sites swabbed, and the precise microbiologic methods used for culture and detection of organisms (Box 1). Collection of cultures between 35 and 37 weeks' gestation is recommended to improve the sensitivity and specificity of detection of women who remain colonized at the time of delivery (*23,28*). Swabbing both the lower vagina and rectum (i.e., through the anal sphincter) increases the yield substantially compared with sampling the cervix or sampling the vagina without also swabbing the rectum (*29*). Studies have indicated that when women in the outpatient clinic setting collect their own screening specimens, with appropriate instruction, GBS yield is similar to when specimens are collected by a health-care provider (*30*). Although swabbing both sites is recommended and use of two swabs can be justified, both swabs should be placed in a single broth culture medium because the site of isolation is not important for clinical management and laboratory costs can thereby be minimized. Because vaginal and rectal swabs are likely to yield diverse bacteria, use of selective enrichment broth is recommended (Box 1) to maximize the isolation of GBS and avoid overgrowth of other organisms. When direct agar plating is used instead of selective enrichment broth, as many as 50% of women who are GBS carriers have false-negative culture results (*31*).

BOX 1. Procedures for collecting and processing clinical specimens for group B streptococcal culture and performing susceptibility testing to clindamycin and erythromycin

Procedure for collecting clinical specimens for culture of group B streptococcus at 35–37 weeks' gestation

- Swab the lower vagina (vaginal introitus), followed by the rectum (i.e., insert swab through the anal sphincter) using the same swab or two different swabs. Cultures should be collected in the outpatient setting by the health-care provider or the patient herself, with appropriate instruction. Cervical cultures are not recommended and a speculum should not be used for culture collection.
- Place the swab(s) into a nonnutritive transport medium. Appropriate transport systems (e.g., Amies or Stuart's without charcoal) are commercially available. If vaginal and rectal swabs were collected separately, both swabs can be placed into the same container of medium. Transport media will maintain GBS viability for up to 4 days at room temperature or under refrigeration.
- Specimen labels should clearly identify that specimens are for group B streptococcal culture. If susceptibility testing is ordered for penicillin-allergic women (Box 2), specimen labels should also identify the patient as penicillin allergic and should specify that susceptibility testing for clindamycin and erythromycin should be performed if GBS is isolated.

Procedure for processing clinical specimens for culture of group B streptococcus

- Remove swab(s) from transport medium.* Inoculate swab(s) into a recommended selective broth medium, such as Todd-Hewitt broth supplemented with either gentamicin (8 µg/ml) and nalidixic acid (15 µg/ml), or with colistin (10 µg/ml) and nalidixic acid (15 µg/ml). Examples of appropriate commercially available options include Trans-Vag broth supplemented with 5% defibrinated sheep blood or LIM broth.†
- Incubate inoculated selective broth for 18–24 hours at 35°–37°C in ambient air or 5% CO_2. Subculture the broth to a sheep blood agar plate (e.g., tryptic soy agar with 5% defibrinated sheep blood).
- Inspect and identify organisms suggestive of GBS (i.e., narrow zone of beta hemolysis, gram-positive cocci, catalase negative). Note that hemolysis may be difficult to observe, so typical colonies without hemolysis should also be further tested. If GBS is not identified after incubation for 18–24 hours, reincubate and inspect at 48 hours to identify suspected organisms.
- Various streptococcus grouping latex agglutination tests or other tests for GBS antigen detection (e.g., genetic probe) may be used for specific identification, or the CAMP test may be employed for presumptive identification.

Procedure for clindamycin and erythromycin disk susceptibility testing of isolates, when ordered for penicillin-allergic patients§

- Use a cotton swab to make a suspension from 18–24-hour growth of the organism in saline or Mueller-Hinton broth to match a 0.5 McFarland turbidity standard.
- Within 15 minutes of adjusting the turbidity, dip a sterile cotton swab into the adjusted suspension. The swab should be rotated several times and pressed firmly on the inside wall of the tube above the fluid level. Use the swab to inoculate the entire surface of a Mueller-Hinton sheep blood agar plate. After the plate is dry, use sterile forceps to place a clindamycin (2 µg) disk onto half of the plate and an erythromycin (15 µg) disk onto the other half.
- Incubate at 35°C in 5% CO_2 for 20–24 hours.
- Measure the diameter of the zone of inhibition using a ruler or calipers. Interpret according to NCCLS guidelines for *Streptococcus* species other than *S. pneumoniae* (2002 breakpoints:§ clindamycin: ≥19 mm = susceptible, 16–18 = intermediate, ≤15 = resistant; erythromycin: ≥21 mm = susceptible, 16–20 = intermediate, ≤15 = resistant).

* Before inoculation step, some laboratories may choose to roll swab(s) on a single sheep blood agar plate or CNA sheep blood agar plate. This should be done only in addition to, and not instead of, inoculation into selective broth. The plate should be streaked for isolation, incubated at 35–37°C in ambient air or 5% CO_2 for 18–24 hours and inspected for organisms suggestive of GBS as described above. If suspected colonies are confirmed as GBS, the broth can be discarded, thus shortening the time to obtaining culture results.

† **Source:** Fenton, LJ, Harper MH. Evaluation of colistin and nalidixic acid in Todd-Hewitt broth for selective isolation of group B streptococci. J Clin Microbiol 1979;9:167–9. Although Trans-Vag medium is often available without sheep blood, direct comparison of medium with and without sheep blood has shown higher yield when blood is added. LIM broth may also benefit from the addition of sheep blood, although the improvement in yield is smaller and sufficient data are not yet available to support a recommendation.

§ **Source:** NCCLS. Performance standard for antimicrobial suceptibility testing, M100-S12, Table 2H, Wayne, Pa.: NCCLS, 2002. NCCLS recommends disk diffusion (M-2) or broth microdilution testing (M-7) for susceptibility testing of GBS. Commercial systems that have been cleared or approved for testing of streptococci other than *S. pneumoniae* may also be used. Penicillin susceptibility testing is not routinely recommended for GBS because penicillin-resistant isolates have not been confirmed to date.

Additional Risk Factors for Perinatal GBS Disease

In addition to colonization with GBS, other factors increase the risk for early-onset disease. These include gestational age <37 completed weeks, longer duration of membrane rupture, intraamniotic infection, young maternal age, black race, Hispanic ethnicity, and low maternal levels of anticapsular antibody (*32–37*). In a 1985 report of predictors of early-onset disease (*24*), women with gestation <37 weeks, membrane rupture of >12 hours, or intrapartum temperature >99.5°F (37.5°C) had 6.5 times the risk of having an infant with early-onset GBS disease compared with women with none of those factors. Of note, women who had one of these risk factors but who had negative prenatal screening cultures were at relatively low risk for early-onset GBS disease (attack rate 0.9 per 1,000 births) compared with women who were colonized prenatally but had none of the risk factors (attack rate 5.1 per 1,000 births) (*24*). In a risk-based strategy promoted during the 1990s as an alternative to prenatal culture-based screening approaches, prematurity (gestation <37 weeks), intrapartum fever (temperature ≥100.4°F or 38°C), or duration of membrane rupture >18 hours were used as clinical indications for intrapartum prophylaxis. Previous delivery of an infant with invasive GBS disease may increase the risk of early-onset disease in subsequent deliveries (*38,39*), and intrapartum treatment of such women in subsequent pregnancies has been promoted. By contrast, colonization with GBS in a previous pregnancy is not considered an indication for intrapartum prophylaxis in subsequent pregnancies; rather, women require evaluation for prenatal colonization in each pregnancy. Because colonization is transient, the predictive value of culture-based screening is too low to be clinically useful when performed more than 5 weeks before delivery (*28*); thus, many women with GBS colonization during one pregnancy will no longer be colonized during subsequent pregnancies.

Impact and Implementation of the 1996 Guidelines

Declines in Perinatal GBS Disease Incidence in the Era of Chemoprophylaxis

Before the widespread use of intrapartum antibiotics, the incidence of invasive neonatal GBS disease ranged from 2 to 3 cases per 1,000 live births (*9,40*). Active, population-based surveillance in selected states in 1990, when GBS prevention was still rarely implemented, projected an incidence of 1.8 cases per 1,000 live births in the United States (early-onset disease: 1.5/1,000; late-onset: 0.35/1,000) (*9*).

Coinciding with active prevention efforts in the 1990s, the incidence of early-onset disease declined by 70% to 0.5 cases per 1,000 live births in 1999 (Figure 1). Projections from active surveillance data for 1999 from the Active Bacterial Core surveillance/Emerging Infections Program Network (ABCs)(*41*) estimate that intrapartum antibiotics prevented nearly 4,500 early-onset cases and 225 deaths that year (*10,11*). Other countries that have adopted perinatal GBS disease prevention guidelines similar to the United States have seen comparable declines in early-onset disease incidence (*42–44*). Recent estimates of early-onset disease incidence in the United States suggest a slight increase in incidence from 1999 to 2000, consistent with a plateau in the impact of prevention efforts (Figure 1).

The incidence of invasive GBS infections among pregnant women in the United States declined by 21% from 0.29 per 1,000 live births in 1993 to 0.23 in 1998 (*10*), suggesting that increased use of intrapartum antibiotics also prevented some cases of maternal GBS amnionitis and endometritis. In contrast, the rate of late-onset disease remained fairly constant throughout the 1990s (Figure 1). Although intrapartum chemoprophylaxis for women with heavy GBS colonization may prevent a portion of late-onset disease, the stable incidence of late-onset disease during a period when use of intrapartum antibiotics was increasing suggests that this intervention is not effective against late-onset disease.

Implementation of Chemoprophylaxis Strategies After the Release of the 1996 Guidelines

Declines in perinatal GBS disease incidence in the 1990s suggest that prevention strategies have been implemented successfully. Several studies have explored directly the challenges of implementation and extent of compliance with recommendations. Surveys of prenatal care providers in Connecticut and Minnesota in 1998 found that over 80% had a GBS prevention policy (Connecticut, 95%; Minnesota, 85%) (*45*). In Minnesota, family physicians were less likely to have a policy than were obstetrician/gynecologists and certified nurse midwives (*45*). A national survey of ACOG members in 2000 found that 98% of respondents had a GBS prevention policy; 75% of respondents reported using a version of the culture-based screening approach (*46*). Providers in all three surveys scored well on questions about their knowledge of the screening and risk-based strategies (*45,46*).

In hospitals that established or revised policies for GBS prevention shortly after the release of the 1996 guidelines, rates of early-onset GBS disease declined by 1997 (*47*). By 1999, although only 63% of hospitals in a multistate survey of hospitals in the ABCs areas had a formal GBS prevention policy (*48*), having a hospital policy was no longer associated with changes in incidence of GBS disease, likely because a high proportion of individual practitioners had adopted policies by this time.

Several studies of single institutions or health maintenance organizations have evaluated adherence of hospital personnel to GBS guidelines (Table 2). Among hospitals with a risk-based policy, intrapartum antibiotics were administered in 40%–80% of preterm deliveries or deliveries with prolonged rupture of membranes (Table 2) (*49–53*). Among hospitals with a culture-based screening policy, close to 90% of delivering women had documented GBS screening, and close to 90% of GBS-positive women received intrapartum antibiotics (Table 2) (*42,51,54–59*).

Correct laboratory processing of culture specimens (Box 1) plays a critical role in successful implementation of the screening policy. A survey of clinical laboratories in selected counties of three states in 1997–1998 found that only a proportion of laboratories were using the recommended selective broth media to process GBS cultures (Georgia, 39% of laboratories; Minnesota, 42%; Connecticut, 62%), suggesting that this may be an area in need of improvement (*31*).

Although surveys of practitioners and laboratories and reports from single hospitals help monitor implementation of GBS prevention guidelines, a recent CDC-sponsored review of labor and delivery records in selected counties of eight states in the ABCs areas in 1998 and 1999 sheds light on actual provider practices 2 to 3 years after the release of the 1996 guidelines (*60*). In this population, GBS screening was documented in 52% of deliveries, although this varied widely, from 24% in selected counties of Oregon to 70% in Maryland.

Among screened women, 24% were GBS positive, consistent with carriage rates reported in earlier studies; 89% of GBS-positive women received intrapartum antibiotics. The median time of GBS culture collection was at 35.6 weeks' gestation, consistent with the recommendation of 35–37 weeks' gestation. Among unscreened women, 24% had at least one intrapartum risk factor; however, only 61% of women with at least one risk factor received intrapartum antibiotics. Preterm delivery (<37 weeks' gestation) was the most common indication for which intrapartum antibiotics were not administered. Thus, this multistate record review confirmed trends in adherence identified in reports from single hospitals (Table 2).

Maximizing Prevention by Chemoprophylaxis

Effectiveness of the Risk-Based Approach Versus the Screening Approach

Despite dramatic declines in GBS incidence in the United States in the 1990s, GBS remains a leading cause of newborn morbidity and mortality, resulting in an estimated 1,600 early-onset cases and 80 deaths annually. Although alternatives to intrapartum antibiotics such as a vaccine may become available in the future, intrapartum chemoprophylaxis remains the most effective available intervention against perinatal GBS disease. However, debate about the most effective strategy for identifying candidates for intrapartum chemoprophylaxis continues.

When the 1996 guidelines were issued, data regarding the relative effectiveness of the risk-based and screening approaches were not available. Theoretical predictions based on population estimates of the proportion of early-onset GBS cases without obstetric risk factors (approximately 45% in the preprevention era [*61*]) suggested that the screening-based approach would lead to greater declines in disease incidence than the risk-based approach (*61,62*). However, because implementation of the risk-based approach has been viewed as simpler than the screening-based approach, which requires correct specimen collection at the prenatal clinic, appropriate laboratory processing, and timely reporting of results to delivery staff, the actual effectiveness of these strategies is unknown. Consequently, since 1996, both approaches have been recommended as equally acceptable pending further data (*6–8*).

Although observational data are now available suggesting that each strategy can lead to reduced incidence of early-onset GBS disease (*49,50,63–65*), the strategies have not been directly compared by clinical trial because of the large sample size required. A series of single hospital analyses finding benefits of screening over the risk-based approach (*51,56,59,66*) were limited by sequential use of the strategies and inability to control for potential confounders. A recent CDC-sponsored multistate study provided the first large-scale direct comparison of the strategies (*60*). By incorporating population-based surveillance for early-onset GBS disease into a sample survey of a population of over 600,000 live births, this analysis found that the screening approach was >50% more effective than the risk-based approach at preventing perinatal GBS disease.

The protective effect of the screening approach was robust and persisted after controlling for risk factors associated with early-onset GBS disease (e.g., preterm delivery, prolonged membrane rupture, young maternal age, black race). The benefit of screening stemmed from two main factors. First, by identifying GBS-colonized women who did not present with obstetric risk factors, screening reached more of the population at risk than did the risk-based approach. Among the cohort of screened women, 18% of all deliveries were to mothers who were colonized with GBS but did not have obstetric risk factors. The efficacy of intrapartum antibiotics in preventing early-onset GBS disease among infants in this cohort was close to 90%, suggesting that chemoprophylaxis of GBS-positive women without obstetric risk factors resulted in significant prevention of early-onset disease.

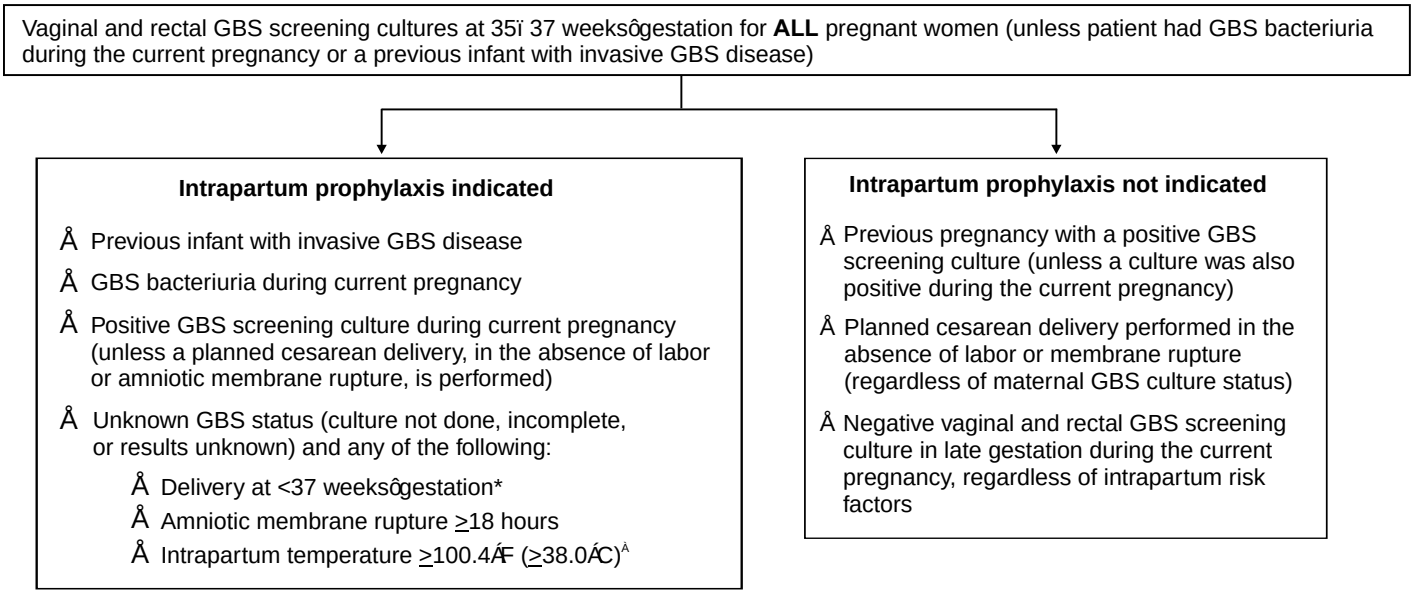
Women who were GBS positive in the screening cohort were also more likely to receive intrapartum antibiotics than were women with obstetric risk factors in the risk cohort. Although improvements in implementation of the risk-based approach would lead to further decline in disease, this would not be as great as with universal screening (*60*).

Finally, because the effectiveness of screening in this study was based on actual implementation of this strategy in clinical practice in 1998 and 1999, further improvements in screening implementation (e.g., improvements in specimen collection and the methods used for processing cultures) are expected to result in further benefits.

Rationale for a Universal Prenatal Screening Strategy to Detect GBS Status

The new availability of category II evidence (Table 1) for a large protective effect of prenatal GBS screening compared with the risk-based approach provides the foundation for a recommendation of universal prenatal GBS screening (Figure 2). Statewide prevention activities in some ABCs areas further demonstrate that culture-based screening can be successfully implemented in a variety of settings and institutions. For example, a health department-led survey of clinical

FIGURE 2. Indications for intrapartum antibiotic prophylaxis to prevent perinatal GBS disease under a universal prenatal screening strategy based on combined vaginal and rectal cultures collected at 35ï 37 weeksôgestation from all pregnant women



* If onset of labor or rupture of amniotic membranes occurs at <37 weeksôgestation and there is a significant risk for preterm delivery (as assessed by the clinician), a suggested algorithm for GBS prophylaxis management is provided (Figure 3).
Á If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS prophylaxis.

laboratories in Connecticut followed by rapid feedback of survey results found that the proportion of laboratories in Connecticut using the correct media for processing GBS screening cultures increased from 62% in 1997 to 92% in 1998 (*67*) and 100% in 2000. Moreover, coinciding with an active prevention campaign launched by the state health department that advocated the screening-based approach, the incidence of early-onset GBS disease in Connecticut declined from 0.6 cases per 1,000 live births in 1996 (*68*) to 0.2 cases per 1,000 live births in 1999.

From the standpoint of implementation, universal screening has two additional benefits over the dual recommendations of 1996. Communication of the public health messages associated with a single strategy is simpler than communicating and educating about multiple strategies. Additionally, screening has clear indicators that facilitate evaluation of implementation (e.g., documentation of GBS test, timing of test, rates of GBS positivity) (*58*) compared with the risk-based approach, in which evidence of prevention implementation cannot be assessed for approximately 75% of deliveries because they have no intrapartum risk factors.

Cost-effectiveness analyses of the screening- and risk-based strategies (*62,69–73*) have indicated that although the initial costs associated with specimen collection and processing make the screening strategy more expensive than the risk-based approach, the overall cost savings due to disease prevention do not differ importantly between strategies. Additionally, multistate review of labor and delivery records in 1998 and 1999 suggests that perfect implementation of the screening- or risk-based strategies will result in a comparable proportion of deliveries in which women receive intrapartum antibiotic prophylaxis for GBS (24% for both strategies) (*60,74*). Thus, the strategies cannot be distinguished in terms of the proportion of deliveries that will be exposed to intrapartum antibiotics.

Adverse Effects and Unintended Consequences of Chemoprophylaxis

Potential adverse or unintended effects of GBS prevention efforts that have raised concern include allergic or anaphylactic reactions to agents used for intrapartum antibiotic prophylaxis, emergence of GBS strains resistant to standard therapies, and increasing incidence of serious neonatal infections caused by pathogens other than GBS, including antimicrobial-resistant strains. Because of the increasing emergence of bacterial resistance to antimicrobial agents in both nosocomial and community settings, assessment of the impact and continued effectiveness of interventions based on antimicrobial prophylaxis is critical.

Antibiotic Allergies Including Anaphylaxis

Anaphylaxis associated with GBS chemoprophylaxis occurs but is sufficiently rare that any morbidity associated with anaphylaxis is greatly offset by reductions in the incidence of maternal and neonatal invasive GBS disease. Anaphylaxis-related mortality is likely to be a rare event since women receiving intrapartum antibiotics will be in hospital settings where rapid intervention is readily available. Estimates of the rate of anaphylaxis caused by penicillin range from 4/10,000 to 4/100,000 recipients. Additionally, as many as 10% of the adult population have less severe allergic reactions to penicillin (*75*). Anaphylaxis associated with GBS prophylaxis was reported in the early 1990s (*76*); since the release of the 1996 guidelines, an additional report of a nonfatal case of anaphylaxis associated with GBS chemoprophylaxis has been published (*77*). In a CDC multistate sample of over 5,000 live births, a single, nonfatal anaphylactic reaction was noted among the 27% of deliveries in which intrapartum antibiotics were administered (*60*). In that case, a single dose of penicillin was administered approximately 4 hours before a preterm cesarean delivery, and an anaphylactic reaction occurred shortly after the mother received a single dose of a cephalosporin following umbilical cord clamping.

Resistance in GBS

GBS isolates with confirmed resistance to penicillin or ampicillin have not been observed to date (*78–83*). Penicillin remains the agent of choice for intrapartum antibiotic prophylaxis. Ampicillin is an acceptable alternative, but penicillin is preferred because it has a narrower spectrum of antimicrobial activity and may be less likely to select for resistant organisms. The efficacy of both penicillin (*27*) and ampicillin (*5*) as intrapartum agents for the prevention of early-onset neonatal GBS disease has been demonstrated in clinical trials. Although the intramuscular route of administration for penicillin has been evaluated (*25*), intravenous administration is the only route of administration recommended for intrapartum chemoprophylaxis to prevent perinatal GBS disease, regardless of the antimicrobial agent used, because of the higher intraamniotic concentrations achieved with this method.

In contrast, the proportions of GBS isolates with in vitro resistance to clindamycin and erythromycin have increased since 1996. The prevalence of resistance among invasive GBS isolates in the United States and Canada ranged from 7% to 25% for erythromycin and from 3% to 15% for clindamycin in reports published between 1998 and 2001(*79–81,84*). Resistance to erythromycin is frequently but not always associated with clindamycin resistance. Resistance of GBS isolates to cefoxitin, a second-generation cephalosporin sometimes used as a component of broad-spectrum coverage for chorioamnionitis, has also been reported (*85*); cefoxitin resistance has similarly been observed among invasive GBS isolates collected from 1996 to 2000 as part of CDC's active surveillance. Whether in vitro resistance of GBS has direct clinical implications remains unclear (*86*). Despite emerging resistance to some drug classes, minimum inhibitory concentrations of cefazolin, a first-generation cephalosporin available in an intravenous formulation, were low ($\leq$0.5 µg/ml) among a sample of invasive U.S. isolates from 1996 to 2000 (*87*), suggesting that GBS isolates are currently susceptible to this agent. Although NCCLS guidelines do not specify susceptibility breakpoints for cefazolin, they recommend that all isolates susceptible to penicillin be considered susceptible to cefazolin (*88*).

In light of the increasing prevalence of resistance to clindamycin, erythromycin, or both, recommended strategies for providing intrapartum antibiotic prophylaxis to penicillin-allergic women are updated (Box 2). Because the efficacy of recommended alternatives to penicillin or ampicillin has not been measured in controlled trials, and because some of the recommended alternatives have a broad spectrum of activity and may be more complicated and costly to administer, verification of a reported history of penicillin allergy is important. Patients with reported penicillin allergy should then be assessed to determine their risk for anaphylaxis. Persons at high risk for anaphylaxis are those who have had immediate hypersensitivity reactions to penicillin (e.g., anaphylaxis, angioedema, or urticaria) or who have a history of asthma or other conditions that would make anaphylaxis more dangerous (*89,90*). An estimated 10% of persons with penicillin allergy also have immediate hypersensitivity reactions to cephalosporins (*90*). Among penicillin-allergic women not at high risk for anaphylaxis, cefazolin, because of its narrow spectrum of activity and ability to achieve high intraamniotic concentrations, is the agent of choice for intrapartum chemoprophylaxis.

For penicillin-allergic women at high risk for anaphylaxis, testing of GBS isolates from prenatal screening for susceptibility to clindamycin and erythromycin is recommended if feasible (Box 1). One of these agents should be employed for intrapartum GBS prophylaxis if the screening isolate is susceptible to both agents.

Vancomycin should be reserved for penicillin-allergic women at high risk for beta-lactam anaphylaxis when clindamycin or erythromycin are not options because of in vitro resistance or unknown susceptibility of a prenatal isolate. Vancomycin use is generally restricted because of emerging vancomycin resistance among some gram-positive organisms (e.g., vancomycin-resistant enterococcus and vancomycin-resistant *Staphylococcus*

BOX 2. Recommended regimens for intrapartum antimicrobial prophylaxis for perinatal GBS disease prevention*

Recommended	Penicillin G, 5 million units IV initial dose, then 2.5 million units IV every 4 hours until delivery
Alternative	Ampicillin, 2 g IV initial dose, then 1 g IV every 4 hours until delivery
If penicillin allergic†	
Patients not at high risk for anaphylaxis	Cefazolin, 2 g IV initial dose, then 1 g IV every 8 hours until delivery
Patients at high risk for anaphylaxis§	
GBS susceptible to clindamycin and erythromycin¶	Clindamycin, 900 mg IV every 8 hours until delivery
	OR
	Erythromycin, 500 mg IV every 6 hours until delivery
GBS resistant to clindamycin or erythromycin or susceptibility unknown	Vancomycin,** 1 g IV every 12 hours until delivery

* Broader-spectrum agents, including an agent active against GBS, may be necessary for treatment of chorioamnionitis.

† History of penicillin allergy should be assessed to determine whether a high risk for anaphylaxis is present. Penicillin-allergic patients at high risk for anaphylaxis are those who have experienced immediate hypersensitivity to penicillin including a history of penicillin-related anaphylaxis; other high-risk patients are those with asthma or other diseases that would make anaphylaxis more dangerous or difficult to treat, such as persons being treated with beta-adrenergic–blocking agents.

§ If laboratory facilities are adequate, clindamycin and erythromycin susceptibility testing (Box 1) should be performed on prenatal GBS isolates from penicillin-allergic women at high risk for anaphylaxis.

¶ Resistance to erythromycin is often but not always associated with clindamycin resistance. If a strain is resistant to erythromycin but appears susceptible to clindamycin, it may still have inducible resistance to clindamycin.

** Cefazolin is preferred over vancomycin for women with a history of penicillin allergy other than immediate hypersensitivity reactions, and pharmacologic data suggest it achieves effective intraamniotic concentrations. Vancomycin should be reserved for penicillin-allergic women at high risk for anaphylaxis.

aureus). An estimated 13.8 million hospitalized patients received vancomycin therapy in 1998 (*91*). If penicillin allergy occurs in approximately 10% of adults, and 25% of parturients are colonized with GBS prenatally, approximately 100,000 of the 4 million annual deliveries would require prophylaxis with vancomycin in the absence of clindamycin and erythromycin susceptibility testing of GBS prenatal isolates. This represents a 7% increase in the number of patients exposed to vancomycin. The total grams of vancomycin used annually would increase by less than 1% if all penicillin-allergic colonized women received vancomycin prophylaxis.

Increased Incidence or Resistance in Non-GBS Pathogens

Decreases in the incidence of early-onset GBS sepsis have not usually been accompanied by increases in incidence of early-onset sepsis caused by other pathogens, including those that are antibiotic resistant. Most studies, including population-based multicenter studies, have found stable (*59,92,93*) or decreasing (*43*) rates of non-GBS early-onset sepsis during a period of increasing use of intrapartum antibiotic prophylaxis for GBS (Table 3). This is true both for overall non-GBS sepsis and for neonatal sepsis caused by *Escherichia coli*, the second leading bacterial cause of neonatal sepsis after GBS (*93,94*). Some single hospital studies have found increased rates or case counts of neonatal sepsis caused by *E. coli*, gram-negative organisms in general, or ampicillin-resistant pathogens (*64,94,95*), but these increases appear to be limited to preterm or low-birth-weight infants. An increasing proportion of *E. coli* neonatal sepsis cases caused by ampicillin-resistant organisms was observed in two studies (*92,94*), but again was limited to preterm or low-birth-weight infants. Furthermore, the proportion of community-acquired *E. coli* infections that are ampicillin resistant has been increasing (*96*), suggesting that trends in antimicrobial resistance should not be attributed to GBS prophylaxis.

An association between intrapartum antibiotic exposure and ampicillin resistance in cases of *E. coli* or other non-GBS early-onset sepsis has been observed in several studies (*36,94,95, 97,98*). These reports established that infections caused by antibiotic-resistant organisms were more frequently preceded by antibiotic use than were infections caused by susceptible organisms, and that more doses or longer duration of antibiotics before delivery increased the chance that a neonatal infection, if it occurred, would be caused by an antibiotic-resistant organism. These studies, however, were not designed to assess whether intrapartum antibiotic use increased the rate of antibiotic-resistant infections. Moreover, findings from these studies are consistent with intrapartum antibiotics inducing

resistance among initially susceptible organisms, but also with intrapartum antibiotics preventing antibiotic-susceptible infections and having no impact on antibiotic-resistant infections, resulting in a net decrease in the total rate of infection.

The reported increases in antibiotic-resistant early-onset infections in a few studies are not of sufficient magnitude to outweigh the benefits of intrapartum antibiotic prophylaxis to prevent perinatal GBS disease. However, to assure early detection of increases in the rate of disease or deaths caused by organisms other than GBS, continued surveillance of neonatal sepsis caused by organisms other than GBS is needed.

Clinical Challenges

GBS Bacteriuria During Pregnancy

The presence of GBS bacteriuria in any concentration in a pregnant woman is a marker for heavy genital tract colonization. Therefore, women with any quantity of GBS bacteriuria during pregnancy should receive intrapartum chemoprophylaxis. Vaginal and rectal screening at 35–37 weeks is not necessary for these women. GBS can cause both symptomatic and asymptomatic urinary tract infections, which should be diagnosed and treated according to current standards of care for urinary tract infections in pregnancy. Women with GBS urinary tract infections during pregnancy should receive appropriate treatment at the time of diagnosis as well as intrapartum GBS prophylaxis. Laboratory personnel should report any presence of GBS bacteriuria in specimens obtained from pregnant women. For this to occur, labeling of urine specimens to indicate that they were obtained from a pregnant woman is imperative.

Planned Cesarean Delivery

Because GBS can cross intact amniotic membranes, a cesarean delivery does not prevent mother-to-child transmission of GBS. Moreover, because cesarean delivery itself is associated with health risks for mother and newborn, GBS colonization of

the mother is not an indication for cesarean delivery, and cesarean delivery should not be used as an alternative to intrapartum antibiotic prophylaxis for GBS prevention.

However, although a risk does exist for transmission of GBS from a colonized mother to her infant during a planned cesarean delivery performed before onset of labor in a woman with intact amniotic membranes, it is extremely low, based on a retrospective study at a single hospital (*99*) and a review of CDC active, population-based surveillance data from the 1990s. Thus, in this specific circumstance, in which the risk for disease is extremely low, the individual risks to a mother and her infant from receiving intrapartum antibiotic prophylaxis may balance or outweigh the benefits. Intrapartum antibiotic prophylaxis to prevent perinatal GBS disease is, therefore, not recommended as a routine practice for women undergoing planned cesarean deliveries in the absence of labor or amniotic membrane rupture, regardless of the GBS colonization status of the mother. Patients expected to undergo planned cesarean deliveries should nonetheless still undergo routine vaginal and rectal screening for GBS at 35–37 weeks because onset of labor or rupture of membranes may occur before the planned cesarean delivery. In rare situations in which patients or providers opt for intrapartum prophylaxis before planned cesarean deliveries, administration of antibiotics at the time of incision rather than at least 4 hours before delivery may be reasonable (*100*).

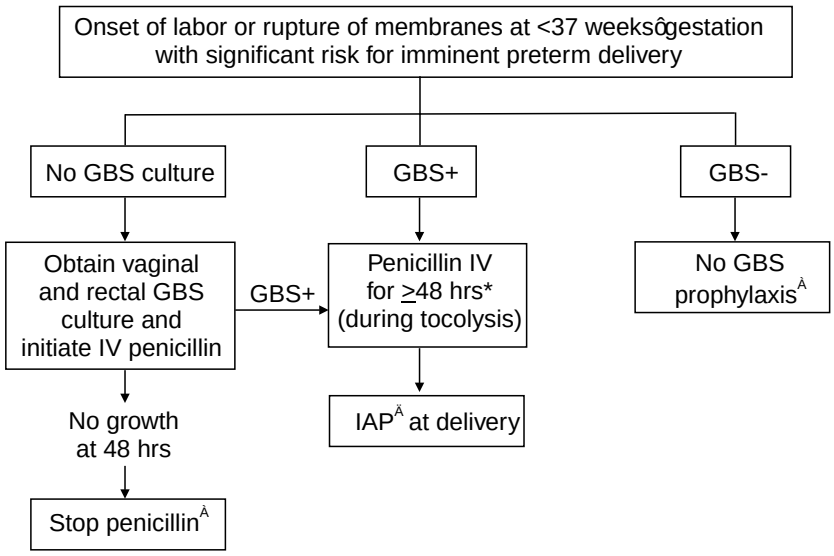
Threatened Preterm Delivery

Because preterm (at <37 weeks' gestation) delivery is an important risk factor for early-onset GBS disease, and because timing of delivery can be difficult to assess, management of intrapartum prophylaxis for women with threatened preterm delivery can be challenging. Assessing the need for intrapartum prophylaxis for these women can also be difficult because GBS screening is recommended at 35 to 37 weeks' gestation, and culture results are not always available when labor or rupture of membranes occur preterm.

A suggested approach to GBS chemoprophylaxis in the context of threatened preterm delivery is outlined (Figure 3). Because insufficient data are available to suggest a single course of management, other management strategies developed by individual physicians or institutions may be appropriate alternatives. The algorithm suggests that if GBS screening culture results from the current pregnancy are not available and if onset of labor or rupture of membranes occurs before 37 weeks' gestation with a substantial risk for preterm delivery (as assessed by the woman's health-care provider), intrapartum antibiotic prophylaxis for GBS should be provided pending culture results. For women not yet screened for GBS, a vaginal and rectal specimen for GBS culture should be obtained if time permits. If a negative culture result within the previous 4 weeks is on record, or if the clinician determines that labor can be successfully arrested and preterm delivery averted, antibiotics for GBS prophylaxis should not be initiated. Because recent clinical trials suggest that antibiotics administered during pregnancy may be associated with adverse neonatal outcomes, such as necrotizing enterocolitis or increased need for supplementary oxygen, without evident benefit for preterm labor or preterm premature rupture of membranes (*101,102*), antibiotics should be reserved for instances in which a significant risk for preterm delivery is present.

No data are available on which to recommend a specific duration of antibiotic administration for GBS-positive women with threatened preterm delivery when delivery is successfully postponed. Management strategies based on scientific opinion

FIGURE 3. Sample algorithm for GBS prophylaxis for women with threatened preterm delivery. This algorithm is not an exclusive course of management. Variations that incorporate individual circumstances or institutional preferences may be appropriate.



* Penicillin should be continued for a total of at least 48 hours, unless delivery occurs sooner. At the physicianõs discretion, antibiotic prophylaxis may be continued beyond 48 hours in a GBS culture-positive woman if delivery has not yet occurred. For women who are GBS culture positive, antibiotic prophylaxis should be reinitiated when labor likely to proceed to delivery occurs or recurs.

Å If delivery has not occurred within 4 weeks, a vaginal and rectal GBS screening culture should be repeated and the patient should be managed as described, based on the result of the repeat culture.

Ä Intrapartum antibiotic prophylaxis.

have been proposed (*100*); without further data, the management approach is left to the discretion of the individual provider. Regardless of management strategy chosen, these women should also receive intrapartum antibiotic chemoprophylaxis for GBS when labor likely to proceed to delivery occurs or recurs.

Previous data (*28*) suggest that the accuracy of GBS screening cultures in predicting colonization status at delivery is greatest if the cultures are collected within 5 weeks of delivery. Therefore, if a woman is screened early for GBS because of threatened preterm delivery but does not deliver within 4 weeks, she should be screened again for GBS colonization and managed according to the result of the repeated screening culture (Figure 3).

Obstetric Procedures for GBS-Colonized Women

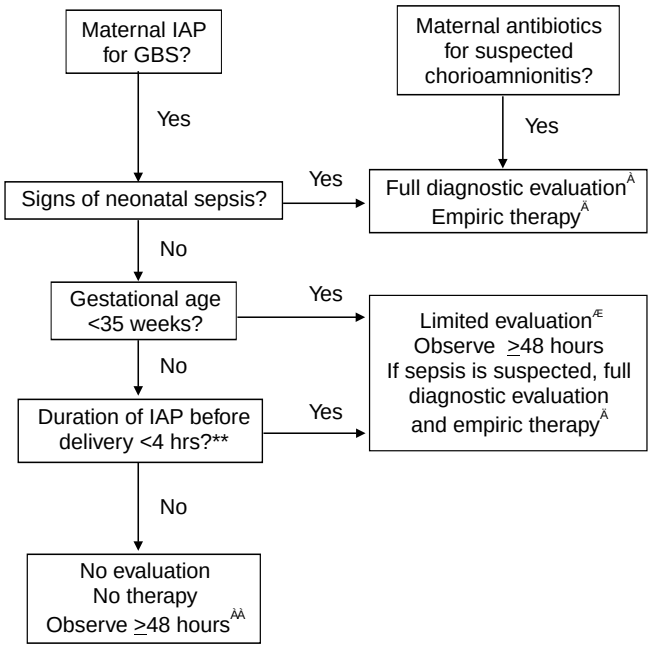
Questions have arisen regarding whether certain obstetric procedures, such as digital vaginal examinations, intrauterine fetal monitoring, and membrane stripping or sweeping to hasten the onset of labor, should be performed on GBS-colonized women. Asymptomatic GBS colonization is not an indication to perform any of these procedures. When such procedures are indicated for other reasons, evidence is currently not sufficient to recommend that particular procedures should be avoided because of increased risk of peripartum or perinatal infection. Although some obstetric procedures (frequent vaginal examinations after onset of labor or membrane rupture [*17,36,103–105*], intrauterine fetal monitoring [*104,106,107*], and mechanical cervical ripening devices [*108*]) have been significantly associated with peripartum or perinatal infectious outcomes, most studies to date have been limited by an inability to randomly allocate women to treatment groups and have yielded conflicting results. Moreover, because many studies were performed before GBS prevention was widely implemented, GBS colonization status was often not known and intrapartum chemoprophylaxis was less common. A meta-analysis of available studies examining the use of membrane stripping among women of undetermined GBS colonization status (*109*) found no significant increases in overall peripartum or perinatal infection rates among women who underwent this procedure and their infants compared with those who did not.

Management of Newborns Exposed to Intrapartum Prophylaxis

On the basis of information available since the publication of the 1996 guidelines, a modified approach for empiric management of newborns born to women who receive intrapartum antibiotics to prevent early-onset GBS disease or to treat suspected chorioamnionitis is provided (Figure 4). Variations in the algorithm that incorporate individual circumstances or institutional preferences may be appropriate. The modified approach contains the following changes:

- If a woman receives intrapartum antibiotics for treatment of suspected chorioamnionitis, her newborn should have a full diagnostic evaluation and empiric therapy pending

FIGURE 4. Sample algorithm for management of a newborn whose mother received intrapartum antimicrobial agents for prevention of early-onset group B streptococcal disease* or suspected chorioamnionitis. This algorithm is not an exclusive course of management. Variations that incorporate individual circumstances or institutional preferences may be appropriate.



* If no maternal intrapartum prophylaxis for GBS was administered despite an indication being present, data are insufficient on which to recommend a single management strategy.

† Includes complete blood cell count and differential, blood culture, and chest radiograph if respiratory abnormalities are present. When signs of sepsis are present, a lumbar puncture, if feasible, should be performed.

¨ Duration of therapy varies depending on results of blood culture, cerebrospinal fluid findings, if obtained, and the clinical course of the infant. If laboratory results and clinical course do not indicate bacterial infection, duration may be as short as 48 hours.

¨ CBC with differential and blood culture.

** Applies only to penicillin, ampicillin, or cefazolin and assumes recommended dosing regimens (Box 2)

†† A healthy-appearing infant who was ≥38 weeksôgestation at delivery and whose mother received ≥4 hours of intrapartum prophylaxis before delivery may be discharged home after 24 hours if other discharge criteria have been met and a person able to comply fully with instructions for home observation will be present. If any one of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until criteria for discharge are achieved.

culture results, regardless of clinical condition at birth, duration of maternal antibiotic therapy before delivery, or gestational age at delivery (*110*). Empiric therapy for the infant should include antimicrobial agents active against GBS as well as other organisms that might cause neonatal sepsis (e.g., ampicillin and gentamicin).

- When clinical signs in the infant suggest sepsis, a full diagnostic evaluation should include a lumbar puncture, if feasible. Blood cultures can be sterile in as many as 15% of newborns with meningitis (*111–113*), and the clinical management of an infant with abnormal cerebrospinal fluid (CSF) findings differs from that of an infant with normal CSF. If a lumbar puncture has been deferred for a neonate receiving empiric antibiotic therapy, and the therapy is continued beyond 48 hours because of clinical instability, CSF should be obtained for cell count, glucose, protein, and culture.
- In addition to penicillin or ampicillin, initiation of intrapartum antibiotic prophylaxis with cefazolin at least 4 hours before delivery can be considered adequate, based on achievable amniotic fluid concentrations of cefazolin (*114*). Although other agents may be substituted for penicillin if the woman has a history of penicillin allergy (Box 2), the effectiveness of these agents in preventing early-onset GBS disease has not been studied and no data are available to suggest the durations before delivery of these regimens that can be considered adequate.
- Based on the demonstrated effectiveness of intrapartum antibiotic prophylaxis at preventing early-onset GBS disease (*65*) and data indicating that clinical onset occurs within the first 24 hours of life in over 90% of infants who contract early-onset GBS disease (*115*), hospital discharge as early as 24 hours after delivery may be reasonable under certain circumstances. Specifically, a healthy-appearing infant who is ≥38 weeks' gestation at delivery and whose mother received ≥4 hours of intrapartum antibiotic prophylaxis before delivery may be discharged home as early as 24 hours after delivery, assuming that other discharge criteria have been met and that a person able to comply fully with instructions for home observation will be present. A key component of following instructions is the ability of the person observing to communicate with health-care providers by telephone and to transport the child promptly to an appropriate health-care facility if clinical signs of sepsis develop. If these conditions are not met, the infant should remain in the hospital for at least 48 hours of observation and until criteria for discharge are achieved.

Investigations since 1996 lend additional support to several components of the algorithm. A retrospective study of over 250,000 live births (*115*) found that administration of intrapartum antibiotic prophylaxis did not change the clinical spectrum of neonatal illness or delay the onset of clinical signs among infants who contracted GBS disease despite prophylaxis. Thus, the algorithm targets infants born to mothers with suspected chorioamnionitis and infants with signs of sepsis for full diagnostic evaluation and empiric therapy. Also, new evidence indicates that 4 or more hours of intrapartum ampicillin or penicillin administered according to recommended dosing intervals (Box 2) significantly reduces vertical transmission of GBS (*116*) and risk of early-onset GBS disease (*65*). Thus, although the American Academy of Pediatrics 1997 guidelines suggested 2 or more doses as a threshold for prophylaxis adequacy for infants ≥35 weeks' gestation (*8*), the revised algorithm continues to use ≥4 hours, administered according to recommended dosing intervals, as the benchmark for optimal prevention of early-onset GBS disease. Moreover, a review of pregnancies at a West Coast health maintenance organization using the GBS culture-based screening strategy found that among women who received intrapartum antibiotic prophylaxis, 50% received prophylaxis at least 4 hours before delivery, whereas only 14% received at least 2 doses of intrapartum antibiotics (*58*); this indicates that duration of prophylaxis is a more practical target than number of doses, in addition to being associated with efficacy.

One objective of developing an algorithm for management of newborns was to minimize unnecessary evaluation and antimicrobial treatment of infants whose mothers received intrapartum prophylaxis. Although early provider surveys indicated that pediatricians and neonatologists were more likely to conduct diagnostic evaluations and initiate empiric antibiotics for an infant whose mother received intrapartum antibiotic prophylaxis (*117–119*), more recent data indicate that implementation of GBS prevention strategies has not resulted in increased use of health services for neonates (*120*), and in some circumstances, when GBS prophylaxis increased a decrease occurred in the proportion of neonates who received laboratory evaluations (*58*).

Intrapartum antibiotic prophylaxis is the method of choice for preventing neonatal early-onset GBS disease. In the event that intrapartum antibiotics are not given despite an indication (e.g., delivery occurred precipitously before antibiotics could be administered to a GBS-positive woman), sufficient data are not available on which to recommend a single management strategy for the newborn. Some centers provide intramuscular penicillin to asymptomatic infants within 1 hour of birth, based on results of observational studies showing

declines in early-onset GBS disease coincident with a policy of universal administration of intramuscular penicillin to all newborns (*121*).

Future Prevention Technology

Rapid Tests to Detect GBS Colonization Status

Rapid tests for detection of GBS colonization at the time of onset of labor or rupture of amniotic membranes might obviate the need for prenatal culture-based screening if their sensitivity and specificity are comparable to culture in selective broth media and they yield results rapidly enough to permit administration of adequate intrapartum antibiotic prophylaxis to women detected as carriers. Currently available rapid tests detect GBS antigen from swab specimens. These tests are insufficiently sensitive to detect light colonization, and therefore are not adequate to replace culture-based prenatal screening (*122,123*) or to use in place of the risk-based approach when culture results are unknown at the time of labor. An adequate rapid intrapartum test must be as sensitive as culture (minimally 85% compared with culture of vaginal and rectal swabs inoculated into selective broth media), rapid so that results are available to clinicians in time for antibiotics to be given before delivery, and convenient for integration into routine laboratory use. Even a highly sensitive rapid detection test would not be adequate if results were not available to clinicians 24 hours a day, 7 days a week. Alternatives to culturing vaginal and rectal swab specimens at 35–37 weeks' gestation using recommended procedures should be validated to show sensitivity similar to recommended culture methods.

A rapid intrapartum test possessing the attributes described above offers the advantage of ascertaining GBS colonization status before delivery among women who have had no prenatal care. Although such tests might initially be introduced selectively in certain facilities with sufficient demand and capability, a general recommendation for their use would require the capacity for effective implementation in a wide range of hospital settings. Drawbacks of rapid tests include delays in administration of intrapartum antibiotic prophylaxis while test results are pending and lack of an isolate for susceptibility testing, which is of particular concern for penicillin-allergic women. Additionally, until rapid tests are universally used, missed opportunities for GBS screening may occur among women who receive prenatal care at institutions relying on intrapartum rapid tests but who deliver at institutions where such tests are not yet available.

In a study of 112 pregnant women at an academic hospital in Quebec, a new, not yet commercially available fluorogenic polymerase chain reaction assay was 97% sensitive and 100% specific when compared with vaginal and rectal cultures collected at admission for delivery. Test results in this study were available within 45 minutes of specimen collection (*124*). Further studies are needed to determine whether this type of test can be adapted for use outside the research setting. If appropriate techniques for rapid detection of GBS become commercially available, they may be integrated into the currently recommended screening strategy.

Vaccines To Prevent GBS Disease

Improved use of intrapartum antimicrobial prophylaxis has resulted in a substantial reduction in early-onset GBS disease, but it is unlikely to prevent most late-onset neonatal infections, GBS-related stillbirths, or prematurity, and does not address GBS disease in nonpregnant adults. Immunization of women during or before pregnancy could prevent peripartum maternal disease and protect infants from perinatally acquired infection by transplacental transfer of protective IgG antibodies (*125,126*). This would eliminate the need for prenatal GBS screening and intrapartum antimicrobial prophylaxis, along with associated costs and concerns regarding the potential adverse effects of intrapartum antibiotic use discussed previously.

Serotype-specific antibodies to GBS capsular polysaccharide, although rare in populations of unvaccinated women, have been shown to protect against disease (*32,127*). Phase 1 and 2 clinical trials among healthy, nonpregnant adults of monovalent protein-conjugate vaccines containing capsular polysaccharide antigens of GBS disease-associated serotypes have shown these vaccines to be well tolerated and immunogenic (*128–130*). One challenge of demonstrating vaccine efficacy in preventing early-onset GBS disease is that the sample size required for clinical trials may be prohibitively large. Identification of surrogate immunologic measures of clinical efficacy may thus be important (*131,132*). Surrogate information on clinical vaccine efficacy may also be gained by measuring the impact of multivalent conjugate vaccines on vaginal GBS colonization (*132,133*).

Anticipated difficulties in making vaccine available to pregnant women have resulted in consideration of other target populations for vaccine administration, including adolescent girls (*134*), women of childbearing age, and infants (*135*). The duration of protection that could be afforded by vaccination is unknown; one or more booster doses might be required, potentially complicating vaccine delivery. Shifts in the GBS serotypes causing disease have provided an additional

challenge to vaccine development (*133*) and may necessitate modification of vaccine serotype composition over time.

Research Priorities and Tools To Aid Prevention

Technological advances that aid the implementation of a universal screening strategy will further prevention efforts. In addition to development of reliable rapid tests that can be performed in a wide range of labor and delivery settings, methods of simplifying prenatal culture procedures, e.g., the development of media with a reliable color indicator to signal presence of GBS, might improve accuracy of prenatal culture results and facilitate prenatal culture processing at clinical laboratories with limited technical capacity. Media that have been developed for this purpose, such as Granada (*136,137*) or GBS medium (*138*), should be further evaluated to determine if sensitivity and specificity are comparable to recommended methods, which consist of culture in selective broth media followed by GBS-specific identification.

Although universal prenatal GBS culture-based screening is likely to result in substantial further declines in the incidence of early-onset disease, intrapartum chemoprophylaxis is not a permanent or comprehensive strategy for GBS disease prevention. Because vaccines under development hold promise to prevent a larger portion of the burden of GBS disease with a simpler and sustainable intervention, further work on GBS vaccine development and support of phase 3 clinical trials are warranted (*139*).

Until a safe, effective, and economical vaccine achieves licensure, it will be important to continue to monitor for potential adverse effects of chemoprophylaxis, with an emphasis on tracking key sentinel events signaling a need for revision of the guidelines. Such sentinel events include the emergence of penicillin resistance among GBS, which to date has not been detected, and an increase in the incidence of disease or deaths due to neonatal pathogens other than GBS that offsets the burden of early-onset disease prevented by chemoprophylaxis. Monitoring for the latter will require long-term surveillance of a large population of term and preterm births (*140*).

Because GBS carriage is common among delivering women in the United States, continued surveillance for GBS disease and evaluation of prevention implementation remains important to minimize missed opportunities for prevention. States are encouraged to monitor incidence of GBS disease, to promote activities that enhance perinatal GBS disease prevention and education, and to assess progress toward national objectives for disease reduction, such as Healthy People 2010, which sets a target of reducing the incidence of early-onset GBS disease in all racial and ethnic groups to 0.5 cases per 1,000 live births (*141*). Practical tools to assist with monitoring for missed opportunities for perinatal GBS prevention within hospitals have been published (*142*); additional prevention information and tools for providers, patients and clinical microbiologists are available at http://www.cdc.gov/groupbstrep, http://www.acog.org, http://sales.acog.com, http://www.aap.org, and http://www.health.state.mn.us/divs/dpc/ades/invbact/strepb.htm.

Recommendations

The following updated recommendations for the prevention of GBS disease are based on critical appraisal of multistate population-based observational data and several studies from individual institutions that have been completed since publication of previous CDC (*7*), ACOG (*6*), and AAP (*8*) recommendations. They replace previous recommendations from CDC. The strength (indicated by a letter) and quality (indicated by a roman numeral) of evidence supporting each recommendation are shown in parentheses, according to the evidence-based rating system outlined in Table 1.

Obstetric-care practitioners, in conjunction with supporting laboratories and labor and delivery facilities, should adopt the following strategy for the prevention of perinatal GBS disease based on prenatal screening for GBS colonization. The risk-based approach is no longer an acceptable alternative except for circumstances in which screening results are not available before delivery (AII).

- All pregnant women should be screened at 35–37 weeks' gestation for vaginal and rectal GBS colonization (Figure 2) (AII). At the time of labor or rupture of membranes, intrapartum chemoprophylaxis should be given to all pregnant women identified as GBS carriers (AII). Colonization during a previous pregnancy is not an indication for intrapartum prophylaxis in subsequent deliveries. Screening to detect GBS colonization in each pregnancy will determine the need for prophylaxis in that pregnancy.
- Women with GBS isolated from the urine in any concentration (e.g., 10^3) during their current pregnancy should receive intrapartum chemoprophylaxis because such women usually are heavily colonized with GBS and are at increased risk of delivering an infant with early-onset GBS disease (BII). Labels on urine specimens from prenatal patients should clearly state the patient's pregnancy status to assist laboratory processing and reporting of results. Prenatal culture-based screening at 35–37 weeks' gestation is not necessary for women with GBS bacteriuria. Women with symptomatic or asymptomatic GBS urinary

tract infection detected during pregnancy should be treated according to current standards of care for urinary tract infection during pregnancy.

- Women who have previously given birth to an infant with invasive GBS disease should receive intrapartum chemoprophylaxis; prenatal culture-based screening is not necessary for these women (BII).
- If the result of GBS culture is not known at the onset of labor, intrapartum chemoprophylaxis should be administered to women with any of the following risk factors: gestation <37 weeks, duration of membrane rupture ≥18 hours, or a temperature of ≥100.4° F (≥38.0°C) (AII). Women with known negative results from vaginal and rectal GBS screening cultures within 5 weeks of delivery do not require prophylaxis to prevent GBS disease even if any of the intrapartum risk factors develop.
- Women with threatened preterm (<37 weeks' gestation) delivery should be assessed for need for intrapartum prophylaxis to prevent perinatal GBS disease. An algorithm for management of women with threatened preterm delivery is provided (Figure 3). Other management approaches, developed by individual physicians or institutions, may be appropriate (CIII).
- Culture techniques that maximize the likelihood of GBS recovery are required for prenatal screening (Box 1). Collection of specimens for culture may be conducted in the outpatient clinic setting by either the patient, with appropriate instruction, or health-care provider (BII). This involves swabbing the lower vagina and rectum (i.e., through the anal sphincter). Because lower vaginal as opposed to cervical cultures are recommended, cultures should not be collected by speculum examination. Specimens should be placed in a nonnutritive transport medium (e.g., Amies or Stuart's without charcoal). Specimen labels should clearly identify that specimens are for group B streptococcal culture. If susceptibility testing is ordered for penicillin-allergic women (Box 2), specimen labels should also identify the patient as penicillin allergic and should specify that if GBS is isolated, it should be tested for susceptibility to clindamycin and erythromycin. Specimens should be inoculated into a selective broth medium (examples of appropriate commercially available media include Trans-Vag Broth supplemented with 5% defibrinated sheep blood or LIM broth), incubated overnight, and subcultured onto solid blood agar medium (AII). Methods of testing prenatal isolates from penicillin-allergic women for susceptibility to clindamycin and erythromycin are outlined (Box 1). Laboratories should report culture results (positive and negative) and susceptibility testing results to the anticipated site of delivery (when known) and to the health-care provider who ordered the test.
- Health-care providers should inform women of their GBS screening test result and the recommended interventions. In the absence of GBS urinary tract infection, antimicrobial agents should not be used before the intrapartum period to treat GBS colonization. Such treatment is not effective in eliminating carriage or preventing neonatal disease and may cause adverse consequences (DI).
- GBS-colonized women who have a planned cesarean delivery performed before rupture of membranes and onset of labor are at low risk for having an infant with early-onset GBS disease. These women should not routinely receive intrapartum chemoprophylaxis for perinatal GBS disease prevention (CII).
- For intrapartum chemoprophylaxis, the following regimen is recommended for women without penicillin allergy (Box 2): penicillin G, 5 million units intravenously initial dose, then 2.5 million units intravenously every 4 hours until delivery (AII). Because of its narrow spectrum of activity, penicillin is the preferred agent. An alternative regimen is ampicillin, 2 g intravenously initial dose, then 1 g intravenously every 4 hours until delivery (AI).
- Intrapartum chemoprophylaxis for penicillin-allergic women takes into account increasing resistance to clindamycin and erythromycin among GBS isolates (Box 2). During prenatal care, history of penicillin allergy should be assessed to determine whether a patient is at high risk for anaphylaxis, i.e., has a history of immediate hypersensitivity reactions to penicillin (e.g., anaphylaxis, angioedema, or urticaria) or history of asthma or other conditions that would make anaphylaxis more dangerous (*89*). Women who are not at high risk for anaphylaxis should be given cefazolin, 2 g intravenously initial dose, then 1 g intravenously every 8 hours until delivery (BIII). For women at high risk for anaphylaxis, clindamycin and erythromycin susceptibility testing, if available, should be performed on isolates obtained during GBS prenatal carriage screening. Women with clindamycin- and erythromycin-susceptible isolates should be given either clindamycin, 900 mg intravenously every 8 hours until delivery; OR erythromycin, 500 mg intravenously every 6 hours until delivery. If susceptibility testing is not possible, susceptibility results are not known, or isolates are resistant to erythromycin or clindamycin, the following regimen can be used for women with immediate penicillin hypersensitivity: vancomycin, 1 g intravenously every 12 hours until delivery (CIII).

- Routine use of antimicrobial prophylaxis for newborns whose mothers received intrapartum chemoprophylaxis for GBS infection is not recommended. However, therapeutic use of these agents is appropriate for infants with clinically suspected sepsis. An updated algorithm for management of infants born to mothers who received intrapartum chemoprophylaxis for GBS infection is provided (Figure 4). This revised algorithm is not an exclusive approach to management; variation that incorporates individual circumstances or institutional preferences may be appropriate (CIII).
- Local and state public health agencies, in conjunction with appropriate groups of hospitals, are encouraged to establish surveillance for early-onset GBS disease and to take other steps to promote perinatal GBS disease prevention and education to reduce the incidence of early-onset GBS disease in their states. Efforts to monitor the emergence of perinatal infections caused by other organisms are also encouraged.

Before full implementation of this strategy can be expected in all health-care settings, all members of the health-care team will need to improve protocols for isolation and reporting of GBS culture results, to improve information management to ensure communication of screening results, and to educate medical and nursing staff responsible for prenatal and intrapartum care. Within institutions, such efforts may take several months.

Even with ideal implementation, cases of early-onset GBS disease will continue to occur. Tools to help promote prevention and educate parents of infants with early-onset GBS disease are available at http://www.cdc.gov/groupbstrep. Additional tools available to assist with prevention implementation are available at http://www.acog.org, http://sales.acog.com, http://www.aap.org and http://www.health.state.mn.us/divs/dpc/ades/invbact/strepb.htm Multiple copies of educational materials published by CDC are available at the Public Health Foundation, 1220 L St., NW Suite 350, Washington, DC 20005, telephone 877-252-1200, or online at http://www.phf.org.

Policy Statement—Alcohol Use by Youth and Adolescents: A Pediatric Concern

abstract

Alcohol use continues to be a major problem from preadolescence through young adulthood in the United States. Results of recent neuroscience research have substantiated the deleterious effects of alcohol on adolescent brain development and added even more evidence to support the call to prevent and reduce underaged drinking. Pediatricians should be knowledgeable about substance abuse to be able to recognize risk factors for alcohol and other substance abuse among youth, screen for use, provide appropriate brief interventions, and refer to treatment. The integration of alcohol use prevention programs in the community and our educational system from elementary school through college should be promoted by pediatricians and the health care community. Promotion of media responsibility to connect alcohol consumption with realistic consequences should be supported by pediatricians. Additional research into the prevention, screening and identification, brief intervention, and management and treatment of alcohol and other substance use by adolescents continues to be needed to improve evidence-based practices. *Pediatrics* 2010;125:1078–1087

ADHD—attention-deficit/hyperactivity disorder

INTRODUCTION

Alcohol use and heavy drinking are common during adolescence and young adulthood, although the minimum legal drinking age across the United States is 21 years. Some individuals may start hazardous alcohol consumption earlier in childhood. The prevalence of problematic alcohol use continues to escalate into the late adolescent and young-adult age range of 18 to 20 years. Drinking by college-aged students remains a major issue. Results of recent research that have demonstrated that brain development continues well into early adulthood[1] and that alcohol consumption can interfere with such development[2,3] indicate that alcohol use by youth is an even greater pediatric health concern.

Use of alcohol at an early age is associated with future alcohol-related problems.[4–6] Data from the National Longitudinal Alcohol Epidemiologic Study[4] substantiated that the prevalence of both lifetime alcohol dependence and alcohol abuse show a striking decrease with increasing age at onset of use. For those aged 12 years or younger at first use, the prevalence of lifetime alcohol dependence was 40.6%, whereas those who initiated at 18 years was 16.6% and at 21 years was 10.6%. Similarly, the prevalence of lifetime alcohol abuse was 8.3% for those who initiated use at 12 years or younger, 7.8% for those who initiated at 18 years, and 4.8% for those who initiated at 21 years. The contribution of

age at alcohol use initiation to the odds of lifetime dependence and abuse varied little across gender and racial subgroups in the study. Early alcohol initiation has been associated with greater sexual risk-taking (unprotected sexual intercourse, multiple partners, being drunk or high during sexual intercourse, and pregnancy)[7]; academic problems; other substance use; and delinquent behavior in mid- to later adolescence.[8] By young adulthood, early alcohol use is associated with employment problems, other substance abuse, and criminal and violent behavior.[8] Independent of genetic risk, exposure to alcohol or other drug use disorders of parents predicts substance use disorders in children.[9]

ALCOHOL USE, MISUSE, ABUSE, AND DEPENDENCE

Adolescent drinking behaviors cover the alcohol use spectrum, from primary abstinence to alcohol dependence. The *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition, Text Revision* (DSM-IV-TR)[10] defines alcohol abuse as a maladaptive pattern of use that leads to clinically significant impairment or distress, as manifested by 1 or more of the following within a 12-month period:

- recurrent alcohol use that results in a failure to fulfill major role obligations at work, school, or home;
- recurrent alcohol use in situations in which it is physically hazardous;
- recurrent alcohol-related legal problems;
- continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the alcohol; and
- the symptoms have never met the criteria for alcohol dependence.

Alcohol dependence is defined as a maladaptive pattern of use that leads to clinically significant impairment or distress, as manifested by 3 or more of the following within the same 12-month period:

- tolerance;
- withdrawal;
- alcohol is often taken in larger amounts or over a longer period than was intended;
- there is a persistent desire or unsuccessful efforts to cut down or control use;
- a great deal of time is spent in activities necessary to obtain alcohol, use alcohol, or recover from its effects;
- important social, occupational, or recreational activities are given up or reduced because of use; or
- alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol.

Because these diagnostic criteria were developed largely from research and clinical work with adults, there are limitations to applying these definitions to classify alcohol use and associated risks to adolescents.[11–13] As defined by the *DSM-IV-TR*, alcohol abuse or dependence may not have had time to develop in an adolescent, especially a younger one, and yet the adolescent may be engaging in very risky behavior. Applicability is also potentially limited in that several of the criteria, such as withdrawal, are not typically experienced by adolescents, and other criteria, such as tolerance, have low specificity for adolescents. Tolerance can be anticipated as a developmental process that will occur over time in most adolescents who drink.[11]

Alcohol misuse can be defined as "alcohol-related disturbances of behavior, disease, or other consequences that are likely to cause an individual, his/her family, or society harm now or in the future."[14] Because the term "alcohol misuse" encompasses earlier stages of problematic alcohol use as well as alcohol dependence that do not meet diagnostic criteria, it may be a more useful concept clinically in pediatrics and when developing alcohol use primary prevention programs for youth.

In examining the use of drugs by US youth, the annual Monitoring the Future Study (sponsored by the National Institute on Drug Abuse and implemented by the University of Michigan)[15] has consistently reported that the drug most commonly used by youth is alcohol, exceeding the use of tobacco and illicit drugs. The 2009 survey of more than 46 000 8th-, 10th-, and 12th-grade students in more than 380 schools nationwide revealed that the prevalence of alcohol use in the previous 30 days had declined by more than one-third since most recently peaking in 1996 but that less of a decline was found for older students. The prevalence of being drunk at least once in the previous month was 5.4% for 8th-graders, 15.5% for 10th-graders, and 27.4% for 12th-graders. Prevalence of use in the previous 30 days of the relatively new flavored alcoholic beverages, also known as "alcopops" or "malternatives," decreased somewhat since initial inclusion in this survey in 2004. Alcopop use in the previous 30 days was reported by 9.5% of 8th-graders, 19.0% of 10th-graders, and 27.4% of 12th-graders in 2009. Recent "binge-drinking," defined as the consumption of 5 or more drinks in a row on at least 1 occasion in the previous 2 weeks, has continued at a relatively stable level, with 7.8% of 8th-graders, 17.5% of 10th-graders, and 25.2% of 12th-graders reporting this activity. Since the start of this century, more than 90% of 12th-graders have reported that alcohol is "fairly easy" or "very easy" to get, and more than 60% of 8th-graders say the same. These

epidemiologic statistics are corroborated by data reported from 2 other large surveys of youth alcohol use in the United States: the Youth Risk Behavior Survey[16] of the Centers for Disease Control and Prevention and the National Survey on Drug Use & Health (formerly the National Household Survey).[17]

HAZARDS OF USE OF ALCOHOL

When compared with use by adults, alcohol use by adolescents is much more likely to be episodic (binge) and heavy, which makes alcohol use by those in this age group particularly dangerous. Rapid binge-drinking, possibly related to a bet or dare, puts the teenager at even higher risk of alcohol overdose or alcohol poisoning, in which suppression of the gag reflex and respiratory drive can be fatal. The adult definition of binge-drinking (the consumption of 5 or more drinks in a row over approximately a 2-hour period) is often also used to describe adolescent or young-adult alcohol use. Recent literature, however, suggests that for 9- to 13-year-old children and girls aged 14 to 17 years, binge-drinking should be defined as 3 or more drinks. For boys, binge-drinking should be defined as 4 drinks or more for those aged 14 or 15 years and 5 or more drinks for those aged 16 or 17 years.[18]

Alcohol use is the primary contributor to the leading causes of adolescent death (ie, motor-vehicle crashes, homicide, and suicide) in the United States.[19] Motor-vehicle crashes rank as the top cause of death for US teenagers and young adults. The Youth Risk Behavior Survey in 2007 revealed that during the 30 days preceding the survey, 29.1% of students nationwide had ridden 1 or more times in a car or other vehicle driven by someone who had been drinking alcohol, and 10.5% of students had driven a car or other vehicle at least once when they had been drinking alcohol.[16] The impressive relationship of alcohol use and motor-vehicle crashes involving youth is also highlighted by the fact that after the legal drinking age was changed uniformly to 21 years across the United States, the number of motor-vehicle fatalities in individuals younger than 21 years significantly decreased.[20] Teenagers drink and drive less frequently than do adults, but their motor-vehicle crash risks are higher than those of adults when they do drink, especially at low and moderate blood alcohol concentrations.[21]

Lower minimum legal drinking ages in the United States have also been associated with higher youth suicide rates.[22] The research literature consistently reports the association of alcohol use or abuse with other risk-taking behaviors, including assault, sexual risk-taking, and other drug use.[12,13,23,24] Thus, alcohol use by adolescents is not safe, even when they are not driving.

Alcohol misuse and alcohol use disorders in adolescents are associated with many other mental and physical disorders. Alcohol use disorders are a risk factor for suicide attempts.[25] Psychiatric conditions most likely to co-occur with alcohol use disorders include mood disorders, particularly depression; anxiety disorders; attention-deficit/hyperactivity disorder (ADHD); conduct disorders; bulimia; and schizophrenia.[23] Associated physical health problems include trauma sequelae,[26] sleep disturbance, modestly elevated serum liver enzyme concentrations, and dental and other oral abnormalities,[27] despite relatively few abnormalities being evident on physical examination.[27,28]

FACTORS THAT CONTRIBUTE TO HAZARDOUS USE

Genetic and Familial Factors

Twin studies in adult populations have consistently demonstrated genetic influences on use and abuse of alcohol,[29–31] but less research has examined genetic influences on the adolescent age range.[32–34] Through a sibling/twin/adoption study of adolescents, Rhee et al[35] examined the relative contribution of genetics and environment on initiation, use, and problem use of substances. The results of this study demonstrated that for adolescents, compared with adult-twin study findings, the magnitude of genetic influences was higher and that of shared environmental influences was lower for problem alcohol or drug use than for initiation of use.

Families play an important role in the development of alcohol and other drug problems in youth. Drug use by parents or older siblings and permissive parental attitudes toward drug use by young people predict greater risk of youth drug and alcohol use.[36,37] Both parental monitoring of children's use and the convincing conveyance of household rules governing use aid in deterring alcohol use among youth.[38,39] In the United States, 7 million children younger than 18 years are children of alcoholic parents. Children of alcohol abusers are at increased risk of many behavioral and medical problems, including delinquent behavior, learning disorders, ADHD, psychosomatic complaints, and problem drinking or alcoholism as adults.[40]

Other Factors

Having friends who use alcohol, tobacco, or other substances is one of the strongest predictors of substance use by youth. Patterns of use in the community also predict individual substance use behaviors. Rates of use are higher in communities in which alcohol and other drugs are less expensive and easily obtainable. Other risk factors for substance abuse include poor school performance, untreated ADHD, and conduct disorder.[36]

Media influences on the use of alcohol by young people are substantial. Jernigan et al[41] examined boys' and girls' exposure to magazine advertising for alcohol compared with that of legal-aged adults and found that underaged youth saw 45% more beer and ale ads, 12% more distilled-spirit ads, and 65% more low-alcohol refresher beverage ads (for alcopops or lemonades, iced teas, or fruity beverages containing alcohol) as well as 69% less wine advertising than did people aged 21 years or older. Exposure to alcohol advertising was greater for girls than for boys. Other media, such as television, movies, billboards, and the Internet, are known to be very influential in promoting alcohol use through attractive portrayals of use without associated negative consequences. Considerable research has shown that media exposure can make children and adolescents more likely to experiment with alcohol.[42,43]

ADOLESCENT DEVELOPMENTAL AND NEUROBIOLOGICAL FACTORS

Over the past decade, great strides have been made in understanding the neurobiological basis of addiction. Studies investigating normal brain development have yielded information that elucidate the effects of alcohol and other drugs on the adolescent brain. As summarized by Sowell et al,[44] results of postmortem studies have shown that myelination, a cellular maturational process of the lipid/protein sheath of nerve fibers, begins near the end of the second trimester of fetal development and extends well into the third decade of life and beyond. Autopsy results have shown both a temporal and spatial systematic sequence of myelination, which progresses from inferior to superior and posterior to anterior regions of the brain. This sequencing results in initial brain myelination occurring in the brainstem and cerebellar regions and myelination of the cerebral hemispheres and frontal lobes occurring last. Converging evidence from electrophysiological and cerebral glucose-metabolism studies has revealed relatively late frontal lobe maturation, and results of neuropsychological studies have shown that performance on tasks that involve the frontal lobes continues to improve into adolescence.

Sowell et al[44] documented reduction in gray matter in the regions of the frontal cortex between adolescence and adulthood, which probably reflects increased myelination in the peripheral regions of the cortex. Gray-matter loss, with pruning and elimination of neural connections during normative adolescent development, seems to reflect a sculpting process that turns the immature brain into a mature one.[45] These changes are thought to improve cognitive processing in adulthood. Results of neuropsychological studies have shown that the frontal lobes are essential for functions such as response inhibition, emotional regulation, planning, and organization, all of which may continue to develop between adolescence and young adulthood. Conversely, parietal, temporal, and occipital lobes show little change in maturation between adolescence and adulthood. Parietal association cortices are involved in spatial relationships and sensory functions, and the lateral temporal lobes are associated with auditory and language processing, and these functions are largely mature by adolescence. Hence, the observed patterns of brain maturational changes are consistent with cognitive development.[44] Connections are being fine-tuned in adolescence with the pruning of overabundant synapses and the strengthening of relevant connections with development and experience. It is likely that the further development of the prefrontal cortex aids in the filtering of information and suppression of inappropriate actions.[45]

The effects of alcohol and other drugs on the adolescent brain are probably multiple, because the immaturity or plasticity of the brain developmental processes likely confers greater vulnerability to both the toxic and the addictive actions of drugs, and drug use itself may directly affect brain development. The use of alcohol and drugs during early adolescence, coupled with genetic predisposition to substance abuse and addiction, may increase the magnitude of risk-taking during adolescence. All substances of abuse that lead to dependence share 2 common effects during withdrawal: a decrease in dopamine 2 (D_2) receptors (which can lead to tolerance) and hypofunctioning of the prefrontal cortex. The effects of drugs and alcohol on an immature prefrontal cortex may increase the incentive to seek substances of abuse, especially to decrease the effects that are felt during withdrawal.[46,47] Continued use may impair an already immature prefrontal cortex and further affect decision-making once substance use begins.

Results of developmentally focused research on how alcohol affects the adolescent brain have started to demonstrate that adolescents with an alcohol use disorder use fewer strategies to learn new information and demonstrate significantly reduced memory skills that continue to deteriorate with continued alcohol use. In neuroimaging studies of patients with adolescent-onset alcohol use disorders, reduced hippocampal volumes and subtle white-matter abnormalities have been documented.[3] Research continues to explore these brain developmental processes that may confer greater vulnerability to the addictive actions of drugs, including alcohol.[2]

NATIONAL CALL TO PREVENT AND REDUCE UNDERAGED DRINKING

In 2007, *The Surgeon General's Call to Action to Prevent and Reduce Underage Drinking*[48] was issued after being developed in collaboration with the National Institute on Alcohol Abuse and Alcoholism (NIAAA) and the Substance Abuse and Mental Health Services Administration (SAMHSA). This call to action identified 6 goals:

- Foster changes in American society that facilitate healthy adolescent development and that help prevent and reduce underaged drinking.
- Engage parents and other caregivers, schools, communities, all levels of government, all social systems that interface with youth, and youth themselves in a coordinated national effort to prevent and reduce underaged drinking and its consequences.
- Promote an understanding of underaged alcohol consumption in the context of human development and maturation that takes into account individual adolescent characteristics as well as environmental, ethnic, cultural, and gender differences.
- Conduct additional research on adolescent alcohol use and its relationship to development.
- Work to improve public health surveillance on underaged drinking and on population-based risk factors for this behavior.
- Work to ensure that policies at all levels are consistent with the national goal of preventing and reducing underaged alcohol consumption.

The Surgeon General's report outlined specific strategies for implementing these goals, including recommendations for parents and other caregivers; schools, colleges, and universities; communities; the criminal and juvenile justice systems and law enforcement; entertainment and media industries; the health care system; professional health care associations; and governments and policy makers.

ROLE OF THE PEDIATRICIAN

Pediatricians and other health care providers who care for children and adolescents should help prevent, identify, and treat alcohol and other substance use by youth. The American Academy of Pediatrics guidelines for the health care of children and adolescents recommend that pediatricians discuss substance use as part of anticipatory guidance and preventive care.[49] Because of their understanding of family dynamics and long-standing relationships with families, pediatricians can identify substance-abusing families and facilitate their care.[50] Pediatricians can be involved in the primary prevention of alcohol misuse through educational and psychological interventions with youth. Although evaluation of such programs has revealed many methodologic weaknesses, there is some evidence to support the effectiveness of family-focused prevention programs and culturally focused skills training in the long-term prevention of alcohol misuse.[14] Pediatricians should support parenting programs that have been shown to reduce or prevent substance use by youth. The most effective programs emphasize active parental involvement and have components that emphasize development of social skills and promote a sense of personal responsibility among young people, as well as address issues related to substance abuse.[51] Pediatricians also have an important advocacy role in health systems' changes as well as legislative efforts, such as increasing alcohol taxes,[52] resisting efforts to weaken minimum-drinking-age laws, and implementing graduated-driver licensing.[21] A recent Cochrane review showed implementation of graduated-driver licensing to be effective in reducing the crash rates of young drivers and, specifically, alcohol-related crashes in most studies in the United States and internationally.[53]

The American Academy of Pediatrics recommends that pediatricians routinely screen and evaluate youth for substance use and provide office interventions and referrals for patients who are using alcohol or other substances.[49] The American Medical Association *Guidelines for Adolescent Preventive Services (GAPS)*[54] and the American Academy of Pediatrics *Bright Futures* guidelines[55] recommend that pediatricians and other health care providers who work with children and adolescents conduct routine annual substance use screening of all adolescents and use brief intervention techniques as indicated. In addition, it is recommended that pediatricians be familiar with community resources and refer patients with problematic use or a substance use disorder for treatment.[56] Despite these recommendations, primary care providers have reported many barriers to implementing alcohol and other drug use screening as a routine. Barriers to such screening have been identified to include insufficient time, lack of training to manage a positive screening, the need to triage competing medical problems, lack of treatment resources, tenacious parents who will not leave the examination room, and unfamiliarity with screening tools.[57]

Brief screening surveys for adolescent substance use are available and include the Alcohol Use Disorders Identification Test (AUDIT) developed by the World Health Organization,[58] the Problem Oriented Screening Instrument for Teenagers (POSIT) substance use/abuse scale developed by the National Institute on Drug Abuse,[59] and the CRAFFT instrument, a 6-question, developmentally appropriate screening tool developed by Knight et al (see Table 1).[60] Although all 3 of these tools

TABLE 1 CRAFFT Questions: A Brief Screening Test of Adolescent Substance Abuse

C	Have you ever ridden in a car driven by someone (including yourself) who was "high" or had been using alcohol or drugs?
R	Do you ever use alcohol or drugs to relax, feel better about yourself, or fit in?
A	Do you ever use alcohol or drugs while you are by yourself, alone?
F	Do you ever forget things you did while using alcohol or drugs?
F	Do your family or friends ever tell you that you should cut down on your drinking or drug use?
T	Have you ever gotten into trouble while you were using alcohol or drugs?

Two or more yes answers suggest a significant problem, abuse, or dependence. The CRAFFT questions were developed with grant support from the Robert Wood Johnson Foundation, the National Institute on Alcohol Abuse and Alcoholism, and the Substance Abuse and Mental Health Services Administration.

have acceptable sensitivity for identifying alcohol problems or disorders in 14- to 18-year-old adolescents,[61] the CRAFFT instrument has emerged as a quick, validated, reliable, and easy-to-use screening tool that can be administered in the primary care setting in verbal or written format and has good discriminative properties for determining substance use disorders in adolescents.[62] Test-retest reliability of the CRAFFT has been shown to be high, especially when the questions are prefaced with the phrase "in the past year" when office-based screening is performed.[63] Recently, the CRAFFT tool use was integrated into an adolescent substance use screening, brief intervention, and referral-to-treatment algorithm and tool kit to augment pediatricians' confidence and ability in responding effectively to screening results.[64]

More research is still needed to aid in developing brief intervention strategies (ie, short, efficient, office-based techniques) that health care providers who work with adolescents can use to detect and intervene with alcohol misuse. Motivational interviewing is one of the most promising brief intervention strategies that can be used in an office-based setting.[65] Motivational interviewing is a patient-centered, directive counseling style that builds on the intrinsic motivation of an individual. When conducting a motivational interview, the pediatrician or counselor creates a partnership with the adolescent patient to explore and resolve his or her ambivalence about behavioral change. Motivational interviewing is often associated with the transtheoretical model described by Prochaska and DiClemente,[66] who identified what they called "stages of change," a continuum of readiness to change behavior. In this model, change is facilitated by matching the counseling strategy to the stage of patient readiness to change behavior. The essential spirit of motivational interviewing comprises 3 elements: collaboration, or forming a partnership with the patient; evocation, or using open-ended questions and reflections to help the patient determine his or her own motivation to change; and autonomy, or accepting that it is the adolescent's responsibility to change his or her behavior and decide how the change will occur and that direct persuasion by a pediatrician or counselor is unlikely to be effective. Expressing empathy, developing discrepancy between goals and current behavior, "rolling" with the resistance a patient may have (ie, avoiding arguing for change), and supporting patient self-efficacy are the 4 principles of motivational interviewing.[67]

Results of research have shown that motivational interviewing as a counseling style has been effective in decreasing alcohol use in both younger and older adolescents.[68–71] The authors of a recent Cochrane review of primary prevention for alcohol misuse by young people noted that, although much research investigating the effectiveness of alcohol interventions was of poor quality, there was "strong design and consistent pattern of results indicating potential value of motivational interviewing."[14] Further research is indicated to improve all aspects of adolescent substance abuse intervention and treatment.[72]

Specific recommendations regarding the best management tools and techniques for treatment will be available in a forthcoming statement from the American Academy of Pediatrics on substance use screening, brief intervention, and referral to treatment for pediatricians. For more information, please see the resources listed at the end of this statement.

RECOMMENDATIONS

Pediatricians and other health care providers who work with children and adolescents are recommended to:

1. Become knowledgeable about all aspects of adolescent alcohol, tobacco, and other substance use through participation in training-program curricula and/or continuing medical education that provide current best-practices training, including media-literacy training.
2. Obtain a complete family medical and social history at prenatal and health supervision visits to explore potential genetic and family influences regarding alcohol and other substance use.
3. Recognize risk factors for alcohol (as well as other drug) use among youth and be aware of coexisting mental health problems, such as depression, that may occur in this age group.
4. Regularly screen for current alcohol (as well as other drug) use by adolescents and young adults by using nonjudgmental, validated screening methods and appropriate confidentiality assurances.

5. Assess patients whose screening results are positive for alcohol use to determine the appropriate level of intervention.
6. Use brief intervention techniques in the clinical setting and be familiar with motivational interviewing techniques to work with patients who use alcohol but do not meet criteria for immediate referral. Offer referral to treatment when indicated.
7. Discuss the hazards of alcohol and other substance use with patients as part of anticipatory guidance and patient/parent education at health supervision visits as well as when relevant at acute-problem visits. Anticipatory guidance aligned with key school calendar events, such as proms and graduation, may be especially meaningful.
8. Strongly advise against the use of alcohol, tobacco, and other illicit drugs by youth.
9. Encourage parents to be good role models for healthy life choices and never allow underaged drinking at their home or other property. Empower parents with the realization that their involvement with their adolescents is a powerful deterrent of substance abuse.
10. Be familiar with local resources to which various pediatric-aged patients with alcohol use disorders, their parents, and other family members can be referred for developmentally appropriate treatment.
11. Support adolescents with substance use disorders throughout and after their treatment.
12. Serve as a resource and support for school and other community-based alcohol use prevention programs.
13. Support advocacy efforts to promote appropriate media modeling of alcohol consumption and consequences, including print media, television, film, and the Internet.
14. Support advocacy efforts to promote legislation that reduces alcohol-related morbidity and mortality, such as graduated-driver licensing; treatment parity from third-party payers; legal ramifications for parent sponsorship of adolescent drinking; increased alcohol excise taxes; and other prevention and treatment policies recommended in the Surgeon General's call to action.[48]
15. Support continuation of the age of 21 as the minimum legal drinking age, and support enforcement that decreases access to alcohol for minors.
16. Support further research into prevention, evidence-based screening and identification, brief intervention, and management and treatment of alcohol and other substance use by adolescents.

abstract

FREE

A variety of triggers can induce common pediatric allergic diseases which include asthma, allergic rhinitis, atopic dermatitis, food allergy, and anaphylaxis. Allergy testing serves to confirm an allergic trigger suspected on the basis of history. Tests for allergen-specific immunoglobulin E (IgE) are performed by in vitro assays or skin tests. The tests are excellent for identifying a sensitized state in which allergen-specific IgE is present, and may identify triggers to be eliminated and help guide immunotherapy treatment. However, a positive test result does not always equate with clinical allergy. Newer enzymatic assays based on anti-IgE antibodies have supplanted the radioallergosorbent test (RAST). This clinical report focuses on allergen-specific IgE testing, emphasizing that the medical history and knowledge of disease characteristics are crucial for rational test selection and interpretation. *Pediatrics* 2012;129:193–197

INTRODUCTION

Allergic diseases (allergic rhinitis [hay fever], asthma, atopic dermatitis, and allergic or anaphylactic reactions to foods, drugs, insect venom, or other allergens) often warrant identification of specific allergic triggers for treatment. Most allergic responses are mediated by immunoglobulin E (IgE) antibodies specific for the trigger allergen, which can be detected with in vitro tests or skin testing. This clinical report focuses on using in vitro allergen-specific IgE (sIgE) testing, which is widely available to pediatricians. A full description of the use of tests for diagnosis and management of allergic disease is beyond the scope of this report, but is described in recent guidelines and practice parameters.[1–9]

TESTS AVAILABLE FOR DETECTING sIgE

A number of enzymatic assays that are based on anti-IgE antibodies have supplanted the radioallergosorbent test.[10] Commercial laboratories that are federally licensed under the Clinical Laboratory Improvement Act of 1988 often use automated systems capable of detecting and quantifying sIgE. Laboratory reports may indicate a number of readouts (eg, classes, counts, or units), but quantification of results in units reflecting concentrations of sIgE is becoming more common (eg, kU_A/L). Although the 3 commercial detection systems approved by the Food and Drug Administration have excellent performance characteristics (analytical sensitivity, 0.1 kU_A/L), the

individual systems appear to detect different populations of IgE antibody or do not measure IgE antibodies with comparable efficiencies. Thus, a result for an allergen in 1 of the 3 test systems may not be equivalent to the same allergen tested in a different system.

The skin prick test (SPT), typically used by allergy specialists, is another means of detecting sIgE antibodies.[11] A number of devices are available for introducing allergen into the surface of the skin with minimal discomfort; a resulting wheal-and-flare response can be measured in 10 to 20 minutes. Saline and histamine controls are placed for comparison. Intradermal skin testing is performed in special circumstances when increased sensitivity is required (eg, after negative SPT for vaccines, venom, penicillin, and some inhalant allergens, such as *Alternaria* organisms and perhaps other outdoor molds).

Both serum sIgE tests and SPT are sensitive and have similar diagnostic properties.[11,12] Advantages of the SPT include immediate results visible to the patient/family and low cost compared with serum sIgE tests. Disadvantages include the need to withhold medications with antihistamine properties and having rash-free skin available for testing. Advantages of the serologic tests include availability and lack of interference from antihistamines or extensive dermatitis. Disadvantages include the need to obtain blood samples, delayed results, and cost. Some discrepancies exist, however; one test or the other may be more sensitive to detect specific allergens, probably because different proteins or IgE binding sites are represented.[2,3,7,9,11,13]

TEST SELECTION AND INTERPRETATION

Tests might be selected to identify triggers from a number of potential common allergens, for confirming a specific trigger when there is suspicion of one, or in less common circumstances, screening for atopy. A positive serum sIgE or skin test denotes a sensitized state. However, detection of sensitization to an allergen is not equivalent to a clinical diagnosis. In fact, many children with positive tests have no clinical illness when exposed to the allergen.[2,3,7,9,11,13] This limitation highlights the need for the clinician to use a detailed medical history and have knowledge of the features of the specific illness when selecting and interpreting tests. For example, there is no need to test for an allergen that is clearly tolerated (eg, egg in a child who eats egg without symptoms) or when exposure is not relevant (eg, testing a pollen to which the child is not geographically exposed). Knowledge of local aerobiology is, therefore, essential. Testing large panels of allergens without consideration of the history, geographic relevance, and disease characteristics may result in many clinically irrelevant positive results, which, if overinterpreted, may lead to costly and socially, emotionally, and/or nutritionally detrimental actions of unnecessary allergen avoidance. Similarly, caution is advised when testing is negative despite a convincing history. Testing for sIgE would also generally not be useful when the disorder has no pathophysiological basis for a relationship to sIgE (eg, behavioral disorders; allergic disorders not related to sIgE, such as allergic contact dermatitis).

Few studies have correlated clinical outcomes to test results.[2,3,4,11] Studies have generally supported the notion that increasingly strong tests correlate with increasing likelihood of clinical reactivity.[2,3,11] Patients should not be told they are allergic based solely on either a skin test or the identification of sIgE. The test characteristics underscore the need to select and interpret tests with consideration of the medical history, which increases diagnostic value by applying previous probability.[4]

A physician interested in screening for atopy (eg, distinguishing recurrent viral infections from allergic rhinitis) might select a small panel of common triggers. Another means to screen for atopy is to use a multiallergen test that contains several common allergens in one test (eg, one test that includes several perennial allergens, such as dust mite, dog dander, and mold). Availability and composition of these tests varies by manufacturer. A positive result will not identify IgE to a specific antigen but can, at less cost than performing many individual tests, identify a child whose symptoms may relate to exposure to a specific allergen and warrant further specific testing or referral. The multiallergen test had excellent predictive value for identifying atopic children compared with SPTs and an allergist's diagnosis.[14,15]

ISSUES SPECIFIC TO RESPIRATORY ALLERGY[1,6,11]

The disorders that respiratory allergy comprises are allergic asthma and seasonal or perennial allergic rhinitis. National asthma guidelines[1] suggest that patients with persistent asthma be evaluated for the role of allergens as contributing factors, with an emphasis on testing for perennial indoor allergens (eg, dust mite, animal dander, cockroach, mold) that might otherwise not be identified as contributing to disease and also suggest testing seasonal or perennial allergens for selected patients with any level of asthma severity as a basis for education about the role of allergens for avoidance and for immunotherapy.

The clinician may be interested in identifying specific indoor (eg, dust mite, animal dander, molds, mice, and cockroach) or outdoor (eg, pollens, molds) triggers. Rational selection and interpretation of specific tests

requires consideration of the environmental exposures (housing, pets, and geographic floristic patterns), medical history (nature of symptoms, timing in relation to exposures), and disease characteristics (eg, pollen allergy is uncommon in infancy; patients are unlikely to have acute symptoms from dust mite exposure; food allergens do not typically cause chronic respiratory disease). Provocation tests can confirm environmental allergy but are not often undertaken for clinical purposes.

ISSUES SPECIFIC TO FOOD ALLERGY[2,3,4,11]

Food allergy may be suspected when specific symptoms (eg, urticaria, angioedema, cough, wheeze, vomit, and anaphylaxis) occur minutes to hours after the ingestion of a food, and in children diagnosed with certain disorders, such as moderate to severe atopic dermatitis, eosinophilic esophagitis, and other allergic gastrointestinal tract disorders. Testing for sIgE to foods might be considered to identify or confirm triggers, to assist in diagnosis of chronic disorders, or to monitor for allergy resolution. However, they are not considered diagnostic in and of themselves. SPT and serum sIgE provide similar sensitivity and specificity.[12] It is common to have positive test results for tolerated foods; therefore, indiscriminate testing (ie, panels that include foods that are already tolerated) is not advised. Additional means to assist in diagnosis include the medical history and results of medically supervised oral food challenges. Elimination diets, if initiated, should not be maintained in the absence of a convincing previous history of a reaction or a medically supervised oral food challenge. A comprehensive description of the diagnostic and management process is reviewed in recent guidelines.[2–4] Key observations include:

- Screening panels of food allergens without previous consideration of the history is not recommended, because sensitization without clinical allergy is common. For example, ~8% have positive test results for peanut, but ~1% are clinically allergic.[16]
- A negative SPT or serum sIgE test result does not entirely exclude a diagnosis of a food allergy. One test may be positive when the other is negative. SPT using fresh food extracts may increase sensitivity, especially for fruits. Caution is needed when tests are negative when a specific food allergy history is convincing; a medically supervised oral food challenge may be needed.
- Cross-reactivity among proteins may result in a much higher degree of positive sIgE test results among related foods than clinical reactions (eg, >50% of patients with peanut allergy test positive to other legumes, but <5% have clinical symptoms of allergy from ingestion of legumes). Cross-reactivity among homologous proteins of aeroallergens and food allergens may result in positive tests to foods, often without clinical allergy (eg, birch pollen with hazelnut, peanut, soy; grass pollen with wheat, peanut; dust mite with shrimp).
- Strong positive test results correlate with increasing probability of clinical allergy, and particularly high values may indicate a high degree (>95%) of likely allergy; however, there are few studies correlating outcomes to test results, and results vary by age, disease, and other factors.
- sIgE serum concentration or SPT wheal size do not accurately predict the severity of allergic reactions, but do reflect the likelihood of an allergic reaction of variable intensity.
- Testing for total IgE does not identify specific allergies. Atopic individuals often have elevated total IgE, but there is no current evidence to support the interpretation of sIgE in relation to total IgE.
- Tests measuring immunoglobulin G (IgG) antibodies for diagnosis are not recommended.
- Intradermal tests are not recommended, because they are too sensitive and carry risk of a severe allergic reaction.
- Food protein-induced enterocolitis and proctocolitis (eg, cell-mediated food allergic disorders) are not associated with positive IgE tests.

ISSUES SPECIFIC TO OTHER ALLERGIES (DRUG ALLERGY, INSECT VENOM, VACCINES, LATEX)[7-9]

The general caveats regarding sensitization and clinical allergy described previously also apply to allergy tests for substances that may cause acute allergic reactions or anaphylaxis, such as medications, insect venom, vaccines, and latex. The medical history is essential in decision making regarding testing and interpretation, including understanding whether the symptoms are likely to be IgE mediated.

Tests for drug allergy (eg, acute allergic reactions) are generally not standardized, and the sensitivity of serum tests appears poor.[8] IgE tests are not relevant for many drug reactions (maculopapular rashes, Stevens-Johnson syndrome). SPT and intradermal tests for penicillin allergy using recently available reagents have potential utility for IgE-mediated allergies.[8]

Allergy testing for venom allergy should be considered when symptoms of anaphylaxis occur after a sting. When anaphylactic allergy to venom is confirmed by skin testing, immunotherapy

is indicated and highly effective.[7,9,11] Isolated, localized swelling at a sting site does not identify a risk of anaphylaxis, and testing is not warranted. Generalized urticaria without other symptoms of anaphylaxis in children 16 years and younger usually does not warrant testing, because more severe reactions appear to be unlikely; however, systemic anaphylaxis in any age group and generalized urticaria in adolescents older than 16 years warrant testing. SPT and intradermal testing are considered the standard means of diagnosis, although serum IgE tests for venom or venom components may be performed when skin tests are negative and the history is suggestive.

SPT and intradermal tests can be performed for vaccines suspected of triggering allergic reactions, although care is needed to choose the proper dilution to prevent irritant reactions.[7,17,18] Skin tests are not available for latex; serum tests are available, but the diagnostic utility is not well characterized.[7,11]

TESTS UNDER DEVELOPMENT AND UNPROVEN TESTS

Tests are under development that detect IgE binding to specific proteins in foods (component-resolved diagnosis), with a potential to more accurately identify people likely to react or with more severe allergies; however, further validation of these tests is needed.[2,3,11] Additional tests requiring more validation include basophil activation and atopy patch tests with foods.[2,3,11] These tests are currently primarily research tools, although specific uses have been identified.[8,11]

A number of tests have no evidence to support their use and are not recommended, including: lymphocyte stimulation, facial thermography, gastric juice analysis, hair analysis, applied kinesiology, provocation-neutralization, allergen-specific IgG/IgG4, cytotoxic assay, electrodermal test (VEGA), and mediator release assay.[2,3,11]

SUMMARY

1. Treatment decisions for infants and children with allergy should be made on the basis of history and, when appropriate, identified through directed serum sIgE or SPT testing. Newer in vitro sIgE tests have supplanted radioallergosorbent tests.
2. Allergy tests for sIgE must be selected and interpreted in the context of a clinical presentation; test relevance may vary according to the patient's age, allergen exposure, and performance characteristics of the test.
3. Positive sIgE test results indicate sensitization, but are not equivalent to clinical allergy. Large panels of indiscriminately performed screening tests may, therefore, provide misleading information.
4. Tests for sIgE may be influenced by cross-reactive proteins that may or may not have clinical relevance to disease.
5. Increasingly higher levels of sIgE (higher concentrations on serum tests or SPT wheal size) generally correlate with an increased risk of clinical allergy.
6. sIgE test results typically do not reflect the severity of allergies.
7. Use of a multiallergen serum test can be helpful for screening for atopic disease if there is a clinical suspicion. If positive, allergen-specific testing may be considered.
8. Tests for allergen-specific IgG antibodies are not helpful for diagnosing allergies.
9. Because test limitations often warrant additional evaluation to confirm the role of specific allergens, consultation with a board-certified allergist-immunologist should be considered.

AMERICAN ACADEMY OF PEDIATRICS

Committee on Injury and Poison Prevention

All-Terrain Vehicle Injury Prevention: Two-, Three-, and Four-Wheeled Unlicensed Motor Vehicles

ABSTRACT. Since 1987, the American Academy of Pediatrics (AAP) has had a policy about the use of motorized cycles and all-terrain vehicles (ATVs) by children. The purpose of this policy statement is to update and strengthen previous policy. This statement describes the various kinds of motorized cycles and ATVs and outlines the epidemiologic characteristics of deaths and injuries related to their use by children in light of the 1987 consent decrees entered into by the US Consumer Product Safety Commission and the manufacturers of ATVs. Recommendations are made for public, patient, and parent education by pediatricians; equipment modifications; the use of safety equipment; and the development and improvement of safer off-road trails and responsive emergency medical systems. In addition, the AAP strengthens its recommendation for passage of legislation in all states prohibiting the use of 2- and 4-wheeled off-road vehicles by children younger than 16 years, as well as a ban on the sale of new and used 3-wheeled ATVs, with a recall of all used 3-wheeled ATVs.

ABBREVIATIONS. CPSC, US Consumer Product Safety Commission; ATV, all-terrain vehicle; AAP, American Academy of Pediatrics.

TWO-WHEELED VEHICLES

Miniature motorcycles intended for off-road use by children and adolescents have enjoyed wide popularity since the 1960s. However, manufacture of these vehicles is not regulated by federal motor vehicle safety standards. Neither the rider nor the vehicle is required to be licensed. Some of these cycles are small enough to be operated by children as young as 4 years, and many have been sold for use by school-aged children.[1]

Minibikes, the smallest and most primitive of the 2-wheelers, are motorized bicycle-style frames that weigh <45 kg and are powered by engines operating at <4 horsepower. The more sophisticated and higher-powered *minicycles* are constructed with suspension systems and transmissions that resemble miniature motorcycles. *Trailbikes* or *trailcycles* are larger than minicycles and have power and design characteristics that make them suitable for rough terrain. They are generally only approved for off-road use. *Mopeds* are bicycles with small, unenclosed assist motors and top speeds of about 30 mph. They are intended for street use but, in many states, neither the mopeds nor their drivers must be licensed.[2] Two-wheeled vehicles generally have a short and relatively unstable wheelbase, small tires, slow acceleration, borderline brakes, and poor visibility in traffic (both of the cycle and by the cycle operator).[2,3] *Motorcycles* are also 2-wheeled cycles, but require licenses in all states; these vehicles are not specifically discussed in this statement.

About 40 000 injuries related to 2-wheeled motorized off-road cycles were treated in emergency departments each year, 1994 through 1996.[4] Of the injuries, 26% were sustained by children younger than 15 years. From 1990 through the first quarter of 1995, the US Consumer Product Safety Commission (CPSC) collected at least 50 reports of deaths related to minibike and trailcycle use. All but 1 of the victims were male, and 42% were 16 years of age or younger.[5]

Injury typically results from loss of control of the cycle after striking rocks, bumps, or holes, or from illegal on-road use. Mopeds are more often involved in collisions with other vehicles, presumably because they are legally used on-road, and frequently in urban areas.[2] Shoulder, knee, and leg injuries account for more than one third of emergency department visits for moped-related injuries. Head injuries account for about half of the deaths.[5] Laryngotracheal trauma may result from driving across open fields into poorly visible wire fences. Thermal burns occur when engines are not enclosed, which is usual for mopeds.[6] Deaths are more likely to be associated with racing or jumping.[5]

THREE- AND FOUR-WHEELED VEHICLES

All-terrain vehicles (ATVs) are motorized cycles, with 3 or 4 balloon-style tires, designed for off-road use on a variety of terrains. Although ATVs give the appearance of stability, the 3-wheeled design is especially unstable on hard surfaces. The ATV stability is further compromised by a high center of gravity, a poor or absent suspension system, and no rear-wheel differential. The danger is magnified because these vehicles can attain substantial speeds (30–50 mph).[7]

Most injuries associated with ATVs occur when the driver loses control, the vehicle rolls over, the driver or passenger is thrown off, or there is a collision with a fixed object.[8] Studies in Alaska and Missouri have identified a number of risk factors for injury, including rider inexperience, intoxication with alcohol, excessive speed, and lack of helmet use.[9,10] The recognition of the significant hazards associated with ATV use led to a federal investigation

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

PEDIATRICS (ISSN 0031 4005).

and the acceptance of consent decrees by the ATV manufacturers in early 1988.[11] Under the decrees, the industry agreed to cease production and sale of new 3-wheeled ATVs (but not to recall old ones), to implement a rider-safety training program nationally, and to develop a voluntary standard to make ATVs safer. Warnings and age recommendations were included on the vehicle and in advertising. ATVs with engines >70 mL could be used only by children 12 years and older; "adult-sized" engines (those >90 mL) were not to be used by children or adolescents under 16 years.[11] Although the decrees did not prohibit the sale of the ATVs with engines <70 mL, which previously had been promoted for children younger than 12 years, none have been manufactured since 1986. After acceptance of the decrees, problems have occurred with some dealers not communicating the age restrictions to consumers, although pressure and enforcement by the CPSC have improved the situation. Nevertheless, children under 12 years still represent 15% of the deaths related to ATVs.[12–14] It is probable that the most effective outcome of the 1988 consent decrees was the attendant publicity that led up to the decrees and the educational campaigns that occurred after them. The consent decrees expired in 1998. At that time, participating manufacturers agreed to an ATV Action Plan in which they agreed not to market or sell 3-wheeled ATVs, not market or sell adult-size ATVs to or for use by children younger than 16, promote training, and conduct safety education campaigns.[15]

The approximately 2.4 million ATVs still in use are associated with significant morbidity and mortality. Almost 2800 deaths have been attributed to ATVs (about 200 to 300 annually) since 1985.[14] The risk of death, approximately .8 to 1.0 per 10 000 ATVs, has remained fairly steady since 1987. Annual emergency department visits for treatment of ATV-related injuries reached a peak of 108 000 in 1986 and declined after that to the present level of about 54 500.[14] Children younger than 16 years account for 47% of the injuries in 1997 and >36% of the deaths since 1985.[15] Head injuries account for most of the deaths, which usually are instantaneous.[12] Serious nonfatal injuries include head and spinal trauma, abdominal injuries, and multiple trauma.[4] Abrasions, lacerations, and clavicle and extremity fractures are common and less serious.[4,13] Some studies have suggested that children suffer more severe injuries. The severity of injury is the same for 3- and 4-wheeled ATVs.[10,13,16] Currently, 4-wheeled vehicles account for 75% of the injuries, largely because of changes in the manufacture and sales of 3-wheeled ATVs after the 1988 consent decree, although many 3-wheeled ATVs remain in use. More injuries occur when ATVs are used for recreation than when they are used for nonrecreational purposes, for example, as farm vehicles.[4]

It is clear that deaths and injuries began to decline in 1986, possibly as an effect of the publicity before the consent decrees on the driving behavior of ATV users. A decline in sales, as well as diminished use by children, occurred after the decrees, but well before the ban on 3-wheelers and design changes to make "safer" vehicles could have had a great effect.

RECOMMENDATIONS

The American Academy of Pediatrics (AAP) now updates its earlier recommendations[10,17] to decrease death and injury related to the use of all 2-, 3-, and 4-wheeled ATVs:

1. Education, public and individual patient and parent, about the hazards of all ATVs should continue. (Besides benefiting the riders, it may increase public demand for greater regulation; eg, helmet laws and limitation on use by children.)
2. During anticipatory guidance, families should be asked, either by direct questioning or intake survey, about the kinds of recreational activities in which they engage. Just as those who have a swimming pool merit special counseling, so do families who engage in off-road vehicle use. The following points should be emphasized:
   - Off-road vehicles are particularly dangerous for children younger than 16 years who may have immature judgment and motor skills.[10] Children who are not licensed to drive a car should not be allowed to operate off-road vehicles.
   - Injuries frequently occur to passengers, therefore riding double should not be permitted.
   - All riders should wear helmets, eye protection, and protective reflective clothing. Appropriate helmets are those designed for motorcycle (not bicycle) use, and should include safety visors/face shields for eye protection.
   - Parents should never permit the street use of off-road vehicles, and nighttime riding should not be allowed.
   - Flags, reflectors, and lights should be used to make vehicles more visible.
   - Drivers of recreational vehicles should not drive after drinking alcohol. Parents should set an example for their children in this regard.
   - Young drivers should be discouraged from on-road riding of any 2-wheeled motorized cycle, even when they are able to be licensed to do so, because they are inherently more dangerous than passenger cars.
3. Although the consent decrees required some equipment modifications to make ATVs safer, further changes have been suggested. They include the following:
   - Install seat belts on 4-wheeled ATVs and require that the vehicles also have a roll bar to prevent the driver from being crushed by the weight of the vehicle in the event of a rollover.
   - Headlights that automatically turn on when the engine is started should be routinely installed on all ATVs to improve visibility by other vehicles.
   - Speed governors (devices that limit maximum speed) should be installed on ATVs used by inexperienced operators.
   - Efforts should be made to design ATVs so that they cannot carry passengers.
   - Engine covers on small 2-wheeled vehicles, such as mopeds and minibikes, could reduce

burn injuries resulting from body contact with the engine and exhaust system. A sturdy leg guard could avoid injuries from sideswiping solid objects or being pinned to the ground.

All of these proposed modifications should be thoroughly evaluated before use and monitored after introduction.

4. Laws should be passed in all states requiring motorcycle-style helmets for off-road use as well as for on-road use. Motorcycle helmet laws have been proven to increase helmet use, and helmet use has been proven to reduce death and serious head injuries.[16,18]
5. Many injuries are caused by various disruptions in the driving surface such as, bumps and holes. Developing and maintaining trails for the use of off-road vehicles may help reduce injury rates.
6. Prehospital care networks and emergency services should be improved in rural areas, which may minimize the effects of injuries and reduce deaths.[11]
7. The AAP recommends a ban on the sale of all 3-wheeled ATVs, new and used, and a recall with a refund for present owners of the 3-wheeled models.
8. Laws should prohibit the use of ATVs, on- or off-road, by children and adolescents younger than 16 years. An automobile driver's license, and preferably some additional certification in ATV use, should be required to operate an ATV. The safe use of ATVs requires the same or greater skill, judgment, and experience as needed to operate an automobile.
9. ATVs should not be used after sunset or before sunrise, and carrying passengers should not be allowed. These provisions should be included in legislation.
10. Pediatricians should advocate for the passage of the AAP's model bill[19] that:
    - prohibits the use of ATVs, on- or off-road, by children and adolescents younger than 16 years;
    - requires an automobile drivers' license, and preferably some additional certification in ATV use;
    - prohibits the use of ATVs on public streets and highways;
    - prohibits passengers from riding on ATVs;
    - prohibits operating an ATV under the influence of alcohol; and
    - prohibits the use of ATVs between sundown and sunrise.

Auditory Integration Training and Facilitated Communication for Autism

ABSTRACT. This statement reviews the basis for two new therapies for autism—auditory integration training and facilitative communication. Both therapies seek to improve communication skills. Currently available information does not support the claims of proponents that these treatments are efficacious. Their use does not appear warranted at this time, except within research protocols.

ABBREVIATIONS. AIT, auditory integration training; FC, facilitated communication.

Auditory integration training (AIT) is a treatment for autism that was originally developed by Guy Berard in France in the 1960s and introduced into the United States in 1991. It has since become increasingly popular with parents of autistic children. The publication of a book[1] in 1991 that described the use of AIT in "curing" a child with autism after a 10-hour intervention program generated extensive interest, particularly among parents of autistic children who were frustrated by the lack of effective traditional medical therapy for autism.[2] AIT has been advocated for children and adults with a wide range of disorders other than autism, including learning disabilities, depression, migraine headaches, and epilepsy. It is important that pediatricians know about this intervention to respond to parents who may ask them for an opinion about its usefulness.[a]

The first step in AIT is to obtain a detailed audiogram, which determines auditory thresholds to a larger series of frequencies (octave and interactive frequencies) than are typically used for measuring hearing ability. An auditory training practitioner then examines the audiogram looking for evidence of hyperacusis,[3] which then is examined in relation to the clinical history of sound sensitivities and behavioral profile. If an individual is determined to be an appropriate candidate for AIT, the treatment program consists of 20 half-hour sessions during a 10- to 12-day period, with two sessions conducted daily. Treatment sessions consist of listening to music that has been computer-modified to remove frequencies to which the individual demonstrates hypersensitivities, and to reduce the predictability of the auditory patterns. A special device (an Audiokinetron) is used to modify the music for the treatment sessions. Audiograms are repeated midway and at the end of the training sessions, to document "progress" and to determine whether additional sessions are needed. Disciples of another proponent of AIT, Tomatis, generally recommend repeating the 20-session series of training sessions during a 4- to 12-month period.[4]

The limitations of the premises on which AIT is based were reviewed by Gravel.[3] She notes that current objective electrophysiologic measures such as auditory-evoked brainstem responses fail to demonstrate differences in hearing sensitivity between autistic and nonautistic children. Moreover, autistic children are extremely difficult to test using behavioral audiometry, because their responses are frequently inconsistent, often showing small (5-decibel) differences between frequencies generally considered within normal clinical variation. Although AIT practitioners declare the technique to be safe, there is some information about both the quality control characteristics of the equipment used and potentially unsafe sound levels produced by it.[5]

AIT practitioners report that individuals who have received AIT demonstrate many benefits: improved attention, improved auditory processing, decreased irritability, reduced lethargy, and improved expressive language and auditory comprehension. Unfortunately, little scientific documentation exists to support these assertions. Rimland and Edelson[6] recently conducted a pilot study of AIT in 17 autistic children aged 4 to 21 years. Eight children underwent AIT for 10 days and 9 children listened to unprocessed music under identical conditions, with evaluators and parents blinded to the treatment received. Although random assignment was not used, and the comparability of the two groups was not described, the authors reported decreases in repetitive behaviors, irritability, and hyperactivity, and improved attention noted by parents in the study group. In addition, Bettison[7] studied 80 children randomized to two groups, one received AIT and the other listened to unmodified music. Twelve months later both groups demonstrated significant improvements in behavior and verbal and performance IQ, suggesting that some aspect of listening to music may have some effect on features of autism. Further studies are underway to better document any effects of this controversial treatment.

Facilitated communication (FC) is a method of providing assistance to a nonverbal person in typing out words using a typewriter, computer keyboard, or

[a] Although there are several AIT methods, this statement addresses that which Berard introduced, for it is the only one that has been studied scientifically.

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

PEDIATRICS (ISSN 0031 4005).

other communication device. FC involves supporting the individual's hand to make it easier for him or her to indicate the letters that are chosen sequentially to develop the communicative statement. This manual prompting, by a trained facilitator, is claimed to provide expressive language abilities to a wide range of individuals, including those with severe intellectual disabilities or autism. Originally applied to assist people with physical disabilities by Jacobson et al,[8] FC was brought to the United States by Biklen in 1989.[9] According to Biklen, this procedure often produces unexpected literacy and reveals normal or even superior intelligence and/or communicative ability that was "trapped in a wordless person."[9,10] FC is at the center of a growing controversy, because several scientific studies have suggested that facilitators may unintentionally influence the communication, perhaps to the extent of actually selecting the words themselves.[11–14] Yet proponents point to a series of nonexperimental reports that promote the use of FC and suggest that it is unethical to use a rigorous scientific method to study its efficacy.[15]

As reviewed by Jacobson et al,[8] FC has been the subject of many controlled studies with consistently negative findings, indicating that the technique is neither reliably replicable nor valid. Methods that have been used include single and double-blind procedures, repeated measures and self-controls, or passing messages about which the facilitator would have no prior information.

For example, Smith et al[16] studied 10 individuals with autism specifically to investigate the effects of facilitator influence and level of assistance on the results of FC. Each subject had six sessions, two with no help, two with partial assistance, and two with full assistance. Results showed that there were no cases of correct responses from the subject unless the facilitator knew the correct response. In addition, numerous responses were typed by the subjects to stimuli that were shown only to the facilitator, and not the subject. Similar results have been found by Regal et al[17] and Eberlin et al.[18]

A recently published study by Cardinal et al[19] attempted to support the ability of experienced FC users to transmit single words to a naive facilitator. They found that this only occurred with prolonged practice of the experimental task, and there were many inconsistencies in the responses, even after prolonged practice. They suggested that further research is needed, especially to develop methodologies to clearly separate facilitator influence from user communication.

Despite this evidence, some states have promoted and supported the use of FC for children and adults with autism and other disabilities, and even issued guidelines to promote technology transfer of FC. There has been widespread national media attention to this alternative therapy, and many parents are interested in exploring this option for their children; the attraction of unlocking the child's "hidden abilities" is a strong incentive for its use.

One complication of the use of FC has been the allegation of abuse, particularly sexual abuse, that has been obtained from individuals through the use of FC against third persons. This has generated adverse publicity and caused severely negative consequences for families who may be unsure of the validity of the allegations. Because of legal mandates regarding reports of child abuse, this becomes a critical issue for teachers and pediatricians alike, who may find the credibility of the report highly questionable but are obligated to fulfill their legal responsibilities. Margolin[20] notes that although more than 50 such allegations have resulted in legal proceedings, most have terminated before trial. The ethical dilemmas posed by FC for practitioners have been reviewed by Jacobson et al.[8]
