Individually Tailored and Stepped-Care Interventions. Recent research has focused on the use of individually tailored materials. Tailored materials are those that are designed to address smoker-specific variables, such as support sources, recency of quitting, and concerns about quitting. Tailored materials can either be print materials, such as letters mailed to patients, or Web-based materials such as interactive Web sites.[238,242] Some applications of tailoring have been shown to be effective and to have broad reach.[241,245,255,256] The Panel also considered the use of stepped-care interventions (see Glossary) and concluded that there is not enough evidence to recommend a stepped-care approach as a basis for tailoring.[257,258] However, these approaches warrant future research.

Computerized Interventions. E-health or Internet interventions have the potential to be accessed by a large percentage of the smoking population, permit extensive tailoring of content to the tobacco user's needs or characteristics, and, due to low personnel costs, are likely to be inexpensive to deliver. Such interventions may be used as stand-alone or adjuvant treatments. These programs typically collect information from the tobacco user and then use algorithms to tailor feedback or recommendations. They also typically permit the user to select from various features, including extensive information on quitting, tobacco dependence, and related topics. Current applications permit multiple iterations of feedback, development and monitoring of a quit plan, and proactive e-mail prompts to users.[259,260] Optimal features of Web site resources have not yet been identified; some sites may be confusing and may not exploit the tailoring potential of this medium.[261] Clearly, more research is needed to identify their optimal structures, features, and contents.[262-265]

E-health tobacco interventions generally have yielded positive results. In a recent review of the use of these interventions with adult tobacco users, Walters et al. found that 7 of 15 studies with adults reported significantly improved outcomes over control conditions.[259] Hall et al. combined computerized individualized feedback designed to motivate smokers using principles of the Stages of Change model with six 30-minute sessions of counseling and the nicotine patch. This was compared with untailored self-help material. Significant improvement due to the more intensive treatment was found at 18-month followup.[266] Strecher et al. compared a multifaceted Web-based intervention (tailored cessation guide based on cognitive-behavioral principles, a medication adherence intervention, tailored e-mails, and a behavioral support person) in concert with the nicotine patch. This was contrasted with the patch alone. Favorable outcomes were obtained at 3 months postquit.[241] Similar positive effects also have been reported for a population study using computer-generated reports based on the Stages of Change model[267] and a Web site study offered in a worksite program.[268] A study with adolescents[269] reported positive results due to access to a complex intervention that comprised an interactive computer intervention, clinician advice, brief motivational interviewing, and telephonic booster sessions. The control condition was information about eating more fruits and vegetables. Null results with computerized or computer-tailored interventions also have been obtained (see, e.g., Velicer et al.[270] and Aveyard et al.[271]). Moreover, in many of the studies yielding positive results, the Web-based intervention is just one

element of a complex intervention, or is considerably more intense than the comparison intervention. Given the potential reach and low costs of such interventions, however, they remain a highly promising delivery system for tobacco dependence.

Future Research

The following topics regarding formats require additional research:

- Which combinations of formats are most effective
- Relative effectiveness of different types of self-help interventions, including computer-based interventions
- Effectiveness of tailoring
- Effectiveness of fax-to-quit programs and other programs designed to increase quitline use
- Effective features of Web-based interventions
- Effect of computer-delivered interventions as a format versus the effect of the content of the intervention
- Optimal methods to decrease barriers and increase the appeal and use of effective counseling treatments

Followup Assessment and Procedures

Recommendation: All patients who receive a tobacco dependence intervention should be assessed for abstinence at the completion of treatment and during subsequent contacts. (1) Abstinent patients should have their quitting success acknowledged, and the clinician should offer to assist the patient with problems associated with quitting (see Chapter 3C, For the Patient Who Has Recently Quit). (2) Patients who have relapsed should be assessed to determine whether they are willing to make another quit attempt. (Strength of Evidence = C)

If the patient is willing to make another quit attempt, provide or arrange additional treatment (see Chapter 3A, For the Patient Willing To Quit).

If the patient is not willing to try to quit, provide or arrange an intervention designed to increase future quit attempts (see Chapter 3B, For the Patient Unwilling To Quit).

All patients should be assessed with respect to their smoking status during followup clinical contacts. In particular, assessments within the first week after quitting should be encouraged.[272,273] Abstinent patients should receive reinforcement for their decision to quit, be congratulated on their success at quitting, and be encouraged to remain abstinent (see Chapter 3C, Strategy C1). The existing evidence does not show that these steps will prevent relapse, but continued involvement on the part of the clinician may increase the likelihood that the patient will consult the clinician in later quit attempts should they be needed. Clinicians also should inquire about and offer to help the patient with potential problems related to quitting (see Chapter 3C, Strategy C2), such as significant weight gain or residual withdrawal symptoms.

Patients who have relapsed should again be assessed for their willingness to quit. Patients who currently are motivated to make another quit attempt should be encouraged to use a tobacco dependence intervention (see Chapter 3A, For the Patient Willing To Quit). Clinicians may wish to increase the intensity of psychosocial treatment at this time or refer the patient to a tobacco dependence specialist/program for a more intensive treatment if the patient is willing. In addition, medication should be offered again to the patient, if appropriate. If the previous quit attempt included medication, the clinician should review whether the patient used the medication in an effective manner and determine whether the medication was helpful. Based on this assessment, the clinician should recommend retreatment with the same medication, another medication, or a combination of medications (see Tables 6.26–6.28). Patients who have relapsed and are unwilling to quit at the current time should receive a brief intervention designed to increase future quit attempts (see Chapter 3B).

Future Research

The following topics regarding followup assessment and treatments require additional research:

- Optimal timing and types of relapse prevention interventions
- Effectiveness of various formats for relapse prevention treatments (e.g., effectiveness of telephone contacts in reducing the likelihood of relapse after a minimal intervention)

3. Treatment Elements

Types of Counseling and Behavioral Therapies

Recommendation: Two types of counseling and behavioral therapies result in higher abstinence rates: (1) providing smokers with practical counseling (problemsolving skills/skills training), and (2) providing support and encouragement as part of treatment. These types of counseling elements should be included in smoking cessation interventions. (Strength of Evidence = B)

Sixty-four studies met selection criteria for meta-analyses in 2000 to examine the effectiveness of interventions using various types of counseling and behavioral therapies. The results, shown in Table 6.18, reveal that four specific types of counseling and behavioral therapy categories yield statistically significant increases in abstinence rates relative to no-contact (i.e., untreated control conditions). These categories are: (1) providing practical counseling such as problemsolving/skills training/stress management; (2) providing support during a smoker's direct contact with a clinician (intratreatment social support); (3) intervening to increase social support in the smoker's environment (extratreatment social support); and (4) using aversive smoking procedures (rapid smoking, rapid puffing, other smoking exposure). A separate analysis was conducted eliminating studies that included the use of U.S. Food and Drug Administration (FDA)-approved medications. The results of this analysis were substantially similar to the main analysis.

Table 6.18. Meta-analysis (2000): Effectiveness of and estimated abstinence rates for various types of counseling and behavioral therapies (n = 64 studies)[a]

Type of counseling and behavioral therapy	Number of arms	Estimated odds ratio (95% C.I.)	Estimated abstinence rate (95% C.I.)
No counseling/behavioral therapy	35	1.0	11.2
Relaxation/breathing	31	1.0 (0.7–1.3)	10.8 (7.9–13.8)
Contingency contracting	22	1.0 (0.7–1.4)	11.2 (7.8–14.6)
Weight/diet	19	1.0 (0.8–1.3)	11.2 (8.5–14.0)
Cigarette fading	25	1.1 (0.8–1.5)	11.8 (8.4–15.3)
Negative affect	8	1.2 (0.8–1.9)	13.6 (8.7–18.5)
Intratreatment social support	50	1.3 (1.1–1.6)	14.4 (12.3–16.5)
Extratreatment social support	19	1.5 (1.1–2.1)	16.2 (11.8–20.6)
Practical counseling (general problemsolving/skills training)	104	1.5 (1.3–1.8)	16.2 (14.0–18.5)
Other aversive smoking	19	1.7 (1.04–2.8)	17.7 (11.2–24.9)
Rapid smoking	19	2.0 (1.1–3.5)	19.9 (11.2–29.0)

[a] Go to *www.surgeongeneral.gov/tobacco/gdlnrefs.htm* for the articles used in this meta-analysis.

The 2008 Guideline Panel decided not to recommend extratreatment social support in the current Guideline update. This change was based on recent literature on extratreatment social support that does not show a strong effect for helping smokers identify and utilize support outside of the treatment relationship.[274-276] Aversive smoking was recommended in the 2000 Guideline. However, new studies that have been conducted since the 2000 Guideline, including a Cochrane Review, cast doubt on the effectiveness of aversive smoking.[277] Because of this and the side effects of this treatment, the Guideline Panel decided not to recommend the use of aversive smoking therapy in the 2008 update.

The strength of evidence for the 2008 Guideline update recommendations regarding practical counseling and intratreatment social support did not warrant an "A" rating for several reasons. First, the evidence reviewed indicated that tobacco use treatments rarely used a particular type of counsel-

ing or behavioral therapy in isolation. Second, various types of counseling and behavioral therapies tended to be correlated with other treatment characteristics. For instance, some types of counseling and behavioral therapies were more likely to be delivered using a greater number of sessions across longer time periods. Third, all of these types of counseling and behavioral therapies were compared with no-contact/control conditions. Therefore, the control conditions in this meta-analysis did not control for nonspecific or placebo effects of treatment. This further restricted the ability to attribute effectiveness to particular types of counseling and behavioral therapies *per se*. Fourth, the studies used in this analysis often tailored the types of counseling and behavioral therapies to the needs of specific populations being studied, thereby affecting the generalizability of the study results. Fifth, there was considerable heterogeneity within each type of counseling and behavioral therapy.

Tables 6.19 and 6.20 outline elements of practical counseling (problemsolving/skills training) and intratreatment social support, respectively. These tables are designed to help clinicians using these counseling and behavioral therapies. It must be noted, however, that these treatment labels are nonspecific and include heterogeneous treatment elements. The effectiveness of encouragement and support as part of treatment is consistent with the literature regarding the importance of providing a caring, empathic, and understanding context in making other health behavior changes.[278-280]

Table 6.19. Common elements of practical counseling (problemsolving/skills training)

Practical counseling (problemsolving/ skills training) treatment component	Examples
Recognize danger situations – Identify events, internal states, or activities that increase the risk of smoking or relapse.	• Negative affect and stress • Being around other tobacco users • Drinking alcohol • Experiencing urges • Smoking cues and availability of cigarettes
Develop coping skills – Identify and practice coping or problemsolving skills. Typically, these skills are intended to cope with danger situations.	• Learning to anticipate and avoid temptation and trigger situations • Learning cognitive strategies that will reduce negative moods • Accomplishing lifestyle changes that reduce stress, improve quality of life, and reduce exposure to smoking cues • Learning cognitive and behavioral activities to cope with smoking urges (e.g., distracting attention; changing routines)

Table 6.19. Common elements of practical counseling (problemsolving/skills training) (continued)

Practical counseling (problemsolving/ skills training) treatment component	Examples
Provide basic information – Provide basic information about smoking and successful quitting.	• The fact that any smoking (even a single puff) increases the likelihood of a full relapse • Withdrawal symptoms typically peak within 1–2 weeks after quitting but may persist for months. These symptoms include negative mood, urges to smoke, and difficulty concentrating. • The addictive nature of smoking

Table 6.20. Common elements of intratreatment supportive interventions

Supportive treatment component	Examples
Encourage the patient in the quit attempt.	• Note that effective tobacco dependence treatments are now available. • Note that one-half of all people who have ever smoked have now quit. • Communicate belief in patient's ability to quit.
Communicate caring and concern.	• Ask how patient feels about quitting. • Directly express concern and willingness to help as often as needed. • Ask about the patient's fears and ambivalence regarding quitting.
Encourage the patient to talk about the quitting process.	Ask about: • Reasons the patient wants to quit. • Concerns or worries about quitting. • Success the patient has achieved. • Difficulties encountered while quitting.

Acupuncture. A separate meta-analysis was conducted in 2000 to evaluate the effectiveness of acupuncture. Evidence, as shown in Table 6.21, did not support the effectiveness of acupuncture as a tobacco use treatment. The acupuncture meta-analysis comparing "active" acupuncture with "control" acupuncture (see Glossary) revealed no difference in effectiveness between the two types of procedures. These results suggest that any effect of acupuncture might be produced by other factors such as positive expectations about the procedure. These results are consistent with the more recent Cochrane analysis.[281] Moreover, the Guideline Panel did not identify scientific literature to support the effectiveness of the more recent electrostimulation or laser acupuncture treatments for tobacco use.

Hypnosis. The 1996 Guideline did not conduct a separate meta-analysis on hypnosis because few studies met inclusion criteria, and those that did used very heterogeneous hypnotic procedures. There was no common or standard intervention technique to analyze. Literature screening for the 2000 Guideline revealed no new published studies on the treatment of tobacco dependence by hypnosis that met the inclusion criteria; therefore, this topic was not reexamined. Moreover, an independent review of nine hypnotherapy trials by the Cochrane Group found insufficient evidence to support hypnosis as a treatment for smoking cessation.[282] In contrast to the Cochrane Review and other reviews, a small recent study reported preliminary positive results with hypnotherapy.[283]

Other Interventions. The number of studies was insufficient to accurately appraise the effectiveness of other types of counseling and behavioral therapies, such as physiological feedback, restricted environmental stimulation therapy,[284] and the use of incentives.[285]

Table 6.21. Meta-analysis (2000): Effectiveness of and estimated abstinence rates for acupuncture (n = 5 studies)[a]

Treatment	Number of arms	Estimated odds ratio (95% C.I.)	Estimated abstinence rate (95% C.I.)
Placebo	7	1.0	8.3
Acupuncture	8	1.1 (0.7–1.6)	8.9 (5.5–12.3)

Future Research

The following topics regarding types of counseling and behavioral therapies require additional research:

- Effectiveness of motivational interventions, cigarette fading, and physiological feedback of smoking effects
- Mechanisms through which counseling interventions exert their effects
- Effectiveness of specific counseling interventions among various patient populations (e.g., those with cancers; chronic obstructive pulmonary disease [COPD]; psychiatric disorders, including substance use disorders; and atherosclerosis)

- Effectiveness of smokefree policies, particularly smokefree homes and worksites, on increasing interest in, and the effectiveness of, tobacco dependence treatment[286]

- Effectiveness of family systems interventions as a means to increase support

Combining Counseling and Medication

Recommendation: The combination of counseling and medication is more effective for smoking cessation than either medication or counseling alone. Therefore, whenever feasible and appropriate, both counseling and medication should be provided to patients trying to quit smoking. (Strength of Evidence = A)

Recommendation: There is a strong relation between the number of sessions of counseling, when it is combined with medication, and the likelihood of successful smoking cessation. Therefore, to the extent possible, clinicians should provide multiple counseling sessions, in addition to medication, to their patients who are trying to quit smoking. (Strength of Evidence = A)

Evidence in this Guideline update supports the independent effectiveness of both counseling interventions and medication interventions. In the 2008 Guideline update, the Panel evaluated whether combining counseling and medication improved cessation rates relative to using either of these treatments alone.

Providing Counseling in Addition to Medication. Eighteen studies met selection criteria to evaluate the effectiveness of providing counseling in addition to medication versus medication alone. The results of this 2008 meta-analysis indicate that providing counseling in addition to medication significantly enhances treatment outcomes (see Table 6.22). These same 18 studies also were analyzed to examine the relation of counseling intensity when it was used in combination with a medication. Results revealed that two or more sessions significantly enhance treatment outcomes, and more than eight sessions produced the highest abstinence rates (see Table 6.23). The counseling provided in these studies was delivered either in person or via telephone.

Table 6.22. Meta-analysis (2008): Effectiveness of and estimated abstinence rates for the combination of counseling and medication vs. medication alone (n = 18 studies)[a]

Treatment	Number of arms	Estimated odds ratio (95% C.I.)	Estimated abstinence rate (95% C.I.)
Medication alone	8	1.0	21.7
Medication and counseling	39	1.4 (1.2–1.6)	27.6 (25.0–30.3)

[a] Go to *www.surgeongeneral.gov/tobacco/gdlnrefs.htm* for the articles used in this meta-analysis.

Table 6.23. Meta-analysis (2008): Effectiveness of and estimated abstinence rates for the number of sessions of counseling in combination with medication vs. medication alone (n = 18 studies)[a]

Treatment	Number of arms	Estimated odds ratio (95% C.I.)	Estimated abstinence rate (95% C.I.)
0–1 session plus medication	13	1.0	21.8
2–3 sessions plus medication	6	1.4 (1.1–1.8)	28.0 (23.0–33.6)
4–8 sessions plus medication	19	1.3 (1.1–1.5)	26.9 (24.3–29.7)
More than 8 sessions plus medication	9	1.7 (1.3–2.2)	32.5 (27.3–38.3)

[a] Go to *www.surgeongeneral.gov/tobacco/gdlnrefs.htm* for the articles used in this meta-analysis.

Providing Medication in Addition to Counseling. The effect of adding medication to counseling also was examined. Nine studies met inclusion criteria and provided 24 arms to compare medication and counseling with counseling alone. The results of this 2008 meta-analysis indicate that providing medication in addition to counseling significantly enhances treatment outcomes (see Table 6.24).

Table 6.24. Meta-analysis (2008): Effectiveness of and estimated abstinence rates for the combination of counseling and medication vs. counseling alone (n = 9 studies)[a]

Treatment	Number of arms	Estimated odds ratio (95% C.I.)	Estimated abstinence rate (95% C.I.)
Counseling alone	11	1.0	14.6
Medication and counseling	13	1.7 (1.3–2.1)	22.1 (18.1–26.8)

[a] Go to *www.surgeongeneral.gov/tobacco/gdlnrefs.htm* for the articles used in this meta-analysis.

Medication and/or counseling are effective and should be provided as stand-alone interventions when it is not feasible to do both or the patient is not interested in both. By combining medication and counseling, however, the clinician can significantly improve abstinence rates. The clinician providing the medication does not need to be the clinician providing the counseling. It may be that a physician, dentist, physician assistant, or nurse practitioner could prescribe medicine, and counseling could be provided by a health educator, dental hygienist, tobacco treatment specialist, pharmacist, or quitline. Adherence to treatment, both medication and counseling, is important for optimal outcomes. Even though there is compelling evidence that both counseling and medications increase smoking cessation success, the clinician should encourage the patient to make a quit attempt even if she or he declines such treatment.

Future Research

The following topics regarding the combination of counseling and medication require additional research:

- Optimal timing and length of counseling and medication interventions (e.g., timing and spacing of postquit counseling sessions)
- Effectiveness and acceptability/appeal of different counseling formats and techniques (e.g., computer-based counseling, quitline counseling, motivational interviewing)
- Strategies to address misconceptions about effective counseling and medication treatments
- Relative cost-effectiveness of various treatment combinations

For Smokers Not Willing To Make a Quit Attempt At This Time

Recommendation: Motivational intervention techniques appear to be effective in increasing a patient's likelihood of making a future quit attempt. Therefore, clinicians should use motivational techniques to encourage smokers who are not currently willing to quit to consider making a quit attempt in the future. (Strength of Evidence = B)

Evidence suggests that a variety of motivational interventions can increase the motivation for behavior change. These interventions have varied contents and labels (e.g., individualized motivational intervention, motivational consulting, and motivational interviewing; see e.g., Chan et al.,[170] Butler et al.,[171] and Brown et al.[173]). The motivational intervention that has perhaps the greatest level of support and content specificity is motivational interviewing.

Motivational interviewing (MI) is a specific counseling strategy that is intended to increase a person's motivation for behavior change.[168] MI comprises a variety of strategies that are designed to help individuals resolve ambivalence about such change.[175] The technique has been used successfully to help individuals attempt and achieve many types of behavior change, including reduced drinking and illicit drug use, and reduction of HIV risk behaviors.[175,287,288]

Several studies have shown that MI techniques appear to be effective in motivating smokers to make quit attempts. A randomized controlled trial of an MI-based intervention among 137 smokers with cancer found that MI significantly increased quit attempts compared to an advice condition.[289] Another study found that a single session of MI, versus either brief psychoeducational counseling or advice, significantly increased the proportion of patients with schizophrenia who contacted a tobacco dependence treatment provider and attended an initial treatment session.[174] A third study showed that two 45-minute individual counseling sessions based on MI principles yielded higher levels of intention to quit smoking among adolescents than did a brief advice condition.[173] No differences in quitting attempts or quitting success were seen in that study, however. Studies that used motivational approaches that shared features of MI (but that were not

MI) yielded a mixed pattern of results, with some studies showing significant increases in quit attempts (see, e.g., Butler et al.[171]); others showed only trends in that direction.[170] Finally, one study that targeted unmotivated smokers showed that counseling based on the "5 R's" (see Chapter 3, Strategy B2) significantly increased the odds of making a quit attempt that lasted at least 24 hours.[169]

The available evidence shows that the reviewed motivational interventions such as MI increase quit attempts when used with individuals not already interested in quitting. The evidence does not show that such interventions are reliably effective as cessation treatments,[173,175,290] nor is there consistent evidence that MI-induced quit attempts translate into higher long-term abstinence rates. Evidence also shows that such interventions are more effective in smokers with little pre-existing motivation to quit.[171,173] Finally, some evidence suggests that extensive training is needed before competence is achieved in the MI technique.[175,291]

Physiological Monitoring/Biological Marker Feedback To Motivate Smokers To Quit

Investigators have sought to determine whether feedback regarding either smoking effects or disease risk motivates quit attempts. Modest evidence indicates that such feedback motivates quit attempts.[292] One small study found that multifaceted feedback involving CO level, vital capacity measurement, and discussion of pulmonary symptoms led to more quit attempts among smokers identified during routine medical screening.[293] In a second study, feedback regarding CO level and genetic susceptibility to cancer was associated with a greater likelihood of quit attempts 1 year later.[294] Although these results are encouraging, there is too little information to evaluate definitively the effects of physiological feedback.[284] In addition, there is insufficient information as to how this feedback affects those at different levels of readiness to quit. It also is unclear whether feedback that a person is *not* at high risk would encourage continued smoking. Finally, data are mixed regarding the effectiveness of feedback as a cessation versus motivational intervention. That is, data are mixed as to whether or not feedback increases abstinence rates.[284,295,296]

Future Research

The following topics require additional research:

- Effectiveness of motivational interviewing and related techniques, including the impact of brief motivational interviewing strategies delivered in primary care settings

- Effectiveness of physiological monitoring and biological marker feedback to motivate smokers to quit and increase abstinence rates

B. Medication Evidence

Recommendation: Clinicians should encourage all patients attempting to quit to use effective medications for tobacco dependence treatment, except where contraindicated or for specific populations for which there is insufficient evidence of effectiveness (i.e., pregnant women, smokeless tobacco users, light smokers, and adolescents). (Strength of Evidence = A)

As with other chronic diseases, the most effective treatment of tobacco dependence requires the use of multiple clinical modalities. Medications are a vital element of a multicomponent approach. The clinician should encourage all patients initiating a quit attempt to use one or a combination of effective medications, although medication use may not be appropriate with some patient groups (e.g., those with medical contraindications, those smoking fewer than 10 cigarettes a day, pregnant/breastfeeding women, smokeless tobacco users, and adolescent smokers). The Guideline Panel identified seven first-line (FDA-approved) medications (bupropion SR, nicotine gum, nicotine inhaler, nicotine lozenge, nicotine nasal spray, nicotine patch, and varenicline) and two second-line (non-FDA-approved for tobacco use treatment) medications (clonidine and nortriptyline) as being effective for treating smokers. Each has been documented to increase significantly rates of long-term smoking abstinence. These results are consistent with other independent reviews.[158,297-300] No other medication treatments were consistently supported by the available scientific evidence.

In this update, the Panel conducted an inclusive meta-analysis of medications that complements the inclusive meta-analysis of psychosocial interventions that was conducted for the 2000 Guideline. For this meta-analysis, all medication trials with at least two studies of a particular medication,

at an appropriate dose and duration, were entered into one analysis. This inclusive medication meta-analysis allows for the comparison of particular medications to both placebo controls and other active medications (Table 6.26), and makes greater use of all information in the available studies. Note also that, although all of these studies were published in peer-reviewed journals, a number of the studies were supported by the pharmaceutical industry.

The medication meta-analysis included predominantly studies with "self-selected" populations (see Chapter 1, Overview and Methods). In addition, in medication studies both experimental and control subjects in the studies typically received substantial counseling. Both of these factors tend to produce higher abstinence rates than typically are observed among self-quitters.

The studies submitted to the inclusive medications meta-analysis were screened and categorized prior to analysis. Screening removed medications for which there were too few acceptable studies to submit to meta-analysis (e.g., the nicotine lozenge, selegeline), and removed study arms that were confounded (e.g., two different medication conditions had counseling adjuvants of different intensities). Decisions about cutscores for treatment duration and dose categories were designed to be consistent with package insert information and data on effectiveness (i.e., prior data indicated rough clinical equivalence of certain dosages). Therefore, although there was an attempt to achieve some uniformity across the medications, decisions about dose and duration categories necessarily were made on a medication-by-medication basis. It is important to note that some medication categories, and some medication recommendations, do not conform with manufacturers' recommendations (e.g., the use of a nicotine patch dose > 25 mg per day). Table 6.25 shows the dosage and duration inclusion criteria for normal course, long-term, and high-dose medication classifications. In the case of medication combinations, the combinations typically comprised two standard-length medication regimens. In one combination, however, *ad libitum* NRT (gum or spray) was paired with long-term nicotine patch use ("patch [long-term] + *Ad Lib* NRT"). Different medications were grouped together into a single use category (e.g., grouping nicotine gum and spray together into the "Long-term *Ad Lib* NRT" condition) when the grouping was clinically and conceptually meaningful and when it permitted greater use of the available research evidence. Analyses were conducted for both 6- and 12-month outcomes, and the results of the

12-month analyses were very similar to the 6-month results shown in Table 6.26.

Table 6.25. Coding rules for medication duration and dose

Medication	Coding	Meaning
Nicotine Patch	Usual duration	6–14 weeks
	Long duration	> 14 weeks
	Usual dose/day	15 mg/16 hours/day 21 mg/24 hours/day
	High dose	> 25 mg/day
Nicotine Gum	Usual duration	6–14 weeks
	Long duration	> 14 weeks
Nicotine Inhaler and Nasal Spray	Usual duration	Up to 6 months
	Long duration	> 6 months
Bupropion SR	Usual duration	Up to 14 weeks
	Usual dose/day	150 mg once daily or twice daily
Varenicline	Usual duration	Up to 14 weeks
	Usual dose/day	1 mg daily or 1 mg twice daily (analyzed separately)

Recommendations Regarding Individual Medications: First-Line Medications

First-line medications are those that have been found to be safe and effective for tobacco dependence treatment and that have been approved by the FDA for this use, except in the presence of contraindications or with specific populations for which there is insufficient evidence of effectiveness (i.e., pregnant women, smokeless tobacco users, light smokers, and adolescents). These first-line medications have an established empirical record of effectiveness, and clinicians should consider these agents first in choosing a medication. For the 2008 update, the first-line medications are listed in Table 6.26 by size of the odds ratio and in the text alphabetically by generic name.

Table 6.26. Meta-analysis (2008): Effectiveness and abstinence rates for various medications and medication combinations compared to placebo at 6-months postquit (n = 83 studies)[a]

Medication	Number of arms	Estimated odds ratio (95% C.I.)	Estimated abstinence rate (95% C.I.)
Placebo	80	1.0	13.8
Monotherapies			
Varenicline (2 mg/day)	5	3.1 (2.5–3.8)	33.2 (28.9–37.8)
Nicotine Nasal Spray	4	2.3 (1.7–3.0)	26.7 (21.5–32.7)
High-Dose Nicotine Patch (> 25 mg) (These included both standard or long-term duration)	4	2.3 (1.7–3.0)	26.5 (21.3–32.5)
Long-Term Nicotine Gum (> 14 weeks)	6	2.2 (1.5–3.2)	26.1 (19.7–33.6)
Varenicline (1 mg/day)	3	2.1 (1.5–3.0)	25.4 (19.6–32.2)
Nicotine Inhaler	6	2.1 (1.5–2.9)	24.8 (19.1–31.6)
Clonidine	3	2.1 (1.2–3.7)	25.0 (15.7–37.3)
Bupropion SR	26	2.0 (1.8–2.2)	24.2 (22.2–26.4)
Nicotine Patch (6–14 weeks)	32	1.9 (1.7–2.2)	23.4 (21.3–25.8)
Long-Term Nicotine Patch (> 14 weeks)	10	1.9 (1.7–2.3)	23.7 (21.0–26.6)
Nortriptyline	5	1.8 (1.3–2.6)	22.5 (16.8–29.4)
Nicotine Gum (6–14 weeks)	15	1.5 (1.2–1.7)	19.0 (16.5–21.9)
Combination therapies			
Patch (long-term; > 14 weeks) + *ad lib* NRT (gum or spray)	3	3.6 (2.5–5.2)	36.5 (28.6–45.3)
Patch + Bupropion SR	3	2.5 (1.9–3.4)	28.9 (23.5–35.1)
Patch + Nortriptyline	2	2.3 (1.3–4.2)	27.3 (17.2–40.4)
Patch + Inhaler	2	2.2 (1.3– 3.6)	25.8 (17.4–36.5)
Patch + Second generation antidepressants (paroxetine, venlafaxine)	3	2.0 (1.2–3.4)	24.3 (16.1–35.0)
Medications not shown to be effective			
Selective Serotonin Re-uptake Inhibitors (SSRIs)	3	1.0 (0.7–1.4)	13.7 (10.2–18.0)
Naltrexone	2	0.5 (0.2–1.2)	7.3 (3.1–16.2)

Bupropion SR (Sustained Release)

Recommendation: Bupropion SR is an effective smoking cessation treatment that patients should be encouraged to use. (Strength of Evidence = A)

Bupropion SR was the first non-nicotine medication shown to be effective for smoking cessation and was approved by the FDA for that use in 1997. Its possible mechanisms of action include blockade of neuronal re-uptake of dopamine and norepinephrine and blockade of nicotinic acetylcholinergic receptors. It is contraindicated in patients with a seizure disorder, a current or prior diagnosis of bulimia or anorexia nervosa, use of a monoamine oxidase (MAO) inhibitor within the previous 14 days, or in patients taking another medication that contains bupropion. Bupropion SR is available exclusively as a prescription medication and can be used in combination with nicotine replacement therapies. Suggestions regarding the clinical use of bupropion SR are provided in Table 3.3.

Twenty-four studies generated the 26 arms that served as the basis for estimating the bupropion SR effect. The bupropion SR dose was 150 mg for 3 of these study arms, and 300 mg for the other 22 of these arms (one study did not report dose). As Table 6.26 reveals, bupropion SR approximately doubles the likelihood of long-term (> 5 month) abstinence from tobacco use as compared to placebo treatment. These results are consistent with other independent reviews.[299]

Nicotine Replacement Therapies (NRTs)

Nicotine replacement therapy (NRT) medications deliver nicotine with the intent to replace, at least partially, the nicotine obtained from cigarettes and to reduce the severity of nicotine withdrawal symptoms.

Nicotine Gum

Recommendation: Nicotine gum is an effective smoking cessation treatment that patients should be encouraged to use. (Strength of Evidence = A)

Recommendation: Clinicians should offer 4 mg rather than 2 mg nicotine gum to highly dependent smokers. (Strength of Evidence = B)

Nicotine gum currently is available exclusively as an OTC medication and is packaged with important instructions on correct usage, including chewing (see Table 3.4 for information on the clinical use of nicotine gum). Nine studies generated the 15 study arms that served as the basis for estimating the effect of nicotine gum. In addition, another four studies generated the six arms that served as the basis for the estimation of effects of long-term gum use (directed use beyond 14 weeks). Two arms used gum for 52 weeks, and the other four arms used gum for 24–26 weeks. Table 6.26 reveals that regular course and long-term nicotine gum use increased the likelihood of long-term abstinence by about 50 percent compared to placebo treatment. These results are consistent with other independent reviews.[300]

Nicotine Inhaler

Recommendation: The nicotine inhaler is an effective smoking cessation treatment that patients should be encouraged to use. (Strength of Evidence = A)

The nicotine inhaler currently is available exclusively as a prescription medication. The nicotine inhaler is not a true pulmonary inhaler, but rather deposits nicotine in the oropharynx, from which it is absorbed across the mucosa. See Table 3.5 for suggestions regarding the clinical use of the nicotine inhaler. Six studies generated the six arms that served as the basis for estimating the nicotine inhaler effect. As Table 6.26 shows, the inhaler approximately doubled smokers' likelihood of long-term abstinence from tobacco as compared to placebo treatment. These results are consistent with other independent reviews.[300]

Nicotine Lozenge

Recommendation: The nicotine lozenge is an effective smoking cessation treatment that patients should be encouraged to use. (Strength of Evidence = B)

Nicotine lozenge is available exclusively as an OTC medication and is packaged with important instructions for correct usage (see Table 3.6). Only one randomized controlled trial of the nicotine lozenge was available for review.[301] Therefore, the nicotine lozenge was not included in the inclusive meta-analysis (Table 6.26). The data from this study of more than 1,800 smokers found that the 2-mg lozenge for low-dependent smokers (smoke

a first cigarette 30 minutes or more after waking) approximately doubled and the 4-mg lozenge for highly dependent smokers (smoke a first cigarette within 30 minutes of waking) approximately tripled the odds of abstinence at 6 months postquit as compared to placebo treatment. See Table 6.27 for the study results. These results are consistent with other independent reviews.[300]

Table 6.27. Effectiveness of the nicotine lozenge: Results from the single randomized controlled trial

Lozenge dose	N for active/N for placebo	Odds Ratio (95% C.I.)	Continuous abstinence rates at 6 months (Active/Placebo)
2 mg	459/458	2.0 (1.4–2. 8)	24.2/14.4
4 mg	450/451	2.8 (1.9–4.0)	23.6/10.2

Nicotine Nasal Spray

Recommendation: Nicotine nasal spray is an effective smoking cessation treatment that patients should be encouraged to use. (Strength of Evidence = A)

The nicotine nasal spray currently is available exclusively as a prescription medication. See Table 3.7 for suggestions regarding the clinical use of the nicotine nasal spray. Four studies generated the four study arms that served as the basis for estimating the nasal spray effect. As Table 6.26 reveals, the nasal spray more than doubles the likelihood of long-term abstinence from tobacco as compared to placebo treatment.

Nicotine Patch

Recommendation: The nicotine patch is an effective smoking cessation treatment that patients should be encouraged to use. (Strength of Evidence = A)

Nicotine patches currently are available both as an OTC medication and as a prescription medication. Awareness of this prescription option is important for insurance plans that include coverage only for prescription medications. Suggestions for the clinical use of the nicotine patch are provided in Table 3.8.

Twenty-five studies generated the 32 study arms that served as the basis for estimating the nicotine patch effect. Of these 32 arms, the peak dose used was 14 or 15 mg in 6 study arms and 21–25 mg in 25 arms (one study did not report dose). As Table 6.26 shows, the nicotine patch almost doubled the likelihood of long-term abstinence compared to placebo treatment. These results are consistent with other independent reviews.[300]

The meta-analysis also addressed the effectiveness of long-term and high-dose nicotine patch therapy. As noted in Table 6.25, high-dose therapy was coded when the highest dose used exceeded 25 mg. This often was achieved by using two patches per day as a dosing regimen. Four studies generated four analyzable study arms with peak patch dosages of 30 mg (2 arms), 35 mg (1 arm), and 42 mg (1 arm). In some of these high-dose arms, patch use was of regular duration (14 weeks or less), although in other arms the duration of directed patch use exceeded 14 weeks.

Table 6.25 shows that long-term patch therapy was coded when the duration of directed patch use exceeded 14 weeks. All of the long-term patch studies used regular-dose patch regimens (15–25 mg). Eight studies generated 10 study arms that served as the basis for estimating the effect of long-term patch therapy. Table 6.26 shows that both long-term therapy and high-dose patch therapy approximately doubled the likelihood that a smoker would achieve long-term abstinence relative to placebo treatment. Thus, neither high-dose nor long-term patch therapy appeared to produce benefit above and beyond that of nicotine patch therapy at the regular duration (6–14 weeks) and dose (14–25 mg).

A time trend analysis of the nicotine patch studies based on data from the current meta-analysis revealed no significant change in the effectiveness of the nicotine patch during the approximately 15 years it has been available.

Varenicline

Recommendation: Varenicline is an effective smoking cessation treatment that patients should be encouraged to use. (Strength of Evidence = A)

Varenicline is a non-nicotine medication that was approved by the FDA for the treatment of tobacco dependence in 2006. Its mechanism of action is presumed to be due to its partial nicotine receptor agonist and antagonist effects. It is well tolerated in most patients. However, a recent publication

reported two case reports of exacerbations of existing psychiatric illness, schizophrenia and bipolar illness, in patients who took varenicline.[302,303] In contrast, one recent smoking cessation study using varenicline included smokers with mental illness (depression, bipolar disorder, and/or psychosis) and reported no evidence that varenicline worsened the patients' mental illness.[304] Importantly, the FDA noted that patients with psychiatric illness were not included in the studies conducted for the approval of this medication.

In February 2008, the FDA added a warning regarding the use of varenicline. Specifically, it noted that depressed mood, agitation, changes in behavior, suicidal ideation, and suicide have been reported in patients attempting to quit smoking while using varenicline. The FDA recommends (1) that patients tell their health care provider about any history of psychiatric illness prior to starting this medication; and (2) that clinicians monitor patients for changes in mood and behavior when prescribing this medication. In light of these FDA recommendations, clinicians should consider eliciting information on their patients' psychiatric history.

Because varenicline is eliminated almost entirely unchanged in the urine, it should be used with caution in patients with severe renal dysfunction (creatinine clearance < 30 ml per min). Varenicline is available exclusively as a prescription medication and is not recommended for use in combination with NRT because of its nicotine antagonist properties. One recent review[297] found that varenicline increased odds of quitting over that of bupropion SR with a minimal to moderate side effect profile. Suggestions regarding the clinical use of varenicline are presented in Table 3.9.

The FDA dosing recommendation for varenicline is a total of 2 mg per day (1 mg twice daily). However, there is evidence that a dose of 1 mg per day also is effective.[305] Therefore, the effectiveness of both doses was addressed in the inclusive meta-analysis. Four studies generated five study arms that served as the basis for estimating the effect of 2 mg varenicline. Two studies generated the three study arms that served as the basis for estimating the effect of 1 mg varenicline. As Table 6.26 shows, the 1 mg total daily dose of varenicline approximately doubles, and the 2 mg total daily dose of varenicline approximately triples, a smoker's likelihood of long-term abstinence from tobacco as compared to placebo treatment. This suggests that the 1 mg per day dose is a viable alternative to the 2 mg per day dose, should the patient experience dose-related side effects.

Evidence indicates that varenicline is well-tolerated for periods up to 1 year[306] and that extended treatment may prove useful in reducing the likelihood of relapse.[307] More research is needed, however, to evaluate varenicline as a relapse prevention medication, to assess its long-term effects, and to evaluate its effectiveness in specific populations.

Interactions of First-Line Tobacco Use Medications With Other Drugs

The goal of treating tobacco use and dependence is abstinence from tobacco products. In achieving this goal, the metabolic effects of tobacco abstinence must be understood with respect to potential changes in homeostasis that occur in response to quitting and, eventually, the elimination of nicotine from the body. This is particularly important for smokers who are on other medications for chronic disease state management because they essentially are in a homeostatic metabolic condition and the titration of their chronic disease medications may have been influenced by their smoking status.

The polycyclic aromatic hydrocarbons in tobacco smoke are metabolic inducers of some isoforms of the hepatic cytochrome P450.[308] Thus, when smokers quit and the P450 system returns to its basal level of functioning, the concentration of drugs metabolized by these particular CYP isoforms may increase. As a result, smokers who quit can experience side effects from supratherapeutic drug levels of caffeine, theophylline, fluvoxamine, olanzapine, and clozapine. This can have serious consequences for selective drugs such as clozapine, with its associated agranulocytosis.[309]

Although nicotine is metabolized by CYP2A6, it does not appear to induce, in a clinically significant way, CYP enzymes. Thus, when a smoker is switched from cigarettes to a nicotine replacement product, changes in drug metabolism are similar to those seen when quitting without NRT.

Nicotine produces sympathetic activation that may reduce the sedative effects of benzodiazepines, and the vasoconstrictive effects of nicotine may decrease subcutaneous absorption of insulin. Nicotine also may attenuate the ability of beta-blockers to lower blood pressure and heart rate and may lessen opioid analgesia. When nicotine replacement products are withdrawn, adjustments in these types of medications may be necessary.

The metabolism of bupropion is mediated primarily by CYP2B6. Three categories of drugs could have clinically significant interactions with bupropion: drugs affecting CYP2B6, drugs metabolized by CYP2D6, and general enzyme inducers/inhibitors.[310] Drugs that affect CYP2B6 metabolism, such as cyclophosphamide and orphenadrine, potentially could alter bupropion metabolism. Bupropion and its metabolites inhibit CYP2D6[311,312] and could affect the impact of agents metabolized by this enzyme (e.g., tricyclic antidepressants, antipsychotics, type 1C anitarrhythmics, or certain beta-blockers). Due to the extensive metabolism of bupropion, enzyme inducers (e.g., carbamazepine, phenobarbital, phenytoin) and inhibitors (e.g., valproate, cimetidine) may alter its plasma concentration. Bupropion can lower seizure threshold. It should be used with caution with medications that can also lower seizure threshold.[310,313] Specifically, use of bupropion within 14 days of discontinuation of therapy with any MAO inhibitor is contraindicated.

Varenicline is eliminated unchanged by kidney excretion and thus is believed to pose no metabolic effects. Cimetidine inhibits the renal secretion of varenicline, although the magnitude of the interaction is small. No significant drug-drug interactions are known.[314]

Recommendations Regarding Second-Line Medications

Second-line medications are medications for which there is evidence of effectiveness for treating tobacco dependence, but they have a more limited role than first-line medications because: (1) the FDA has not approved them for a tobacco dependence treatment indication; and (2) there are more concerns about potential side effects than exist with first-line medications. Second-line medications should be considered for use on a case-by-case basis after first-line medications (either alone or in combination) have been used without success or are contraindicated. The listing of the second-line medications is alphabetical by generic name.

Clonidine

Recommendation: Clonidine is an effective smoking cessation treatment. It may be used under a physician's supervision as a second-line agent to treat tobacco dependence. (Strength of Evidence = A)

Three studies generated three analyzable study arms that served as the basis for estimating clonidine's effects on long-term abstinence. These studies all were conducted prior to 1997. Table 6.26 reveals that the use of clonidine approximately doubles abstinence rates when compared to a placebo. These studies varied the clonidine dose from 0.1 to 0.75 mg per day. The drug was delivered either transdermally or orally. It should be noted that abrupt discontinuation of clonidine can result in symptoms such as nervousness, agitation, headache, and tremor, accompanied or followed by a rapid rise in blood pressure and elevated catecholamine levels.

Clonidine is used primarily as an antihypertensive medication and has not been approved by the FDA as a medication for treating tobacco use and dependence. Therefore, clinicians need to be aware of the specific warnings regarding this medication as well as its side-effect profile. Additionally, a specific dosing regimen for the use of clonidine in smoking cessation has not been established. The Guideline Panel chose to recommend clonidine as a second-line as opposed to first-line agent because of the warnings associated with clonidine discontinuation, variability in dosages used to test this medication, and lack of FDA approval. As such, clonidine should be considered for treating tobacco use under a physician's monitoring with patients unable to use first-line medications because of contraindications or with patients who were unable to quit when using first-line medications. An independent review[298] indicated that clonidine is effective in promoting smoking abstinence, but prominent side effects limit its usefulness. Suggestions regarding clinical use of clonidine are provided in Table 3.10.

Nortriptyline

Recommendation: Nortriptyline is an effective smoking cessation treatment. It may be used under a physician's supervision as a second-line agent to treat tobacco dependence. (Strength of Evidence = A)

Four studies generated the five analyzable study arms that served as the basis for estimating the effect of nortriptyline on long-term abstinence. Nortriptyline dosages were 75 mg per day (3 arms) and 100 mg per day (2 arms), with treatment lasting from 6 to 13 weeks across the five arms. As Table 6.26 shows, nortriptyline almost doubles a smoker's likelihood of achieving long-term abstinence from tobacco as compared to placebo treatment. A recent independent review[158] also indicated that nortriptyline is effective in treating tobacco dependence. Suggestions regarding the

clinical use of nortriptyline are provided in Table 3.11. Nortriptyline is used primarily as an antidepressant and has not been evaluated or approved by the FDA as a medication for treating tobacco use and dependence. Clinicians need to be aware of the specific warnings regarding this medication as well as its side-effect profile. Because of the side-effect profile and the lack of FDA approval for tobacco dependence treatment, nortriptyline is recommended as a second-line rather than a first-line agent. As such, nortriptyline should be considered for treating tobacco use under a physician's direction with patients unable to use first-line medications because of contraindications or with patients who were unable to quit using first-line medications.

Combination Medications

Recommendation: Certain combinations of first-line medications have been shown to be effective smoking cessation treatments. Therefore, clinicians should consider using these combinations of medications with their patients who are willing to quit. Effective combination medications are:

- **Long-term (> 14 weeks) nicotine patch + other NRT (gum and spray)**
- **The nicotine patch + the nicotine inhaler**
- **The nicotine patch + bupropion SR (Strength of Evidence = A)**

The number and variety of analyzable articles was sufficient to assess the effectiveness of five combinations of medications relative to placebo. Only the patch + bupropion combination has been approved by the FDA for smoking cessation.

Nicotine Patch + Bupropion SR

Three studies yielded three analyzable study arms that served as the basis for estimating the effect of the nicotine patch + bupropion SR on long-term abstinence. Both the patch and bupropion SR were used at standard durations and doses (see Table 6.25).

Nicotine Patch + Nicotine Inhaler

Two studies generated two arms that served as the basis for estimating the effect of the nicotine patch + the nicotine inhaler. The 15-mg patch was used in both studies at a regular treatment duration. The directed duration of use of the inhaler was 12 weeks in one arm and 26 weeks in the other arm.

Long-Term Nicotine Patch Use + *Ad Libitum* NRT

Three studies yielded three analyzable study arms that served as the basis for estimating the effect of long-term nicotine patch use + *ad libitum* NRT use. All arms involved nicotine patch therapy that exceeded 14 weeks, with durations that ranged from 18 to 24 weeks. The *ad libitum* NRT condition involved nicotine gum in two arms and the nicotine nasal spray in one arm. The two gum arms both used 2-mg gum, with directed use lasting 26 weeks in one arm and 52 weeks in another arm. The third arm involved nicotine nasal spray, with directed use lasting 52 weeks.

Nicotine Patch + Nortriptyline

Two studies generated three analyzable arms that served as the basis for estimating the effects of the nicotine patch + nortriptyline. The 21-mg nicotine patch served as the highest patch dose in all study arms, and the nortriptyline dose was 75 mg per day in one arm and 100 mg per day in the other arm. Both medications were used for standard durations (8–14 weeks).

Nicotine Patch + Second Generation Antidepressants

Three studies yielded three analyzable arms that served as the basis for estimating the effects of second generation antidepressants + the nicotine patch. The antidepressants used included the specific serotonin re-uptake inhibitor paroxetine (20 mg per day for 9 weeks for 2 arms), and the atypical antidepressant venlafaxine (22 mg per day for 21 weeks). The 21- or 22-mg patch served as the highest patch dose, with the duration of patch therapy being 6 or 8 weeks.

Effectiveness of Medication Combinations

Table 6.26 displays the 2008 meta-analytic results describing the effectiveness data for the five medication combinations. The data reveal that the nicotine patch + bupropion SR, the nicotine patch + inhaler, the long-term nicotine patch + *ad libitum* NRT, the nicotine patch + nortriptyline, and the nicotine patch + second generation antidepressants all significantly increased a smoker's likelihood of abstinence relative to placebo treatment. A meta-analysis using 12-month abstinence rates had similar results. The first three medication combinations involve only first-line medications and therefore are recommended for use as first-line treatments.

Decisions about use of a medication combination may be based on considerations other than abstinence. Evidence indicates, for instance, that a combination of medication may result in greater suppression of tobacco withdrawal symptoms than does the use of a single medication.[148,315,316] Patient preferences also may play a role, because some combinations of medications may produce more side effects and cost more than individual medications.[315,317,318]

Relative Effectiveness of Medications

Information on the relative effectiveness of medications may help the clinician and patient select an appropriate medication intervention. To this end, all medication conditions in Table 6.26 were compared with the nicotine patch. The nicotine patch was selected as a comparison condition because more study arms were available for this condition than for any other, and because this condition was of moderate effectiveness relative to other conditions (see Table 6.26; OR = 1.9). Contrasts between all treatments were not conducted because of concerns about Type I error due to multiple testing. Also, a conservative Hochberg[319] adjustment to the alpha level was used so that only treatments that were substantially different in effectiveness would be found to be significantly different. These comparisons of the different medications should be viewed as suggestive rather than definitive. For instance, the studies of one type of medication may differ from studies evaluating a different medication on numerous bases such as year of publication, type of population, and newness of the medication. It is possible that such differences could have affected the relative size of the odds ratios obtained for the different medications. Existing studies that provide head-to-head comparisons of medications

(which were included in this meta-analysis) provide an additional source of information on this topic.

The *a posteriori* tests resulted in three treatment conditions being statistically different from the effectiveness of the nicotine patch when it is used at regular doses and durations. The 2 mg per day varenicline and the combination of long-term patch use + *ad libitum* NRT (gum or spray) were both found to produce significantly greater likelihood of long-term abstinence than the patch by itself (see Table 6.28). Two treatments produced a lower likelihood of long-term abstinence: selective serotonin re-uptake inhibitors (SSRIs) and naltrexone. The analyses presented in Table 6.28 represent 6-month abstinence rates. Similar conclusions were reached in a meta-analysis of 12-month abstinence rates.

Table 6.28. Meta-analysis (2008): Effectiveness of and abstinence rates of medications relative to the nicotine patch (n = 83 studies)[a]

Medication	Number of arms	Estimated odds ratio (95% C. I.)
Nicotine Patch (reference group)	32	1.0
Monotherapies		
Varenicline (2 mg/day)	5	1.6 (1.3–2.0)
Nicotine Nasal Spray	4	1.2 (0.9–1.6)
High-Dose Nicotine Patch (> 25 mg; standard or long-term)	4	1.2 (0.9–1.6)
Long-Term Nicotine Gum (> 14 weeks)	6	1.2 (0.8–1.7)
Varenicline (1 mg/day)	3	1.1 (0.8–1.6)
Nicotine Inhaler	6	1.1 (0.8–1.5)
Clonidine	3	1.1 (0.6–2.0)
Bupropion SR	26	1.0 (0.9–1.2)
Long-Term Nicotine Patch (> 14 weeks)	10	1.0 (0.9–1.2)
Nortriptyline	5	0.9 (0.6–1.4)
Nicotine Gum	15	0.8 (0.6–1.0)
Combination therapies		
Patch (long-term; > 14 weeks) + NRT (gum or spray)	3	1.9 (1.3–2.7)
Patch + Bupropion SR	3	1.3 (1.0–1.8)

Table 6.28. Meta-analysis (2008): Effectiveness of and abstinence rates of medications relative to the nicotine patch (n = 83 studies)[a] (continued)

Medication	Number of arms	Estimated odds ratio (95% C. I.)
Combination therapies		
Patch + Nortriptyline	2	0.9 (0.6–1.4)
Patch + Inhaler	2	1.1 (0.7–1.9)
Second-generation antidepressants & Patch	3	1.0 (0.6–1.7)
Medications not shown to be effective		
Selective Serotonin Re-uptake Inhibitors (SSRIs)	3	0.5 (0.4–0.7)
Naltrexone	2	0.3 (0.1-0.6)

Precessation NRT Use

Recent studies have investigated the use of NRT prior to a quit attempt. Some of these studies involved smokers who are planning to quit, and others involved smokers who were not willing to quit but who were willing to reduce their smoking. The use of NRT while smoking contradicts NRT package inserts. The existence of multiple studies on this prequit medication strategy led the Panel to review this topic as part of this Guideline update. The results of this review (see below) suggest that NRT prior to quitting may be effective in increasing abstinence rates, but the Panel chose not to recommend this intervention (see below). If this strategy is used clinically, patients should be advised to cease NRT use if they develop symptoms of nicotine toxicity (e.g., nausea, vomiting, dizziness).

Precessation Use of NRT Among Patients Making a Quit Attempt. Two randomized controlled studies examined the effect of initiating the use of NRT prior to a quit attempt among patients making a quit attempt. One study examined the use of nicotine patches, either active or placebo, 2 weeks prior to quitting, after which all participants received active patches for 12 weeks following the quit day.[320] Results revealed no differences in adverse events, and smokers who had received the active patches during the prequit period were more likely to be abstinent at 6 months postquit. In a second study, Rose and colleagues[321] found that precessation patch use significantly increased abstinence rates at 4 weeks postquit but not at 6 months.

Finally, a small pilot study found that prequit patch use was well tolerated by smokers wanting to quit.[322] Given the limited data on this strategy, the Panel declined to recommend precessation use of NRT among patients making a quit attempt. However, this topic warrants further research.

Use of NRT Among Patients Unwilling to Make a Quit Attempt at This Time. Research has examined the use of NRT in patients who are not currently willing to make a quit attempt but who state that they are willing to reduce their smoking. In general, these studies found that NRT used in this way increased the likelihood that smokers will make a quit attempt and succeed in quitting. Sufficient studies were available to meta-analyze this topic for the Guideline update. Five studies generated five arms that met criteria for the analysis of the effect of NRT compared to placebo with smokers not willing to quit (but who were willing to reduce the number of cigarettes smoked and use a nicotine replacement medication). As Table 6.29 shows, the use of NRT more than doubled the likelihood that a smoker would be abstinent at 12 months, despite the smoker's unwillingness to make a quit attempt at the time of initial assessment. The nicotine replacement products in these studies included nicotine gum (2 or 4 mg for 6–12 months), the nicotine inhaler (10 mg for 6–24 months), the nicotine patch (16-hour 15-mg patch for up to 6 months), or the choice of a combination of these medications.

Because of the selective participant inclusion criteria and other aspects of this research, it is unclear that the results described above would be relevant to the broader population of smokers unwilling to quit. For instance, most patients in the studies included in the analysis in Table 6.29 were not offered a cessation intervention prior to study induction. It is possible that some of the participants would have opted for a free cessation treatment had it been offered. Also, in some instances, the recruitment material may have made it clear that treatment was available only for those uninterested in quitting. It is unclear how this perceived contingency affected the sample. Further, it is not clear if the results would be true for only those interested in reducing their smoking and not for uninterested patients, in general. Additionally, there was concern that if clinicians routinely asked about interest in cutting down, this might suggest to tobacco users that reduction confers health benefits, is a recommended strategy for persons trying to quit, or is a recommended goal of treatment (rather than quitting smoking)—and that these perceptions might decrease the proportion of smokers willing to make a quit attempt. Because of such concerns, the Panel

decided not to recommend medication use as a standard intervention for smokers unwilling to quit. A recent Cochrane analysis[323] found that NRT significantly increased quit rates among smokers not initially motivated to quit. The authors concluded, however, that there was insufficient evidence to recommend this as a standard treatment approach with this population. The Panel believes that this topic warrants further research.

Table 6.29. Meta-analysis (2008): Effectiveness of and abstinence rates for smokers not willing to quit (but willing to change their smoking patterns or reduce their smoking) after receiving NRT compared to placebo (n = 5 studies)[a]

Intervention	Number of arms	Estimated odds ratio (95% C.I.)	Estimated abstinence rate (95% C.I.)
Placebo	5	1.0	3.6
Nicotine replacement (gum, inhaler, or patch)	5	2.5 (1.7–3.7)	8.4 (5.9–12.0)

Medications Not Recommended by the Guideline Panel

Antidepressants Other Than Bupropion SR and Nortriptyline

Smoking is significantly more prevalent among individuals with a past history of depression, and these individuals have more difficulty quitting smoking than do smokers without a past history of depression.[324-328] One antidepressant, bupropion SR, has been documented as effective for treating tobacco use and approved by the FDA for this use (see Bupropion SR [sustained release], page 110). Nortriptyline also has been documented to be effective (see Nortriptyline, page 117), although the FDA has not evaluated this medication for treatment of tobacco dependence. The Panel's review of the extant literature revealed a sufficient body of research to evaluate one class of antidepressants that is dissimilar from both bupropion SR and nortriptyline: selective serotonin re-uptake inhibitors (SSRIs).

Selective Serotonin Re-Uptake Inhibitors (SSRIs)

Two studies yielded three analyzable arms that served as the basis for estimating the effects of SSRIs. Sertraline (200 mg per day) served as the medication in one arm, and fluoxetine (30 to 60 mg per day) served as the medication in the other two arms. The treatment duration was 10 weeks in all arms. Results showed that treatment with SSRIs did not significantly increase the likelihood of abstinence relative to placebo treatment. These results are consistent with other independent reviews[299] (see Table 6.26).

Anxiolytics/Benzodiazepines/Beta-Blockers

A few trials have evaluated anxiolytics and other agents that reduce the somatic signs or the symptoms of anxiety. Early individual trials of propranolol, a beta-blocker,[329] and diazepam, an anxiolytic,[330] did not reveal a beneficial effect for these drugs compared with control interventions. Likewise, of the early studies assessing the anxiolytic buspirone that met inclusion criteria, only one revealed evidence of effectiveness relative to placebo.[331] Further studies of buspirone have failed to replicate this effect.[332-334] These results are consistent with other independent reviews.[333] Because of a lack of data, no meta-analyses were conducted, and no conclusions were drawn regarding the effectiveness of anxiolytics in smoking cessation.

Opioid Antagonists/Naltrexone

Two studies yielded the analyzable study arms that served as the basis for estimating the effects of the opiate antagonist naltrexone. Table 6.26 reveals that naltrexone treatment did not increase the likelihood of abstinence relative to placebo treatment. These results are consistent with other independent reviews.[335] Two studies[336,337] also examined whether naltrexone added to the effectiveness of the nicotine patch. The studies used different naltrexone and patch dosing regimens. The patch use regimen in one study did not meet meta-analysis inclusion criteria. Therefore, these patch + naltrexone studies could not be submitted to meta-analysis. Neither study reported significant benefit from adding naltrexone to the nicotine patch.

Silver Acetate

Due to limitations of the literature available regarding silver acetate, this agent was not included in the inclusive meta-analysis. Several randomized clinical trials[338-340] of silver acetate, however, revealed no beneficial effects for smoking cessation; a Cochrane review concurs with this finding.[341]

Mecamylamine

In the single study that compared mecamylamine alone to placebo, no effectiveness was noted.[342] Another early study compared a combination of mecamylamine plus the nicotine patch to placebo and found a significant effect for this combination.[343] A more recent study comparing nicotine patch alone to nicotine patch plus mecamylamine found no significant differences.[344] These findings are consistent with other independent reviews.[345] Because of these findings, the Panel drew no conclusions regarding mecamylamine as a monotherapy.

Extended Use of Medications

For some patients, it may be appropriate to continue medication treatment for periods longer than is usually recommended. Results of the inclusive meta-analysis indicated that long-term patch and gum use are effective. Evidence indicates that the long-term use of gum may be more effective than a shorter course of gum therapy (Table 6.26). The Lung Health Study, of almost 4,000 smokers with evidence of early COPD, reported that approximately one-third of long-term quitters still were using nicotine gum at 12 months,[346] and some for as long as 5 years, with no serious side effects.[347] Other studies also have found that, among patients given free access to nicotine gum, 15 to 20 percent of successful abstainers continue to use the gum for a year or longer.[348] Thus, it may be that certain groups of smokers may benefit from long-term medication use. Although weaning should be encouraged for all patients using medications, continued use of such medication clearly is preferable to a return to smoking with respect to health consequences. This is because, unlike smoking, these medications do not (a) contain non-nicotine toxic substances (e.g., "tar," carbon monoxide, formaldehyde, benzene); (b) produce sharp surges in blood nicotine levels; and/or (c) produce strong dependence.[349,350] Finally, it should be noted that the medication treatment that produced the largest effects on abstinence rates, of those analyzed, involved long-term nicotine patch therapy + *ad libitum* NRT (Table 6.26).

Use of NRT in Cardiovascular Patients

Soon after the nicotine patch was released, the media reported a possible link between the use of this medication and cardiovascular risk. This question has been studied systematically since that time. Separate analyses now have documented the lack of an association between the nicotine patch and acute cardiovascular events,[351-356] even in patients who continued to smoke while on the nicotine patch,[357] although a recent study raised questions regarding NRT use in intensive care units.[358] Because of inaccurate media coverage in the past, it may be important to inform patients who are reluctant to use NRTs that there is no evidence of increased cardiovascular risk with these medications. Note that package inserts recommend caution in patients with acute cardiovascular diseases (see Tables 3.3–3.11).

Future Research

The following pharmacotherapeutic topics require additional research:

- Relative effectiveness and safety of the seven FDA-approved medications, in general and for specific subpopulations (e.g., women; adolescents; older smokers; smokeless tobacco users; individuals with psychiatric disorders, including substance use disorders; postmyocardial infarction patients) and for long-term treatment
- Use of combined tobacco dependence medications in general and for specific subpopulations (e.g., highly dependent smokers)
- Effectiveness of long-term medications
- Effectiveness of prequit NRT use in increasing abstinence rates
- Strategies to address widespread misconceptions about effective smoking cessation medications and common barriers to their appropriate use
- Effectiveness of MAO inhibitors, especially for those with depression

Use of Over-the-Counter Medications

Recommendation: Over-the-counter nicotine patch therapy is more effective than placebo, and its use should be encouraged. (Strength of evidence = B)

No new studies were identified for the 2008 update that examined the effectiveness of nicotine patch versus placebo patch in an OTC setting. Based on the 2000 Guideline, there were three placebo-controlled studies with six arms that met selection criteria for the meta-analysis of medication interventions in OTC settings. These three studies specifically examined the effect of patch versus placebo. The only additional treatments in these studies were a self-help manual, instructions contained in the package, or written directions for using the patch. As shown in Table 6.30, the use of the nicotine patch in OTC settings nearly doubles abstinence rates when compared to a placebo. These results are consistent with a more recent (2003) meta-analysis of active versus placebo patch in an OTC setting that found an odds ratio of 2.5 (95% C.I. = 1.8–3.6) for active nicotine patch.[359] A study that did not meet inclusion criteria for meta-analysis reported low abstinence rates when the nicotine patch was used in the OTC setting.[360] Too few studies were done in the OTC setting to permit meta-analysis of the OTC effect of any other medication. The "B" strength of evidence rating reflects the Panel's concern about the external validity of the studies designed to reflect the OTC context.

The FDA has approved nicotine gum, the nicotine lozenge, and the nicotine patch for OTC use. The patches and gum are identical to those previously available only via prescription. Although the OTC status of these medications has increased their availability and use,[361] this does not reduce the clinician's responsibility to intervene with smokers or insurers/managed care organizations/payers to cover the costs of such treatment. Moreover, OTC availability may enhance the capacity of a broad array of clinicians to intervene comprehensively when treating tobacco dependence.

All clinicians have specific responsibilities regarding these products, such as encouraging their use when appropriate, identifying patients with specific contraindications, providing counseling and followup, encouraging total abstinence during a quit attempt, offering instruction on appropriate use, addressing common patient misconceptions, and providing prescriptions

when needed for select populations to ensure reimbursement (e.g., Medicaid patients). Additionally, patients should be urged to read the package insert and consult with their pharmacist. Finally, the clinician should advise patients regarding the selection and use of medications, whether purchased OTC or by prescription. Debate has arisen in the field regarding the effectiveness of OTC NRT use. For instance, a population-based study found no long-term effects of OTC nicotine patch use.[34] However, cross-sectional surveys have methodolgical constraints (e.g., patients may self-select certain treatments based on dependence or perceived difficulty of quitting).[362]

Table 6.30. Meta-analysis (2000): Effectiveness of and estimated abstinence rates for OTC nicotine patch therapy (n = 3 studies)[a]

OTC therapy	Number of arms	Odds Ratio (95% C.I.)	Estimated abstinence rate (95% C.I.)
Placebo	3	1.0	6.7
OTC nicotine patch therapy	3	1.8 (1.2–2.8)	11.8 (7.5–16.0)

[a] Go to *www.surgeongeneral.gov/tobacco/gdlnrefs.htm* for the articles used in this meta-analysis.

Future Research

Important topics for future research are:

- Effectiveness of nicotine patch, gum, and lozenge when access is OTC
- Extent to which individuals use medications appropriately when access is OTC
- Extent to which the effectiveness of OTC medication is enhanced by other treatments (e.g., pharmacist counseling, telephone counseling, computer self-help resources, clinician interventions)
- Extent to which OTC status increases or reduces the use of medications by poor or minority populations
- Strategies for improving the accessibility and appropriate use of OTC medications

C. Systems Evidence

Clinician Training and Reminder Systems

Recommendation: All clinicians and clinicians-in-training should be trained in effective strategies to assist tobacco users willing to make a quit attempt and to motivate those unwilling to quit. Training appears to be more effective when coupled with systems changes. (Strength of Evidence = B)

Meta-analyses were conducted to analyze the effects of clinician training and other systems changes. It was necessary to include studies in these analyses in which higher level units (clinicians or clinical sites) served as units of randomization. This strategy was adopted because relatively few studies in this area of research randomized individual patients to treatment or intervention conditions. Studies randomized at higher level units were considered for the analyses only if the study's analytic plan accounted for the dependency of data nested under such units or if the outcome, such as providing advice to quit, was analyzed at the same level as the randomization (e.g., clinician or clinic level). In fact, however, the few studies that analyzed data at the level of the clinician or clinic shared no common outcomes and could not be used in the meta-analysis.

Table 6.31 depicts meta-analytic results for studies that examined the effects of training on abstinence outcomes. Only two studies, somewhat heterogenous, were available for this analysis. Thus, although the meta-analysis showed a significant effect of training, the Panel elected to assign this recommendation a "B" strength of evidence.

Table 6.31. Meta-analysis (2008): Effectiveness of and estimated abstinence rates for clinician training (n = 2 studies)[a]

Intervention	Number of arms	Odds Ratio (95% C.I.)	Estimated abstinence rate (95% C.I.)
No intervention	2	1.0	6.4
Clinician training	2	2.0 (1.2–3.4)	12.0 (7.6–18.6)

[a] Go to *www.surgeongeneral.gov/tobacco/gdlnrefs.htm* for the articles used in this meta-analysis.

Clinician training and other systems changes are intended to increase rates of tobacco use assessment and intervention. Therefore, additional meta-analyses were conducted to ascertain the effects of systems changes on

outcomes such as clinician assessment of smoking status ("Ask"), provision of treatment ("Assist"), and arranging for treatment followup ("Arrange"). Thus, these meta-analyses focused on systems change impact on specific clinician behaviors. In the analyzed studies, clinician behavior was assessed via patient report or chart review (not via clinician report). Analyses of such clinician behaviors are of public health significance because of evidence that the provision of treatment has been shown to lead to higher tobacco cessation rates.

As noted in Table 6.32, training clinicians increases the percentage of smokers who receive treatment, such as a discussion of benefits/obstacles to quitting or strategies to prevent relapse, medication, and provision of support. Further, combining clinician training with a charting system, such as chart reminder stickers or treatment algorithms attached to the chart, increases rates of tobacco use assessment (Table 6.33), setting a quit date (Table 6.34), providing materials (Table 6.35), and arranging for followup (Table 6.36). Thus, clinician training, especially when coupled with other systems changes such as reminder systems, increases the rates at which clinicians engage in tobacco interventions that reliably boost tobacco cessation. The *Guide to Community Preventive Services*[92] found insufficient evidence to recommend provider education systems as stand-alone interventions, separate from other system changes, but does recommend provider education when part of other system changes such as reminder systems.

Table 6.32. Meta-analysis (2008): Effectiveness of clinician training on rates of providing treatment ("Assist") (n = 2 studies)[a]

Intervention	Number of arms	Odds Ratio (95% C.I.)	Estimated rate (95% C.I.)
No intervention	2	1.0	36.2
Clinician training	2	3.2 (2.0–5.2)	64.7 (53.1–74.8)

These meta-analyses support the finding that clinician training increases the delivery of effective tobacco use treatments. Training elements provided in these interventions included didactic presentation of material, group discussions, and role playing. These studies also examined a range of clinician training, from formal training during residency to onsite clinician training within the community.

Training should be directed at both clinicians-in-training as well as practicing clinicians. Training should be reinforced throughout the clinicians' education and practice.[363-368] Such training has been shown to be cost-effective.[369] For clinicians-in-training, most clinical disciplines currently neither

provide training nor require competency in tobacco use interventions,[370] although this is improving slowly.[371,372] One survey of U.S. medical schools found that most medical schools (69%) did not require clinical training in tobacco dependence treatment.[373] The National Cancer Institute's Prevention and Cessation Education in Medical Schools (PACE) reported that, in 2004, about 36 percent of medical school courses offered about 10 hours of tobacco-related teaching over 4 years,[374] and PACE has developed competencies for graduating medical students.[375]

Similarly, the American Dental Education Association has guidelines recommending tobacco use cessation clinical activities (TUCCA) education for dental and dental hygiene students and, in 1998, 51 percent of dental schools reported clinical training in this area.[376] Tobacco-related curricula may be taught as part of a preventive medicine or substance abuse course or as a class by itself. Similar recommendations would be relevant to virtually all other clinical disciplines. Training in tobacco use interventions should not only transmit essential treatment skills (see Chapter 3), but also should inculcate the belief that tobacco dependence treatment is a standard of good clinical practice.[130,208,250]

Several factors would promote the training of clinicians in tobacco intervention activities:[370]

- Inclusion of education and training in tobacco dependence treatments in the required curricula of all clinical disciplines
- Evaluation of effective tobacco dependence treatment knowledge and skills in licensing and certification exams for all clinical disciplines
- Adoption by medical specialty societies of a uniform standard of competence in tobacco dependence treatment for all members

Finally, clinicians who currently use any tobacco product should participate in treatment programs to stop their own tobacco use permanently. Clinicians are important role models for their patients, and those who use tobacco probably are less likely to counsel their patients to quit.[377] Therefore, it is heartening that many types of clinicians have dramatically decreased their own tobacco use during the past 40 years,[378] although this has not been universal.

Future Research

The following topics regarding clinician training require additional research:

- Effectiveness of training programs for other health disciplines, such as nursing, psychology, dentistry (including hygienists), social work, and pharmacy
- Effective elements in successful training programs (e.g., continuing medical education, interactive components)
- Combined effect of multiple systems changes, such as clinician training, reminder systems, clinician feedback, incentive payments, and recruitment of opinion leaders

Cost-Effectiveness of Tobacco Dependence Interventions

Recommendation: The tobacco dependence treatments shown to be effective in this Guideline (both counseling and medication) are highly cost-effective relative to other reimbursed treatments and should be provided to all smokers. (Strength of Evidence = A)

Recommendation: Sufficient resources should be allocated for systems support to ensure the delivery of efficacious tobacco use treatments. (Strength of Evidence = C)

Smoking exacts a substantial financial burden on the United States. A recent report of the Centers for Disease Control and Prevention estimated that tobacco dependence costs the Nation more than $96 billion per year in direct medical expenses and $97 billion in lost productivity.[28] Given these substantial costs, research has focused on the economic impact and cost-effectiveness of tobacco cessation interventions.

Tobacco use treatments, ranging from brief clinician advice to specialist-delivered intensive programs, including medication, have been shown not only to be clinically effective, but also to be extremely cost-effective relative to other commonly used disease prevention interventions and

medical treatments. Cost-effectiveness analyses have shown that tobacco dependence treatment compares favorably with routinely reimbursed medical interventions such as the treatment of hypertension and hypercholesterolemia, as well as preventive screening interventions such as periodic mammography or Papanicolaou smears.[222,224,379-382] For example, the cost per life-year saved of tobacco dependence treatment has been estimated at $3,539,[194] which compares favorably to hypertension screening for men ages 45 to 54 ($5,200) and annual cervical screening for women ages 34 to 39 ($4,100).[383] Treating tobacco dependence also is important economically in that it can prevent the development of a variety of costly chronic diseases, including heart disease, cancer, and pulmonary disease. In fact, tobacco dependence treatment has been referred to as the "gold standard" of health care cost-effectiveness.[225]

Cost-effectiveness can be measured in a variety of ways, including cost per quality-adjusted-life-year saved (QALY), cost per quit, health care costs and utilization pre- and postquit, and return on investment (ROI) for coverage of tobacco dependence treatment.

Cost per Quality-Adjusted-Life-Year Saved and Cost per Quit

Numerous analyses have estimated the cost per QALY saved resulting from use of effective tobacco dependence interventions.[187,222,380,384-389] In general, evidence-based tobacco use interventions compare favorably with other prevention and chronic disease interventions such as treatment of hypertension and mammography screening when using this criterion. Specific analyses have estimated the costs of tobacco use treatment to range from a few hundred to a few thousand dollars per QALY saved.[228,385] Separate analyses have computed the estimated costs of treatment in terms of the cost per quit. Compared to other interventions, the cost of tobacco use treatments has been modest, ranging from a few hundred to a few thousand dollars per quit.[194,212,384,390-393]

Managed Care Organizations (MCOs) often assess the per member per month (PMPM) cost of a benefit, and the PMPM cost for tobacco use treatment has been assessed in a variety of settings. In general, the PMPM cost for tobacco use treatments has been low relative to other covered benefits, ranging from about $0.20 to about $0.80 PMPM.[210,228,391,394]

Health Care Costs and Utilization Pre- and Postquit

A substantial body of research has investigated the effect of tobacco use treatment on health care costs.[395-399] A synthesis of these findings suggests that: (1) among individuals who quit tobacco use, health care costs typically increase during the year in which smokers quit then decline progressively, falling below those of continuing smokers for 1 to 10 years after quitting; (2) in general, smokers' health care costs begin to rise in the time period immediately prior to quit attempts; and (3) higher health care utilization predicts smoking cessation among smokers with and without chronic diseases. These findings suggest that quitting smoking often occurs in response to serious and expensive health problems. Such research also suggests that increases in health care costs, including hospitalizations, during the year of quitting may be a cause rather than a consequence of successful smoking cessation.

Return on Investment for Coverage of Tobacco Dependence Treatment

The ROI tool is used frequently to estimate the amount of time it takes for an expenditure to earn back some or all of its initial investment. The economic arguments supporting the decision to provide insurance coverage for tobacco use treatments would be enhanced if the costs of such coverage are modest compared to economic benefits resulting from successful cessation (reductions in health care expenditures, increased productivity, and/or other costs).

Studies have documented that tobacco dependence treatments provide a timely return on investment when considered by the employer. Such analyses have concluded that providing coverage for tobacco use treatment for employees often produces substantial net financial savings through increased health care savings, increased productivity, reduced absenteeism, and reduced life insurance payouts.[229,400-402]

Financial savings are more difficult to attain for a health plan given factors such as member turnover, the difficulty of attributing reduced health care expenditures to tobacco dependence, and the absence of economic benefits resulting from productivity gains. Although most analyses have

not demonstrated cost savings, insurance coverage of evidence-based tobacco dependence treatments are highly cost-effective relative to other frequently paid-for health care services. One recent effort to simulate the financial implications of covering tobacco use treatments by MCOs found that at 5 years, coverage of tobacco use treatment cost an MCO a modest $0.61 PMPM, with quitters gaining an average of 7.1 years of life and a direct coverage cost of about $3,500 for each life-year saved.[228] The authors concluded that coverage of such cost-effective tobacco use treatment programs by MCOs should be strongly encouraged. Another study examined the trend in health care costs for former smokers over 7 years postquitting compared to continuing smokers.[395] The authors found that, by the seventh year, former smokers' cumulative costs (including increased cost in the year they quit) were lower than those of continuing smokers. A more recent analysis concluded that at 10 years, the ROI of providing a comprehensive tobacco use treatment benefit, considering only health care costs, ranged from 75 percent to 92 percent, indicating that health care savings alone have repaid more than three-fourths of the investment.[229] Other analyses have shown that multiple tobacco use treatment components, including telephone counseling and various medications,[227,403,404] yield a favorable ROI. The American Health Insurance Plans (AHIP) has provided a Web link for health plans to compute their ROI for the provision of tobacco use treatment: *www.businesscaseroi.org/roi/default.aspx*.

Tobacco cessation treatment is particularly cost-effective in certain populations, such as hospitalized patients and pregnant women. For hospitalized patients, successful tobacco abstinence not only reduces general medical costs in the short term, but also reduces the number of future hospitalizations.[9,355,405] Tobacco dependence interventions for pregnant women are especially cost-effective because they result in fewer low birth-weight babies and perinatal deaths; fewer physical, cognitive, and behavioral problems during infancy and childhood; and yield important health benefits for the mother.[406,407] One study found that interventions with U.S. pregnant smokers could net savings up to $8 million in direct neonatal inpatient costs given the cost of an intervention ($24–$34) versus the costs saved ($881) for each woman who quits smoking during pregnancy.[408] Another study showed that, for each low-income pregnant smoker who quit, Medicaid saved $1,274.[409] A simulation study found that a 1 percent decrease in smoking prevalence among U.S. pregnant women would save $21 million (1995 dollars) in direct medical costs in the first year.[406,410,411]

Tobacco Dependence Treatment as a Part of Assessing Health Care Quality

Recommendation: Provision of Guideline-based interventions to treat tobacco use and dependence should remain in standard ratings and measures of overall health care quality (e.g., NCQA HEDIS). These standard measures should also include measures of outcomes (e.g., use of cessation treatment, short- and long-term abstinence rates) that result from providing tobacco dependence interventions. (Strength of Evidence = C)

The provision of tobacco dependence treatment should be increased by: (1) attention to health organization "report cards" (e.g., HEDIS, The Joint Commission, Physician Consortium for Performance Improvement, National Quality Forum, Ambulatory Quality Alliance),[89,412-414] which support smoker identification and treatment; (2) accreditation criteria used by The Joint Commission and other accrediting bodies that include the presence of effective tobacco assessment and intervention policies; and (3) increasing the use of tobacco-related measures in pay-for-performance initiatives.

Future Research

The following topics regarding cost-effectiveness and health systems require additional research:

- Cost-effectiveness of the various tobacco dependence treatments, both short- and long-term
- Optimal ways to remove systemic barriers that prevent clinicians from effectively delivering tobacco dependence treatments
- Systemic interventions to encourage provider and patient utilization of effective tobacco dependence treatments
- Relative costs and economic impacts of different formats of effective treatments (e.g., proactive telephone counseling, face-to-face contact, medication)

- Impact of using tobacco intervention performance measures on clinician intervention and patient outcomes, including the use of such measures in "pay for performance" programs

Providing Treatment for Tobacco Use and Dependence as a Covered Benefit

Recommendation: Providing tobacco dependence treatments (both medication and counseling) as a paid or covered benefit by health insurance plans has been shown to increase the proportion of smokers who use cessation treatment, attempt to quit, and successfully quit. Therefore, treatments shown to be effective in the Guideline should be included as covered services in public and private health benefit plans. (Strength of Evidence = A)

Multiple studies have assessed the impact of including tobacco dependence treatment as a covered health insurance benefit for smokers. Most studies have documented that such health insurance coverage increases both treatment utilization rates and the rates of cessation,[210,212,391,415] although some research is not consistent with these findings.[416] A recent Cochrane analysis (2005) concluded that health care financing systems that offered full payment for tobacco use treatment increased self-reported prolonged abstinence rates at relatively low costs when compared with a partial benefit or no benefit. Moreover, the presence of prepaid or discounted prescription drug benefits increases patients' receipt of medication and smoking abstinence rates.[231,348,417] These studies emphasize that removing all cost barriers yields the highest rates of treatment utilization.

Three studies met criteria to be included in a 2008 Guideline update meta-analysis of the effects of providing tobacco use treatments as a covered health insurance benefit. Three different outcomes were examined: rates of treatment provision, quit attempts, and quit rates. As can be seen in Tables 6.37 through 6.39, compared to not having tobacco use treatment as a covered benefit, individuals with the benefit were more likely to receive treatment, make a quit attempt, and abstain from smoking.

Table 6.37. Meta-analysis (2008): Estimated rates of intervention for individuals who received tobacco use interventions as a covered health insurance benefit (n = 3 studies)[a]

Treatment	Number of arms	Estimated odds ratio (95% C.I.)	Estimated intervention rate (95% C.I.)
Individuals with no covered health insurance benefit	3	1.0	8.9
Individuals with the benefit	3	2.3 (1.8–2.9)	18.2 (14.8–22.3)

[a] Go to *www.surgeongeneral.gov/tobacco/gdlnrefs.htm* for the articles used in this meta-analysis.

Table 6.38. Meta-analysis (2008): Estimated rates of quit attempts for individuals who received tobacco use interventions as a covered health insurance benefit (n = 3 studies)[a]

Treatment	Number of arms	Estimated odds ratio (95% C.I.)	Estimated quit attempt rate (95% C.I.)
Individuals with no covered benefit	3	1.0	30.5
Individuals with the benefit	3	1.3 (1.01–1.5)	36.2 (32.3–40.2)

[a] Go to *www.surgeongeneral.gov/tobacco/gdlnrefs.htm* for the articles used in this meta-analysis.

Table 6.39. Meta-analysis (2008): Estimated abstinence rates for individuals who received tobacco use interventions as a covered benefit (n = 3 studies)[a]

Treatment	Number of arms	Estimated odds ratio (95% C.I.)	Estimated abstinence rate (95% C.I.)
Individuals with no covered benefit	3	1.0	6.7
Individuals with the benefit	3	1.6 (1.2–2.2)	10.5 (8.1–13.5)

[a] Go to *www.surgeongeneral.gov/tobacco/gdlnrefs.htm* for the articles used in this meta-analysis.

It may be in the best interests of insurance companies, MCOs, purchasers, and governmental bodies within a specific geographic area to work collaboratively to ensure that tobacco dependence interventions are a covered benefit and that enrollees are aware of these benefits. This would allow the financial benefits of the successful use of these services to be realized by all of the health plans within a community.

Future Research

- Impact of promotion or communication of tobacco dependence treatment benefits on utilization and resulting population health and economic effects
- Cost-effectiveness of specific elements of tobacco dependence treatment
- Appropriate level of payment needed to optimize clinician delivery of tobacco dependence treatment

Chapter 7 Specific Populations and Other Topics

Background

Many factors could affect the acceptability, use, and effectiveness of tobacco dependence treatments. This raises the question of whether interventions should be tailored or modified on the basis of personal characteristics or contextual factors such as gender, race/ethnicity, age, comorbidity, or hospitalization status. Should pregnant smokers receive tobacco dependence medication? Do tobacco dependence interventions interfere with nontobacco chemical dependency treatments? These and other specific populations and issues are considered in this chapter. The answers to these questions are relevant to a range of clinicians who routinely deal with specific populations of smokers (e.g., obstetricians, gynecologists, pediatricians, psychiatrists, internists, cardiologists, nurses, pharmacists, dentists, and dental hygienists).

Recommendation: The interventions found to be effective in this Guideline have been shown to be effective in a variety of populations. In addition, many of the studies supporting these interventions comprised diverse samples of tobacco users. Therefore, interventions identified as effective in this Guideline are recommended for all individuals who use tobacco, except when medication use is contraindicated or with specific populations in which medication has not been shown to be effective (pregnant women, smokeless tobacco users, light smokers, and adolescents). (Strength of Evidence = B)

Effective Treatments for Specific Populations

The above recommendation applies to the broad population of smokers, including HIV-positive smokers; hospitalized smokers; lesbian/gay/bisexual/transgender smokers; those with low socioeconomic status (SES)/limited formal education; smokers with medical comorbidities; older smokers; smokers with psychiatric disorders, including substance use disorders; racial and ethnic minorities; and women smokers. It does not apply to adolescents, pregnant smokers, light smokers, and smokeless tobacco users (see below).

The recommendation that tobacco dependence treatments be used with broad populations of tobacco users arises from several considerations. One is that many of the randomized trials that generated the treatment recommendations comprised diverse samples. A second consideration is that the studies that tested interventions in homogeneous, specific populations show that interventions that are effective in one population tend to be effective in other populations. Finally, the relative safety of the tobacco dependence treatments versus the hazards of continued tobacco use supports some extrapolation from extant data. Table 7.1 reviews the randomized clinical trial (RCT) evidence of effectiveness of various treatments in different populations. Unless specifically stated, this table presents evidence from individual, screened RCTs rather than from meta-analyses. It is not intended to provide a comprehensive review of the relevant literature, but rather to provide some key findings from that review. Importantly, adolescents, pregnant smokers, light smokers, and smokeless tobacco users each have their own sections of this Guideline update, given that they usually are excluded from the RCTs used to evaluate the effectiveness of interventions presented in this Guideline and may have other special issues (e.g., safety).

Table 7.1. Evidence of effectiveness of tobacco dependence interventions in specific populations

Population of Smokers	Review of Evidence
HIV-positive	No long-term RCTs have examined the effectiveness of interventions in this population. More research is needed. • One study with 3-month followup indicated that telephone counseling is promising.[418] • Pilot data indicate that effective treatments work with this population.[419]
Hospitalized patients	2007 Cochrane analyses[420] revealed that intensive intervention (inpatient contact plus followup for at least 1 month) was associated with a significantly higher quit rate compared to control conditions (OR = 1.65; 95% CI = 1.44–1.90, 17 trials). Specific additional Cochrane findings: • Posthospitalization followup appears to be a key component of effective interventions. • No significant effect of medication was seen in this population. However, the effect sizes were comparable to those obtained in other clinical trials, suggesting that nicotine replacement therapy (NRT) and bupropion SR may be effective in this population.

Table 7.1. Evidence of effectiveness of tobacco dependence interventions in specific populations (continued)

Population of Smokers	Review of Evidence
Hospitalized patients (continued)	• Intervention is effective regardless of the patient's reason for admission. There was no strong evidence that clinical diagnosis of the medically comorbid condition affected the likelihood of quitting. Interventions that have been shown to be effective in individual studies are: counseling and medication[57,355,421-423] and other psychosocial interventions, including self-help via brochure or audio/videotape; chart prompt reminding physician to advise smoking cessation; hospital counseling; and postdischarge counseling telephone calls.[424,425] Some data suggest NRT might not be appropriate in intensive care patients.[358]
Lesbian, gay, bisexual, transgender	No long-term RCTs have examined the effectiveness of interventions specifically in this population.
Low SES/ limited formal education[a]	• Meta-analysis (2008): 5 studies met selection criteria and contributed to a 2008 Guideline meta-analysis comparing counseling vs. usual care or no counseling among individuals with low SES/limited formal education. Meta-analytic results showed that counseling is effective in treating smokers with low SES/limited formal education (OR = 1.42; 95% C.I. = 1.04–1.92) (Abstinence rate without counseling = 13.2%; with counseling, abstinence rate = 17.7% [95% C.I. = 13.7%–22.6%]) • Interventions included in the meta-analysis were motivational messages with and without telephone counseling for low-income mothers and low-income African Americans,[172,426] proactive telephone counseling in addition to nicotine patches,[427,428] tailored bedside counseling and followup for hospitalized African-American patients.[429]
Medical comorbidities	Tobacco use treatments have been shown to be effective among smokers with a variety of comorbid medical conditions. The comorbid conditions and effective interventions include: • Cardiovascular disease: psychosocial interventions;[430-439] exercise;[440,441] bupropion SR,[439,442] but one study did not find significant long-term effects;[443] nicotine patch, gum, or inhaler.[439] • Lung/COPD patients: intensive cessation counseling,[444] intensive behavioral (relapse prevention) program combined with nicotine replacement therapy,[445] bupropion SR,[446,447] nortriptyline,[447] nicotine patch or inhaler.[448] • Cancer: counseling and medication,[251,449,450] motivational counseling.[451]

Table 7.1. Evidence of effectiveness of tobacco dependence interventions in specific populations (continued)

Population of Smokers	Review of Evidence
Older smokers	• Research has demonstrated the effectiveness of the "4 A's" (ask, advise, assist, and arrange followup) in patients ages 50 and older.[452-454] Counseling interventions,[455-457] physician advice,[118,456] buddy support programs,[458] age-tailored self-help materials,[456,459-461] telephone counseling,[460,461] and the nicotine patch[454,462,463] all have been shown to be effective in treating tobacco use in adults 50 and older.
Psychiatric disorders, including substance use disorders[a]	• Meta-analysis (2008): Four studies met selection criteria and were relevant to a 2008 Guideline meta-analysis comparing antidepressants (bupropion SR and nortriptyline) vs. placebo for individuals with a past history of depression. Meta-analytic results showed that antidepressants, specifically bupropion SR and nortriptyline, are effective in increasing long-term cessation rates in smokers with a past history of depression (OR = 3.42; 95% C.I. = 1.70–6.84; abstinence rates = 29.9%, 95% C.I. = 17.5%–46.1%). Note that these studies typically included intensive psychosocial interventions for all participants. • Although psychiatric disorders may place smokers at increased risk for relapse, such smokers can be helped by tobacco dependence treatments.[464-468] • Some data suggest that bupropion SR and NRT may be effective for treating smoking in individuals with schizophrenia and may improve negative symptoms of schizophrenia and depressive symptoms.[467,469-472] Data suggest that individuals on atypical antipsychotics may be more responsive to bupropion SR for treatment of tobacco dependence than those taking standard antipsychotics.[472] • Current evidence is insufficient to determine whether smokers with psychiatric disorders benefit more from tobacco use treatments tailored to psychiatric disorder/symptoms than from standard treatments.[266,473] • Evidence indicates that tobacco use interventions, both counseling and medication, are effective in treating smokers who are receiving treatment for chemical dependency.[464,474-476] • There is little evidence that tobacco dependence interventions interfere with recovery from nontobacco chemical dependencies among patients who are in treatment for such dependencies.[475,477-482] One study suggests that delivery of smoking cessation interventions concurrent with alcohol dependence interventions may compromise alcohol abstinence outcomes, although there was no difference in smoking abstinence rates.[483]

Table 7.1. Evidence of effectiveness of tobacco dependence interventions in specific populations (continued)

Population of Smokers	Review of Evidence
Psychiatric disorders, including substance use disorders[a] (continued)	• The use of varenicline has been associated with depressed mood, agitation, suicidal ideation, and suicide. The FDA recommends that patients tell their health care provider about any history of psychiatric illness prior to starting varenicline and that clinicians monitor for changes in mood and behavior when prescribing this medication. In light of these FDA recommendations, clinicians should consider eliciting information on their patients' psychiatric history. For more information, see the FDA package insert.
Racial/ethnic minorities	RCTs have examined the effectiveness of interventions in specific racial/ethnic minority populations: African Americans • Bupropion SR,[484] in-person motivational counseling,[176] nicotine patch,[485] clinician advice,[486,487] counseling,[488] biomedical feedback,[489] tailored self-help manuals and materials, and telephone counseling[486,490] have been shown to be effective with African-American smokers. Asian and Pacific Islanders • No long-term RCTs have examined the effectiveness of interventions specifically in this population. Hispanics • Nicotine patch;[491] telephone counseling;[492] self-help materials, including a mood management component;[493] and tailoring[494] have been shown to be effective with Hispanic smokers. American Indians and Alaska Natives • Screening for tobacco use, clinician advice, clinic staff reinforcement, and followup materials have been shown to be effective for American Indian and Alaska Native populations.[495]
Women	• Evidence shows that both men and women benefit from bupropion SR, NRT, and varenicline;[496] evidence is mixed as to whether women show as great a benefit from NRT as do men.[150,155-157,496-498] • Psychosocial interventions, including proactive phone counseling[462] individually tailored followup,[499] and advice to quit geared toward children's health[500] are effective with women. There is some evidence that exercise is effective for women;[501] however, these findings are not consistent.[502]

[a] Go to *www.surgeongeneral.gov/tobacco/gdlnrefs.htm* for the articles used in this meta-analysis.

Clinical Issues for Specific Populations

There are population-specific concerns and clinical issues regarding prevalence and treatment of tobacco dependence (see Table 7.2).

Table 7.2. Clinical issues for treating specific populations

Issue	Approach
Language	• Ensure that interventions are provided in a language the patient understands. Most quitlines provide counseling in Spanish, and some provide counseling in other languages.[503] • All textual materials used (e.g., self-help brochures) should be written at an appropriate reading level. This is particularly important given epidemiological data showing that tobacco use rates are markedly higher among individuals of lower educational attainment.[504,505]
Culture	• Interventions should be culturally appropriate to be relevant and acceptable to the patient.[506] The extent to which cultural tailoring enhances intervention effectiveness requires further research.[490] • Clinicians should remain sensitive to individual differences and spiritual and health beliefs that may affect treatment acceptance, use, and success in all populations (see Chapter 6A, Specialized Assessment).
Medical comorbidity	• Examine the possibility of medication interactions (See Chapter 6B, Interactions of First-Line Tobacco Use Medications With Other Drugs).[308] • Address how exposure to tobacco can alter the liver's ability to metabolize different medications (HIV-positive patients).

HIV-Positive Smokers

HIV-positive individuals are more likely to smoke than the general population.[507-510] Currently, HIV-positive individuals are living longer, due to treatment advances, making the issue of cigarette smoking in this population a significant clinical concern.[511,512] HIV-positive smokers have higher mortality rates and report lower quality of life than HIV-positive nonsmokers.[513,516] In addition, HIV-positive smokers appear to be at greater risk for developing invasive pneumococcal diseases and CNS infections compared with non-HIV infected individuals.[514,517] Also, compared to nonsmoking HIV-positive individuals, smoking among HIV-positive persons is associated with increased risk of several opportunistic infections[518-520] and spontaneous pneumothorax.[521] Data suggest that HIV-positive smokers underestimate the effects of smoking on their health, and some state that

they will not live long enough for the health effects of smoking to matter.[507,522] In addition, some HIV-positive smokers report that smoking is an effective way to cope with the stress of their illness.[522]

Future Research

The following topics regarding HIV-positive smokers require additional research:

- Effectiveness of medications and counseling/behavioral interventions, including tailored interventions
- Effectiveness of motivational interviewing and educational approaches in increasing motivation to quit
- Effectiveness of community and social support networks in bolstering quitting motivation and improving treatment outcomes

Hospitalized Smokers

It is vital that hospitalized patients attempt to quit using tobacco because tobacco use may interfere with their recovery and overall health. Among cardiac patients, second heart attacks are more common in those who continue to smoke.[9,523] Lung, head, and neck cancer patients who are successfully treated for their cancer but who continue to smoke are at elevated risk for a second cancer.[524-531] Additionally, smoking negatively affects COPD as well as bone and wound healing.[531-538]

Hospitalized patients may be particularly motivated to make a quit attempt for two reasons. First, the illness resulting in hospitalization may have been caused or exacerbated by tobacco use, highlighting the patient's perceived vulnerability to the health risks of smoking[539] and making the hospitalization a "teachable moment." Second, every hospital in the United States must now be smoke-free if it is to be accredited by The Joint Commission. As a result, every hospitalized smoker is temporarily housed in a smoke-free environment. In addition, more hospitals are adopting policies establishing tobacco-free campuses, thus extending smoke-free space from indoor facilities to surrounding outdoor environments.[540-542] For these reasons, clinicians should use hospitalization as an opportunity to promote smoking cessation.[11,543,544] This also is an opportunity for clinicians to

prescribe medications to alleviate withdrawal symptoms. If patients have positive experiences with the alleviation of their withdrawal symptoms, they may be more likely to use intensive treatments in a future quit attempt or maintain their hospital-enforced abstinence. Patients in long-term care facilities also should receive tobacco dependence interventions identified as effective in this Guideline. Suggested interventions for hospitalized patients can be found in Table 7.3.

Table 7.3. Suggested interventions for hospitalized patients

For every hospitalized patient, the following steps should be taken:

- Ask each patient on admission if he or she uses tobacco and document tobacco use status.
- For current tobacco users, list tobacco use status on the admission problem list and as a discharge diagnosis.
- Use counseling and medications to help all tobacco users maintain abstinence and to treat withdrawal symptoms.
- Provide advice and assistance on how to quit during hospitalization and remain abstinent after discharge.
- Arrange for followup regarding smoking status. Supportive contact should be provided for at least a month after discharge.

The importance of posthospitalization followup has been demonstrated by research.[355,545-546] However, there are systems-level issues that may complicate the ability of hospital-based clinicians to follow up with smoking patients. The development of fax-to-quit links with quitline services may be an effective and efficient way for hospitals to refer patients for smoking cessation followup.[195,199,547]

Future Research

The following topics regarding hospitalized patients require additional research:

- Effectiveness of interventions provided by different hospital personnel, including nurses and respiratory therapists
- Effectiveness of counseling and medications with hospitalized patients
- Relapse prevention once the patient leaves the hospital, including use of fax-to-quit programs

Lesbian/Gay/Bisexual/Transgender (LGBT) Smokers

LGBT individuals, both adolescents and adults, are more likely to smoke than the general population,[548-550] and tobacco marketing is targeted at these communities.[551-554] LGBT individuals are more likely to have other risk factors for smoking, including daily stress related to prejudice and stigma.[555-558]

Future Research

The following topics regarding LGBT smokers require additional research:

- Accessibility and acceptability of tobacco dependence interventions
- Rates of intervention use and effectiveness of both medications and counseling treatments, including quitlines
- Effectiveness of tailored interventions

Low SES/Limited Formal Education

Individuals with low SES and/or limited formal education, including the homeless, bear a disproportionate burden from tobacco.[559] Addressing this particular disparity is an important part of improving the overall health of the American public.[560] These patients are more likely to: smoke,[561,562] have limited access to effective treatment,[563,564] be misinformed about smoking cessation medications,[565] be exposed to more permissive environmental and workplace smoking policies,[562] and be targeted by tobacco companies.[566] They are less likely to receive cessation assistance.[564] Moreover, smokers with low SES/limited formal education are more likely to be uninsured or on Medicaid than are other smokers.[567] Only 25 percent of smokers on Medicaid reported receiving any practical assistance with quitting. However, low SES smokers or those with limited formal education express significant interest in quitting[404,507,508,568] and appear to benefit from treatment.[569,570] Due to the prevalence of smoking in this population, it is vital that clinicians intervene with such individuals. It is important that interventions, particularly written materials, be delivered in a manner that is understandable to the patient.

Future Research

The following topics regarding low SES/limited formal education smokers require additional research:

- Effectiveness of and compliance with medications shown to be effective with general populations of smokers
- Effectiveness and utilization of novel treatment delivery settings (e.g., pharmacy-based, community-based, worksite)
- Effectiveness of quitlines, including ability of this population to access services using this modality
- Strategies for addressing misconceptions about effective cessation treatment that may be more common in these populations
- Cost-effectiveness of cessation interventions delivered as part of chronic disease management programs

Medical Comorbid Conditions, Including Cancer, Cardiac Disease, COPD, Diabetes, and Asthma

Smokers with comorbid medical conditions such as cancer, cardiac disease, COPD, diabetes, and asthma are important to target for tobacco use treatments, given the role that smoking plays in exacerbating these conditions.[447,538,571-581] Clinicians treating smokers with these conditions have an ideal "teachable moment" in that they are treating a disease that may have been caused or exacerbated by smoking and that can be ameliorated by quitting[198,582-588] but not by cutting down. Using chronic disease management programs to integrate tobacco dependence interventions into treatment may be an effective and efficient way to deliver tobacco use interventions to these populations.

Future Research

The following topics regarding smokers with comorbid medical conditions require additional research:

- Effectiveness of counseling and cessation medications among individuals with diabetes and asthma

- Impact and effectiveness of specialized assessment and tailored interventions in these populations

Older Smokers

It is estimated that more than 18 million Americans age 45 and older smoke cigarettes, accounting for 41 percent of all adult smokers in the United States;[589] 4.5 million adults over age 65 smoke cigarettes.[590] Even smokers over the age of 65 can benefit greatly from abstinence.[9,405,523,591] Older smokers who quit can reduce their risk of death from coronary heart disease, COPD, and lung cancer and decrease their risk of osteoporosis.[544,592,593] Moreover, abstinence can promote more rapid recovery from illnesses that are exacerbated by smoking and can improve cerebral circulation.[453,594,595] In fact, age does not appear to diminish the desire to quit[596] or the benefits of quitting smoking,[166,597] and treatments shown to be effective in this Guideline have been shown to be effective in older smokers (see Table 7.1). However, smokers over the age of 65 may be less likely to receive smoking cessation medications identified as effective in this Guideline.[598] Issues particular to this population (e.g., mobility, medications) make the use of proactive telephone counseling appear particularly promising. Importantly, Medicare has expanded benefits for tobacco cessation counseling and prescription medications (through Medicare Part D) for tobacco dependence treatment.[219]

Future Research

The following topics regarding older smokers require additional research:

- Effectiveness of tailored as well as general counseling interventions for older smokers in promoting tobacco abstinence
- Effectiveness and side effects of medications
- Effective methods to motivate older smokers to make a quit attempt

Psychiatric Disorders, Including Substance Use Disorders

Psychiatric disorders are more common among smokers than in the general population. For instance, as many as 30 to 60 percent of patients seeking

tobacco dependence treatment may have a past history of depression,[599,600] and 20 percent or more may have a past history of alcohol abuse or dependence.[601-603] Smoking occurs at rates well above the population average among abusers of alcohol and drugs (i.e., greater than 70 percent),[604-607] and one study found that these individuals have increased mortality from tobacco-related diseases.[608] These individuals may present themselves less frequently for tobacco dependence treatment. However, such treatments could be conveniently delivered within the context of chemical dependence or mental health clinics.[609]

As noted in the Specialized Assessment section in Chapter 6A, smokers currently experiencing a psychiatric disorder are at heightened risk for relapse to smoking after a cessation attempt.[246,466,610-613]

All smokers with psychiatric disorders, including substance use disorders, should be offered tobacco dependence treatment, and clinicians must overcome their reluctance to treat this population.[614] However, the clinician may wish to offer the tobacco dependence treatment when psychiatric symptoms are not severe. Although patients in inpatient psychiatric units are able to stop smoking with few adverse effects (e.g., little increase in aggression),[615-617] stopping smoking or nicotine withdrawal may exacerbate a patient's comorbid condition. For instance, stopping smoking may elicit or exacerbate depression among patients with a prior history of affective disorder.[325,618,619] One study suggests that alcohol treatment should precede tobacco dependence treatment to maximize the effect of the alcohol treatment.[483] Considerable research, however, also indicates that tobacco dependence treatment does not interfere with patients' recovery from the abuse of other substances.[474,475,477,480-482,620] Treating tobacco dependence in individuals with psychiatric disorders is made more complex by the potential for multiple psychiatric diagnoses and multiple psychiatric medications. Stopping tobacco use may affect the pharmacokinetics of certain psychiatric medications.[308,621] Therefore, clinicians should closely monitor the level or effects of psychiatric medications in smokers making a quit attempt.[75]

Future Research

The following topics regarding psychiatric disorders, including substance use disorders, require additional research:

- Relative effectiveness and reach of different tobacco dependence medications and counseling strategies in patients with psychiatric comorbidity, including depression
- Effectiveness and impact of tobacco dependence treatments within the context of nontobacco chemical dependency treatments
- Importance and effectiveness of specialized assessment and tailored interventions in these populations
- Impact of stopping tobacco use on psychiatric disorders and their management

Racial and Ethnic Minority Populations

Some racial and ethnic minority populations in the United States—African Americans, American Indians and Alaska Natives, Asians and Pacific Islanders, Hispanics—experience higher mortality in a number of disease categories compared with others. For example, African Americans experience substantial excess mortality from cancer, cardiovascular disease, and infant death, all of which are directly affected by tobacco use.[622-626] Moreover, they experience greater exposure to tobacco advertising.[627-629] American Indian and Alaska Natives have some of the highest documented rates of infant mortality caused by SIDS,[630,631] which also is affected by tobacco use and exposure to secondhand smoke. Therefore, the need to deliver effective tobacco dependence interventions to ethnic and racial minority smokers is critical. Unfortunately, evidence indicates that large proportions of some racial/ethnic groups lack adequate access to primary care providers and are more likely to have low SES.[632,633] These populations may be less aware of Medicaid or other available benefits[564,633-635] and more likely to harbor misconceptions about tobacco dependence treatments.[636-639] Finally, these populations may be less likely to receive advice to stop smoking[640,641] or use tobacco dependence treatment[635,637,642] than are other individuals. This suggests that special efforts and resources should be provided to meet the treatment needs of these underserved populations.[4,643]

The differences between racial and ethnic minorities and whites in smoking prevalence, smoking patterns, pharmacokinetics of nicotine, and quitting behavior in the United States are well documented.[587,642,644-656] In addition, smoking prevalence and patterns vary substantially across and

within minority subgroups (e.g., gender, level of acculturation, tribal communities).[636,657-663] Racial and ethnic minority groups also differ from whites in awareness of the health effects of smoking[636,664-667] and awareness of the benefits of proven treatments, and some racial and ethnic minority populations report a greater sense of fatalism that may affect disease prevention efforts.[637,660] On the other hand, both tobacco dependence and desire to quit appear to be prevalent across varied racial and ethnic groups.[642,667-671] In fact, smokers in several racial and ethnic groups attempt to quit as often as or more often than nonminority smokers, but use effective treatments less often and have lower success rates.[642,672]

Future Research

The following topics regarding racial and ethnic minorities require additional research:

- Effectiveness of specific tobacco dependence interventions, including medications and quitlines, in these populations (e.g., American Indian and Alaska Native smokers)
- Effectiveness of culturally adapted versus generic interventions for different racial and ethnic minority populations
- Identification and development of interventions to address the specific barriers or impediments to treatment delivery, use, or success (e.g., SES, inadequate access to medical care, treatment misconceptions, not viewing tobacco use as problematic)
- Identification of motivators of cessation that are especially effective with members of racial and ethnic minority populations (e.g., fear of illness requiring long-term care and disability)

Women

Data suggest that women are more likely to seek assistance in their quit attempts than are men.[673] Research suggests that women benefit from the same interventions as do men, although the data are mixed on whether they benefit as much as men.[156,157] Women may face different stressors and barriers to quitting that may be addressed in treatment. These include greater likelihood of depression, greater weight control concerns, hormon-

al cycles, greater nonpharmacologic motives for smoking (e.g., for socialization), educational differences, and others.[248] This suggests that women may benefit from tobacco dependence treatments that address these issues, although few studies have examined programs targeted at one gender.

Future Research

The following topics regarding gender differences require additional research:

- Gender differences in the effectiveness of tobacco dependence treatments found to be effective in this Guideline, including counseling and the effectiveness of varenicline and combination medications
- Impact of gender-specific motives that may increase quit attempts and success (e.g., quitting to improve fertility and reproductive health, pregnancy outcomes, physical appearance, and osteoporosis)

Other Specific Populations and Topics

Children and Adolescents

Recommendation: Clinicians should ask pediatric and adolescent patients about tobacco use and provide a strong message regarding the importance of totally abstaining from tobacco use. (Strength of Evidence = C)

Recommendation: Counseling has been shown to be effective in treatment of adolescent smokers. Therefore, adolescent smokers should be provided with counseling interventions to aid them in quitting smoking. (Strength of Evidence = B)

Recommendation: Secondhand smoke is harmful to children. Cessation counseling delivered in pediatric settings has been shown to be effective in increasing abstinence among parents who smoke. Therefore, to protect children from secondhand smoke, clinicians should ask parents about tobacco use and offer them cessation advice and assistance. (Strength of Evidence = B)

Background

Tobacco use is a pediatric concern. In the United States, about 4,000 children and adolescents under age 18 smoke their first cigarette each day, and an estimated 1,200 children and adolescents become daily cigarette smokers each day.[44,674] Among adults who ever smoked daily, 90 percent tried their first cigarette before age 21.[675] It is estimated that in 2006, 3.3 million U.S. adolescents aged 12 to 17 were current (past month) users of tobacco products and 2.6 million were current cigarette smokers.[43] Although use of cigarettes and cigars declined slightly from 2005 among this age group, the use of smokeless tobacco increased.[43] If current patterns persist, an estimated 6.4 million youth will die prematurely from a smoking-related disease.[675] Young people experiment with or begin regular use of tobacco for a variety of reasons, including social and parental norms, advertising, movies and popular media, peer influence, parental smoking, weight control, and curiosity.[676-685] Nicotine dependence, however, is established rapidly even among adolescents.[686-689] Because of the importance of primary prevention, clinicians should ensure that they deliver tobacco prevention and cessation messages to pediatric patients and their parents. Because tobacco use often begins during preadolescence,[690] clinicians should routinely assess and intervene with this population. Intervention research remains a priority for this population. Current reviews of smoking prevention and cessation interventions for adolescents have, so far, demonstrated limited evidence of effectiveness.[691,692] A 2007 national survey of youth tobacco cessation programs showed a lack of such programs in communities most in need—those in which youth smoking prevalence is increasing.[693] Prevention strategies useful in more general settings can be found in the Institute of Medicine report *Growing Up Tobacco Free*[694] and in the 2000 Surgeon General's Report *Reducing Tobacco Use*[6] and recently have been addressed by several authors.[695,696]

Young people vastly underestimate the addictive potential of nicotine. Adolescent smokers, both occasional and daily smokers, are more likely than nonsmokers to think they can quit at any time.[697] However, only about 4 percent of smokers aged 12 to 19 successfully quit smoking each year,[698,699] and the rate of failed adolescent quit attempts exceeds that of adult smokers.[32] Adolescents are very interested in quitting; 82 percent of 11- to 19-year-olds who smoke are thinking about quitting,[700] and 77 percent have made a serious quit attempt in the past year.[701,702] Adolescent quit attempts are rarely planned, and adolescents tend to choose unassisted

rather than assisted quit methods,[32] even though young people who enroll in a tobacco cessation program are twice as likely to succeed in their quit attempt.[703,704]

Tobacco Use Treatments in Children and Adolescents

Counseling. Seven studies met selection criteria and were included in a new 2008 analysis comparing counseling to usual care among adolescent smokers. Results of this analysis are shown in Table 7.4. As can be seen from this analysis, the use of counseling approximately doubles long-term abstinence rates when compared to usual care or no treatment. In these studies usual care may have included brief advice, self-help pamphlets, reading materials, or a referral. Note that although counseling does significantly boost abstinence rates, absolute abstinence rates were quite low, attesting to the need for improved counseling interventions for adolescents. An inspection of the included studies revealed significant heterogeneity among analyzed articles. Thus, the Panel decided to make a "B" level recommendation rather than "A" level recommendation. A recent Cochrane meta-analysis produced mixed findings for counseling as a tobacco use treatment for youth.[705]

Table 7.4. Meta-analysis (2008): Effectiveness of and estimated abstinence rates for counseling interventions with adolescent smokers (n = 7 studies)[a]

Adolescent smokers	Number of arms	Estimated odds ratio (95% C.I.)	Estimated abstinence rate (95% C.I.)
Usual care	7	1.0	6.7
Counseling	7	1.8 (1.1–3.0)	11.6 (7.5–17.5)

[a] Go to *www.surgeongeneral.gov/tobacco/gdlnrefs.htm* for the articles used in this meta-analysis.

There were too few studies to perform meta-analyses on specific counseling techniques (e.g., motivational interviewing). The adolescent intervention studies that yielded significant effects used interventions that varied in intensity, format, and content. One study used an intervention that had one in-person counseling session and one telephone call; the other two interventions comprised six and eight sessions of counseling delivered in a group format. The counseling content of these interventions involved efforts to enhance motivation, establish rapport, set goals, promote problemsolving and skill training, and prevent relapse.[482,706,707] One recent meta-analysis found significant effects for studies that employed cognitive-

behavioral strategies (self-monitoring and coping skills), social influence strategies (addressing social influences that serve to promote or maintain smoking), and motivational strategies (techniques to clarify desire for change and reduce ambivalence toward change).[704]

A series of studies comparing intensive group sessions based on social/cognitive therapy to a 10- to 20-minute brief intervention produced promising results, at least when measured at the end of treatment, across diverse adolescent populations.[708-716] Interventions should be developmentally appropriate across the adolescent age span (e.g., appropriate for a 12-year-old vs. an 18-year-old). Additionally, counseling and other interventions have been recommended for young adults ages 18 to 24 years old.[717]

Recent studies indicate that adolescent smokers are identified and counseled to quit in about 33 to 55 percent of physician visits[120,718,719] and about 20 percent of dental visits.[120] Receipt of assistance in quitting was reported by 42 percent of adolescents and followup by only 16 percent of adolescents.[719] Yet, in a survey of 5,000 adolescents (all of the 11th graders in the Memphis City Schools), more than 79 percent reported they would acknowledge their smoking if asked.[718] Therefore, clinicians need to assess adolescent tobacco use, offer counseling, and follow up with these patients. Asking about tobacco use and advising adolescents to quit are the entry points for providing effective interventions. Clinicians may use motivational interventions such as those listed in Chapter 3B, which can be adapted for use with adolescents.[173,706,720,721] It is important for clinicians to intervene with adolescents in a manner that respects confidentiality and privacy (e.g., interviewing adolescents without parents present).

Counseling Provided to Parents During the Pediatric Visit. Recent research suggests that tobacco use interventions provided to parents in pediatric clinics or during child hospitalizations increase parents' interest in stopping smoking,[198,722] parents' quit attempts[198,199] and parents' quit rates,[172,723,724] although one study failed to find such an effect.[428]

Children and adolescents also benefit if parents are given information on secondhand smoke exposure. A review of the studies conducted by the expert Panel showed that giving parents information on the harms of secondhand smoke reduces childhood exposure to such smoke and may reduce parental smoking rates.[198,725]

Questions have been raised about whether and how clinicians caring for children and adolescents might offer treatment for tobacco dependence to their parents who smoke. Would such treatment interfere with the doctor-patient relationship that parents might have with their physicians? In response to this concern, the American Medical Association adopted a policy statement in 2005 supporting the practice of pediatricians addressing parental smoking.[726]

Tobacco Use Medications. Although nicotine replacement has been shown to be safe in adolescents, there is little evidence that these medications and bupropion SR are effective in promoting long-term smoking abstinence among adolescent smokers.[727-731] As a result, they are not recommended as a component of pediatric tobacco use interventions. One small pilot study (N = 22) found some positive initial effects for bupropion SR.[730] However, other studies have found no difference between placebo and patch at 10 or 12 weeks postquit[727] or between placebo versus gum or patch at 6 months postquit.[729,732] The majority of these studies also included an intensive counseling component (6 or more sessions).

Future Research

The following topics regarding adolescents and children require additional research:

- Effectiveness of using the 5 A's in pediatric clinics to treat both adolescents and parents
- Safety and effectiveness of medications in adolescents, including bupropion SR, NRT, varenicline, and a nicotine vaccine
- Effectiveness of counseling interventions designed specifically to motivate youth to stop using tobacco
- Effectiveness of child-focused versus family-focused or peer-focused interventions as well as interventions accessed via the Internet, quitlines, and school-based programs
- Strategies for increasing the efficacy, appeal, and reach of counseling treatments for adolescent smokers

Light Smokers

Recommendation: Light smokers should be identified, strongly urged to quit, and provided counseling cessation interventions. (Strength of Evidence = B)

The field of tobacco dependence research has not achieved consensus regarding the definition of a light smoker. For the purposes of this Guideline, the Panel considered a light smoker to be anyone who smokes fewer than 10 cigarettes per day, given that these individuals frequently are excluded from the RCTs that are the basis of some of the treatment recommendations. This definition includes individuals who may not smoke daily. Light smoking does not refer to smoking low-tar/low-nicotine cigarettes. Despite lower consumption levels, light smokers are at risk for developing smoking-related diseases.[733,734] A large, longitudinal study in Norway (N = 42,722) found an increase in risk of death from ischemic heart disease and other tobacco-related causes for both men and women who smoked one to four cigarettes per day.[735] Similar results were found in a Finnish cohort, in which men who reported being "occasional smokers" demonstrated increased cardiovascular morbidity and mortality.[736]

Light smoking is becoming more common, perhaps due to smoking restrictions and increases in the price of cigarettes.[734,737] A recent National Health Interview Survey (NHIS) survey found that among adult smokers in the United States, approximately 25.4 percent report smoking 10 or fewer cigarettes per day, and 11.6 percent smoke 5 or fewer cigarettes per day.[738] Many light smokers want to quit but have difficulty doing so.[734] This is consistent with evidence that many light smokers are dependent, even though they smoke relatively few cigarettes.[739] Light smokers also are less likely to receive treatment than are heavier smokers.[734,740]

Light smokers should be provided counseling treatments identified as effective in this Guideline. One study found that health education was more effective than motivational interviewing for African-American light smokers (≤ 10 cigarettes per day).[176]

Tobacco Use Medications. Two studies examined the effectiveness of medications with light smokers. One study found that use of the nicotine lozenge significantly increased 12-month abstinence rates among light smok-

ers (≤ 15 cigarettes per day) compared to placebo.[741] Another study found no difference in effectiveness of 2-mg gum versus placebo.[176]

Future Research

The following topic regarding light smokers requires additional research:

- Effectiveness of specific counseling and medication interventions with lighter smokers

Noncigarette Tobacco Users

Recommendation: Smokeless tobacco users should be identified, strongly urged to quit, and provided counseling cessation interventions. (Strength of Evidence = A)

Recommendation: Clinicians delivering dental health services should provide brief counseling interventions to all smokeless tobacco users. (Strength of Evidence = A)

Recommendation: Users of cigars, pipes, and other noncigarette forms of smoking tobacco should be identified, strongly urged to quit, and offered the same counseling interventions recommended for cigarette smokers. (Strength of Evidence = C)

Like cigarette smoking, the use of smokeless tobacco, such as chewing tobacco, snuff, or moist snuff, produces addiction to nicotine and has serious health consequences.[742-744] Smokeless tobacco use was reported among 4 percent of adult men, but less than 1 percent of women in 2005.[591,745] Health risks from these products include abrasion of teeth, gingival recession, periodontal bone loss, leukoplakia, and oral and pancreatic cancer.[745,746] Thus, the use of smokeless tobacco is not a safe alternative to smoking,[747] nor is there evidence to suggest that it is effective in helping smokers quit.

Evidence shows that counseling treatments are effective in treating smokeless tobacco users.[748-750] Therefore, clinicians should offer quitting advice and assistance to their patients who use tobacco, regardless of the formulation of the tobacco product. Some information may be particularly relevant

in the treatment of smokeless tobacco use. For instance, a large majority of moist snuff users have identifiable oral lesions, and emphasizing this information during an oral exam may be useful in motivating a quit attempt. A close review of the literature showed that dental health clinicians (e.g., dental hygienists) delivering brief advice to quit using smokeless tobacco, in the context of oral hygiene feedback, can increase abstinence rates.[250,751]

Cigar smokers are at increased risk for coronary heart disease; COPD; periodontitis; and oral, esophageal, laryngeal, lung, and other cancers; with evidence of dose-response effects.[752-756] The prevalence of cigar smoking was 5 percent for men and less than 1 percent for women.[590] Although cigarette sales have declined over the last decade, cigar sales have increased in the United States, increasing 15.3 percent in 2005,[757] and sales of "little cigars" were at an all-time high in 2006.[758] Cigar smokers are known to discount the health effects of cigar smoking, believing it to be less detrimental than cigarettes.[752,759]

Clinicians should be aware of and address the use of other noncigarette tobacco products, including pipes, water pipes (also known as hookahs and narghile), cigarillos, loose tobacco, bidis, and betel quid. The use of cigars, pipes, and bidis is associated with cancers of the lung, stomach, oral cavity, larynx, and esophagus.[760] Further, the evidence is mixed as to whether or not individuals who use noncigarette tobacco products, either alone or in addition to cigarettes, find it more or less difficult, in comparison to cigarette smokers, to become abstinent from tobacco.[761,762]

Tobacco Use Medications. Current evidence is insufficient to suggest that the use of tobacco cessation medications increases long-term abstinence among users of smokeless tobacco. Studies conducted to date with various medications have not shown that they increase abstinence rates in this population.[750,751,763,764]

Future Research

The following topics regarding noncigarette tobacco products require additional research:

- Effectiveness of advice and counseling treatments in promoting abstinence among users of noncigarette tobacco products, especially among users of pipes, cigars, and hookahs

- Effectiveness of medications to promote abstinence among users of noncigarette tobacco products, including users of smokeless tobacco, pipes, cigars, and hookahs

- Effectiveness of combined medications and counseling and behavioral therapies with users of noncigarette tobacco products

- Effectiveness of medication and counseling interventions with individuals who both smoke cigarettes and use noncigarette tobacco products ("dual users")

Pregnant Smokers

Recommendation: Because of the serious risks of smoking to the pregnant smoker and the fetus, whenever possible pregnant smokers should be offered person-to-person psychosocial interventions that exceed minimal advice to quit. (Strength of Evidence = A)

Recommendation: Although abstinence early in pregnancy will produce the greatest benefits to the fetus and expectant mother, quitting at any point in pregnancy can yield benefits. Therefore, clinicians should offer effective tobacco dependence interventions to pregnant smokers at the first prenatal visit as well as throughout the course of pregnancy. (Strength of Evidence = B)

Psychosocial Interventions. The selection criteria for the pregnancy meta-analysis were adjusted to be appropriate for this unique population. Abstinence data were included only if they were biochemically confirmed, due to reports of deception regarding smoking status among pregnant women.[765-769] Two different followup time periods were analyzed: prebirth abstinence (> 24 weeks gestation) and greater than 5 months postpartum abstinence. For the meta-analysis, either minimal interventions (< 3 minutes) or interventions labeled as "usual care" constituted the reference condition. Eight studies met the criteria and were included in the analysis comparing person-to-person psychosocial smoking cessation interventions with usual care in pregnant women. A "usual care" intervention with pregnant smokers typically consists of a recommendation to stop smoking, often supplemented by provision of self-help material or referral to a stop-smoking program or brief counseling. Person-to-person psychosocial interventions typically involved these treatment components as well as more intensive

counseling than minimal advice. One study included 12 telephone counseling sessions after an initial in-person counseling session, and the remainder of the studies had at least two in-person counseling sessions. One study used a group intervention, and all of the other studies provided individual counseling. Six of the studies provided counseling only during pregnancy, one provided counseling in the hospital, and one provided counseling postdelivery. As Table 7.5 shows, psychosocial interventions are significantly more effective than usual care in getting pregnant women to quit while they are pregnant. These findings are consistent with other independent reviews.[770] A meta-analysis also was conducted to examine the effects of psychosocial interventions on postpartum abstinence. The odds ratio for psychosocial intervention was consistent with a positive effect of counseling on postpartum abstinence; however, the results were not statistically significant (OR = 1.6, 95 percent C.I. = 0.7–3.5). Studies using telephone counseling as the only format that compared biochemically verified outcomes to a minimal intervention suggest a possible differential effect on light versus heavy smokers and underscore the need for further research about this format.[771,772]

Table 7.5. Meta-analysis (2008): Effectiveness of and estimated preparturition abstinence rates for psychosocial interventions with pregnant smokers (n = 8 studies)[a]

Pregnant smokers	Number of arms	Estimated odds ratio (95% C.I.)	Estimated abstinence rate (95% C.I.)
Usual care	8	1.0	7.6
Psychosocial intervention (abstinence preparturition)	9	1.8 (1.4–2.3)	13.3 (9.0–19.4)

[a] Go to *www.surgeongeneral.gov/tobacco/gdlnrefs.htm* for the articles used in this meta-analysis.

Components of some person-to-person psychosocial interventions are listed in Table 7.6. These interventions were selected from articles included in the Table 7.5 meta-analysis and should guide clinicians when treating pregnant smokers.

Table 7.6. Examples of effective psychosocial interventions with pregnant patients

Physician advice regarding smoking-related risks (2–3 minutes); videotape with information on risks, barriers, and tips for quitting; midwife counseling in one 10-minute session; self-help manual; and followup letters.[773]
Pregnancy-specific self-help materials (*Pregnant Woman's Self-Help Guide To Quit Smoking*) and one 10-minute counseling session with a health educator.[774]
Counselor provided one 90-minute counseling session plus bimonthly telephone followup calls during pregnancy and monthly telephone calls after delivery.[775]

Smoking in pregnancy imparts risks to both the woman and the fetus. Cigarette smoking by pregnant women has been shown to cause adverse fetal outcomes, including stillbirths, spontaneous abortions, decreased fetal growth, premature births, low birth-weight, placental abruption, and sudden infant death syndrome (SIDS); and has been linked to cognitive, emotional, and behavioral problems in children.[776,777] Many women are motivated to quit during pregnancy, and health care professionals can take advantage of this motivation by reinforcing the knowledge that cessation will reduce health risks to the fetus and that there are postpartum benefits for both the mother and child.[778-780]

The first step in intervention is assessment of tobacco use status. This is especially important in a population in which a stronger stigma against smoking increases the potential for deception.[781,782] Research has shown that the use of multiple choice questions (see Table 7.7), as opposed to a simple yes/no question, can increase disclosure among pregnant women by as much as 40 percent.[783,784]

Table 7.7. Clinical practice suggestions for assisting a pregnant patient in stopping smoking

Clinical practice	Rationale
Assess pregnant woman's tobacco use status using a multiple-choice question to improve disclosure.	Many pregnant women deny smoking, and the multiple-choice question format improves disclosure. For example: Which of the following statements best describes your cigarette smoking? • I smoke regularly now; about the same as before finding out I was pregnant. • I smoke regularly now, but I've cut down since I found out I was pregnant. • I smoke every once in a while.

Table 7.7. Clinical practice suggestions for assisting a pregnant patient in stopping smoking (continued)

Clinical practice	Rationale
Assess pregnant woman's tobacco use status using a multiple-choice question to improve disclosure.	• I have quit smoking since finding out I was pregnant. • I wasn't smoking around the time I found out I was pregnant, and I don't currently smoke cigarettes.
Congratulate those smokers who have quit on their own.	To encourage continued abstinence.
Motivate quit attempts by providing educational messages about the impact of smoking on both maternal and fetal health.	These are associated with higher quit rates.
Give clear, strong advice to quit as soon as possible.	Quitting early in pregnancy provides the greatest benefit to the fetus.
Use problemsolving counseling methods and provide social support and pregnancy-specific self-help materials.	Reinforces pregnancy-specific benefits and increases cessation rates.
Arrange for followup assessments throughout pregnancy, including further encouragement of cessation.	The woman and her fetus will benefit even when quitting occurs late in pregnancy.
In the early postpartum period, assess for relapse and be prepared to continue or reapply tobacco cessation interventions, recognizing that patients may minimize or deny smoking.	Postpartum relapse rates are high, even if a woman maintains abstinence throughout pregnancy.

Quitting smoking prior to conception or early in the pregnancy is most beneficial, but health benefits result from abstinence at any time.[742,785-787] It is estimated that 20 percent or more of low birth-weight births could be prevented by eliminating smoking during pregnancy.[592,788] Therefore, a pregnant smoker should receive encouragement and assistance in quitting throughout her pregnancy. Women attending preconception or other medical visits also should be offered tobacco use interventions, as smoking may decrease fertility[789,790] and some adverse effects occur early in the pregnancy.[788] In addition, treating tobacco dependence prior to conception

offers more options to the clinician, including medication options, as fetal health concerns are not present.

Even women who have maintained total abstinence from tobacco for 6 or more months during pregnancy have a high rate of relapse in the postpartum period.[787,791,792] Postpartum relapse may be decreased by continued emphasis on the relationship between maternal smoking and poor health outcomes in infants and children (e.g., SIDS, respiratory infections, asthma, and middle ear disease).[793-798] One pilot study found that a relapse prevention intervention was effective;[799] however, two reviews of relapse prevention trials (both pre- and postdelivery) found no significant reduction in relapse.[185,770] There is a great need for research on the prevention of postpartum relapse. Table 7.7 outlines clinical factors to address when counseling pregnant women about smoking.

Meta-analytic results support the effectiveness of self-help materials compared to either basic information sheets or no intervention in assisting women to quit during pregnancy (see Table 7.8). Pamphlets and quitting guides were used as the self-help intervention in both studies analyzed. Other studies document favorable outcomes when self-help materials, with or without brief discussion/counseling, are added to standard advice to quit smoking.[774,800]

Table 7.8. Meta-analysis (2008): Effectiveness of and estimated preparturition abstinence rates for self-help interventions with pregnant smokers (n = 2 studies)[a]

Pregnant smokers	Number of arms	Estimated odds ratio (95% C.I.)	Estimated abstinence rate (95% C.I.)
Usual care	2	1.0	8.6
Self-help materials (preparturition)	2	1.9 (1.2–2.9)	15.0 (10.1–21.6)

[a] Go to *www.surgeongeneral.gov/tobacco/gdlnrefs.htm* for the articles used in this meta-analysis.

Tobacco use medication and pregnant smokers—Effectiveness. The data on the effectiveness of nicotine replacement therapy with pregnant smokers include three randomized, controlled nicotine patch studies. One study randomly assigned 250 pregnant women who still were smoking after the first trimester to either a 15-mg, 16-hour active patch for 8 weeks and a 10-mg, 16-hour patch for 3 additional weeks or to a placebo. No significant

differences were seen in smoking abstinence rates, number of cigarettes smoked, birthweight, or number of preterm deliveries.[801] A similar study of the nicotine patch with 30 pregnant women who still were smoking 15 or more cigarettes a day after the first trimester found moderate but nonsignificant differences in abstinence rates (23% in the active patch and counseling condition vs. 0% in the placebo patch and counseling condition).[802] A recent study[803] randomized 181 pregnant women to cognitive behavioral therapy (CBT) and NRT or CBT alone. Women in the CBT plus NRT group were significantly more likely to be abstinent at 7 weeks post-randomization (29% vs. 10%) and at 38 weeks gestation (22% vs. 7%). This study was stopped prior to completion (see safety section below). Based on these data, the Panel did not make a recommendation regarding medication use during pregnancy.

Tobacco use medication and pregnant smokers—Safety. Cigarette smoking during pregnancy is the greatest modifiable risk factor for pregnancy-related morbidity and mortality in the United States.[804] Adverse effects of smoking during and after pregnancy include increased risks of spontaneous abortion,[805] premature labor and delivery,[806] placental abruption,[807] fetal growth retardation,[808-810] SIDS,[811,812] and many health risks for the woman and her child.[794,813]

Cigarette smoke contains thousands of chemicals, many of which may contribute to reproductive toxicity. Of particular concern are carbon monoxide, nicotine, and oxidizing chemicals.[814] High levels of carbon monoxide exert neuroteratogenic effects.[815,816] Oxidizing chemicals are likely to contribute to an increased risk of thrombotic complications and, by reducing nitric oxide availability, contribute to placental vasoconstriction and premature labor.[817,818]

Nicotine may contribute to adverse effects of cigarette smoking during pregnancy and result in injury to the fetus.[819-821] Nicotine has been postulated to cause uteroplacental insufficiency via vasoconstriction, to produce fetal neurotoxicity resulting in delayed or impaired brain development, to inhibit the maturation of pulmonary cells and to increase the risk of SIDS. These concerns are based primarily on animal studies. Relatively little human research with pure nicotine has been done in pregnant smokers.

Several studies of brief exposure to nicotine patches or nicotine gum have demonstrated small hemodynamic effects in the mother and fetus, gener-

ally less than those seen with cigarette smoking.[822] The three clinical trials of NRT in pregnant women have yielded information relative to safety. The Wisborg trial of 250 women randomized to nicotine patch (15 mg) or placebo for 11 weeks found no evidence of serious adverse effects of nicotine.[801] To the contrary, birth weight was significantly higher in the NRT group, possibly due to reduced cigarette smoking in the NRT group. The Kapur study included 30 women randomized to nicotine patches (15 mg) or placebo, and reported no serious adverse effects of NRT.[802] One placebo-treated woman experienced extreme nicotine withdrawal, associated with increased fetal movements, prompting discontinuation of the trial. The Pollack study included 181 women, 122 randomized to CBT plus NRT, and 59 to CBT alone.[803] The NRT group could select nicotine patches, gum, or lozenge, or no NRT. More than half the women selected nicotine patches, the dose of which was adjusted according to the number of cigarettes smoked per day on study entry. As described in the "effectiveness" section above, women treated with NRT had significantly higher quit rates during pregnancy than did women receiving CBT alone. However, the study was terminated early by the Data Safety Monitoring Board (DSMB) due to a higher incidence of adverse events. Serious adverse events occurred in 30 percent of the NRT group compared to 17 percent of the CBT-alone group. The most frequent cause of serious adverse events was preterm labor. There was evidence that this difference in preterm labor was due to a difference between groups in history of preterm labor that predated study entry. The DSMB indicated that the study had to be terminated due to *a priori* stopping rules; however, they did not believe that the serious adverse events were related to NRT use. The authors concluded that this study cannot support or negate published literature about the harm of NRT during pregnancy.

Morales-Suarez-Varela et al. reported data from a retrospective cohort study suggesting that the use of NRT in women who quit smoking but who used nicotine substitutes during the first 12 weeks of pregnancy was associated with a small but significant increase in congenital malformations compared to mothers who smoked during the first trimester.[823] This study suffers from multiple, substantial methodological problems, however, making its findings difficult to interpret. Also, the number of malformation cases in the NRT group was quite small, and the relative prevalence rate ratios for malformations in cases compared to controls were of borderline significance. Further, concerns exist about possible undetected spontaneous abortion among continuing smokers. In addition, most women who

use NRT do so in the second or third trimester, and no adverse event data were reported in these women.

Safety is not categorical. A designation of "safe" reflects a conclusion that a drug's benefits outweigh its risks. Nicotine most likely does have adverse effects on the fetus during pregnancy. Although the use of NRT exposes pregnant women to nicotine, smoking exposes them to nicotine plus numerous other chemicals that are injurious to the woman and fetus. These concerns must be considered in the context of inconclusive evidence that cessation medications boost abstinence rates in pregnant smokers.

Future Research

The following topics regarding smoking and pregnancy require additional research:

- Relapse prevention with pregnant women and women who have recently given birth
- Effectiveness of psychosocial treatment provided via nonface-to-face modalities, such as quitlines or Web-based programs
- The safety and effectiveness of tobacco dependence medications (bupropion SR, NRTs, and varenicline) during pregnancy for the woman and the fetus, including: the relative risks and benefits of medication use as a function of dependence, and the appropriate formulation and timing of medication use
- Safety and effectiveness of tobacco dependence medications, especially varenicline and bupropion SR as well as various forms of NRT, to the woman and child during nursing
- Effectiveness of economic incentives to promote quitting and sustained abstinence
- Effects of smoking during fertility treatment and the effects and effectiveness of cessation interventions on the infertile population, both men and women

- Effects of reporting smoking status and the provision of cessation interventions as part of the national database for assisted reproductive technology treatments (the Center for Disease Control and Prevention's Assisted Reproductive Technology [ART] database, *www.cdc.gov/art*)

- Effectiveness of relapse prevention programs for spontaneous "self-quitters amongst pregnant women"

- Effectiveness of different types of counseling, behavioral therapies, and motivational interventions (e.g., physiological feedback of adverse impacts, quitting benefits) for pregnant women in general and in high-prevalence populations (e.g., American Indian and Alaska Native women, especially)

- Strategies for linking preconception, pregnancy, and postpartum (including pediatric) interventions

Weight Gain After Stopping Smoking

Recommendation: For smokers who are greatly concerned about weight gain, it may be most appropriate to prescribe or recommend bupropion SR or NRT (in particular, nicotine gum and nicotine lozenge), which have been shown to delay weight gain after quitting. (Strength of Evidence = B)

The majority of smokers who quit smoking gain weight. Most will gain fewer than 10 pounds, but there is a broad range of weight gain, with as many as 10 percent of quitters gaining as much as 30 pounds.[824-827] However, weight gain that follows stopping smoking is a modest health threat compared with the risks of continued smoking.[824]

Women tend to gain slightly more weight than men do.[828] For both sexes, African Americans, people under age 55, and heavy smokers (those smoking more than 25 cigarettes per day) are at elevated risk for major weight gain.[826,829-831]

For some smokers, especially women, concerns about weight or fears about weight gain are motivators to start smoking or continue smoking.[832-836]

Adolescents, even as young as middle-school age, who are concerned about their weight initiate smoking more often than do other adolescents.[683,837-838]

Concern about weight varies substantially by ethnicity. For example, adolescent African-American females are much less likely to report that they smoke to control weight than are white European Americans.[683,839] This is an important area for further study, as little tobacco research focuses on women in racial/ethnic minority groups.[683]

There is no convincing evidence that counseling interventions specifically designed to mitigate weight gain during attempts to stop smoking result in reduced weight gain.[165,499,840] It also is unclear that such interventions affect cessation success; specifically, these interventions do not appear to adversely affect cessation.[499,840-842]

Nicotine replacement—in particular, 4-mg nicotine gum and 4-mg nicotine lozenge—appears to be effective in delaying postcessation weight gain. Moreover, there appears to be a dose-response relation between gum use and weight suppression (i.e., the greater the gum use, the less weight gain occurs). Bupropion SR also appears to be effective in delaying postcessation weight gain.[484,843-845] Once either nicotine gum or bupropion SR therapy is stopped, however, the quitting smoker, on average, gains an amount of weight that is about the same as if she or he had not used these medications.[843,846-848]

Postcessation weight gain appears to be caused both by increased intake (e.g., eating, including high-caloric foods, and alcohol consumption) and by decreased metabolism. The involvement of metabolic mechanisms suggests that even if smokers do not increase their caloric intake upon quitting, they will, on average, gain some weight.[849-852] Once an individual relapses and begins smoking at precessation levels, he or she usually will lose some or all of the weight gained during the quit attempt.

The research evidence reviewed above shows why concerns about weight gain can be barriers to smoking abstinence. Many smokers (especially women) are concerned about their weight and fear that quitting will produce weight gain. Many also believe that they can do little to prevent postcessation weight gain except return to smoking. These beliefs are difficult to address clinically because smoking does appear to affect weight.

Recommendations to Clinicians When Addressing Weight Gain

How should the clinician deal with concerns about weight gain? First, the clinician should neither deny the likelihood of weight gain nor minimize its significance to the patient. Rather, the clinician should inform the patient about the likelihood of weight gain and prepare the patient for its occurrence. The clinician also should counter exaggerated fears about weight gain given the relatively moderate weight gain that typically occurs. Certain types of information may help prepare the patient for postcessation weight gain (see Table 7.9). Clinicians also should inform the patient that smoking presents a much greater health risk than the negligible health risk involved in the modest weight gain associated with smoking abstinence.

Second, during the quit attempt, the clinician should offer to help the patient address weight gain (either personally or via referral) once the patient has successfully quit smoking. The patient should be encouraged to maintain or adopt a healthy lifestyle, including engaging in moderate exercise, eating plenty of fruits and vegetables, and limiting alcohol consumption.[502,853]

Exercise

Available research does not show that interventions to increase exercise reliably boost smoking abstinence rates.[842,854] One recent study, however, showed that an exercise program occurring in three 45-minute sessions per week increases long-term smoking abstinence in women and delays weight gain when it is combined with a cognitive-behavioral smoking cessation program.[853] As was the case for weight loss interventions, there is no evidence that exercise interventions undermine success in stopping smoking. Some evidence suggests that weight gain is reduced if smoking abstinence is accompanied by a moderate increase in physical activity.[855] Vigorous exercise programs should not be implemented without consulting a physician. Although it may be difficult to get smokers to adhere to a vigorous exercise program, smokers should be encouraged to engage in moderate exercise and physical activity as part of a healthy lifestyle.[856]

Table 7.9. Clinician statements to help a patient prepare for and cope with post-cessation weight gain

Clinician statements
The great majority of smokers gain weight once they quit smoking. However, even without special attempts at dieting or exercise, weight gain is usually 10 lbs. or less.
Some medications, including bupropion SR and nicotine replacement medicines, may delay weight gain.
There is evidence that smokers often gain weight once they quit smoking, even if they do not eat more. However, there are medications that will help you quit smoking and limit or delay weight gain. I can recommend one for you.
The amount of weight you will likely gain from quitting will be a minor health risk compared with the risks of continued smoking.
I know that you don't want to gain a lot of weight. However, let's focus on strategies to get you healthy rather than on weight. Think about eating plenty of fruits and vegetables, getting regular exercise, getting enough sleep, and avoiding high-calorie foods and beverages. Right now, this is probably the best thing you can do for both your weight and your health.
Although you may gain some weight after quitting smoking, compare the importance of this with the added years of healthy living you will gain, your better appearance (less wrinkled skin, whiter teeth, fresher breath), and good feelings about quitting.

Future Research

The following topics regarding weight gain during tobacco dependence treatment require additional research:

- Effectiveness of weight control measures during quit attempts and their effect on tobacco abstinence and weight, including issues of timing of weight control interventions
- Effectiveness of medications to control weight gain during quit attempts
- Effectiveness of the use of exercise to control weight gain during a quit attempt, including the optimal "dose" of exercise to minimize weight gain and not jeopardize cessation outcome
- Impact of weight gain concerns on specific populations, including adolescents who smoke and ethnic/minority women
- Strategies to increase adherence to exercise protocols as part of cessation interventions that include efforts to decrease weight gain

Glossary

Abstinence percentage. The percentage of smokers who achieve long-term abstinence from smoking. The most frequently used abstinence measure for this Guideline was the percentage of smokers in a group or treatment condition who were abstinent at a followup point that occurred at least 5 months after treatment.

Acupuncture. A treatment involving the placement of needles in specific areas of the body with the intent to promote abstinence from tobacco use. Acupuncture also can be accomplished using electrostimulation or laser.

Addiction. Compulsive drug use, with loss of control, the development of dependence, continued use despite negative consequences, and specific withdrawal symptoms when the drug is removed.

All-comers. Individuals included in a tobacco treatment study regardless of whether they sought to participate. For example, if treatment was delivered to all smokers visiting a primary care clinic, the treatment population would be coded as "all-comers." Presumably, individuals who seek to participate in tobacco treatment studies ("want-to-quit" smokers) likely are more motivated to quit, and studies limited to these individuals may produce higher quit rates. All-comers can be contrasted with "want-to-quit" or self-selected populations.

Agonist. A drug action that generally mimics or enhances the effect of another drug at a neural receptor site. Nicotine is a cholinergic agonist.

Antagonist. A drug action that generally blocks or neutralizes the effect of another drug at a neural receptor site. Naltrexone and mecamylamine are examples of antagonists.

Anxiolytic. A medication used to reduce anxiety symptoms.

Assessment. All tobacco cessation interventions begin with identifying tobacco users and performing an assessment. The assessment is used to identify the most beneficial intervention for each smoker. Assessments may be specialized and may be ongoing throughout a smoking cessation program or occur at followups.

Aversive smoking. Several types of therapeutic techniques that involve smoking in an unpleasant or concentrated manner. These techniques pair smoking with negative associations or responses. Notable examples include rapid smoking, rapid puffing, focused smoking, and satiation smoking.

Behavioral therapy. A psychotherapeutic approach aimed at identifying and modifying the behaviors associated with human problems.

Benzodiazepine. Medication used as an anxiolytic. Benzodiazepines do not have an FDA indication for treating tobacco use and dependence.

Bidis. Small, thin, hand-rolled cigarettes, often consisting of flavored tobacco wrapped in tendu or temburni leaves. Bidis have a higher concentration of nicotine, tar, and carbon monoxide than conventional cigarettes sold in the United States. They are imported to the United States from India and other Southeast Asian countries.

Biochemical confirmation. The use of biological samples (expired air, blood, saliva, or urine) to measure tobacco-related compounds such as thiocyanate, cotinine, nicotine, and carboxyhemoglobin to verify users' reports of abstinence.

Bupropion SR (bupropion sustained-release). A non-nicotine aid for smoking cessation, originally developed and marketed as an antidepressant. It is chemically unrelated to tricyclics, tetracyclics, selective serotonin re-uptake inhibitors, or other known antidepressant medications. Its mechanism of action is presumed to be mediated through its capacity to block the reuptake of dopamine and norepinephrine centrally.

Buspirone. A nonbenzodiazepine drug with anxiolytic properties. Buspirone does not have an FDA indication for treating tobacco use and dependence.

Coordinated intervention. Tobacco dependence treatment strategy that involves the clinician, health care administrator, insurer, and purchaser to ensure the provision of tobacco dependence treatment as an integral element of health care delivery.

Chronic disease model. Recognizes the long-term nature of tobacco dependence, with an expectation that patients may have periods of relapse and remission. The chronic disease model emphasizes the importance of continued patient education, counseling, and advice over time.

Cigarette fading/smoking reduction prequit. An intervention strategy designed to reduce the number of cigarettes smoked or nicotine intake prior to a patient's quit date. This may be accomplished through advice to cut down or to systematically restrict access to cigarettes. These interventions use computers and/or strategies to accomplish prequitting reductions in cigarette consumption or nicotine intake.

Clinician. A professional directly providing health care services.

Clinic screening system. The strategies used in clinics and medical practices for the delivery of clinical services. Clinic screening system interventions involve changes in protocols designed to enhance the identification of and intervention with patients who smoke. Examples include affixing tobacco use status stickers to patients' charts, expanding the capture of vital signs to include tobacco use, incorporating tobacco use status items into patient questionnaires, and including prompts for tobacco use monitoring in electronic medical records.

Clonidine. An alpha-2-adrenergic agonist typically used as an antihypertensive medication, but also documented in this Guideline as an effective medication for smoking cessation.

Cochrane Review. A service of the Cochrane Collaboration, an international nonprofit and independent organization (*www.cochrane.org/index.htm*) that regularly publishes evidence-based reviews about health care interventions.

Cognitive behavioral therapy (CBT). A psychotherapeutic approach aimed at identifying and modifying faulty or distorted negative thinking styles and the maladaptive behaviors associated with those thinking styles.

Combination medications. Treatment that combines two or more nicotine-containing medications or a nicotine-containing medication with another tobacco treatment medication such as bupropion SR.

Community-level interventions. Interventions for the primary prevention or treatment of tobacco use that usually are not implemented in primary care practice settings. These interventions most often are implemented through mass media campaigns.

Comorbidity. Coexistence of tobacco use with other medical diseases/illnesses, including mental illnesses.

Confidence intervals. Estimated range of values, which is likely to include an unknown population parameter. The estimated range is calculated from a given set of sample data.

Contingency contracting/instrumental contingencies. Interventions that incorporate the use of tangible rewards for cigarette abstinence and/or costs for smoking. For the purposes of analysis, simple agreements about a quit date, or other agreements between treatment providers and patients without specifiable consequences, as well as deposits refunded based on study attendance and/or other incentives that were not contingent on smoking abstinence or relapse were not considered examples of contingency contracting.

Continuous abstinence. A measure of tobacco abstinence based on whether subjects are continuously abstinent from smoking/tobacco use from their quit day to a designated outcome point (e.g., end of treatment, 6 months after the quit day).

Cost effectiveness. Quantified analysis of tobacco dependence program costs relative to tobacco use related costs.

Diazepam. A benzodiazepine medication intended to reduce anxiety.

Discrepancy. A strategy used in motivational interviewing to highlight how a patient's expressed priorities, values, and goals may conflict with the use of tobacco.

Efficacy and effectiveness. *Efficacy* is the outcome achieved from a treatment provided under near-ideal circumstances of control (typically, in a research study). Efficacy studies involve recruitment of motivated participants, random assignment, intensive assessment, and methods designed to keep participants in treatment. *Effectiveness* is the outcome achieved from a treatment provided in a "real-world setting" (in a clinic or community

setting). Such studies typically involve participants who do not seek out the study or treatment, and the treatment is delivered in a manner consistent with its likely use in real-world settings. This 2008 clinical update uses the term "effectiveness" exclusively, recognizing that the majority of the studies summarized here reflect efficacy research that requires random assignment and a high degree of experimental control. This was done for purposes of clarity for its intended clinical audience.

Environmental tobacco smoke (ETS). Also known as "secondhand smoke" (SHS). The smoke inhaled by an individual not actively engaged in smoking, but who is exposed to smoke from the lit end of a cigarette and the smoke exhaled by the smoker.

Exercise/fitness component. Refers to an intervention that contains a component related to exercise/fitness. The intensity of interventions falling within this category varies from the mere provision of information/advice about exercise/fitness to exercise classes.

Extratreatment social support component. Interventions or elements of an intervention in which patients are provided with tools or assistance in obtaining social support outside the treatment environment. This category is distinct from intratreatment social support, in which social support is delivered directly by treatment staff.

Fax-to-quit. Patient referral in which the patient and health care provider fill out a form with pertinent patient information, which is faxed to a quitline for followup.

Food and Drug Administration (FDA). Federal regulatory agency that has control over the safety and release of drugs marketed in the United States.

First-line medications. First-line medications have been found to be safe and effective for tobacco dependence treatment and have been approved by the FDA for this use. First-line medications have an established empirical record of efficacy and should be considered first as part of tobacco dependence treatment, except in cases of contraindications.

Fluoxetine. A selective serotonin re-uptake inhibitor used as a treatment for depression. Fluoxetine does not have an FDA indication for treating tobacco use and dependence.

Formats. Refers to tobacco dependence intervention delivery strategies that include self-help, proactive telephone counseling, computerized or e-health services, individual counseling, and group counseling.

Healthcare Effectiveness Data and Information Set (HEDIS). Serves as a "report card" for providing information on quality, utilization, enrollee access and satisfaction, and finances for managed care organizations and other health care delivery entities.

Higher intensity counseling. Refers to interventions that involve extended contact between clinicians and patients. It is coded based on the length of contact between clinicians and patients (greater than 10 minutes). If that information is unavailable, it is coded based on the content of the contact between clinicians and patients.

Hookah. A smoking pipe designed with a long tube passing through an urn of water that cools the smoke as it is drawn through. Also called "waterpipe," "hubble-bubble," "narghile," "shisha."

Hotline/helpline. A reactive telephone line dedicated to over-the-phone smoking intervention. Hotline/helpline treatment occurs when a hotline/helpline number is provided to a patient, or a referral to a hotline/helpline is made. The key distinction between a hotline/helpline and proactive telephone counseling is that, in the former, the patient must initiate each clinical contact.

Hypnosis. A treatment by which a clinician induces an altered attention state and heightened suggestibility in a tobacco user for the purpose of promoting abstinence from tobacco use. Also referred to as hypnotherapy.

Individualized interventions. Refers to tailoring an intervention to fit the needs of a particular smoker. For example, relapse prevention can be individualized based on information obtained about problems the patient has encountered in maintaining abstinence. See also Tailored Interventions.

Intent-to-treat. Treatment outcome analyses that determine abstinence percentages based on all subjects randomized to treatment conditions, rather than on just those subjects who completed the intervention or those who could be contacted at followup.

Intensive interventions. Comprehensive treatments that may occur over multiple visits for long periods of time and may be provided by more than one clinician.

Internet (Web-based) interventions. Interventions delivered through the use of a computer. The smoker may navigate within a specific Web site to access general treatment and treatment information, or the smoker may interact with a program that delivers a tailored intervention.

Intervention. An action or program that aims to bring about identifiable outcomes. In tobacco dependence treatment, the intervention generally is clinical in nature and may consist of counseling and the use of medications. Also referred to as "treatment."

Intratreatment social support. Refers to an intervention component that is intended to provide encouragement, a sense of concern, and empathic listening as part of the treatment.

Light smoker. The field of tobacco dependence research has not achieved consensus regarding the definition of a light smoker. For this publication, it refers to anyone who smokes between 1 and 10 cigarettes per day.

Literature review. A critical analysis of the research conducted on a particular topic or question in the field of science.

Logistic regression. Statistical technique to determine the statistical association or relation between/among two or more variables, in which the dependent variable is dichotomous (has only two levels of magnitude, e.g., abstinent vs. smoking).

Low-intensity counseling. Low-intensity counseling refers to interventions that involve contact between clinicians and patients that last between 3 and 10 minutes. If the information on length of contact is unavailable, it is coded based on the description of content of the clinical intervention.

Managed care organizations (MCOs). Any group implementing health care using managed care concepts, such as preauthorization of treatment, utilization review, system-wide quality improvement strategies, and a network of providers.

Mecamylamine. A nicotine antagonist used as an antihypertensive agent. Mecamylamine does not have an FDA indication for treating tobacco use and dependence.

Meta-analysis. A statistical technique that estimates the impact of a treatment or variable across a set of related studies, publications, or investigations.

Minimal counseling. Minimal counseling refers to interventions that involve very brief contact between clinicians and patients. It is coded based on the length of contact between clinicians and patients (3 minutes or less). If that information is unavailable, it is coded based on the content of the clinical intervention.

Motivation. Refers to a patient's intent or resolve to quit. Motivation can be bolstered through actions, such as setting a quit date, using a contract with a specified quit date, reinforcing correspondence (letters mailed from clinical/study staff congratulating the patient on his or her decision to quit or on early success), and providing information about the health risks of smoking.

Motivational intervention. An intervention designed to increase the smoker's motivation to quit.

Motivational interviewing (MI). A directive and patient-centered counseling method used to increase motivation and facilitate change.

Naltrexone. An opioid receptor antagonist used in substance abuse treatment. Naltrexone does not have an FDA indication for treating tobacco use and dependence.

National Committee for Quality Assurance (NCQA). Reviews and accredits managed care organizations, develops processes for measuring health plan performance, and disseminates information about quality so consumers can make informed choices (e.g., through "report cards," such as HEDIS).

Negative affect/depression intervention. A type of intervention designed to train patients to cope with negative affect after smoking cessation. The intensity of the interventions in this category may vary from prolonged counseling to the provision of information about coping with negative

moods. To receive this code, interventions target depressed mood, not simply stress. Interventions aimed at teaching subjects to cope with stressors are coded as problemsolving. When it is unclear whether an intervention is directed at negative affect/depression or at psychosocial stress, problemsolving is used as the default code.

Neuroteratogenic. The capability of some substances to cause abnormal development of the nervous system in the fetus.

Neurotoxicity. The capablility of some substances to cause damage to the nervous system.

Nicotine gum. Nicotine-containing gum, a smoking cessation aid, that delivers nicotine through the oral mucosa. It is available without a prescription.

Nicotine inhaler. Nicotine-containing inhaler, a smoking cessation aid, that delivers nicotine in a vapor that is absorbed through the oral mucosa. It is available by prescription only.

Nicotine lozenge. Nicotine-containing hard lozenge, a smoking cessation aid, that delivers nicotine through the oral mucosa. It is available without a prescription.

Nicotine nasal spray. Nicotine-containing spray, a smoking cessation aid, that delivers nicotine in a mist that is absorbed in the nasal passages. It is available by prescription only.

Nicotine patch. A nicotine-containing patch, a smoking cessation aid, that delivers nicotine through the skin; available with or without a prescription.

Nicotine replacement therapy (NRT). Refers to medications containing nicotine that are intended to promote smoking cessation. There are five NRT delivery systems currently approved for use in the United States. These include nicotine gum, nicotine inhaler, nicotine lozenge, nicotine nasal spray, and nicotine patch.

Nortriptyline. A tricyclic antidepressant identified by the Guideline Panel as a second-line medication for smoking cessation. Nortriptyline does not have an FDA indication for treating tobacco use and dependence.

Odds ratio. The odds of an outcome on one variable, given the certain status of another variable(s). This ratio expresses the increase in risk of a given outcome if a specific variable is present.

Opioid antagonists. A class of medications that block action at opiate receptor sites. Naltrexone is one type of opioid antagonist. No opioid antagonist has an FDA indication for treating tobacco use and dependence.

Oral mucosa. The mucous membranes that line the mouth.

Over-the-counter (OTC). Drug or medication for which a prescription is not needed.

Pay for performance. An incentive program in which a health care purchaser provides additional payments or other rewards usually to a clinic or provider if a specified goal is met.

Person-to-person intervention. In-person or face-to-face contact between a clinician and a patient for the purpose of tobacco use intervention or assessment.

Physiological monitoring/biological marker feedback. A treatment by which a clinician provides to a tobacco user biological information, such as spirometry readings, carbon monoxide readings, or genetic susceptibility information, for the purpose of increasing abstinence from tobacco use.

Placebo. An inactive, harmless substance with no known direct beneficial effects. Usually used in clinical studies as a comparison to the effectiveness of an experimental drug or regimen.

Point prevalence. A measure of tobacco abstinence based on smoking/tobacco use occurrence within a set period (usually 7 days), prior to a followup assessment.

Potential reduced exposure products (PREP). Products designed to reduce levels of tobacco intoxicants including: (1) modified tobacco products, (2) tobacco products that are heated rather than burned, (3) oral, low-nitrosamine tobacco products, and (4) medicinal nicotine products (e.g., NRTs). With the exception of NRTs, little research has been conducted to evaluate PREPs.

Practical counseling (problemsolving/skills training). Refers to a tobacco use treatment in which tobacco users are trained to identify and cope with events or problems that increase the likelihood of their tobacco use. For example, quitters might be trained to anticipate stressful events and to use coping skills, such as distraction or deep breathing, to cope with an urge to smoke. Related interventions are coping skill training, relapse prevention, and stress management.

Primary care clinician. A clinician (e.g., in medicine; nursing; psychology; pharmacology; dentistry/oral health; physical, occupational, and respiratory therapy) who provides basic health care services for problems other than tobacco use *per se*. Primary care providers are encouraged to identify tobacco users and to intervene, regardless of whether tobacco use is the patient's presenting problem.

Proactive telephone counseling. A quitline that responds to incoming calls and makes outbound followup calls. Following an initial request by the smoker or via a fax-to-quit program, the clinician initiates telephone contact to counsel the patient (see Hotline/Helpline).

Propranolol. A beta-adrenergic blocker often used as an antihypertensive medication. Propranolol does not have an FDA indication for treating tobacco use and dependence.

Psychosocial interventions. Refers to intervention strategies that are designed to increase tobacco abstinence rates due to psychological or social support mechanisms. These interventions comprise counseling, self-help, and behavioral treatment, such as rapid smoking and contingency contracting.

Purchaser. A corporation, company, Government agency, or other consortium that purchases health care benefits for a group of individuals.

Quality-adjusted life years (QALY). Measure of both the quality and the quantity of life lived. Used as a means of quantifying the benefits of a medical intervention.

Quit day. The day of a given cessation attempt during which a patient tries to abstain totally from tobacco use. Also refers to a motivational intervention, whereby a patient commits to quit tobacco use on a specified day.

Quitline. A telephone counseling service that can provide both proactive telephone counseling and reactive telephone counseling (see Proactive Telephone Counseling and Reactive Telephone Counseling).

Randomized controlled trial. A study in which subjects are assigned to conditions on the basis of chance, and where at least one of the conditions is a control or comparison condition.

Random effects modeling. A model in which both study sampling errors (variance) and between-study variation are included in the assessment of the uncertainty (confidence interval) of the results of a meta-analysis. If there is significant heterogeneity among the results of included studies, random effects models will give wider confidence intervals than fixed effect models.

Rapid puffing/smoking. A smoking cessation technique that involves the pairing of concentrated smoking with negative associations or responses (e.g., nausea).

Reactive telephone counseling. Telephone counseling that provides an immediate response to a patient-initiated call for assistance. It is a quitline intended to respond only to incoming calls (see Hotline/Helpline).

Reference group. In meta-analyses, refers to the group against which other groups are compared (i.e., a comparison or control group).

Relapse. Return to regular smoking by someone who has quit. A distinction is sometimes made between "relapse" and a "lapse" (or a "slip"), which is a return to reduced smoking or brief smoking after quitting that falls short of a return to regular smoking (see also Slip).

Relapse prevention. Various intervention strategies intended to prevent a recent quitter from returning to regular smoking.

Relaxation/breathing. An intervention strategy in which patients are trained in relaxation techniques, such as meditation and breathing exercises. This intervention should be distinguished from "problemsolving," which includes a much wider range of stress-reduction/management strategies.

Restricted environmental stimulation therapy (REST). A treatment involving the use of sensory deprivation to promote abstinence from tobacco use.

Return on investment (ROI). Amount of money gained or lost, including money that would have been spent for health care, in relation to the amount of money needed to provide the treatment.

Screening. See Clinic Screening System.

Secondhand smoke. Also known as environmental tobacco smoke (ETS). The smoke inhaled by an individual not actively engaged in smoking, but who is exposed to smoke from the lit end of a cigarette and the smoke exhaled by the smoker.

Second-line medications. Second-line medications are medications for which there is evidence of efficacy for treating tobacco dependence. They have a more limited role than first-line medications because: (1) the FDA has not approved them for a tobacco dependence treatment indication, and (2) there are more concerns about potential side effects than exist with first-line medications. Second-line treatments should be considered for use on a case-by-case basis after first-line treatments have been used or considered.

Selective Serotonin Re-uptake Inhibitors (SSRIs). A class of antidepressant used in the treatment of clinical depression that has been studied for use in tobacco dependence treatment. No SSRI has an FDA indication for treating tobacco use and dependence.

Self-efficacy. One's beliefs about his/her capability to successfully act to achieve specific goals or influence events that affect one's life.

Self-help. An intervention strategy in which the patient uses a nonpharmacologic physical aid to achieve abstinence from tobacco. Self-help strategies typically involve little contact with a clinician, although some strategies (e.g., reactive hotline/helpline) involve patient-initiated contact. Types of self-help materials include: pamphlets/booklets/mailings/manuals; videos; audios; referrals to 12-step programs; mass media, community-level interventions; lists of community programs; reactive telephone hotlines/helplines; and computer programs/Internet.

Self-reported abstinence. Abstinence based on the patient's claim, which may or may not be verified clinically by biochemical confirmation.

Sertraline. A selective serotonin re-uptake inhibitor. Sertraline does not have an FDA indication for treating tobacco use and dependence.

Serum nicotine. Level of nicotine in the blood. This often is used to assess a patient's tobacco/nicotine self-administration prior to quitting, and to confirm abstinence self-reports during followup. Nicotine commonly is measured in urine and saliva.

Serum nicotine/cotinine levels. Level of nicotine/cotinine in the blood. Cotinine is nicotine's major metabolite, which has a significantly longer half-life than nicotine. This often is used to estimate a patient's tobacco/nicotine self-administration prior to quitting, and to confirm abstinence self-reports during followup. Cotinine commonly is measured in urine and saliva.

Side effects. Undesired actions or effects of a drug used in tobacco use treatment, such as insomnia or dry mouth.

Silver acetate. Silver acetate reacts with cigarette smoke to produce an unpleasant taste and has been investigated as a smoking deterrent. It is not approved by the FDA for this use.

Skills training. Refers to a tobacco use treatment in which tobacco users are trained to identify and cope with events or problems that may increase the risk of tobacco use. For example, quitters might be trained to anticipate stressful events and to use coping skills, such as distraction or deep breathing, to cope with an urge to smoke. Related interventions are practical counseling, relapse prevention, and stress management.

Slip. A brief or reduced return to smoking after quitting. Also referred to as a "lapse" (see Relapse).

Smokeless tobacco. Any form of unburned tobacco, including chewing tobacco, snus, and snuff. Use of smokeless tobacco is as addictive as smoking and can cause cancer of the gum, cheek, lip, mouth, tongue, throat, and pancreas.

Social support. Nonmedicinal support for the smoking cessation patient that provides personal encouragement and empathetic listening. Tobacco dependence treatments include two types of social supports: intratreatment social support and extratreatment social support.

Socioeconomic status (SES). Position of an individual or group in a population or society, usually based on income, education, or occupational categories.

Specialized assessments. Refers to assessment of patient characteristics, such as nicotine dependence and motivation for quitting, that may allow clinicians to tailor interventions to the needs of the individual patient.

Stepped-care. The practice of initiating treatment with a low-intensity intervention and then exposing treatment failures to successively more intense interventions.

Sudden Infant Death Syndrome (SIDS). Unexpected and sudden death of an apparently healthy infant during sleep with no autopsic evidence of disease. It is the leading cause of death in infants between 2 weeks and 1 year of age. The cause is unknown, but certain risk factors have been identified, such as prematurity; low birth-weight; birth in winter months; and mothers who are very young, smoke, are addicted to a drug, or have had a recent upper respiratory infection. Also called "cot death" and "crib death."

Tailored interventions. Tailored interventions are based on a dimension or a subset of dimensions of the individual (i.e., weight concerns, dependency, etc.). See also Individualized Interventions.

The Joint Commission (TJC) (formerly Joint Commission on Accreditation of Healthcare Organizations, JCAHO). An independent, not-for-profit organization that evaluates and accredits more than 19,500 health care organizations in the United States, including hospitals, health care networks, managed care organizations, and health care organizations that provide home care, long-term care, behavioral health care, and laboratory and ambulatory care services.

Tobacco dependence. Dependence on any form of tobacco, including, but not exclusive to, cigarettes, pipes, cigars, and chewing tobacco.

Tobacco treatment specialists. These specialists typically provide intensive tobacco interventions. Specialists are not defined by their professional affiliation or by the field in which they trained. Rather, specialists view tobacco dependence treatment as a primary professional role. Specialists possess the skills, knowledge, and training to provide effective interventions across a range of intensities, and often are affiliated with programs offering intensive treatment interventions or services.

Tobacco user. A person addicted to one or more forms of tobacco products.

Transdermal. Refers to delivery of a substance by absorption through the skin. Transdermal nicotine often is used as a synonym for "nicotine patch."

Treatment matching. Differential assignment of a patient to treatment based on the patient's pretreatment characteristics. Treatment matching is based on the notion that particular types of tobacco users are most likely to benefit from particular types of treatments.

Treatment. An action or program that aims to bring about identifiable outcomes. For tobacco dependence, the treatment generally is clinical in nature and may consist of counseling and the use of medications. Also may be referred to as "intervention."

Unaided quit attempts. Quit attempts made by patients, without the assistance of any clinical intervention or medications. Also known as "quitting cold turkey."

Varenicline. FDA-approved, non-nicotine recommended smoking cessation medication. Its mechanism of action is thought to be a function of its ability to serve both as a partial nicotine receptor agonist and a nicotine receptor antagonist. Available by prescription only.

Vital signs. Standard patient measurements to assess the critical body functions, including blood pressure, pulse, weight, temperature, and respiratory rate. The first step (i.e., the first "A") to providing smoking cessation interventions is identifying smokers. Vital signs should be expanded to include tobacco use status (current, former, never) or an alternative universal identification system in patient records.

Web-based interventions. See Internet Interventions.

Weight/diet/nutrition. An intervention strategy designed to address weight gain or concerns about weight gain. Interventions that teach weight/diet/nutrition management strategies, incorporate daily/weekly weight monitoring (for reasons other than routine data collection), require or suggest energy intake maintenance/reduction, and/or convey nutritional information/tips/counseling receive this code.

Withdrawal symptoms. A variety of unpleasant symptoms (e.g., difficulty concentrating, irritability, anxiety, anger, depressed mood, sleep disturbance, and craving) that occur after use of an addictive drug is reduced or stopped. Withdrawal symptoms are thought to increase the risk for relapse.

Contributors

Guideline Panel

Michael C. Fiore, MD, MPH
Panel Chair
Professor, Department of Medicine
Director, Center for Tobacco Research and Intervention
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

Dr. Fiore completed medical school at Northwestern University and his internal medicine training at Boston City Hospital. His postgraduate education included a master's degree in public health in epidemiology from Harvard University. Dr. Fiore received additional training in epidemiology as an Epidemic Intelligence Service Officer for the Centers for Disease Control and Prevention, where he completed a preventive medicine residency program. Dr. Fiore worked as a medical epidemiologist at the U.S. Office on Smoking and Health, where he contributed to a wide range of national research, educational, and policy projects to control the epidemic of tobacco-related diseases. He is Director of the Center for Tobacco Research and Intervention and a Professor of Medicine at the University of Wisconsin School of Medicine and Public Health. He served as Chair of the Agency for Healthcare Policy and Research Panel that produced the *Smoking Cessation Clinical Practice Guideline No. 18* (1996) and Chair of the Public Health Service Panel that produced *Treating Tobacco Use and Dependence: A Clinical Practice Guideline* (2000). Dr. Fiore serves as Director (with Dr. Susan Curry) of a Robert Wood Johnson Foundation National Program, Addressing Tobacco in Health Care.

Carlos Roberto Jaén, MD, PhD, FAAFP
Panel Vice Chair
Professor and Chair, Department of Family and Community Medicine
Co-Director, Center for Research in Family Medicine and Primary Care
University of Texas Health Science Center at San Antonio
San Antonio, Texas

Dr. Jaén completed medical school at the State University of New York at Buffalo, and his family medicine residency and primary care research fellowship at Case Western Reserve University in Cleveland, Ohio. His graduate education included a PhD in epidemiology, with a concentration in

tobacco control at Roswell Park Cancer Institute. He is Professor and Chair of the Department of Family and Communty Medicine at the University of Texas Health Science Center at San Antonio. He also is Co-Director of the American Academy of Family Physicians-funded Center for Research in Family Medicine and Primary Care. Dr. Jaén, active in primary care and public health research since 1985, has authored more than 70 publications on smoking cessation and related subjects, clinical preventive service delivery in primary care offices, and access to care by the urban poor and Hispanic populations. In 2005, he was appointed to the National Advisory Council to the Agency for Healthcare Research and Quality of the U.S. Public Health Service. He is a practicing family physician in the University of Texas Health Science Center at San Antonio and has been selected to the Best Doctors in America since 2002.

Timothy B. Baker, PhD
Senior Scientist
Professor, Department of Medicine
Associate Director, Center for Tobacco Research and Intervention
University of Wisconsin School of Medicine and Public Health
Madison, Wisconsin

Dr. Baker is a Professor of Medicine at the University of Wisconsin School of Medicine and Public Health. His principal research goals are to increase understanding of the motivational bases of addictive disorders and to develop and evaluate treatments for such disorders. He also is highly interested in developing and using technological advances to deliver effective treatments to ameliorate health problems such as addictive disorders and cancer. Dr. Baker is a long-serving member of the NIDA-E study section, has served as the Editor of the *Journal of Abnormal Psychology*, is the principal investigator of the University of Wisconsin Transdisciplinary Tobacco Use Research Center award (NIDA), and has contributed chapters to multiple Reports of the Surgeon General.

William C. Bailey, MD, FACP, FCCP
Director, Lung Health Center
University of Alabama at Birmingham
Birmingham, Alabama

Dr. Bailey graduated from Tulane University Medical School in 1965. He is a Diplomate of the American Board of Internal Medicine in both Internal Medicine and Pulmonary Disease, having received certified specialty

training in these disciplines at Tulane University Medical Center and Charity Hospital of Louisiana. He has been on the faculty of the University of Alabama at Birmingham (UAB) since 1973. He has practiced medicine, taught, performed research, and been involved in administrative endeavors for his entire career. He has served on the Board of Directors of the American Thoracic Society and also has served on the Council of the National Heart, Lung, and Blood Institute. He has been a member of many editorial review boards of peer-reviewed journals and has served as a frequent scientific reviewer of both scientific articles and peer-reviewed research. He currently holds the Eminent Scholar Chair in Pulmonary Diseases and also is the Director of the UAB Lung Health Center, which is devoted to research in the prevention of lung disease.

Neal L. Benowitz, MD
Chief, Division of Clinical Pharmacology and Experimental Therapeutics
University of California-San Francisco
San Francisco, California

Dr. Benowitz is Professor of Medicine, Psychiatry, and Biopharmaceutical Sciences and Chief, Division of Clinical Pharmacology and Experimental Therapeutics, University of California, San Francisco (UCSF). He received his MD from the University of Rochester School of Medicine in 1969, and he served as a resident in internal medicine at the Bronx Municipal Hospital Center from 1969 to 1971. He then completed a postdoctoral fellowship in clinical pharmacology at UCSF and joined the faculty at UCSF in 1974. His research interests have focused primarily on the human pharmacology and toxicology of nicotine, caffeine, and other stimulant drugs. He has published more than 300 research papers. Dr. Benowitz was a scientific editor of the 1988 *United States Surgeon General's Report on Smoking and Health: Nicotine Addiction,* and served as a member of the NIH Pharmacology Study Section. Dr. Benowitz is a member of a number of medical societies, including the American Society for Clinical Investigation and the Association of American Physicians. He has served as President of the American Society for Clinical Pharmacology and Therapeutics and the Society for Research on Nicotine and Tobacco. He has received the Ove Ferno, Alton Ochsner, and Rawls Palmer Progress in Medicine awards and the Oscar B. Hunter Award in Therapeutics for his research on nicotine, tobacco, and health, and was the 2002 UCSF Annual Distinguished Clinical Research Lecturer. Dr. Benowitz is currently Director of the Flight Attendants Medical Research Institute Center of Excellence

at UCSF, principal investigator of the Pharmacogenetics of Nicotine Addiction Research Consortium, and Program Leader of the Tobacco Control Program of the UCSF Comprehensive Cancer Center.

Susan J. Curry, PhD
Director, Institute for Health Research and Policy
University of Illinois-Chicago
Chicago, Illinois

Dr. Curry is the Director of the Institute for Health Research and Policy and Professor of Health Policy and Administration at the University of Illinois at Chicago (UIC). Prior to joining UIC in 2001, she was Professor of Health Services in the School of Public Health and Community Medicine at the University of Washington, and Director and Senior Investigator at the Center for Health Studies, Group Health Cooperative. Dr. Curry's research in tobacco includes studies of motivation to quit smoking; randomized trials of promising smoking cessation and prevention interventions; and evaluations of the use and cost-effectiveness of tobacco cessation treatments under different health insurance plans, and health care costs and utilization associated with tobacco cessation. Dr. Curry serves as Director (with Dr. Michael Fiore) of a Robert Wood Johnson Foundation National Program, Addressing Tobacco in Health Care, and heads the Helping Young Smokers Quit national initiative funded by the Robert Wood Johnson Foundation, Centers for Disease Control and Prevention, and the National Cancer Institute (NCI). She currently serves on the Board of Directors for the American Legacy Foundation and is a member of the Board of Scientific Advisors for NCI.

Sally Faith Dorfman, MD, MSHSA
Associate Director, Medical Affairs, Infertility
Ferring Pharmaceuticals, Inc.
Parsippany, New Jersey

Dr. Dorfman holds a degree in economics from Harvard College, a master's degree in health services administration, and an MD from Stanford University. She trained in reproductive health epidemiology as an Epidemic Intelligence Service Officer at the Centers for Disease Control and Prevention. She is board certified both in obstetrics and gynecology and in public health/general preventive medicine, and is an alumna of the Public Health Leadership Institute. Dr. Dorfman has consulted for state, regional, national, and international organizations, and was Commissioner of Health

for Orange County, New York, from 1988 to 1994, effectively implementing New York State's then new Clean Indoor Air Act. She has published and presented extensively for professional and lay audiences, co-chaired the American Medical Women's Association (AMWA) Anti-Smoking Task Force, chaired the AMWA Reproductive Health Initiative, and is the recipient of numerous honors and awards. In addition to administrative, research, and editorial responsibilities, Dr. Dorfman remains clinically active as a gynecologist.

Erika S. Froehlicher, PhD, RN, MA, MPH
Professor, Department of Physiological Nursing
Department of Epidemiology & Biostatistics
Schools of Nursing and Medicine
University of California San-Francisco
San Francisco, California

Dr. Froehlicher holds degrees in nursing with a minor in business administration from the University of Washington, Seattle, and an MPH and a PhD from the University of California, Los Angeles. Her areas of research and teaching are in the primary, secondary, and tertiary prevention (rehabilitation) of cardiovascular disease. She served as Co-Chair for the Cardiac Rehabilitation Guideline 1995, and as a reviewer for the Unstable Angina and Congestive Heart Failure Federal Guideline. Her specific research focus is on behavioral interventions to promote physical activity and exercise, women's health issues, and international health. Her focus with respect to smoking is on randomized clinical trials to study the efficacy of nurse-managed smoking cessation in women with cardiovascular disease, the older American smoker, and the African-American population; as well as international initiatives in Korea, Jordan, and Japan.

Michael G. Goldstein, MD
Associate Director, Clinical Education and Research
Institute for Healthcare Communication
New Haven, Connecticut

Dr. Goldstein is board certified in internal medicine and psychiatry and currently serves as an Associate Director for Clinical Education and Research at the Institute for Healthcare Communication (IHC) in New Haven, Connecticut. The IHC is a nonprofit foundation dedicated to improving health care through enhanced clinician-patient communication. Also, he is an investigator at the Centers for Behavioral and Preventive Medicine

at the Miriam Hospital in Providence, Rhode Island, and an Adjunct Professor of Psychiatry and Human Behavior at the Warren Alpert Medical School of Brown University. Dr. Goldstein's primary research interests have included developing and testing interventions to enhance the delivery of smoking cessation and other preventive care interventions in primary care settings. Dr. Goldstein has served as a member of the Task Force on Nicotine Dependence of the American Psychiatric Association (APA) and also served on the APA Nicotine Dependence Practice Guideline Panel. He has published extensively in the areas of behavioral medicine, smoking cessation, and health care communication.

Cheryl Healton, DrPH
President and Chief Executive Officer
American Legacy Foundation
Washington, DC

Following the creation of the American Legacy Foundation in 1999, Dr. Healton joined the staff as the first President and Chief Executive Officer of this groundbreaking public health nonprofit, created by the historic Master Settlement Agreement between 46 state attorneys general, five U.S. territories, and the tobacco industry. Dr. Healton was selected for this post following a nationwide search, and she has worked tirelessly to further the foundation's ambitious mission: "To build a world where young people reject tobacco and anyone can quit." During her tenure with the Foundation, she has guided the highly acclaimed, national youth tobacco prevention counter-marketing campaign, *truth,*® which has been credited in part with reducing youth smoking prevalence to its current 28-year low.

Although her current focus is aimed at reducing the deadly toll of tobacco on Americans, Dr. Healton's long and dynamic career in the field of public health has earned her national recognition and praise. She holds a doctorate from Columbia University's School of Public Health and a master's degree in public administration at New York University for health policy and planning. She joined the American Legacy Foundation from Columbia University's Joseph L. Mailman School of Public Health in New York, where she served as Head of the Division of Socio-Medical Sciences and Associate Dean for Program Development.

Patricia Nez Henderson, MD, MPH
Vice President
Black Hills Center for American Indian Health
Rapid City, South Dakota

Dr. Nez Henderson received her bachelor of science degree in biochemistry from the University of Arizona and earned her doctor of medicine and master of public health degrees from Yale University. Upon graduating from medical school, Dr. Nez Henderson joined the Black Hills Center for American Indian Health, an American Indian nonprofit health organization located in Rapid City, South Dakota, where she currently serves as Vice President. In addition, Dr. Nez Henderson is a faculty member at the University of Colorado at Denver Health Sciences Center within the American Indian and Alaska Native Programs. For the past 7 years, her research interest has focused on tobacco-related issues in American Indian communities. Her research findings have been published in peer-reviewed medical journals. Through culturally appropriate and relevant research, she plans to provide Native communities with information that can be used for health planning and policy decisionmaking.

Richard B. Heyman, MD
Former Chair, Committee on Substance Abuse
American Academy of Pediatrics
Cincinnati, Ohio

A graduate of the Columbia University College of Physicians and Surgeons, Dr. Heyman practices pediatric and adolescent medicine in Cincinnati, Ohio, and serves as an Adjunct Professor of Clinical Pediatrics at the University of Cincinnati College of Medicine. He is a consultant to several adolescent chemical dependency programs and lectures widely in the area of substance abuse. As former Chairman of the Committee on Substance Abuse of the American Academy of Pediatrics, he has played a major role in the creation of the Academy's educational programs and materials, as well as the development of policy in the area of alcohol, tobacco, and other drug abuse.

Howard K. Koh, MD, MPH, FACP
Harvey V. Fineberg Professor of the Practice of Public Health
Associate Dean for Public Health Practice
Director of the Division of Public Health Practice
Harvard School of Public Health
Boston, Massachusetts

Dr. Koh graduated from Yale College and Yale University School of Medicine. He completed his postgraduate training at Boston City Hospital and Massachusetts General Hospital, serving as Chief Resident in both institutions. Dr. Koh has earned board certification in four medical fields (internal medicine, hematology, medical oncology, and dermatology) as well as a master of public health degree from Boston University School of Public Health. While serving as Commissioner of Public Health for the Commonwealth of Massachusetts (1997–2003), he oversaw the nationally recognized Massachusetts Tobacco Control Program. During this time, Massachusetts ranked as one of the healthiest states in the country. Dr. Koh is principal investigator of the National Cancer Institute-funded initiative MassCONECT (Massachusetts Community Networks to Eliminate Cancer Disparities through Education, Research, and Training), a project to eliminate cancer disparities in underserved communities. He has published more than 200 scientific articles in the medical and public health literature. President Bill Clinton appointed Dr. Koh to the National Cancer Advisory Board (2000–2002). Dr. Koh also has been elected to the Institute of Medicine (IOM) of the National Academies and is a member of the IOM Roundtable on Racial and Ethnic Health Disparities.

Thomas E. Kottke, MD, MSPH
Senior Clinical Investigator
HealthPartners Research Foundation
Minneapolis, Minnesota
Professor of Medicine
University of Minnesota
Consulting Cardiologist
Regions Hospital
St. Paul, Minnesota

Dr. Kottke is a clinical cardiologist, epidemiologist, and health services researcher whose primary interest is describing, defining, and overcoming the barriers to the delivery of clinical services for the primordial, primary, and secondary prevention of chronic diseases. He has published widely on

the evidence that clinical support systems are necessary for physicians and other health care professionals to provide these services to the patients they serve. Dr. Kottke was a member of the first U.S. Preventive Services Task Force.

Harry A. Lando, PhD
Professor, Division of Epidemiology and Community Health
University of Minnesota
Minneapolis, Minesota

Dr. Lando is internationally recognized for his work in smoking cessation. He has been active in this field since 1969 and has published extensively in this area, with a total of more than 170 scientific publications. He was a scientific editor of the *1988 Report of the Surgeon General, The Health Consequences of Smoking: Nicotine Addiction* and a member of the Center for Child Health Research Tobacco Consortium of the American Academy of Pediatrics. He is Deputy Regional Editor for *Addiction*. He has consulted actively with such government and voluntary agencies as the National Heart, Lung, and Blood Institute; the National Cancer Institute; the Centers for Disease Control and Prevention; the National Institute on Drug Abuse; the Agency for Healthcare Research and Quality; the American Cancer Society; the American Lung Association; and the World Health Organization. Dr. Lando is a past president of the Society for Research on Nicotine and Tobacco and currently chairs the SRNT Global Network Committee. He is a 2006 recipient of the University of Minnesota Award for Global Engagement; this award carries with it the title of "Distinguished International Professor." He is serving as Vice President of the 14th World Conference on Tobacco OR Health, to be held in 2009 in Mumbai, India.

Robert E. Mecklenburg, DDS, MPH
Consultant, Tobacco and Public Health
Potomac, Maryland

Dr. Mecklenburg is a Diplomate of the American Board of Dental Public Health and an Assistant Surgeon General (ret. O-8). He organized and managed dental affairs for the National Cancer Institute's (NCI) Tobacco Control Research Branch and was the Tobacco-Related Research and Development Advisor for the National Institute of Dental and Craniofacial Research's Office of Science Policy and Analysis. He chaired the National Dental Tobacco-Free Steering Committee and was Vice-Chairman of the Dentistry Against Tobacco Section/Tobacco and Oral Health Committee of

the FDI World Dental Federation. He chaired the committee on noncancer oral effects of tobacco for the first Surgeon General's report on smokeless tobacco. He was the principal author of the NCI publications, *Tobacco Effects in the Mouth* and *How to Help Your Patients Stop Using Tobacco: A Manual for the Oral Health Team*. Dr. Mecklenburg has published and lectured widely in the United States and abroad about dental professionals' involvement in the creation of a tobacco-free society.

Robin Mermelstein, PhD
Deputy Director, Institute for Health Research and Policy
Director, Center for Health Behavior Research
Professor, Department of Psychology
University of Illinois-Chicago
Chicago, Illinois

Dr. Mermelstein is Professor of Psychology, Director of the Center for Health Behavior Research, and Deputy Director of the Institute for Health Research and Policy at the University of Illinois at Chicago. She holds a PhD in clinical and community psychology from the University of Oregon. Her research interests fall broadly in the area of tobacco use, with studies ranging from longitudinal examinations of the etiology of youth smoking and interventions for adolescents to stop smoking to cessation interventions for adult smokers. Dr. Mermelstein has been the principal investigator on several grants from the National Cancer Institute (NCI) investigating trajectories of adolescent smoking, with a focus on social and emotional contextual factors. In addition, she has been funded by the Centers for Disease Control and Prevention to examine factors related to youth smoking, and by the National Heart, Lung, and Blood Institute and NCI for studies of adult smoking cessation. Dr. Mermelstein was the Director of the Robert Wood Johnson Foundation's (RWJF) Program Office, A Partners with Tobacco Use Research Centers: A Transdisciplinary Approach to Advancing Science and Policy Studies. As part of this program, the RWJF collaborated with both NCI and the National Institute on Drug Abuse in funding the Transdisciplinary Tobacco Use Research Centers.

Patricia Dolan Mullen, DrPH
Professor of Health Promotion and Behavioral Sciences
University of Texas School of Public Health
Houston, Texas

Dr. Mullen received her graduate training at the University of California, Berkeley, School of Public Health and has extensive experience in managed care. Her tobacco cessation research has focused on pregnant and postpartum women (non-Hispanic white, African American, and Hispanic) from urban and rural environments, who were both privately insured and covered by Medicaid. She also has collaborated on smoking cessation research with international populations. Dr. Mullen served on the U.S. Expert Panel for the Content of Prenatal Care and on research advisory panels on prenatal smoking cessation for the National Institutes of Health, Centers for Disease Control and Prevention, the American Cancer Society, and the Robert Wood Johnson Foundation Smoke-Free Families Program. She has conducted systematic reviews and meta-analyses of smoking cessation programs for pregnant women and other topics and served as a member and Vice-Chair of the U.S. Community Preventive Services Task Force.

C. Tracy Orleans, PhD
Senior Scientist and Distinguished Fellow
Robert Wood Johnson Foundation
Princeton, New Jersey

Dr. Orleans has led or co-led the Robert Wood Johnson Foundation (RWJF) public policy- and health care system-based grant making in the areas of tobacco control, physical activity promotion, childhood obesity prevention, and chronic disease management. She led the Foundation's Health & Behavior Team and has developed and/or managed numerous RWJF national initiatives, including Addressing Tobacco in Healthcare, Smoke-Free Families, Helping Young Smokers Quit, Bridging the Gap/Impact Teen, Substance Abuse Policy Research, Improving Chronic Illness Care, Active Living Research, and Healthy Eating Research. An internationally known clinical health psychologist, Dr. Orleans has authored or co-authored more than 200 publications; contributed to several Surgeon General's reports; served on numerous journal editorial boards, national scientific panels, and advisory groups (e.g., U.S. Preventive Services Task Force, Institute of Medicine, National Commission on Prevention Priorities); and as President of the Society of Behavioral Medicine.

Lawrence Robinson, MD, MPH
Deputy Health Commissioner
Philadelphia Department of Public Health
Health Promotion/Disease Prevention
Philadelphia, Pennsylvania

A graduate of Harvard College, Dr. Robinson received his MD from the University of Pennsylvania School of Medicine. He received his MPH and completed a residency in preventive medicine at Johns Hopkins University. He was a resident and faculty member at Rush and Columbia University while performing his internal medicine training. As Deputy Commissioner for Health Promotion/Disease Prevention for the Philadelphia Department of Public Health, Dr. Robinson is responsible for the development, planning, implementation, and evaluation of various programs delivering medical, chronic disease prevention, and health education services. Local antitobacco projects include banning vending machines, assisting the county jail move to a smoke-free environment, Nicotrol Patch replacement, and the American Cancer Society Fresh Start Program. This train-the-trainer program was provided to the mentally ill and other targeted populations. Dr. Robinson also is a board member of the Pennsylvania American Cancer Society and Chairman of the State Tobacco Core Team. He is a member of various groups, organizations, and agencies in the community working on issues such as the State Tobacco Settlement (No Butts/Do the Right Thing) and smoking prevention for youth and specific populations, such as pregnant women.

Maxine L. Stitzer, PhD
Professor, Department of Psychiatry and Behavioral Sciences
Behavioral Biology Research Center
Johns Hopkins/Bayview Medical Center
Baltimore, Maryland

Dr. Stitzer received her PhD in psychology and training in psychopharmacology from the University of Michigan. At Johns Hopkins University, she has developed a varied and extensive grant-supported research program focusing on both pharmacological and behavioral approaches to the treatment of substance abuse. Her many publications reflect active research interests in both illicit drug abuse and tobacco dependence. She has served as President of the Division on Psychopharmacology and Substance Abuse of the American Psychological Association, President of the Society for Research on Nicotine and Tobacco, and as a member of the Board of Directors of the College on Problems of Drug Dependence.

Anthony C. Tommasello, PhD, MS
Director, Office of Substance Abuse Studies
University of Maryland School of Pharmacy
Baltimore, Maryland

Dr. Tommasello, a pharmacist, is an Associate Professor in the Department of Pharmaceutical Health Services Research at the University of Maryland School of Pharmacy and Director, Office of Substance Abuse Studies, which he founded. He received his PhD in policy sciences from the University of Maryland, Baltimore County, and has worked in the addiction field since 1973. He is active in clinical and policy research and in addictions treatment and has created educational programs that have served as national models for pharmacists and other health and human service workers. Dr. Tommasello is President of the Maryland Pharmacists' Education and Advocacy Council, which provides advocacy and treatment referrals for impaired pharmacists. He has published in the areas of general principles of assessment and treatment, methadone maintenance care, and adolescent drug abuse and addiction and the pharmacist's role in substance abuse and addiction management.

Louise Villejo, MPH, CHES
Director, Patient Education Office
Office of Public Affairs
University of Texas M.D. Anderson Cancer Center
Houston, Texas

As Director of the Patient Education Office at the M.D. Anderson Cancer Center, Ms. Villejo is responsible for the design, implementation, evaluation, and management of institution-wide patient and family education programs. She has designed and implemented Patient/Family Learning Centers as well as award-winning, disease-specific patient education programs, and produced more than 100 patient education print materials and videotapes. For the past 10 years, she has served on the National Cancer Institute's Advisory Boards and Patient Education Network's Steering Committee, and on numerous other Federal and private advisory and planning boards and committees. Ms. Villejo's publications include articles on cancer patient education and cultural diversity in health care.

Mary Ellen Wewers, PhD, MPH, RN
Professor, College of Public Health
The Ohio State University
Columbus, Ohio

Dr. Wewers, an Adult Nurse Practitioner, received her PhD in nursing from the University of Maryland and an MPH from Harvard University. She has been funded by the National Institutes of Health (NIH) to investigate reinforcement for nicotine in both human and animal models of dependence. Her current NIH-funded research examines nurse-managed tobacco cessation interventions in underserved groups. Dr. Wewers is past Chair of the Nursing Assembly of the American Thoracic Society and a past member of the Society's Board of Directors. She serves as Co-Program Leader for Cancer Control at The Ohio State University Comprehensive Cancer Center.

Appendixes

Appendix A. Financial Disclosure for Panel Members, Liaisons, and Peer Reviewers

Panel Members

The evaluation of conflict for the 2008 Guideline Update comprised a two-stage procedure designed to obtain increasingly detailed and informative data on potential conflicts over the course of the Guideline development process.

1. In July 2006 and prior to the initial meeting in October 2006, Panel members completed a general screen, reporting any potential conflicts over the previous 5 years. Where potential conflicts existed, Panel members provided a narrative listing of the relevant organizations and types of conflict. Panel members were asked to update this screen as new information or potential conflicts became known.

2. Prior to the second in-person Panel meeting in June 2007, and before any decisions regarding Panel recommendations were made, Panel members were required to complete a more exhaustive disclosure process for calendar years 2005, 2006, and 2007, based on the United States Department of Health and Human Services, PHS Title 42, Chapter 1, Part 50 guidelines for the conduct of research (*ori.hhs.gov/policies/fedreg42cfr50.shtml*). Moreover, Panel members were asked to update this report as new information or potential conflicts became known. In keeping with the PHS-based guidelines, a potential conflict was designated as "significant" if one or more of three criteria were met:

A. Net reportable compensation in excess of $10,000 in any reporting year to the Panel member, spouse, or dependent child for outside activities from any entity whose interests may be affected by the recommendations in the Guideline (excluding public or nonprofit entities).

B. Leadership as an officer, director, or trustee in any reporting year by the Panel member, spouse, or dependent child in any entity whose interests may be affected by the recommendations in the Guideline (excluding public or nonprofit entities).

C. Ownership interests either in excess of $10,000 or 5 percent of the business in any reporting year by the Panel member, spouse, or dependent child in any entity whose interests may be affected by the recommendations in the Guideline (excluding public or nonprofit entities).

Panel members were asked to complete this PHS-based report for 3 calendar years (2005, 2006, 2007), that comprised both the 18-month period before the Guideline Panel was constituted, as well as the full period of Guideline development. For any significant conflict that was disclosed, Panel members provided a detailed description of the relevant organizational tie, including categorizing the amount of compensation or financial interests involved. Of the Panel members listed in this document, 21 of 24 had no significant financial interests as defined by the PHS-based criteria. In addition to these mandatory disclosures regarding compensation, leadership, and ownership, members were asked to disclose any other information that might be disclosed in a professional publication.

Three Panel members whose disclosures exceeded the PHS criteria for significant financial interest were recused from Panel deliberations relating to their areas of conflict; one additional Panel member voluntarily recused himself.

The following is a summary listing for any of the years 2005, 2006, and 2007 of all significant financial interests as defined above, as well as any additional disclosures Panel members chose to make.

William C. Bailey reported significant financial interests in the form of compensation from three different pharmaceutical companies in 2006 and two in 2007 for speaking engagements.

Timothy B. Baker reported no significant financial interests. Under additional disclosures, he reported that he has served as a co-investigator on research studies at the University of Wisconsin that were sponsored by four pharmaceutical companies.

Neal L. Benowitz reported significant financial interest in the form of compensation from one pharmaceutical company for each of the years 2005–2007, as well as stock ownership in one pharmaceutical company.

Under additional disclosures, he reported providing expert testimony in lawsuits against tobacco companies.

Susan J. Curry reported no significant financial interests and no additional disclosures.

Sally Faith Dorfman reported no significant financial interests. Under additional disclosures, she reported her employment by Ferring Pharmaceuticals, Inc., a company whose business does not relate to treating tobacco dependence.

Michael C. Fiore reported no significant financial interests. Under additional disclosures, he reported that he served as an investigator on research studies at the University of Wisconsin (UW) that were supported wholly or in part by four pharmaceutical companies, and in 2005 received compensation from one pharmaceutical company. In addition, he reported that, in 1998, the UW appointed him to a named Chair, which was made possible by an unrestricted gift to the UW from GlaxoWellcome.

Erika S. Froehlicher reported no significant financial interests and no additional disclosures.

Michael G. Goldstein reported no significant financial interests. Under additional disclosures, he reported that his employer received support from Bayer Pharmaceutical prior to 2005 and that he was employed by Bayer Pharmaceutical Corporation prior to January 1, 2005. His organization received payments for his professional services from two pharmaceutical companies and one commercial Internet smoking cessation site during the period 2005–2007.

Cheryl Healton reported no significant financial interests and no additional disclosures.

Patricia Nez Henderson reported no significant financial interests and no additional disclosures.

Richard B. Heyman reported no significant financial interests and no additional disclosures.

Carlos Roberto Jaén reported no significant financial interests and no additional disclosures.

Howard K. Koh reported no significant financial interests and no additional disclosures.

Thomas E. Kottke reported no significant financial interests and no additional disclosures.

Harry A. Lando reported no significant financial interests. Under additional disclosures, he reported serving on an advisory panel for a new tobacco use cessation medication and attending 2-day meetings in 2005 and 2006 as a member of this panel.

Robert E. Mecklenburg reported no significant financial interests. Under additional disclosures, he reported assisting Clinical Tools, Inc., through a governmental contract to develop a PHS 2000 Guideline-based Internet continuing education course.

Robin Mermelstein reported no significant financial interests and no additional disclosures.

Patricia Dolan Mullen reported no significant financial interests and no additional disclosures.

C. Tracy Orleans reported significant financial interests in the form of a dependent child who owns pharmaceutical stock, and no additional disclosures.

Lawrence Robinson reported no significant financial interests and no additional disclosures.

Maxine L. Stitzer reported no significant financial interests. Under additional disclosures, she reported participation on a pharmaceutical scientific advisory panel for a new tobacco use cessation medication.

Anthony C. Tommasello reported no significant financial interests and no additional disclosures.

Louise Villejo reported no significant financial interests and no additional disclosures.

Mary Ellen Wewers reported no significant financial interests and no additional disclosures.

Liaisons

Liaisons followed the same process as Panel members in reporting significant financial interests. Their disclosures are summarized below:

Glen Bennett reported no significant financial interests and no additional disclosures.

Stephen Heishman reported no significant financial interests and no additional disclosures.

Corinne Husten reported no significant financial interests and no additional disclosures.

Glen Morgan reported no significant financial interests and no additional disclosures.

Ernestine W. Murray reported no significant financial interests and no additional disclosures.

Christine Williams reported no significant financial interests and no additional disclosures.

Peer Reviewers

Peer reviewers were required to report significant financial interests at the time they submitted their peer reviews. The interests were reviewed prior to the adjudication of each reviewer's comments. Any significant financial interests are noted below their listing in the Contributors Section of this Guideline.

Outside Comments

The availability of the draft Guideline report for review was announced in the *Federal Register* on September 28, 2007 (Volume 72, Number 188). Individuals who had informed Panel members or staff that they wished the opportunity to review the document were provided with an opportunity to do so. All those submitting comments were asked to disclose significant financial interests at the time their comments were submitted. Prior to each set of comments being considered and adjudicated, the disclosure information (or lack of disclosure) was noted and taken into consideration.

Appendix B. Helpful Web Site Addresses

The inclusion of Web sites in this appendix is intended to assist readers in finding additional information regarding the treatment of tobacco use and dependence and related topics and does not constitute endorsement of the contents of any particular site. All Web sites listed are either Government-sponsored organizations or nonprofit foundations.

Appendix C. Coding Information Regarding the Diagnosis of and Billing for Tobacco Dependence Treatment

Coding for the Treatment of Tobacco Use

Clinicians, clinic administrators, and health care delivery systems require appropriate diagnostic and billing codes for the documentation and reimbursement of tobacco dependence treatment. Information on such codes may help address a common clinical concern regarding the treatment of tobacco-dependent patients: it is difficult to accurately document and obtain reimbursement for this treatment. Although examples of such codes are provided below, clinicians and billing coders may use other diagnostic and reimbursement codes to document and obtain payment for this medical treatment. Additionally, it is incumbent on the clinician to ensure that appropriate billing guidelines are followed and to recognize that reimbursement of these codes may vary by payor or benefits package. For example, although psychiatric therapeutic codes appropriate for treating tobacco dependence exist, some payors or benefits packages have restrictions on mental health benefits. Similarly, reimbursement for preventive visits varies greatly among payors and benefits packages.

A systems-based approach will facilitate the understanding and use of such codes by clinicians. For example, various clinic or hospital meetings (e.g., business sessions, grand rounds, seminars, and coding in-service sessions) can explain and highlight the use of tobacco dependence codes for diagnosis and reimbursement. Additionally, these diagnostic codes can be preprinted on the billing and diagnostic coding sheets as a "check-off" so that clinicians are not required to recall and manually document such treatment. Finally, clinicians can be reminded that counseling by itself is a reimbursable activity and can be billed-for based on the number of minutes of counseling.

1. Diagnostic Codes (ICD-9-CM)

When clinicians provide treatment to patients dependent on tobacco, the following diagnostic codes can be used. They can be found in the ICD-9-CM (*International Classification of Diseases, 9th Revision, Clinical Modification*) coding manual under several sections:

Mental Disorders (290-319)

305.1 Tobacco Use Disorder (Tobacco Dependence). Cases in which tobacco is used to the detriment of a person's health or social functioning or in which there is tobacco dependence. Tobacco dependence is included here rather than under drug dependence because tobacco differs from other drugs of dependence in its psychotropic effect. This excludes: History of tobacco use (V15.82).

V Codes

V15.82 History of Tobacco Use. This excludes: Tobacco dependence (305.1).

Diseases of Oral Cavity, Salivary Glands, and Jaws

523.6 Accretions on teeth
Supragingival: Deposits on teeth: tobacco.

Accidental Poisoning by Other Solid and Liquid Substances, Gases, and Vapors

E869.4 Secondhand tobacco smoke.

Complications Mainly Related To Pregnancy

649.0 Tobacco use disorder complicating pregnancy, childbirth, or the puerperium.

2. Billing Codes (Current Procedural Terminology [CPT] Codes)

A number of billing codes may be used for reimbursement of the provision of tobacco dependence treatment. The examples provided fall under the general categories of preventive medicine services, psychiatric therapeutic procedures, and dental codes.

A. Preventive Medicine Services

The following codes are used to report the preventive medicine evaluation and management of infants, children, adolescents, and adults.

The "comprehensive" nature of the Preventive Medicine Services codes 99383–99397 reflects an age- and gender-appropriate history/exam and is NOT synonymous with the "comprehensive" examination required in Evaluation and Management codes 99201–99350.

Codes 99383–99397 include counseling/anticipatory guidance/risk factor reduction interventions, which are provided at the time of the initial or periodic comprehensive preventive medicine examination. (Refer to codes 99401–99412 for reporting those counseling/anticipatory guidance/risk factor reduction interventions that are provided at an encounter separate from the preventive medicine examination.)

A1. Initial or Periodic Comprehensive Preventive Medicine Examination

New Patient

99383 Initial comprehensive preventive medicine.

Initial comprehensive preventive medicine evaluation and management of an individual, including an age and gender-appropriate history, examination, counseling/anticipatory guidance/risk factor reduction interventions, and the ordering of appropriate immunization(s), laboratory/diagnostic procedures, new patient; late childhood (age 5 through 11 years).

99384 Adolescent (age 12–17 years).

99385 Adult (age 18–39 years).

99386 Adult (age 40–64 years).

99387 Adult (age 65 years and older).

Established Patient

99393 Periodic comprehensive preventive medicine.

Reevaluation and management of an individual, including an age- and gender-appropriate history, examination, counseling/anticipatory guidance/risk factor reduction interventions, and the ordering of appropriate immunization(s), laboratory/diagnostic procedures, established patient; late childhood (age 5 through 11 years).

99394 Adolescent (age 12–17 years).

99395 Adult (age 18–39 years).

99396 Adult (age 40–64 years).

99397 Adult (age 65 years and older).

A2. Counseling and/or Risk Factor Reduction Intervention.

These codes are used to report services provided to individuals at a separate encounter for the purpose of promoting health and preventing illness or injury. As such, they are appropriate for the specific treatment of tobacco use and dependence. They are appropriate for initial or followup tobacco dependence treatments (new or established patient). For the specific preventive medicine counseling codes, the number of minutes counseled determines the level of billing (codes **99400–99404** for 15 to 60 minutes of counseling).

Preventive Medicine, Individual Counseling

99401 Preventive medicine counseling and/or risk factor reduction intervention(s) provided to an individual (separate procedure); approximately 15 minutes.

99402 Approximately 30 minutes.

99403 Approximately 45 minutes.

99404 Approximately 60 minutes.

Smoking Cessation Counseling

These codes are for face-to-face counseling by a physician or other qualified health care professional, using "standardized, evidence-based screening instruments and tools with reliable documentation and appropriate sensitivity."

99406 For intermediate visit of between 3 and 10 minutes.

99407 For an intensive visit lasting longer than 30 minutes.

Preventive Medicine, Group Counseling

99411 Preventive medicine counseling and/or intervention to treat the risk factor of tobacco use provided to an individual (separate procedure); approximately 30 minutes.

99412 Approximately 60 minutes.

B. Psychiatric Therapeutic Procedures/Codes for Billing

The psychiatric therapeutic procedure billing codes are typically used for insight-oriented, behavior modifying, and/or supported psychotherapy. This refers to the development of insight of affective understanding, the use of behavior modification techniques, the use of supportive interactions, the use of cognitive discussion of reality, or any combination of the above to provide therapeutic change. All of the counseling interventions for tobacco dependence demonstrated to be effective in this Guideline fall under these headings.

It should be noted that these billing codes can be modified for those patients receiving only counseling (psychotherapy) and for others that receive counseling (psychotherapy), medical evaluation, and management services. These evaluation and management services involve a variety of responsibilities unique to the medical management of psychiatric patients, such as medical diagnostic evaluation (e.g., evaluation of comorbid medical conditions, drug interactions, and physical examinations); drug management when indicated; physician orders; and interpretation of laboratory or other medical diagnostic studies and observations. Thus, the use of a psychiatric therapeutic billing code with medical evaluation and management services would be appropriate for the clinician who provides both of the key tobacco dependence interventions documented as effective in the Guideline: counseling and medications.

In documenting treatment for tobacco dependence using the psychiatric therapeutic procedure codes, the appropriate code is chosen on the basis of the type of psychotherapy (e.g., insight-oriented, behavior modifying, and/or supportive using verbal techniques); the place of service (office vs. inpatient); the face-to-face time spent with the patient during the treatment (both for psychotherapy and medication management); and whether evaluation and management services are furnished on the same date of service as psychotherapy.

B1. Office or Other Outpatient Facility

Insight-oriented, behavior modifying, and/or supportive psychotherapy.

90804 Individual psychotherapy, insight oriented, behavior modifying and/or supportive, in an office or outpatient facility, approximately 20 to 30 minutes face-to-face with the patient.

90805 With medical evaluation and management services.

90806 Individual psychotherapy, insight-oriented, behavior modifying, and/or supportive, in an office or outpatient facility, approximately 45 to 50 minutes face-to-face with the patient.

90807 With medical evaluation and management services.

90808 Individual psychotherapy, insight-oriented, behavior modifying, and/or supportive, in an office or outpatient facility, approximately 75 to 80 minutes face-to-face with the patient.

90809 With medical evaluation and management services.

B2. Inpatient Hospital, Partial Hospital, or Residential Care Facility

Insight-oriented, behavior modifying, and/or supportive psychotherapy.

90816 Individual psychotherapy, insight-oriented, behavior modifying, and/or supportive, in an inpatient hospital, partial hospital, or residential care setting, approximately 20 to 30 minutes face-to-face with the patient.

90817 With medical evaluation and management services.

90818 Individual psychotherapy, insight-oriented, behavior modifying, and/or supportive, in an inpatient hospital, partial hospital or residential care setting, approximately 45 to 50 minutes face-to-face with the patient.

90819 With medical evaluation and management services.

90821 Individual psychotherapy, insight-oriented, behavior modifying, and/or supportive, in an inpatient hospital, partial hospital or residential care setting, approximately 75 to 80 minutes face-to-face with the patient.

90822 With medical evaluation and management services.

B3. Other Psychotherapy

90853 Group psychotherapy (other than a multiple-family group).

C. Dental Code –CDT Codes

D1320 Tobacco counseling for the control and prevention of oral disease.

Please Note: The following section is included for informational purposes only.

The National Center for Health Statistics (NCHS), the Federal agency responsible for use of the International Statistical Classification of Diseases and Related Health Problems, 10th revision (ICD-10) in the United States, has developed a clinical modification of the classification for morbidity purposes. The **ICD-10** is used to code and classify mortality data from death certificates, having replaced ICD-9 for this purpose as of January 1, 1999. ICD-10-CM is planned as the replacement for ICD-9-CM, volumes 1 and 2.

An updated July 2007 release **of ICD-10-CM** is available for public viewing. **However, at the time of this printing, the codes in ICD-10-CM are not currently valid for any purpose or use other than mortality coding. Once implemented, this information must be validated as current before use.**

F17 Nicotine dependence

Excludes1: history of tobacco dependence (Z87.82) tobacco use NOS (Z72.0) Excludes2: tobacco use (smoking) during pregnancy, childbirth, and the puerperium (O99.33-) toxic effect of nicotine (T65.2-).

F17.2 Nicotine dependence

F17.20	Nicotine dependence, unspecified
F17.200	Nicotine dependence, unspecified, uncomplicated
F17.201	Nicotine dependence, unspecified, in remission
F17.203	Nicotine dependence, unspecified, with withdrawal nicotine-induced disorders
F17.209	Nicotine dependence, unspecified, with unspecified nicotine-induced disorders

F17.21 Nicotine dependence, cigarettes
F17.210 Nicotine dependence, cigarettes, uncomplicated
F17.211 Nicotine dependence, cigarettes, in remission
F17.213 Nicotine dependence, cigarettes, with withdrawal
F17.218 Nicotine dependence, cigarettes, with other nicotine-induced disorders
F17.219 Nicotine dependence, cigarettes, with unspecified nicotine-induced disorders

F17.22 Nicotine dependence, chewing tobacco
F17.220 Nicotine dependence, chewing tobacco, uncomplicated
F17.221 Nicotine dependence, chewing tobacco, in remission
F17.223 Nicotine dependence, chewing tobacco, with withdrawal
F17.228 Nicotine dependence, chewing tobacco, with other nicotine-induced disorders
F17.229 Nicotine dependence, chewing tobacco, with unspecified nicotine-induced disorders

F17.29 Nicotine dependence, other tobacco product
F17.290 Nicotine dependence, other tobacco product, uncomplicated
F17.291 Nicotine dependence, other tobacco product, in remission
F17.293 Nicotine dependence, other tobacco product, withwithdrawal
F17.298 Nicotine dependence, other tobacco product, with other nicotine-induced disorders
F17.299 Nicotine dependence, other tobacco product, with unspecified nicotine-induced disorders

O99.3 Mental disorders and diseases of the nervous system complicating pregnancy, childbirth, and the puerperium

O99.33 Smoking (tobacco) complicating pregnancy, childbirth, and the puerperium
Use additional code from F17 to identify type of tobacco.
O99.330 Smoking (tobacco) complicating pregnancy, unspecified trimester
O99.331 Smoking (tobacco) complicating pregnancy, first trimester

O99.332 Smoking (tobacco) complicating pregnancy, second trimester
O99.333 Smoking (tobacco) complicating pregnancy, third trimester
O99.334 Smoking (tobacco) complicating childbirth
O99.335 Smoking (tobacco) complicating the puerperium

T65 Toxic effect of other and unspecified substances

T65.2 Toxic effect of tobacco and nicotine

Excludes2: nicotine dependence (F17.-).

T65.21 Toxic effect of chewing tobacco
T65.211 Toxic effect of chewing tobacco, accidental (unintentional)
Toxic effect of chewing tobacco NOS
T65.212 Toxic effect of chewing tobacco, intentional self-harm
T65.213 Toxic effect of chewing tobacco, assault
T65.214 Toxic effect of chewing tobacco, undetermined

T65.22 Toxic effect of tobacco cigarettes
Toxic effect of tobacco smoke
Use additional code for exposure to secondhand tobacco smoke (Z57.31, Z58.7).
T65.221 Toxic effect of tobacco cigarettes, accidental (unintentional)
Toxic effect of tobacco cigarettes NOS
T65.222 Toxic effect of tobacco cigarettes, intentional self-harm
T65.223 Toxic effect of tobacco cigarettes, assault
T65.224 Toxic effect of tobacco cigarettes, undetermined

T65.29 Toxic effect of other tobacco and nicotine
T65.291 Toxic effect of other tobacco and nicotine, accidental (unintentional)
Toxic effect of other tobacco and nicotine NOS
T65.292 Toxic effect of other tobacco and nicotine, intentional self-harm
T65.293 Toxic effect of other tobacco and nicotine, assault
T65.294 Toxic effect of other tobacco and nicotine, undetermined

Z71 Persons encountering health services for other counseling and medical advice, not elsewhere classified

Z71.6 Tobacco abuse counseling
Use additional code for nicotine dependence (F17.-).

Z72 Problems related to lifestyle

Z72.0 Tobacco use
Tobacco use NOS
Excludes1: history of tobacco dependence (Z87.82), nicotine dependence (F17.2-), tobacco dependence (F17.2-), tobacco use during pregnancy (O99.33-).

Z87 Personal history of other diseases and conditions

Z87.8 Personal history of other specified conditions
Z87.82 Personal history of nicotine dependence
Excludes1: current nicotine dependence (F17.2-).

Appendix D. Key Recommendation Changes From the 2000 PHS-Sponsored Clinical Practice Guideline: Treating Tobacco Use and Dependence

Below is a summary of the substantive changes in recommendations from the 2000 Guideline to the 2008 Guideline Update. These changes include new 2008 update recommendations as well as recommendations that were deleted or changed substantially from the 2000 Guideline.

NEW RECOMMENDATIONS IN THE 2008 UPDATE

Most, but not all, of the new recommendations appearing in the 2008 Treating Tobacco Use and Dependence Update resulted from new meta-analyses of the topics chosen by the Guideline Panel.

1. Formats of Psychosocial Treatments

Recommendation: Tailored materials, both print and Web-based, appear to be effective in helping people quit. Therefore, clinicians may choose to provide tailored self-help materials to their patients who want to quit. (Strength of Evidence = B)

2. Combining Counseling and Medication

Recommendation: The combination of counseling and medication is more effective for smoking cessation than either medication or counseling alone. Therefore, whenever feasible and appropriate, both counseling and medication should be provided to patients trying to quit smoking. (Strength of Evidence = A)

Recommendation: There is a strong relation between the number of sessions of counseling when it is combined with medication, and the likelihood of successful smoking abstinence. Therefore, to the extent possible, clinicians should provide multiple counseling sessions, in addition to medication, to their patients who are trying to quit smoking. (Strength of Evidence = A)

3. For Smokers Not Willing To Make a Quit Attempt at This Time

Recommendation: Motivational intervention techniques appear to be effective in increasing a patient's likelihood of making a future quit attempt. Therefore, clinicians should use motivational techniques to encourage smokers who currently are not willing to quit to consider making a quit attempt in the future. (Strength of Evidence = B)

4. Nicotine Lozenge

Recommendation: The nicotine lozenge is an effective smoking cessation treatment that patients should be encouraged to use. (Strength of Evidence = B)

5. Varenicline

Recommendation: Varenicline is an effective smoking cessation treatment that patients should be encouraged to use. (Strength of Evidence = A)

6. Specific Populations

Recommendation: The interventions found to be effective in this Guideline have been shown to be effective in a variety of populations. In addition, many of the studies supporting these interventions comprised diverse samples of tobacco users. Therefore, interventions identified as effective in this Guideline are recommended for all individuals who use tobacco, except when medically contraindicated or with specific populations in which medication has not been shown to be effective (pregnant women, smokeless tobacco users, light smokers, and adolescents). (Strength of Evidence = B)

7. Light Smokers

Recommendation: Light smokers should be identified, strongly urged to quit, and provided counseling cessation interventions. (Strength of Evidence = B)

RECOMMENDATIONS FROM THE 2000 GUIDELINE THAT WERE DELETED FROM THE 2008 UPDATE

All "C" level recommendations were reconsidered by the Panel, with the goal of limiting those that are based, in part, on Panel opinion. The 2008 Guideline Update has 8 "C" recommendations; the 2000 Guideline had 18. There were additional deletions of recommendations from the 2000 Guideline. Some of these other deletions reflect addressing specific populations differently in the 2008 Guideline update.

1. Advice To Quit Smoking

Recommendation: All clinicians should strongly advise their patients who use tobacco to quit. Although studies independently have not addressed the impact of advice to quit by all types of nonphysician clinicians, it is reasonable to believe that such advice is effective in increasing their patients' long-term quit rates. (Strength of Evidence = B)

2. Types of Counseling and Behavioral Therapies

Recommendation: Aversive smoking interventions (rapid smoking, rapid puffing, other aversive smoking techniques) increase abstinence rates and may be used with smokers who desire such treatment or who have been unsuccessful using other interventions**.** (Strength of Evidence = B)

3. Medications

Recommendation: Long-term smoking cessation medications should be considered as a strategy to reduce the likelihood of relapse. (Strength of Evidence = C)

4. Gender

Recommendation: The same smoking cessation treatments are effective for both men and women. Therefore, except in the case of the pregnant smoker, the same interventions can be used with both men and women. (Strength of Evidence = B)

5. Pregnancy

Recommendation: Medications should be considered when a pregnant woman otherwise is unable to quit, and when the likelihood of quitting,

with its potential benefits, outweighs the risks of the medications and potential continued smoking. (Strength of Evidence = C)

6. Racial and Ethnic Minority Populations

Recommendation: Smoking cessation treatments have been shown to be effective across different racial and ethnic minorities. Therefore, members of racial and ethnic minorities should be provided treatments shown to be effective in this Guideline. (Strength of Evidence = A)

Recommendation: Whenever possible, tobacco dependence treatments should be modified or tailored to be appropriate for the ethnic or racial populations with which they are used. (Strength of Evidence = C)

7. Hospitalized Smokers

Recommendation: Smoking cessation treatments have been shown to be effective for hospitalized patients. Therefore, hospitalized patients should be provided smoking cessation treatments shown to be effective in this Guideline. (Strength of Evidence = B)

8. Psychiatric Illness and/or Nontobacco Chemical Dependency

Recommendation: Smokers with comorbid psychiatric conditions should be provided smoking cessation treatments identified as effective in this Guideline. (Strength of Evidence = C)

Recommendation: Bupropion SR and nortriptyline, efficacious treatments for smoking cessation in the general population, also are effective in treating depression. Therefore, bupropion SR and nortriptyline especially should be considered for the treatment of tobacco dependence in smokers with current or past history of depression. (Strength of Evidence = C)

Recommendation: Evidence indicates that smoking cessation interventions do not interfere with recovery from chemical dependency. Therefore, smokers receiving treatment for chemical dependency should be provided smoking cessation treatments shown to be effective in this Guideline, including both counseling and medications. (Strength of Evidence = C)

9. Children and Adolescents

Recommendation: When treating adolescents, clinicians may consider prescriptions for bupropion SR or NRT when there is evidence of nicotine dependence and desire to quit tobacco use. (Strength of Evidence = C)

10. Older Smokers

Recommendation: Smoking cessation treatments have been shown to be effective for older adults. Therefore, older smokers should be provided smoking cessation treatments shown to be effective in this Guideline. (Strength of Evidence = A)

11. Weight Gain After Stopping Smoking

Recommendation: The clinician should acknowledge that quitting smoking is often followed by weight gain. Additionally, the clinician should: (1) note that the health risks of weight gain are small when compared to the risks of continued smoking; (2) recommend physical activities and a healthy diet to control weight; and (3) recommend that patients concentrate primarily on smoking cessation, not weight control, until exsmokers are confident that they will not return to smoking. (Strength of Evidence = C)

12. Cost-Effectiveness of Tobacco Interventions

Recommendation: Intensive smoking cessation interventions are especially efficacious and cost-effective, and smokers should have ready access to these services as well as to less intensive interventions. (Strength of Evidence = B)

Note: The tobacco dependence treatments shown to be effective in this Guideline still are recommended as highly cost-effective with Strength of Evidence = A. The above recommendation, number 12, was deleted because it refers only to "intensive" smoking cessation interventions.

RECOMMENDATIONS FROM THE 2000 GUIDELINE THAT WERE SUBSTANTIALLY CHANGED IN THE 2008 UPDATE:

The results of meta-analyses or consideration of literature not available for the 2000 Guideline led to substantive changes in some of the 2000 Guideline recommendations. Minor changes in wording are not listed here.

1. Screening and Assessment

2000 Guideline. Recommendation #1: All patients should be asked if they use tobacco and should have their tobacco-use status documented on a regular basis. Evidence has shown that this significantly increases rates of clinician intervention. (Strength of Evidence = A)

2000 Guideline. Recommendation #2: Clinic screening systems, such as expanding the vital signs to include tobacco use status, or the use of other reminder systems, such as chart stickers or computer prompts, are essential for the consistent assessment, documentation, and intervention with tobacco use. (Strength of Evidence = B)

2008 Guideline Update. Recommendation: All patients should be asked if they use tobacco and should have their tobacco use status documented on a regular basis. Evidence has shown that clinic screening systems, such as expanding the vital signs to include tobacco use status, or the use of other reminder systems, such as chart stickers or computer prompts, significantly increase rates of clinician intervention. (Strength of Evidence = A)

2. Types of Counseling and Behavioral Therapies

2000 Guideline. Recommendation: Three types of counseling and behavioral therapies result in higher abstinence rates: (1) providing smokers with practical counseling (problemsolving skills/skills training); (2) providing social support as part of treatment; and (3) helping smokers obtain social support outside the treatment environment. These types of counseling and behavioral therapies should be included in smoking cessation interventions. (Strength of Evidence = B)

2008 Guideline Update. Recommendation: Two types of counseling and behavioral therapies result in higher abstinence rates: (1) providing smokers with practical counseling (problemsolving skills/skills training); and

(2) providing support and encouragement as part of treatment. These types of counseling elements should be included in smoking cessation interventions. (Strength of Evidence = B)

3. Medications

2000 Guideline. Recommendation: All patients attempting to quit should be encouraged to use effective medications for smoking cessation, except in the presence of special circumstances. (Strength of Evidence = A)

2008 Guideline Update. Recommendation: Clinicians should encourage all patients attempting to quit to use effective medications for tobacco dependence treatment, except where contraindicated or for specific populations for which there is insufficient evidence of effectiveness (i.e., pregnant women, smokeless tobacco users, light smokers, and adolescents). (Strength of Evidence = A)

4. Combination Medications

2000 Guideline. Recommendation: Combining the nicotine patch with a self-administered form of nicotine replacement therapy (either the nicotine gum or nicotine nasal spray) is more efficacious than a single form of nicotine replacement, and patients should be encouraged to use such combined treatments if they are unable to quit using a single type of first-line medication. (Strength of Evidence = B)

2008 Guideline Update. Recommendation: Certain combinations of first-line medications have been shown to be effective smoking cessation treatments. Therefore, clinicians should consider using these combinations of medications with their patients who are willing to quit. Effective combination medications are long-term (> 14 weeks) nicotine patch + other NRT (gum and spray), the nicotine patch + the nicotine inhaler, and the nicotine patch + bupropion SR. (Strength of Evidence = A)

5. Children and Adolescents

2000 Guideline. Recommendation #1: Counseling and behavioral interventions shown to be effective with adults should be considered for use with children and adolescents. The content of these interventions should be modified to be developmentally appropriate. (Strength of Evidence = C)

2008 Guideline Update. Recommendation #1: Counseling has been shown to be effective in treatment of adolescent smokers. Therefore, adolescent smokers should be provided with counseling interventions to aid them in quitting smoking. (Strength of Evidence = B)

2000 Guideline. Recommendation #2: Clinicians in a pediatric setting should offer smoking cessation advice and interventions to parents to limit children's exposure to secondhand smoke. (Strength of Evidence = B)

2008 Guideline Update. Recommendation #2: Secondhand smoke is harmful to children. Cessation counseling delivered in pediatric settings has been shown to be effective in increasing cessation among parents who smoke. Therefore, to protect children from secondhand smoke, clinicians should ask parents about tobacco use and offer them cessation advice and assistance. (Strength of Evidence = B)

6. Noncigarette Tobacco Users

2000 Guideline. Recommendation: Smokeless/spit tobacco users should be identified, strongly urged to quit, and treated with the same counseling cessation interventions recommended for smokers. (Strength of Evidence = B)

2008 Guideline Update. Recommendation: Smokeless tobacco users should be identified, strongly urged to quit, and provided counseling cessation interventions. (Strength of Evidence = A)

7. Cost-Effectiveness of Tobacco Dependence Interventions

2000 Guideline. Recommendation: Sufficient resources should be allocated for clinician reimbursement and systems support to ensure the delivery of efficacious tobacco use treatments. (Strength of Evidence = C)

2008 Guideline Update. Recommendation: Sufficient resources should be allocated for systems support to ensure the delivery of effective tobacco use treatments. (Strength of Evidence = C)

8. Tobacco Dependence Treatment as a Part of Assessing Health Care Quality

2000 Guideline. Recommendation: Provision of Guideline-based interventions to treat tobacco use and addiction should be included in standard

ratings and measures of overall health care quality (e.g., NCQA HEDIS, the Foundation for Accountability [FACCT]). (Strength of Evidence = C)

2008 Guideline Update. Recommendation: Provision of Guideline-based interventions to treat tobacco use and dependence should remain in standard ratings and measures of overall health care quality (e.g., NCQA, HEDIS). These standard measures also should include measures of outcomes (e.g., use of cessation treatment, short- and long-term abstinence rates) that result from providing tobacco dependence interventions. (Strength of Evidence = C)

9. Providing Smoking Cessation Treatments as a Covered Benefit

2000 Guideline. Recommendation: Smoking cessation treatments (both medication and counseling) should be included as a paid or covered benefit by health benefit plans, because doing so improves utilization and overall abstinence rates. (Strength of Evidence = B)

2008 Guideline Update. Recommendation: Providing tobacco dependence treatments (both medication and counseling) as a paid or covered benefit by health insurance plans has been shown to increase the proportion of smokers who use cessation treatment, attempt to quit, and successfully quit. Therefore, treatments shown to be effective in the Guideline should be included as covered services in public and private health benefit plans. (Strength of Evidence = A)

Guideline Availability

This Guideline is available in several formats suitable for health care practitioners, the scientific community, educators, and consumers.

The *Clinical Practice Guideline* presents recommendations for health care providers, with brief supporting information, tables and figures, and pertinent references.

The *Quick Reference Guide* is a distilled version of the clinical practice Guideline, with summary points for ready reference on a day-to-day basis.

The *Consumer Version* is an information booklet for the general public to increase consumer knowledge and involvement in health care decisionmaking.

The full text of the Guideline, with and without the text references and the meta-analyses references (listed by evidence table), is available by visiting the Surgeon General's Web site at: *www.ahrq.gov/path/tobacco.htm#Clinic*.

Single copies of these Guideline products and further information on the availability of other derivative products can be obtained by calling any of the following Public Health Service organizations' toll-free numbers:

Practice parameter: Treatment of the child with a first unprovoked seizure

Report of the Quality Standards Subcommittee of the American Academy of Neurology and the Practice Committee of the Child Neurology Society*

D. Hirtz, MD; A. Berg, PhD; D. Bettis, MD; C. Camfield, MD; P. Camfield, MD; P. Crumrine, MD; W.D. Gaillard, MD; S. Schneider, MD; and S. Shinnar, MD, PhD

Abstract—The Quality Standards Subcommittee of the American Academy of Neurology and the Practice Committee of the Child Neurology Society develop practice parameters as strategies for patient management based on analysis of evidence regarding risks and benefits. This parameter reviews published literature relevant to the decision to begin treatment after a child or adolescent experiences a first unprovoked seizure and presents evidence-based practice recommendations. Reasons why treatment may be considered are discussed. Evidence is reviewed concerning risk of recurrence as well as effect of treatment on prevention of recurrence and development of chronic epilepsy. Studies of side effects of anticonvulsants commonly used to treat seizures in children are also reviewed. Relevant articles are classified according to the Quality Standards Subcommittee classification scheme. Treatment after a first unprovoked seizure appears to decrease the risk of a second seizure, but there are few data from studies involving only children. There appears to be no benefit of treatment with regard to the prognosis for long-term seizure remission. Antiepileptic drugs (AED) carry risks of side effects that are particularly important in children. The decision as to whether or not to treat children and adolescents who have experienced a first unprovoked seizure must be based on a risk–benefit assessment that weighs the risk of having another seizure against the risk of chronic AED therapy. The decision should be individualized and take into account both medical issues and patient and family preference.

NEUROLOGY 2003;60:166–175

Population-based studies of the incidence of first unprovoked seizures suggest that there are between 25,000 and 40,000 children per year in the United States who experience a first unprovoked seizure.[1-4] Until relatively recently, it was common practice for physicians to begin long-term, daily antiepileptic drug (AED) therapy after a child or adolescent experienced a single seizure of any type. The rationale for this practice was based on the belief that all seizures were likely to recur and that seizures could be dangerous and cause brain damage. Furthermore, it was thought that if any recurrence were to take place, this would lead to progressively more seizures. It was also assumed that AED were safe, had few side effects, and were effective in prevention of seizure recurrences. These assumptions have undergone substantial modification over the last 20 years, leading to a more optimistic view about the nature of seizures and a more conservative approach to the use of treatment. However, no clear evidence-based guidelines have emerged regarding the initiation of treatment after a first unprovoked seizure in the pediatric population.

Practice parameters are developed by the Quality

Approved by the Quality Standards Subcommittee on April 16, 2002. Approved by the Practice Committee on August 3, 2002. Approved by the AAN Board of Directors on October 19, 2002.

This statement has been endorsed by the American Epilepsy Society; the American Academy of Pediatrics; and the Child Neurology Society.

Table 1 *Evidence classification scheme of the American Academy of Neurology: rating of therapeutic article*

Class I: Prospective, randomized, controlled clinical trial with masked outcome assessment, in a representative population. The following are required:
a. Primary outcome(s) is/are clearly defined.
b. Exclusion/inclusion criteria are clearly defined.
c. Adequate accounting for dropouts and crossovers with numbers sufficiently low to have minimal potential for bias.
d. Relevant baseline characteristics are presented and substantially equivalent among treatment groups or there is appropriate statistical adjustment for differences.
Class II: Prospective matched group cohort study in a representative population with masked outcome assessment that meets a–d above *or* a randomized, controlled trial in a representative population that lacks one criteria a–d.
Class III: All other controlled trials (including well-defined natural history controls or patients serving as own controls) in a representative population, where outcome assessment is independent of patient treatment.
Class IV: Evidence from uncontrolled studies, case series, case reports, or expert opinion.

Standards Subcommittee of the American Academy of Neurology and the Child Neurology Society and are evidence-based documents about diagnostic or prognostic evaluations and therapeutic interventions. These involve a systematic evaluation and classification of available evidence (table 1) that determine whether specific recommendations can be made and, if so, the strength of the recommendations (table 2).

This practice parameter reviews the current evidence about treatment with AED after a child experiences a first unprovoked seizure. We examine the risk of seizure recurrence and predictors that may affect that risk. We review and classify the published evidence on whether treatment prevents recurrences as well as chronic epilepsy. We also evaluate potential risks and side effects of AED commonly used to treat seizures in children.

This is the second of two parameters addressing a child's first unprovoked seizure; the first concerned the initial evaluation.[5] Febrile seizures have been addressed separately in recently published recommendations from the American Academy of Pediatrics[6] and are not included here. This parameter pertains to children and adolescents with first seizures only and does not include children diagnosed with epilepsy, defined as the occurrence of two or more seizures without acute provocation. For this reason, absence, myoclonic, and atonic seizures were excluded because they typically are not recognized until there have been multiple occurrences. The seizure types covered by this parameter include all partial seizures as well as generalized onset tonic-clonic or tonic seizures.

We defined the first seizure using the International League Against Epilepsy criteria to include multiple seizures within 24 hours with recovery of consciousness between seizures.[7] Children with a known immediate precipitating head trauma or those with previously diagnosed CNS infection, tumor, or other known acute precipitating causes such as hypoglycemia were excluded. We also excluded neonatal seizures ($\leq$28 days) and febrile seizures because these disorders are diagnostically and therapeutically different. Status epilepticus, defined as a seizure lasting $>$30 minutes without regaining of consciousness,[7] was included when data were available. Most articles describing pediatric studies covered up to age 18 years; studies including both adolescents and adults were also examined. The recommendations of this parameter pertain to children (excluding the neonate) and adolescents.

Before any treatment decisions are approached, it is critical to determine whether the event is truly a seizure and whether it is the child's first.[5] A detailed history from a reliable observer and careful medical history and neurologic examination may provide information allowing the physician to rule out nonepileptic events.

Description of process. A literature search was performed including Ovid Medline and Ovid Biosys and Current Contents for relevant articles published from 1980 to 2001 using the following key words: treatment, antiepileptics, medications, therapy, management, epilepsy, seizures, convulsions, child, newborn, and adolescent. Standard search procedures were used, and subheadings were applied as appropriate. These searches produced 948 titles of journal articles.

Titles and abstracts were reviewed for content re-

Table 2 *Evidence classification scheme of the American Academy of Neurology: recommendations*

Translation of evidence to recommendations	Rating of recommendation
Level A rating requires at least one convincing Class I study or at least two consistent, convincing Class II studies.	A = established as effective, ineffective, or harmful for the given condition in the specified population.
Level B rating requires at least one convincing Class II study or overwhelming Class III evidence.	B = probably effective, ineffective, or harmful for the given condition in the specified population.
Level C rating requires at least two convincing Class III studies.	C = possibly effective, ineffective, or harmful for the given condition in the specified population.
—	U = data inadequate or conflicting. Given current knowledge, treatment is unproven.

garding first unprovoked seizures in children and adults. Articles from the searches were identified as relevant, and additional articles from the references in these primary articles were included. Articles pertaining to children with both first seizures and established epilepsy were included but were excluded if they did not report data from either children or adults who had experienced only a single seizure. References were classified as to whether they contained data related to children and adults or just children. Articles were reviewed from searches, bibliographies, and suggestions by colleagues and committee members. In most reports pertaining to both children and adults, results were not categorized according to subsets of age groups.

A recently revised classification of evidence to determine the quality of data was used for the evaluation of reports of therapeutic studies (see table 1). Each article containing data regarding treatment was reviewed and classified by two or more reviewers. Abstracted data included numbers of subjects, study design, ages, seizure types, whether first seizures only or a mixture of single and multiple seizures, seizure recurrences, types of treatment, side effects, and measurement of compliance and length of follow-up. Methods of data analysis and power were noted when available. Recommendations were based on the level of evidence (see table 2).

What are the potential risks resulting from having a second seizure? Preventing seizure recurrences has been a concern ever since Gowers wrote: "The tendency of the disease is to self perpetuation; each attack facilitates the occurrence of another, by increasing the instability of the nerve elements."[8] This clinical belief has been supported by animal studies on kindling, an experimental technique for inducing epilepsy by a series of subclinical electrical stimulations of the temporal lobe that induce progressive intensification of evoked electrographic and behavioral seizures.[9-11] There is evidence from animal models that prolonged or recurrent seizures, under certain circumstances, cause neuronal injury and predispose to epilepsy.[12,13] There is recent evidence that seizures, some prolonged, that occur during critical periods of brain development in animals may alter neuronal activity and circuitry in a manner that may predispose to the later development of epilepsy.[14,15] The relevance of data from these animal models to seizures in humans is unclear.[10,11,16] Data from children indicate that even prolonged seizures rarely cause clinically discernible brain damage unless associated with an underlying acute neurologic insult.[17]

One reason why treatment may be considered is concern about the risk of physical injury or death from a subsequent seizure. Serious injury from a seizure in a child is a rare event, usually from a fall with loss of consciousness. To reduce that risk, restrictions are recommended that would apply to any young child, such as bicycling on a sidewalk rather than the street and always with a helmet and swimming only with a buddy. Showering rather than bathing is recommended for children and adolescents, unless they are supervised. Sudden unexpected death in children with epilepsy is, fortunately, very uncommon. When death occurs in children, it is nearly always related to an underlying neurologic handicap rather than the epilepsy.[18-20] One population-based study found that the risk of death in those with childhood-onset epilepsy is the same as that for the general population for children without significant neurologic handicap.[21] No studies were found that examined whether treating a child after a first unprovoked seizure would reduce the risk of either subsequent significant injury or sudden death.

Psychosocial considerations. The effect of taking daily medication on the child's self-perception may be a concern in some cases.[22,23] A child who is taking chronic medication is perceived to have a chronic illness by the child, family, and possibly others such as teachers. Additionally, chronic treatment to prevent seizure recurrence may affect the family's ability to obtain health insurance or day care. Issues in teenagers become more complicated as concerns about driving privileges and teratogenicity come into play.[24]

How likely is a second seizure? The probability of having a second seizure has been explored in several large, observational Class III studies with long-term follow-up. Results presented in table 3 are limited to studies that included children with or without adults. The cumulative risk of recurrence increases over time; however, in studies where the information is available, the majority of the recurrences occur early (within the first 1 to 2 years).[25-33] At any given time, the reported risk of recurrence is highly variable. For example, at 1 year, it ranges from a low of 14%[26] to a high of 65%.[33] In all these Class III studies, there is variability in the mix of patients, the nonrandomized use of treatment, and the distributions of important prognostic factors. Some methodologic differences in seizure identification, age ranges included, recruitment, and follow-up of study participants may also contribute to this variability.

How likely are multiple recurrences in children who present with a first unprovoked seizure? A minority of children will go on to experience not just one but many recurrences. One study that enrolled 207 children with follow-up for 2 years found that in addition to an overall recurrence rate of 54%, 26% of the enrolled children were still experiencing one or more seizures during the last 6 months of the study follow-up, that is, >18 months after the index event.[27] Another study with longer follow-up enrolled 407 children and followed them for an average of >10 years. Of these, 46% had one or more recurrences during that period of time. Over the extended follow-up period, 19% of the children

Table 3 *Risk of recurrence after a first seizure*

Study	Age range	n	Treated, %	Risk of recurrence at different times since first seizure, %				
				6 mo	1 y	2 y	3 y	5 y
Children and adolescents only								
27	1–16 y	156	0	40	46	54	—	—
33	3–21 y	78	58	55	65	69	—	—

26	All ages	208	≈80	—	14	25	29	34

enrolled experienced ≥4 seizures and only 10% experienced ≥10 seizure episodes.[28] Few of the children in either study met criteria for intractability.[34]

Are there factors that increase the recurrence risk? Certain factors may elevate the risk of experiencing a second seizure. The underlying etiology and whether the EEG is normal or abnormal are consistently related to the risk of recurrence.[35] The recurrence rate is higher in individuals who have a remote symptomatic etiology. In those with an idiopathic or cryptogenic etiology, it is significantly lower.[25-28,30,33] We use the term "remote symptomatic" to mean without immediate cause but with a prior identifiable major brain insult such as severe trauma or accompanying a condition such as cerebral palsy or mental retardation. Idiopathic seizures are not associated with a known CNS disorder and are of suspected genetic etiology (such as occur with benign rolandic epilepsy), and cryptogenic seizures occur in individuals otherwise normal with no clear etiology.[7] The estimates of risk at 2 years are highly variable. The extent to which treatment was used also varied and may have influenced, to some degree, the overall risk observed. For children with first seizures that are idiopathic/cryptogenic, the recurrence risk is generally between 30 and 50% by 2 years,[25,27-30] and for remote symptomatic seizures, the estimate of recurrence risk is generally above 50%.[25,27,28,30,33] An EEG performed after the initial seizure also helps to predict recurrence,[25-27,29-31,33] particularly if there is an epileptiform abnormality. Patients with remote symptomatic seizures and abnormal EEG were more likely to be treated than those with idiopathic/cryptogenic seizures and normal EEG. All of these studies addressing recurrence risk represent Class III evidence.

Are there special considerations if the first seizure is prolonged? Approximately 10 to 12% of children and adults with a first unprovoked seizure will present with a seizure lasting ≥30 minutes (status epilepticus) as their first seizure.[36] In the absence of an acute or progressive brain injury or disease, the morbidity and mortality of status epilepticus in children are relatively low.[17,37] Of 46 children with "idiopathic" seizures in a study of sequelae of status epilepticus in 193 children, 2 children had mental retardation, but they had been recruited retrospectively and details of the clinical circumstances were not clear. None of children studied prospectively had residual motor or cognitive disability.[17]

Evidence concerning the impact of status epilepticus on the risk of recurrence and, in particular, the risk of a prolonged recurrence is available from one Class III prospective observational study of 407 children with a first unprovoked seizure.[25,36] The overall recurrence risk following a prolonged first seizure was no different from the recurrence risk following a brief first seizure. However, if a child with an initial prolonged seizure did experience a seizure recurrence, it was more likely to be prolonged. Of 24 children with initial episodes of status epilepticus who had a recurrence, 5 (21%) had status epilepticus as a recurrence, whereas of 147 whose first seizures were brief and who had a recurrence, 2 (1%) had status epilepticus as their recurrence.[25] Thus, the risk of a recurrent seizure being prolonged is limited largely to those children whose first seizure was prolonged (Class III studies).

How effective is treatment after a first seizure in prevention of recurrences? *Evidence.* There are four randomized clinical trials including children and adolescents that have examined the efficacy of treatment after a first seizure.[38-41] Only one of these studies consisted solely of children randomized to treatment versus no treatment after a first nonfebrile seizure (Class II).[41] In this study with a total of 31 children, 2 of 14 children (14%) treated with carbamazepine (CBZ) experienced a recurrence compared with 9 of 17 (53%)

Table 4 *Recurrence rate by treatment in studies of children*

Study	Class	n	Recurrence rate, n (%)	Treated vs untreated	Length of follow-up, y
41	II	31	11/31	2/14 vs 9/17, 14.3% vs 52.9%	1
42	III	284	196/284 (69)	No difference	To 7
29	III	119	40/119 (32)	27% vs 38%, no difference	3
25	III	407	151/393 (38) at 2 y, 171/375 (46) at 5 y	No difference	6.3, mean
33	III	78, includes 12 symptomatic	54/78 at 2 y (69)	No difference	5.2

who were not treated. Follow-up was for 1 year, and compliance was monitored. Although the recurrence rate up to 1 year was significantly lower in the treated group, only 6 of 14 (43%) patients randomized to CBZ completed the year with no significant side effects or seizure recurrence and 7 of 17 (41%) assigned to no medication had no seizure recurrence.

In studies involving both children and adults, outcome was not provided based on age. One Class I study in which 228 subjects were randomized to valproic acid (VPA) or placebo included 33 adolescents between the ages of 16 and 19.[38] The follow-up period for this trial was between 9 months and 5 years. Five (4%) of the treated group experienced a recurrence compared with 63 (56%) of those treated with placebo. However, these results were not found in another Class II randomized study (n = 419), in which 114 subjects were between 2 and 16 years old. Twenty-four percent of patients treated after a first seizure and 42% untreated patients had a recurrence by 1 year, but no difference by initial treatment assignment was seen after 2 years; 32% of those treated and 40% of those untreated had a recurrence by 2 years.[39]

In other studies in children (Class III), although the cohorts are prospectively followed, treatment was not randomly assigned and therefore baseline factors affecting risk of recurrence were not comparable.[25,29,33,42] None of these studies found a significant difference in recurrence rate in the treated and untreated children (table 4).

Summary. Studies of children and adults in which treatment assignment was randomized usually indicate that treatment with AED after a first seizure reduces the risk of seizure recurrence. The magnitude of the impact is variable, and the evidence from pediatric studies alone is weak (see table 4). Differences among the studies, the populations targeted, and the method in which treatment was administered may explain some of the variability. In the only randomized study restricted to the pediatric age group, the sample size is small and the confidence intervals are accordingly wide, ranging from 0 to 93% efficacy.[41]

Does treatment with AED after a first seizure change the long-term prognosis for seizure remission? *Evidence.* Although treatment after a first unprovoked seizure may reduce the risk of a second seizure, does treatment at this time make any difference in the patient's long-term prognosis for seizure control? This question is addressed in two randomized, prospective, but not placebo-controlled (Class II) first-seizure studies. One study had 419 subjects, of whom 114 were between 2 and 16 years of age.[39] This study compared the probability of experiencing a remission, that is, 1 or 2 seizure-free years, in patients treated after a first seizure versus in patients treated after a second seizure. Follow-up was for at least 3 years or a minimum of 2 years seizure-free. Patients treated after the first seizure and those treated after a second seizure had the same probability of achieving a 1- or 2-year seizure remission (68%, n = 215 versus 60%, n = 204) (risk of recurrence [RR] = 1.04, 95% CI = 1.30 to 0.82). Another smaller study[43] of 31 children randomized to CBZ (n = 14) or no treatment (n = 17) echoes the results of this large study. After a 15-year follow-up, the rate of 2-year terminal remission was the same in both the treated and the untreated groups (RR = 0.79, 95% CI = 0.3 to 2.1).

Summary. Two Class II studies provide no evidence of a difference when treatment is started after the first seizure versus after a second seizure in achieving a 1-or 2-year seizure remission.

What are the nature and frequency of side effects of AED commonly used after a first seizure in children? *Evidence.* AED may cause systemic side effects such as rash, hirsutism, and weight gain. Severe reactions such as hepatic toxicity, bone marrow toxicity, and Stevens–Johnson syndrome cannot be anticipated and require early recognition of symptoms. Side effects of AED occurring in children include effects on behavior and higher cortical function,[44] which are often dose related and may be under-recognized. Dose-related side effects may be highest initially and amenable to dosage reduction, but this may also limit the potential effectiveness of AED. If the patient is a teenage girl who may become pregnant, the risk of teratogenicity is an additional consideration.[24,45]

Trials that report data relating to efficacy do not always include data relating to side effects. Data regarding toxicity or side effects of AED are not specifically available for treatment after a first seizure. However, studies that include initial treatment of

Table 5 *Behavioral and cognitive side effects of antiepileptic drugs in children treated for epilepsy*

Study	Age, y	Follow-up	Medication (n)	Reported side effects
Class I				
50,51	5–14	1 y	CBZ (23)	Impaired recent recall, reported slow by teachers
			PHT (20)	Impaired information processing at 1 mo
			VPA (21)	No change
49	7–15	6 and 12 mo	CBZ (26)	No change
			PB (25)	Disturbed information processing (auditory event-related potentials prolonged)
			VPA (25)	No change
47	2–16	12 mo	CBZ (78)	29 of total of 116 had moderate/severe behavior problems
			PHT (38)	
48	6–14	6 mo	PB	Did less well on cognitive tests, more hyperactivity
			VPA	No change
53	—	None	CBZ (50)	No difference high vs. low level
54			VPA (46)	Low doses gave better accuracy and response time
55			PHT (50)	No difference high vs. low level
52	4–12	2 y	PB (51)	22% hyperactivity
			VPA (48)	13% hyperactivity
			PHT (52)	8% impaired school performance
Class 2				
56	3–16	3 y	PB (10)	6 withdrew owing to side effects
			PHT (50)	5 withdrew owing to side effects
			CBZ (54)	2 withdrew owing to side effects
			VPA (49)	2 withdrew owing to side effects
51	Average 9	12 mo	VPA (26)	Increase in IQ
			PB (23)	Significant impairment in learning
58	6–17	6 mo	CBZ (17)	No difference
			VPA (11)	No difference
			PHT (1)	No difference
59	7–12	12 mo	VPA (34)	No difference
			CBZ (29)	No difference
60	4–16	26–6 mo	CBZ (5)	No difference
		12–12 mo	VPA (3)	No difference
			Ethosuximide (4)	No difference

CBZ = carbamazepine; PHT = phenytoin; VPA = valproic acid; PB = phenobarbital.

children for epilepsy provide information that may be extrapolated to treatment after a first seizure.

Behavioral and cognitive side effects. Five Class I studies reported on behavioral and cognitive side effects in children with epilepsy treated with AED.[46-52] One study reported that 29 of 116 children treated with either CBZ or phenytoin (PHT) had moderate to severe behavioral or mood changes.[46,47] In a blinded, randomized, crossover study comparing phenobarbital (PB) with VPA, children taking PB had lower scores on four tests of cognitive function and had more behavior problems that were not dose related, particularly hyperactivity.[48] Although Wechsler Intelligence Scale for Children–Revised scores were not different, a study that included auditory event-related potentials found prolonged latencies indicating delayed information processing associated with PB.[49] In a Class I study of children with newly diagnosed epilepsy in which 23 children received CBZ, 20 received PHT, and 21 received VPA, those on CBZ and PHT were slower on tests of information processing, and children on CBZ showed increased irritability[50,51] (table 5).

A series of three Class I studies each designed to compare the cognitive effects of low versus high levels of one AED in children with epilepsy found no differences between low and high levels with either CBZ or PHT.[53,54] Children with a lower level of VPA performed better on specific cognitive tasks such as accuracy and response time than those with a higher level.[55] In one Class II study, 15 of 163 children assigned to AED withdrew because of intolerable side

Table 6 *Systemic side effects of antiepileptic drugs in children treated for epilepsy*

Study	n	Follow-up	Medication (n)	Side effects
Class I				
51	64	1 y	CBZ (23)	3 h/a, anorexia, nausea
			PHT (20)	1 depression, anorexia
			VPA (21)	0
47	116	1 y	CBZ (78)	9 n&v, 10 ataxia, 5 rash, 5 gingival hyperplasia
			PHT (38)	
52	151	29 mo, mean	PB (51)	17 patients including behavioral
			VPA (48)	15 patients, including behavioral
			PHT (52)	33 patients had at least 1, 30 gingival hyperplasia, 13 dose-related ataxia
Class II				
41	31	1 y	CBZ (14)	2 somnolence, 2 allergic rash
56	167	4 y	PB (10)	5 behavior, 1 drowsy
			PHT (54)	2 drowsy, 1 rash, 1 blood dyscrasia, 1 hirsutism
			CBZ (54)	1 drowsy, 1 blood dyscrasia
			VPA (49)	1 behavior problem, 1 tremor
61	260	1 y	VPA (130)	Half had adverse events, e.g., somnolence, ataxia, rash; 12% d/c owing to "adverse events" such as increased appetite, weight gain, alopecia
			CBZ (130)	7% d/c owing to side effects

CBZ = carbamazepine; PHT = phenytoin; VPA = valproic acid; PB = phenobarbital; h/a = headache; n&v = nausea and vomiting; d/c = discontinued.

effects,[56] and in another, children taking PB did not show an expected increase in IQ on retest.[57] In three other studies, which included 48 children taking VPA, 1 taking PHT, and 51 taking CBZ, evidence was not seen of behavioral or cognitive impairment[58-60] (see table 5).

A report from the American Academy of Pediatrics[44] regarding general recommendations for awareness of behavioral and cognitive effects of AED noted that high blood levels of some AED (PHT, PB, primidone) were significantly related to cognitive decline. Cognitive and behavioral effects of AED were described as subtle and affecting isolated functions. These effects were seen in conjunction with academic underachievement and neuropsychological impairment in children with epilepsy.

Systemic side effects. Systemic side effects other than behavioral or cognitive also occur in children placed on AED (table 6). In a Class I study of 116 children randomized to CBZ or PHT, 24 had one or more side effects including nausea and vomiting (9), ataxia (10), rash (5), gingival hyperplasia (3), and dizziness (3).[47] Another Class I study reported that of 23 children on CBZ, 3 experienced headache, anorexia, nausea or abdominal pain, and increased irritability. Systemic side effects were not reported for the 20 children on PHT or the 21 on VPA.[50,51] Dropout because of failure to comply with treatment, possibly due to side effects, occurred in several cases in all three groups.

In the one prospective, randomized, but not blinded study in children that pertains to first seizures only, 2 of 14 children on CBZ discontinued medication because of rash and 2 of 14 because of excessive somnolence.[41] When four drugs were compared in a Class II study of 167 children with newly diagnosed epilepsy, PB was dropped after 6 of 10 children had unacceptable side effects. Side effects occurred at a rate of 9% for PHT, 4% for CBZ, and 4% for VPA.[56] Included were behavioral problems, drowsiness, sleep problems, blood dyscrasia, hirsutism, and tremor. A randomized and blinded prospective study of 151 children with epilepsy found that 32% of children on PB, 19% of children on VPA, and 40% of children on PHT had more than one toxic side effect. Fifty-eight percent of those on PHT experienced gingival hyperplasia, and 25% had dose-related ataxia or sedation. Follow-up was 2 years.[52] In a Class II study of 130 children assigned to VPA and 130 assigned to CBZ, by 1 year, 13% discontinued VPA and 7% discontinued CBZ owing to adverse effects such as somnolence, fatigue, weight gain, headache, nausea, vomiting, and rash.[61]

In a Class III study of first seizures, four AED were used and an overall rate of side effects of 24% was reported. These were noted as behavior disorders, hyperkinesias, and sleepiness.[29] The exacerbation of seizures by CBZ has been reported in 11 of 129 cases of new-onset epilepsy.[62]

Several of the newer AED carry warnings or precautions for Stevens–Johnson syndrome (lamotrigine, zonisamide, felbamate), hepatic toxicity (lamotrigine, felbamate), aplastic anemia (felbamate), renal stones (topiramate, zonisamide), and

other rare medical complications such as hyperthermia secondary to hypohidrosis and hyponatremia (zonisamide and oxcarbazepine). The spectrum and incidence of medical ill effects of the newer AED in special populations such as children may not become apparent until after several years of use.[63] There are not yet adequate data on behavioral or cognitive side effects of newer AED in children, and they are not currently approved for monotherapy in children. A new form of treatment for acute seizure activity that may be used at home is diazepam administered in a rectal solution, but this is approved for use in selected refractory patients to control acute, repetitive seizure activity and is not used after a single unprovoked seizure.[64,65]

Summary. Whereas evidence from studies of treatment after only a single unprovoked seizure is lacking, Class I and II evidence concerning the AED accepted for use as first-line anticonvulsants in children (PB, PHT, VPA, CBZ) indicates that clinically relevant cognitive and behavioral effects may occur, particularly with PB. Parents and teachers may often overlook such cognitive and behavioral effects. In addition, one or more important systemic side effects such as rash, hirsutism, weight gain, or nausea may occur with a frequency ranging from 7 to 58%.

Conclusions. The majority of children who experience a first unprovoked seizure will have few or no recurrences. Only approximately 10% will go on to have many ($\geq$10) seizures regardless of therapy. Treatment with AED after a first seizure as opposed to after a second seizure has not been shown to improve prognosis for long-term seizure remission (Class II evidence).

Treatment has been shown in several studies combining both children and adults to reduce the risk of seizure recurrence (Class II evidence). There is a relative paucity of data from studies involving only children after a first seizure. AED therapy in children who have epilepsy (at least two seizures) has potential serious pharmacologic and psychosocial side effects (Class I evidence). No separate data exist specifically for treatment side effects in children who have experienced only a single seizure.

There is no evidence about whether treatment specifically after the first seizure alters the risk of sudden unexpected death in epilepsy patients in children.

Recommendations. The decision as to whether or not to treat with AED following a first unprovoked seizure in a child or adolescent must be based on a risk–benefit assessment that weighs the risk of another seizure (both the statistical risk of recurrence and the potential consequences of a recurrence) against the risk (cognitive, behavioral, and physical as well as psychosocial) of chronic AED therapy. This decision must be individualized and take into account both medical issues and patient and family preference. Therefore, the following recommendations are made for children and adolescents who have experienced a first seizure:

1. Treatment with AED is not indicated for the prevention of the development of epilepsy (Level B).
2. Treatment with AED may be considered in circumstances where the benefits of reducing the risk of a second seizure outweigh the risks of pharmacologic and psychosocial side effects (Level B).

Future research recommendations. Although evidence reviewed in this practice parameter does not support the routine treatment of every child who presents with a first unprovoked seizure, a minority of children (approximately 10%) will develop difficult-to-control and protracted epilepsy. Prediction of who these children will be is currently not possible; the prognosis becomes evident only after months or years have passed. Research is needed to identify these children after a first seizure and to determine which treatment and management options are best. Imaging studies may help determine if and under what circumstances children may sustain neuronal injury due to seizure. Identifying genetic, immune, or imaging markers may improve prediction of prognosis.

More research is needed on the efficacy and side effects in children of the new AED. Behavioral and cognitive side effects need to be better evaluated, especially for new AED, and individual risks as well as group differences assessed on tests of cognition. A goal of pharmacogenetics will be to minimize the likelihood of adverse events from medication. Identification of children at risk for idiosyncratic adverse reactions to AED and understanding the pharmacogenetics of responders to specific AED may improve our ability to identify those children who should be treated and to use only those treatments to which they are likely to respond.

Determinants of psychosocial factors involved in seizures and AED therapy must be better understood for the different ages of children and their families, so that overall best possible quality of life is the goal of management. Research on seizure disorders in the next decade will be focused on "no seizures, no side effects" and, most importantly, toward strategies for prevention and cure of the underlying process.[66]

Committee on Children With Disabilities

The Treatment of Neurologically Impaired Children Using Patterning

ABSTRACT. This statement reviews patterning as a treatment for children with neurologic impairments. This treatment is based on an outmoded and oversimplified theory of brain development. Current information does not support the claims of proponents that this treatment is efficacious, and its use continues to be unwarranted.

ABBREVIATION. AAP, American Academy of Pediatrics.

Patterning has been advocated for more than 40 years for treating children with brain damage and other disorders, such as learning disabilities, Down syndrome, cerebral palsy, and autism.[1–5] A number of organizations have issued cautionary statements about claims for efficacy of this therapy,[6–10] including the American Academy of Pediatrics (AAP) in 1968 and 1982.[3,11] Media coverage,[12] inquiries from parents and public officials, the use of alternative forms of treatment by parents for their children,[13] and the existence of a new generation of pediatricians who may be unaware of the programs that involve patterning have prompted the AAP to review the current status of this controversial treatment.

Patterning is a series of exercises designed to improve the "neurologic organization" of a child's neurologic impairments. It requires that these exercises be performed over many hours during the day by several persons who manipulate a child's head and extremities in patterns purporting to simulate prenatal and postnatal movements of nonimpaired children.[14] Concern about patterning has been raised because promotional methods have made it difficult for parents to refuse treatment for their children without questioning their motivation and adequacy as parents.[3] Moreover, dire health consequences for children are implied if parents do not make arrangements to have their child begin patterning.

Several treatment options are offered, ranging from a home program to an intensive treatment program, which states that each succeeding option "offers greater chance of success." Participation in the intensive treatment program requires completion of 3 of the 5 preceding programs, is by invitation only for the "most capable families," and potentially could deplete substantially a family's financial resources. The regimens prescribed can be so demanding, time-consuming, and inflexible that they may place considerable stress on parents and lead them to neglect other family members.[15,16(pp251–252)]

Patterning programs use a developmental profile designed by the Institute for the Achievement of Human Potential both to assess a child's neurologic functioning and to document change over time.[16(p40),17] However, the validity of using this profile for these domains has not been demonstrated, nor has it been compared with currently accepted methods of measuring a child's development. In addition to making claims that a number of conditions may be improved or cured by patterning, proponents of the program assert that patterning can make healthy children superior in physical and cognitive skills.[18–22]

The aims of treatment programs include attainment of normality of physical, intellectual, and social growth in children with brain injuries. According to providers of patterning therapy,[1] the majority of children treated are claimed to achieve at least 1 of those goals. To our knowledge, however, no new data have been presented to support the use of patterning since the AAP reissued its policy statement in 1982. The lack of supporting evidence for the use of this therapy brings into question once again its effectiveness in neurologically impaired children.

THE THEORY

Neurologic organization, the principle central to the patterning theory of brain functioning, is an oversimplified concept of hemispheric dominance and the relationship of individual sequential phylogenetic development.[16,23–25] This theory also states that failure to complete properly any stage of neurologic organization adversely affects all subsequent stages and that the best way to treat a damaged nervous system is "to regress to more primitive modes of function and to practice them."[17] According to this theory, the majority of cases of mental retardation, learning problems, and behavior disorders are caused by brain damage or improper neurologic organization, and these problems lie on a single continuum of brain damage, for which the most effective treatments are those advocated by patterning.[3,16]

Current information does not support these contentions. In particular, the lack of dominance or sidedness probably is not an important factor in the cause of, or the therapy for, these conditions.[3,16,17] Several careful reviews of the theory have concluded that it is unsupported, contradicted, or without merit based on scientific study.[16,17,23,25] Others have described the hypothesis of neuro-

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

logic organization to be without merit[23] and concluded that the theoretical rationale for the treatment is inconsistent with accepted views of neurologic development.[24,27(pp207–235)28(pp207–247)]

STATUS OF CLAIMED THERAPEUTIC RESULTS

Results published on patterning have been inconclusive.[29–31] Although reports of improvement in reading ability after treatment have been heralded as support for the theory,[32,33] statistical analysis revealed few demonstrable benefits.[34,35] Controlled studies of reading skills have shown little or no benefit from treatment.,[16(pp333–352)36–38]

Some disabled children who purportedly benefited from treatment had been given a misdiagnosis or an unduly pessimistic prognosis. The course of maturation in children with neurologic impairments varies, which leads to unwarranted claims that improvements in their conditions were the result of a specific form of treatment.[17,39] Some of the cases publicized involved children with traumatic brain injury or encephalitis, who may make substantial health improvements without special treatment.

A well-controlled investigation[40] compared 3 groups of children, all of whom were severely mentally disabled and institutionalized. One group received patterning, a second was treated by motivational techniques, and a third received routine care. Using a wide variety of behavioral measures, the investigators found no significant differences among the 3 groups. On the basis of this study, the investigators found nothing to recommend patterning treatment over routine care.[40] They concluded that patterning cannot be considered superior to any other method of treatment for institutionalized mentally disabled children.

Other less well-designed studies[41,42] also investigated the effect of patterning therapy on children with a heterogeneous range of disabilities. One showed a significant, but short-term, effect on developmental progress in comparison with that attained by children receiving traditional programs in New Zealand.[41] The investigators disclosed that the relative success of the program was linked to the families' desire to take greater responsibility for their children's education. Another investigation demonstrated no significant progress in the development of mentally disabled children who had undergone patterning therapy.[42] A review of the use of patterning to arouse children in a coma and for sensory stimulation in brain-injured children and adults also gave no scientific evidence or theoretical rationale for its use.[43]

CONCLUSION AND RECOMMENDATION

Pediatricians need to work closely with the families of their patients with neurologic disabilities and ensure that they have access to all standard services available in their communities. After the proper diagnosis is made, physicians should discuss controversial treatments as part of the child's initial management plan. Pediatricians, therefore, need to be acquainted with routine and controversial treatments, schedule ample time for their discussion, and explain to parents the placebo effect and the importance of basing treatment decisions on controlled research trials.

Treatment programs that offer patterning remain unfounded; ie, they are based on oversimplified theories, are claimed to be effective for a variety of unrelated conditions, and are supported by case reports or anecdotal data and not by carefully designed research studies. In most cases, improvement observed in patients undergoing this method of treatment can be accounted for based on growth and development, the intensive practice of certain isolated skills, or the nonspecific effects of intensive stimulation.

Physicians and therapists need to remain aware of the issues in the controversy over this specific treatment and the available evidence. On the basis of past and current analyses, studies, and reports, the AAP concludes that patterning treatment continues to offer no special merit, that the claims of its advocates remain unproved, and that the demands and expectations placed on families are so great that in some cases their financial resources may be depleted substantially and parental and sibling relationships could be stressed.

Type 2 Diabetes in Children and Adolescents

AMERICAN DIABETES ASSOCIATION

Type 2 diabetes is a serious and costly disease affecting more than 15 million adult Americans. The chronic complications of diabetes include accelerated development of cardiovascular disease, end-stage renal disease, loss of visual acuity, and limb amputations. All of these complications contribute to the excess morbidity and mortality in individuals with diabetes. Moreover, the prevalence of type 2 diabetes in adults is increasing. Superimposed on this disturbing picture in adults are the recent reports of the emerging problem of type 2 diabetes in children and adolescents.

If the incidence and prevalence of type 2 diabetes in children are increasing and if this increase cannot be reversed, our society will face major challenges. That is, the burden of diabetes and its complications will affect many more individuals than currently anticipated, and the cost of diabetes to our society will cause us to consume enormous resources. Also, many more Americans will be taking potent medications, which have attendant risks, for most of their lives.

Despite the wealth of experience and knowledge concerning the epidemiology, pathophysiology, and medical management of type 2 diabetes in adults, we know little about the disease in children. To assess our present knowledge and understanding and to provide guidance to practitioners on medical management, the American Diabetes Association (ADA) convened a consensus development conference on type 2 diabetes in children and adolescents from 30 August 1999 to 1 September 1999.

An eight-member panel of experts in diabetes in children, complemented by representatives from the National Institute of Diabetes and Digestive and Kidney Diseases, the Division of Diabetes Translation at the Centers for Disease Control and Prevention, and the American Academy of Pediatrics, developed a consensus position on the following six questions:

1. What is the classification of diabetes in children and adolescents?
2. What is the epidemiology of type 2 diabetes in children and adolescents?
3. What is the pathophysiology of type 2 diabetes in children and adolescents?
4. Who should be tested for diabetes?
5. How should children and adolescents with type 2 diabetes be treated?
6. Can type 2 diabetes in children and adolescents be prevented?

QUESTION 1: What is the classification of diabetes in children and adolescents?

The diagnostic criteria and etiologic classification (Table 1) of diabetes (Table 2) outlined by the ADA's Expert Committee report apply to children (1). In the pediatric population, the recent experience with nonimmune-mediated diabetes has highlighted the difficulty in distinguishing the etiology of diabetes in some children without sophisticated laboratory evaluation. This experience has created confusion over the criteria that should be used to classify diabetes in children.

Until recently, immune-mediated type 1 diabetes was the only type of diabetes considered prevalent among children, with only 1–2% of children considered to have type 2 diabetes or other rare forms of diabetes. Recent reports indicate that 8–45% of children with newly diagnosed diabetes have nonimmune-mediated diabetes. The variation in the percentages reported appears to depend on race/ethnicity and sampling strategy. The majority of these children have type 2 diabetes, but other types are being increasingly identified. For example, idiopathic or nonimmune-mediated type 1 diabetes has been reported, particularly in the African-American population.

Individuals with nonimmune-mediated diabetes may have clinical presentations indistinguishable from those of patients with immune-mediated type 1 diabetes. This is relevant because as the number of children with type 2 diabetes increases, it becomes increasingly important to classify their diabetes correctly so that appropriate therapy may be instituted.

The initial classification is usually based on the clinical picture at presentation. Typically, children with immune-mediated type 1 diabetes are not overweight and have recent weight loss, polyuria, and polydipsia. As the U.S. population becomes increasingly overweight, however, the percentage of children with immune-mediated type 1 diabetes who are obese is increasing. As many as 24% may be overweight at the time of diagnosis. Children with immune-mediated diabetes usually have a short duration of symptoms and frequently have ketosis; 30–40% have ketoacidosis at presentation (2). After metabolic stabilization, they may have an initial period of diminished insulin requirement (i.e., honeymoon period), after which they require insulin for survival and are at continual risk for ketoacidosis. Of children with immune-mediated type 1 diabetes, 5% have a first- or second-degree relative with the same disease.

In contrast, most children with type 2 diabetes are overweight or obese at diagnosis and present with glycosuria without ketonuria, absent or mild polyuria and polydipsia, and little or no weight loss. But up to 33% have ketonuria at diagnosis, and 5–25% of patients who are subsequently classified as having type 2 diabetes have ketoacidosis at presentation. These patients may have ketoacidosis without any associated stress, other illness, or infection. Children with type 2 diabetes

This statement was endorsed by the American Academy of Pediatrics in January 2000.

Table 1—*Criteria for the diagnosis of diabetes*

- Symptoms of diabetes plus casual plasma glucose concentration ≥200 mg/dl (11.1 mmol/l). Casual is defined as any time of day without regard to time since last meal. The classic symptoms of diabetes include polyuria, polydipsia, and unexplained weight loss.

or

- FPG ≥126 mg/dl (7.0 mmol/l). Fasting is defined as no caloric intake for at least 8 h.

or

- 2-h PG ≥200 mg/dl (11.1 mmol/l) during an OGTT. The test should be performed as described by the World Health Organization (20), using a glucose load containing the equivalent of 75-g anhydrous glucose dissolved in water.

In the absence of unequivocal hyperglycemia with acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day. The third measure (OGTT) is not recommended for routine clinical use. Adapted from the Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus (1).

usually have a family history of type 2 diabetes, and those of non-European ancestry (Americans of African, Hispanic, Asian, and American Indian descent) are disproportionately represented.

While there is heterogeneity in the presentation of both type 1 and type 2 diabetes, there are certain clinical features that suggest type 2 diabetes. As noted above, obesity is a hallmark of type 2 diabetes, with up to 85% of affected children either overweight or obese at diagnosis. Occasionally, obesity may be masked by significant weight loss in the months or year before diagnosis. A family history of diabetes is usually present; 45–80% of patients have at least one parent with diabetes and may have a history of diabetes over several generations. Of the patients, 74–100% have a first- or second-degree relative with type 2 diabetes. Of note, diabetes in the parent or other relative may not be recognized until the child is diagnosed.

Acanthosis nigricans and polycystic ovarian syndrome (PCOS), disorders associated with insulin resistance and obesity, are common in youth with type 2 diabetes. Acanthosis is a cutaneous finding characterized by velvety hyperpigmented patches most prominent in intertriginous areas and is present in as many as 90% of children with type 2 diabetes (A. Fagot-Campagna, D.J. Pettitt, M.M. Engelgau, N.R. Burrows, L.S. Geiss, R. Valdez, G. Beckles, J. Saaddine, E.W. Gregg, D.F. Williamson, K.M. Venkat Narayan, *J Pediatrics*. In press). It is recognized more frequently in darker-skinned obese individuals. PCOS is a reproductive disorder characterized by hyperandrogenism and chronic anovulation not due to specific diseases of the ovaries, adrenals, and pituitary. Lipid disorders and hypertension also occur in children with type 2 diabetes.

Currently, children with type 2 diabetes are usually diagnosed over the age of 10 years and are in middle to late puberty. As the childhood population becomes increasingly overweight, type 2 diabetes may be expected to occur in younger prepubertal children.

Children with idiopathic type 1 diabetes may be difficult to distinguish from those with immune-mediated type 1 diabetes. The majority of those described with idiopathic type 1 diabetes have what has been termed atypical diabetes mellitus (ADM, type 1.5, or "Flatbush" diabetes) and are African-American (3,4). Their family history is positive for early-onset diabetes in many relatives in multiple generations. Insulin may not be required for survival after the resolution of the acute metabolic deterioration. Metabolic control, however, is poor without insulin therapy, and ketoacidosis may recur.

Maturity-onset diabetes of the young (MODY) is a rare form of diabetes in children that includes several disorders caused by monogenic defects in β-cell function inherited in an autosomal-dominant fashion (5). Recent studies suggest that the clinical spectrum of MODY is broad, ranging from asymptomatic hyperglycemia to a severe acute presentation. MODY has been reported in all races/ethnicities. These gene abnormalities are thought to be rare, and molecular diagnostic testing, currently only available in research laboratories, is required for specific classification. Until such testing becomes commonplace, children with MODY should be classified as having the type of diabetes that best fits their clinical picture.

In most patients, classification can be made reliably on the basis of clinical presentation and course. In the unusual circumstance that requires a specific classification to be made, other tests may be necessary, such as a fasting insulin or C-peptide determination, and occasionally, β-cell autoantibody measurements (Fig. 1). Individuals with type 2 diabetes do not generally have autoantibodies to β-cell proteins; fasting insulin and C-peptide levels are usually normal or elevated, although not as elevated as might be expected for the degree of hyperglycemia.

Specific autoantibodies to insulin, to GAD, or to the tyrosine phosphatases insulin antibody (IA)-2 and IA-2β are found at presentation in 85–98% of individuals with immune-mediated type 1 diabetes. To

Table 2—*Etiologic classification of diabetes*

- Type 1 diabetes* (β-cell destruction, usually leading to absolute insulin deficiency)
  - Immune-mediated
  - Idiopathic
- Type 2 diabetes* (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with insulin resistance)
- Other specific types
  - Genetic defects of β-cell function (e.g., MODY)
  - Genetic defects in insulin action (e.g., lipoatrophic diabetes)
  - Diseases of the exocrine pancreas (e.g., cystic fibrosis)
  - Endocrinopathies (e.g., Cushing's syndrome)
  - Drug- or chemical-induced (e.g., glucocorticoids)
  - Infections (e.g., congenital rubella)
  - Uncommon forms of immune-mediated diabetes
  - Other genetic syndromes sometimes associated with diabetes (e.g., Prader-Willi syndrome)
- Gestational diabetes mellitus (GDM)

*Patients with any form of diabetes may require insulin treatment at some stage of their disease. Use of insulin does not, of itself, classify the patient. Adapted from the Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus (1).

Table 3—*Estimates of the magnitude of type 2 diabetes in North American children*

	Years	Race/ethnicity	Age (years)	Estimates
Study types				
Population-based studies				Prevalence per 1,000
Arizona	1992–1996	Pima Indians	10–14	22.3
			15–19	50.9
Manitoba	1996–1997	First Nations	10–19	36.0 in girls
NHANES III, all U.S.	1988–1994	Whites, African-Americans, Mexican Americans	12–19	4.1*
Clinic-based studies				
Indian Health Services (all U.S.)	1996	American Indians	0–14	1.3*
			15–19	4.5*
Manitoba	1998	First Nations	5–14	1.0
			15–19	2.3
Clinic-based studies				Incidence per 100,000/year
Cincinnati, OH	1994	Whites, African-Americans	10–19	7.2
Case series				Percentage of type 2 diabetes among new cases of diabetes
Cincinnati, OH	1994	Whites, African-Americans	0–19	16
			10–19	33
Charleston, SC	1997	Blacks	0–19	46†
San Diego, CA	1993–1994	Whites, African-Americans, Hispanics, Asian Americans	0–16	8
San Antonio, TX	1990–1997	Hispanics, Whites		18
Ventura, CA	1990–1994	Hispanics	0–17	45

*Estimates include type 1 and 2 diabetes; †percentage of type 2 diabetes among nonincident cases of diabetes. Adapted from A. Fagot-Campagna, D.J. Pettitt, M.M. Engelgau, N.R. Burrows, L.S. Geiss, R. Valdez, G. Beckles, J. Saaddine, E.W. Gregg, D.F. Williamson, K.M. Venkat Narayan, *J Pediatrics*. In press.

achieve a high degree of sensitivity, a combination of tests is required, which greatly increases the cost of classification. In the future, these tests may be standardized, more reliable, and less expensive. Immune-mediated type 1 diabetes also has a strong HLA association; however, HLA typing is not a useful diagnostic tool. Endogenous fasting insulin and C-peptide production in type 1 patients is low, with little or no increase after oral or intravenous glucose administration or after ingestion of a mixed meal. Specific laboratory evaluation to classify diabetes in children should only be used by diabetologists with pediatric expertise and only when a definitive classification is clinically required.

Patients with immune-mediated type 1 diabetes more frequently develop autoimmune disorders that may cause thyroid or adrenal disease, vitiligo, or pernicious anemia. Individuals with autoimmune diabetes are also more prone to celiac disease. The presence of other autoimmune disorders or celiac disease may suggest the need for further evaluation of a patient classified as having non–type 1 diabetes. Patients classified as having type 1 diabetes may also need to be reevaluated if their clinical course or family history is more consistent with type 2 diabetes.

QUESTION 2: What is the epidemiology of type 2 diabetes in children and adolescents?

The limited amount of information about the epidemiology of type 2 diabetes in children is in large part due to the relatively recent recognition of its emergence in this age-group. Table 3 summarizes the studies and reports that provide estimates of the frequency of type 2 diabetes in children (A. Fagot-Campagna, D.J. Pettitt, M.M. Engelgau, N.R. Burrows, L.S. Geiss, R. Valdez, G. Beckles, J. Saaddine, E.W. Gregg, D.F. Williamson, K.M. Venkat Narayan, *J Pediatrics*. In press). The Pima Indians in Arizona, known to have a high prevalence of type 2 diabetes, have been extensively studied. An analysis from 1992 to 1996 revealed a prevalence of type 2 diabetes of 22.3 per 1,000 in the 10- to 14-year-old age-group and 50.9 per 1,000 in the 15- to 19-year-old age-group. Affected individuals were identified in the course of clinical care or by having a 2-h blood glucose value ≥200 mg/dl during an oral glucose tolerance test (OGTT) (2-h plasma glucose [2-h PG]).

The Third National Health and Nutrition Examination Survey (NHANES III) constitutes a representative sample of the American population including 2,867 individuals aged 12–19 years who had blood glucose measurements between 1988 and 1994. Thirteen of those sampled had diabetes: nine based on insulin treatment, two based on treatment with oral agents, and two based on elevated blood glucose levels. These results projected a national prevalence estimate for all types of diabetes of 4.1 per 1,000 in this age-group, which can be compared with a prevalence of 0.3 per 1,000 for cystic fibrosis, one of the most common inherited disorders in U.S. children (6).

Additional information comes from reports of diagnosed cases in different areas of the U.S. For example, in Cincinnati, Ohio, the incidence of type 2 diabetes in 10- to 19-year-old patients increased from 0.7 per 100,000 in 1982 to 7.2 per 100,000 in 1994.

Evidence is accumulating suggesting that type 2 diabetes is increasing in children and adolescents in the U.S. The population-based data derived from the Pima Indians show a statistical increase in prevalence from 1967 to 1996 for those aged 10–14 and 15–19 years. Between 1988 and 1996, the Indian Health Service also documented a 54% increase in

prevalence of reported diabetes in 15- to 19-year-old adolescents. Registry data from Allegheny County, Pennsylvania, and Chicago, further suggest an increase in type 2 diabetes. Finally, in other case series, type 2 diabetes constituted an increasing percentage of incident pediatric cases of diagnosed diabetes, with fewer than 4% reported before the 1990s and up to 45% in recent studies.

The emergence of type 2 diabetes in children is not limited to North America. The annual incidence of type 2 diabetes among junior high school children in Tokyo, detected by urine glucose screening and confirmed by glucose tolerance testing, increased from 7.3 per 100,000 in 1976–1980 to 12.1 per 100,000 in 1981–1985, and to 13.9 per 100,000 in 1991–1995. Data from Libya, Bangladesh, and aboriginal children in Australia and Canada indicate that childhood type 2 diabetes is occurring in these populations as well. One possible explanation for the emergence of type 2 diabetes in children is the increase of obesity and decreasing physical activity in children. Obesity is now reaching epidemic proportions in the U.S. and elsewhere.

Obesity is a very common finding in children with type 2 diabetes (A. Fagot-Campagna, D.J. Pettitt, M.M. Engelgau, N.R. Burrows, L.S. Geiss, R. Valdez, G. Beckles, J. Saaddine, E.W. Gregg, D.F. Williamson, K.M. Venkat Narayan, *J Pediatrics*. In press). In a young Pima Indian cohort with diabetes, 85% were obese. This association has been consistent in all reports, although the criteria for obesity and its severity have varied. The reported mean BMI ranges from 27 to 38 kg/m^2, and in most patients, the BMI was greater than the 85th percentile for age and sex. Although it has been well established in adults and in many populations that a "Westernized" lifestyle is associated with an increased frequency of type 2 diabetes, there are no well-controlled studies that have examined this issue in children. Decreased exercise and increased calorie and fat intake have been implicated as risk factors.

Family history of diabetes is strongly associated with type 2 diabetes in children. The frequency of a history of type 2 diabetes in a first- or second-degree relative has ranged from 74 to 100%. Among Pima Indians below the age of 25 years, diabetes has been reported exclusively in individuals with at least one diabetic parent. In the Pimas, offspring of mothers who had diabetes during pregnancy had a markedly increased prevalence of diabetes compared with offspring of mothers without diabetes and those whose mothers developed diabetes after the child's birth. Low birth weight has also been associated with the development of type 2 diabetes in Pima Indian children. These findings have not been reported in other childhood populations.

Sex and puberty are also possible risk factors. In the U.S. adult population, the prevalence of diagnosed type 2 diabetes is slightly higher in women than in men. Most of the studies in children, including those that are population-based, indicate a higher frequency in females. Reported cases of type 2 diabetes in children showed a peak age of diagnosis during the usual pubertal age period, although there have been individuals described who were diagnosed prepubertally. The mean age of diagnosis was between 12 and 16 years. The youngest patient who has been described is a 4-year-old Pima Indian.

There are a number of factors that may influence the accuracy of much of the information discussed above. Although the population-based studies are carefully done and accurately reflect the North American populations examined, case study reports probably underestimate the true magnitude of the problem, since they only describe diagnosed cases. If pediatric type 2 diabetes mirrors the adult experience, there will be many affected individuals who are undiagnosed. There is also suspicion that with the relatively recent recognition of type 2 diabetes in this age-group, many children are still being misdiagnosed as having type 1 diabetes. Indeed, the Chicago Registry indicates that this misclassification occurred as frequently as in 25% of cases.

As this problem continues to be defined and described, there remain a number of research needs. It will be necessary to better define the magnitude of type 2 diabetes in children and confirm that there is a significant trend toward increasing incidence and prevalence. It will also be important to clearly define the characteristics of those affected and the risk factors for developing the disease. Finally, it will be important to describe the natural history of the disease in those affected at young ages.

QUESTION 3: What is the pathophysiology of type 2 diabetes in children and adolescents?

Type 2 diabetes is a complex metabolic disorder of heterogeneous etiology with social, behavioral, and environmental risk factors unmasking the effects of genetic susceptibility (7). There is a strong hereditary (likely multigenic) component to the disease, with the role of genetic determinants illustrated when differences in the prevalence of type 2 diabetes in various racial groups are considered. The recent increases observed in diabetes prevalence have occurred too quickly to be the result of increased gene frequency and altered genetic pool, emphasizing the importance of environmental factors.

Glucose homeostasis depends on the balance between insulin secretion by the pancreatic β-cells and insulin action. For hyperglycemia to develop, insulin resistance alone is not sufficient and inadequate β-cell insulin secretion is necessary. There has been considerable debate about whether insulin resistance or insulin hyposecretion is the primary defect in type 2 diabetes in adults. The constellation of clinical characteristics in children with type 2 diabetes suggests that the initial abnormality is impaired insulin action, compounded later with β-cell failure.

It is well recognized that resistance to insulin-stimulated glucose uptake is a characteristic finding in patients with type 2 diabetes and impaired glucose tolerance. Cross-sectional and longitudinal studies in populations at high risk for developing type 2 diabetes demonstrate that hyperinsulinemia and insulin resistance are present in the prediabetic normoglycemic state. The evolution from normal to impaired glucose tolerance is associated with a worsening of insulin resistance. In patients with type 2 diabetes, impaired insulin action and insulin secretory failure are both present. The failure of the β-cell to continue to hypersecrete insulin underlies the transition from insulin resistance (with compensatory hyperinsulinemia and normoglycemia) to clinical diabetes (with overt fasting hyperglycemia and increased hepatic glucose production).

It has been proposed that hyperglycemia may worsen both insulin resistance and insulin secretory abnormalities, thus enhancing the transition from impaired glucose tolerance to diabetes or aggravating the diabetes. This way, hyperglycemia may beget more hyperglycemia—a concept called glucose toxicity. Glucose toxicity–induced abnormalities of insulin secretion and action can be ameliorated by correction of hyperglycemia.

Puberty appears to play a major role in the development of type 2 diabetes in children. During puberty, there is increased resistance to the action of insulin, resulting

in hyperinsulinemia (8). It has been known for many years that insulin responses during an OGTT increase significantly from the toddler ages to adolescence. After puberty, basal and stimulated insulin responses decline. Hyperinsulinemic-euglycemic clamp studies demonstrate that insulin-mediated glucose disposal is on average 30% lower in adolescents between Tanner stages II and IV compared with prepubertal children in Tanner stage I and compared with young adults. In the presence of normal pancreatic β-cell function, puberty-related insulin resistance is compensated by increased insulin secretion.

Both growth hormone and sex steroids have been considered as candidates for causing insulin resistance during puberty. The fact that sex steroids remain elevated after puberty while insulin resistance decreases makes sex steroids an unlikely cause of insulin resistance. Conversely, mean growth hormone levels increase transiently during puberty coincidental with the decrease in insulin action. In addition, administering growth hormone to non–growth hormone–deficient adolescents is associated with deterioration in insulin action, while testosterone administration has no such effect. Thus, increased growth hormone secretion is most likely responsible for the insulin resistance during puberty, and both growth hormone secretion and insulin resistance decline with completion of puberty.

Given this information, it is not surprising that the peak age at presentation of type 2 diabetes in children coincides with the usual age of mid-puberty. In an individual who has a genetic predisposition for insulin resistance, compounded with environmental risk exposure, the additional burden of insulin resistance during puberty may tip the balance from a state of compensated hyperinsulinemia with normal glucose tolerance to inadequate insulin secretion and glucose intolerance that continues beyond puberty.

The adverse effect of obesity on glucose metabolism is evident early in childhood. In healthy white children, total adiposity accounts for ~55% of the variance in insulin sensitivity. Obese children are hyperinsulinemic and have ~40% lower insulin-stimulated glucose metabolism compared with nonobese children. Moreover, the amount of visceral fat in obese adolescents is directly correlated with basal and glucose-stimulated hyperinsulinemia and inversely correlated with insulin sensitivity. In African-American children, as BMI increases, insulin-stimulated glucose metabolism decreases and fasting insulin levels increase. Furthermore, in these children, the inverse relationship between insulin sensitivity and abdominal fat is stronger for visceral than for subcutaneous fat. In a 7-year longitudinal study of African-American and white young adults 18 years and older, the strongest predictor for increases in both insulin and glucose concentrations was an increase in BMI.

Data about hyperandrogenism and type 2 diabetes are limited in the pediatric age-group. In adults, however, women with PCOS are at increased risk of type 2 diabetes because they have profound insulin resistance, independent of obesity, and they have abnormalities in β-cell function. In women with PCOS, 31% have impaired glucose tolerance and 7.5–16% have type 2 diabetes (9). Adolescents with PCOS have evidence of skeletal muscle insulin resistance with ~40% reduction in insulin-stimulated glucose disposal, compared with body composition–matched nonhyperandrogenic control subjects. Those adolescents with PCOS who have impaired glucose tolerance have ~50% decrement in first-phase insulin secretion.

Racial differences in insulin sensitivity are also evident in childhood. African-American 7- to 11-year-old children have significantly higher insulin levels than age-matched white children. The Bogalusa Heart Study evaluated plasma glucose and insulin levels during an OGTT in 377 children aged 5–17 years from a biracial community. After adjusting for weight, age, ponderal index, and pubertal stage, African-Americans showed higher insulin responses than their white counterparts, suggesting compensated insulin resistance. In other studies using clamp experiments, insulin sensitivity was 30% lower in African-American adolescents compared with white adolescents. These data suggest that minority children may have a genetic predisposition to insulin resistance, which, in the presence of environmental modulators, could increase their risk of type 2 diabetes and result in disease expression during physiologic (puberty) or pathologic (obesity) states of insulin resistance.

QUESTION 4: Who should be tested for diabetes?

Consistent with the recommendations of the ADA for screening in adults, only children at substantial risk for the presence or the development of type 2 diabetes should be tested. Case finding in an at-risk population requires that the condition tested for must be sufficiently common and serious to justify the cost and risks of testing. This criterion is met by the substantial risk for type 2 diabetes in obese children with a positive family history or signs of insulin resistance. Moreover, diabetes is associated with significant morbidity and premature mortality, and its complications are a major burden to individuals and to society.

The condition tested for should also have a prolonged latency period without symptoms during which abnormality can be detected. For example, case finding for type 1 diabetes in asymptomatic individuals is not considered appropriate because the latency period is relatively brief. As with type 2 diabetes in adults, a substantial number of children with type 2 diabetes can be detected in the asymptomatic state. Also, it is likely that, as with adults, there are many undiagnosed children with type 2 diabetes.

Further requirements for testing an asymptomatic group include the availability of a test that is sensitive (few false negatives) and accurate with acceptable specificity (minimal number of false positives). The fasting glucose test and 2-h OGTT have been applied to high-risk populations and are acceptably sensitive and specific. Lastly, there must be an intervention that is effective in the latency phase, and we do have interventions to reverse hyperglycemia, with the goal of preventing complications.

Testing recommendations

Population selection. Acknowledging that there are insufficient data to make definite recommendations, the Consensus Panel recommends that if an individual is overweight (defined as BMI >85th percentile for age and sex [10], weight for height >85th percentile, or weight >120% of ideal [50th percentile] for height) and has any two of the other risk factors listed below, testing should be done every 2 years starting at age 10 years or at onset of puberty if it occurs at a younger age. Testing may be considered in other high-risk patients who display any of the following characteristics:

- Have a family history of type 2 diabetes in first- and second-degree relatives;
- Belong to a certain race/ethnic group (American Indians, African-Americans, Hispanic Americans, Asians/South Pacific Islanders);

Table 4—*Testing for type 2 diabetes in children*

- Criteria*
  - Overweight (BMI >85th percentile for age and sex, weight for height >85th percentile, or weight >120% of ideal for height)
  - Plus
  - Any two of the following risk factors:
    - Family history of type 2 diabetes in first- or second-degree relative
    - Race/ethnicity (American Indian, African-American, Hispanic, Asian/Pacific Islander)
    - Signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, PCOS)
- Age of initiation: age 10 years or at onset of puberty if puberty occurs at a younger age
- Frequency: every 2 years
- Test: FPG preferred

*Clinical judgment should be used to test for diabetes in high-risk patients who do not meet these criteria.

- Have signs of insulin resistance or conditions associated with insulin resistance (acanthosis nigricans, hypertension, dyslipidemia, PCOS).

Test methods. As stated above, the fasting plasma glucose (FPG) and 2-h PG are both suitable. The FPG is preferred because of its lower cost and greater convenience. Fasting is defined as no consumption of food or beverage other than water for at least 8 h before testing. The recommended criteria for testing are given in Table 4.

The above recommendations are based on limited data. School- or community-based studies are needed. Such studies could establish the strength and risk level of various factors that might influence the development of type 2 diabetes (blood pressure, obesity, fat distribution, acanthosis nigricans, family history, race/ethnicity, and socioeconomic status). They would also provide useful information about the value of individual tests, including the FPG, 2-h PG, random glucose, and HbA_{1c}. These studies should be carried out in populations with sufficient numbers of children who are at high risk. In addition, longitudinal studies are needed to define the natural history and risk factors of the disease.

QUESTION 5: How should children and adolescents with type 2 diabetes be treated?

The ideal goal of treatment is normalization of blood glucose values and HbA_{1c} (11). Successful control of the associated comorbidities, such as hypertension and hyperlipidemia, is also important. The ultimate goal of treatment is to decrease the risk of the acute and chronic complications associated with diabetes. There is strong evidence from the U.K. Prospective Diabetes Study that normalization of blood glucose substantially decreases the frequency of microvascular complications of type 2 diabetes in adults (12). Macrovascular outcomes were not significantly decreased; however, a substudy investigating the effectiveness of tight control of blood pressure did show a decrease in cardiovascular events that was statistically significant. The early age of onset of type 2 diabetes in children may particularly increase the risk of microvascular complications, which are known to be directly related to duration of diabetes and hyperglycemia.

The initial treatment of type 2 diabetes will vary depending on the clinical presentation. The spectrum of disease at diagnosis ranges from asymptomatic hyperglycemia to diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar nonketotic (HHNK) states. Both DKA and HHNK crisis are associated with high morbidity and mortality in children. Cerebral edema can occur in either circumstance. Early consultation and referral to pediatric and adolescent diabetologists/endocrinologists with experience in the management of DKA and HHNK should be considered.

Patients who are not ill at diagnosis can be managed initially with medical nutrition therapy and exercise, but most will eventually require drug therapy. Although insulin is the only drug approved by the Food and Drug Administration (FDA) for the treatment of diabetes in children, most pediatric diabetologists use oral agents for children with type 2 diabetes. Advantages of oral agents include potentially greater compliance and convenience for the patient and family. There is little evidence that insulin is superior to oral agents for initial treatment of type 2 diabetes in children.

Clinical features suggesting initial treatment with insulin include dehydration, presence of ketosis, and acidosis. In the less ill child with type 2 diabetes, initial treatment with diet, exercise, and an oral agent may be appropriate. In all patients, identification and treatment of comorbid conditions are important. With time and treatment, metabolic control may change, necessitating reevaluation of treatment, such as tapering of insulin and introduction of an oral agent in the patient whose glycemic control improves after insulin therapy.

Lifestyle changes

All children with type 2 diabetes should receive comprehensive self-management education. The National Standards for Diabetes Self-Management Education is a useful framework for providing this invaluable component of treatment (13). Self-management education should include teaching self-monitoring of blood glucose (SMBG). SMBG should be performed as needed and during periods of acute illness or when symptoms of hyper- or hypoglycemia occur. Patients on insulin or sulfonylureas should also monitor periodically for asymptomatic hypoglycemia. Routine blood glucose monitoring should be tailored to individual needs but should probably include a combination of fasting and postprandial glucose measurements. HbA_{1c} should be assayed to monitor glycemic control and the results and their significance shared with the patient and family.

Referral to a dietitian with knowledge and experience in nutritional management of children with diabetes is necessary. Dietary recommendations should be culturally appropriate, sensitive to family resources, and provided to all caregivers. Encouraging healthy eating habits by the entire family is important. Behavior modification strategies for changing lifestyle and decreasing high-caloric high-fat food choices should be discussed (14).

Increasing caloric expenditure by increasing daily physical activity is an important component of therapy. Exercise can decrease insulin resistance and is an important component of weight management. Decreasing sedentary activity, such as television viewing and computer use, has been shown to be an effective way to increase daily physical activity in children. Involvement of family members can pro-

vide positive reinforcement and make overall family health a higher priority.

Successful treatment with diet and exercise is defined as cessation of excessive weight gain with normal linear growth, near-normal fasting blood glucose values (<126 mg/dl), and near-normal HbA_{1c} (less than ~7% in most laboratories). Follow-up should include periodic reevaluation and reinforcement of treatment modalities as well as appropriate SMBG and contact with the health care team when treatment goals are not met.

Successful diabetes management without oral medication or insulin occurs in fewer than 10% of adult patients with diabetes over time. In addition, data from adults suggest that type 2 diabetes is a progressive disorder, and over time, worsening glycemic control will result in the need for one or more oral agents and ultimately insulin alone or in combination with oral agents, even with good adherence to dietary and lifestyle changes.

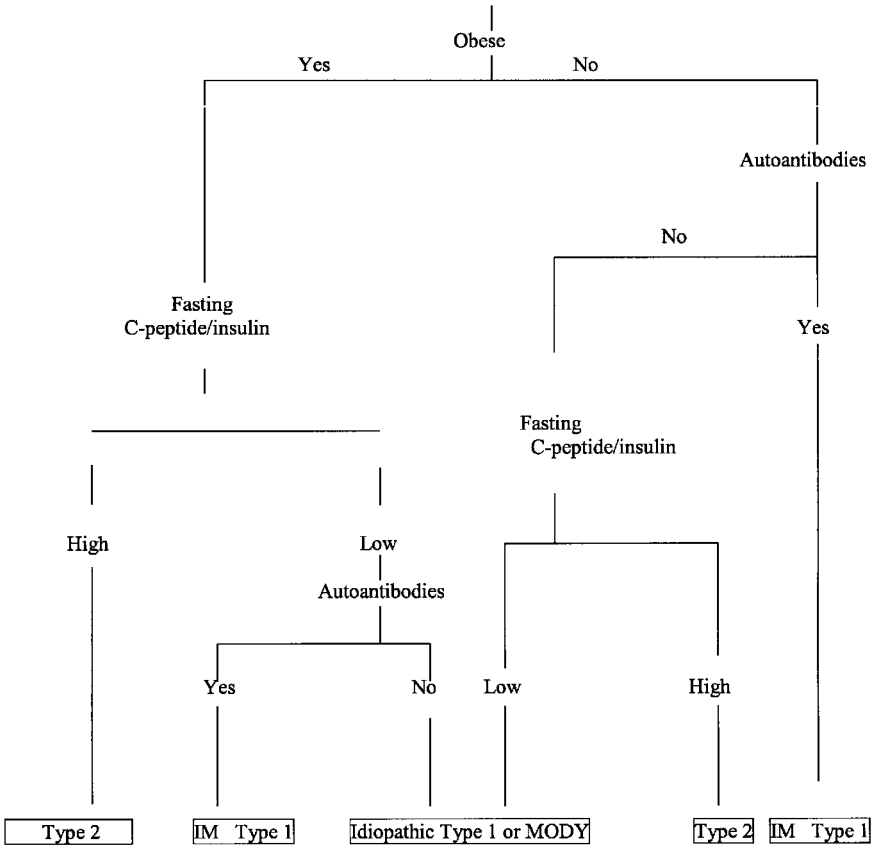

Figure 1—*Research schema for classification of diabetes in children and youth. Americans of non-European descent are at greater risk for type 2 diabetes than those of European ancestry. In addition, 50–90% of youth with type 2 diabetes will have a BMI >27 kg/m^2 (or >85% for age). The prepon - derance of children with type 2 diabetes are over 10 years of age, are in middle or late puberty, and have a strong family history for diabetes. Until the full clinical spectrum of MODY is understood, it cannot be excluded in those not tested for β-cell autoantibodies or in autoantibody-negative individuals. The final diagnostic classification may require knowledge of the patient's clinical course during the initial 1–3 years after diagnosis. IM, immune-mediated.*

Pharmaceutical therapy

Currently, there are five types of glucose-lowering oral agents available in the U.S. for the treatment of type 2 diabetes (15). Because the pathophysiology of type 2 diabetes in children and adolescents appears to be similar to that of type 2 diabetes in adults, it is reasonable to assume that such agents will be effective in children. Of note is the fact that efficacy and safety data are not available for children nor are any of the oral drugs FDA approved for use in children.

The available pharmaceutical agents and their mechanisms of action are as follows:

- Biguanides: decrease hepatic glucose output and enhance primarily hepatic and also muscle insulin sensitivity without a direct effect on β-cell function: metformin
- Sulfonylureas: promote insulin secretion: acetohexamide, chlorpropamide, gliclazide, glimepiride, glipizide, glyburide, tolazamide, and tolbutamide
- Meglitinide: short-term promotion of glucose-stimulated insulin secretion: repaglinide
- Glucosidase inhibitors: slow hydrolysis of complex carbohydrates and slow carbohydrate absorption: acarbose and miglitol
- Thiazolidenediones: improve peripheral insulin sensitivity: troglitazone, rosiglitazone, and pioglitazone.

Troglitazone has been associated with fatal hepatic failure; therefore, its use in children is not recommended. Until additional safety information about the other drugs in this class are available, their routine use in children cannot be recommended.

If treatment goals with nutrition education and exercise are not met, pharmacologic therapy is indicated. The first oral agent used should be metformin. Metformin has the advantage over sulfonylureas of a similar reduction in HbA_{1c} and in overall glucose levels without the risk of hypoglycemia. In addition, weight is either decreased or remains stable, and LDL cholesterol and triglyceride levels decrease.

Treatment with metformin also may normalize ovulatory abnormalities in girls with PCOS and increase the risk of unplanned pregnancy. Therefore, preconception and pregnancy counseling should be part of the treatment regimen, as for all girls and women of childbearing age with type 2 diabetes. No oral agent should be used during pregnancy, highlighting the importance of counseling adolescents with type 2 diabetes about sexuality and pregnancy.

Because of concerns about lactic acidosis, metformin is contraindicated in patients with impaired renal function and should be discontinued with the administration of radiocontrast material. Metformin should not be used in patients with known hepatic disease, hypoxemic conditions, severe infections, or alcohol abuse. Metformin should be temporarily discontinued with any acute illness associated with dehydration or hypoxemia. Insulin should be used if glycemic control deteriorates acutely. The most common side effects of metformin are gastrointestinal disturbances. Because proper dosing in children has not been evaluated and because most patients are near or

at adult weight, it is reasonable to use the doses recommended for adults.

If monotherapy with metformin is not successful over a reasonable period of time (i.e., 3–6 months), several alternatives can be considered. Some clinicians would add a sulfonylurea, whereas others might add insulin. Other insulin secretogogues are acceptable (e.g., meglitinide) as well as a glucosidase inhibitor, but these have been less frequently used in children. In the adolescent with an irregular eating schedule, meglitinide may have special advantages.

With greatly elevated blood glucose levels or in very symptomatic patients, starting treatment with insulin (bedtime insulin alone, twice-a-day insulin or multidose insulin regimens) may most effectively bring hyperglycemia and symptoms under control. When glucose control is established, adding metformin while decreasing insulin is a therapeutic option. Monitoring for urine ketones during this period may be helpful to identify those patients who have been misdiagnosed and actually have type 1 diabetes.

Monitoring for complications

Dilated eye examinations should be performed in adolescents with type 2 diabetes according to the ADA's standards of medical care (11). Screening for microalbuminuria should also be performed yearly. It is unclear whether foot examinations are important in this age-group; however, these examinations are painless, inexpensive, and provide an opportunity for education about foot care.

Other than testing for and treating elevated blood pressure and lipid abnormalities, studies to detect macrovascular disease are probably not indicated, although there are no data in this age-group.

Hypertension treatment

Careful control of hypertension in children is critical. ACE inhibitors are the agents of choice in children with microalbuminuria; because of the beneficial effects of ACE inhibitors on preventing diabetic nephropathy, many diabetologists consider ACE inhibitors the first line of therapy. The Joint National Committee VI report (16) also recommends α-blockers, calcium antagonists (long-acting), and low-dose diuretics. Although there has long been concern that use of β-blockers may worsen hypoglycemia and mask hypoglycemic symptoms, their benefits may outweigh their risks in selected patients. If normotension (for age and sex) is not achieved, combination therapy may be needed.

Hyperlipidemia treatment

Children with type 2 diabetes may be hyperlipidemic. Weight loss, increased activity, and improvement in glycemic control often results in improvement in lipid levels. Changing food choices and their preparation may also be helpful. If these actions fail, medications should be used (17). Dyslipidemia far outweighs all other risk factors for cardiovascular disease in adults with type 2 diabetes, and this may also be true for children with type 2 diabetes. HMG CoA reductase inhibitors ("statins") are absolutely contraindicated in pregnancy and should not be used in females of childbearing potential unless highly effective contraception is in use and the patient has been extensively counseled.

QUESTION 6: Can type 2 diabetes in children and adolescents be prevented?

Attempts to prevent type 2 diabetes in children should follow the same general paradigm as those to prevent type 2 diabetes in adults. Primary prevention efforts can be directed to high-risk individuals or to the overall population of children. Prevention of type 2 diabetes in high-risk children requires the ability to accurately identify those at an increased risk and provide them with the service they need. Prevention of type 2 diabetes should be considered at two stages in its natural history. Intervention can take place at an early stage when blood glucose levels are still normal or at the stage of impaired glucose tolerance (IGT)/impaired fasting glucose (IFG) when glucose levels are elevated but not yet diagnostic of diabetes. To whatever degree hyperinsulinemia and insulin resistance contribute to long-term cardiovascular morbidity and mortality, early lifestyle intervention may have long-term beneficial effects.

Primary care providers have an obligation to encourage lifestyle modifications that might delay or prevent the onset of type 2 diabetes in children at high risk. Lifestyle interventions focusing on weight management and increasing physical activity should be promoted in all children at high risk for the development of type 2 diabetes. For those who have progressed to IGT/IFG, these lifestyle interventions should be more aggressively implemented, along with regular assessment and follow-up.

In the adult population at risk for type 2 diabetes, intervention strategies that have been considered include lifestyle changes in diet and physical activity and pharmacologic interventions. Results of prevention trials using drugs are not likely to become available for several years. Until the results of current trials with oral hypoglycemic agents in children are available, intervention using glucose-lowering drugs for prevention of diabetes in children is not recommended.

In obese adults, weight reduction is known to reduce insulin resistance and circulating insulin levels. This reduction is beneficial in the treatment of the obese type 2 diabetic subject. It is also possible that weight reduction will slow the progression of IGT/IFG to type 2 diabetes. In adults, reduction of calorie and fat intake and increased consumption of fruits and vegetables have been associated with weight loss and a reduced risk of progression to type 2 diabetes. However, sustained weight reduction in adults is unusual. Dietary intervention data in pediatric populations are limited, but nutritional surveys have demonstrated that children eat more fat and fewer servings of fruits and vegetables than is recommended in dietary guidelines.

Nutritional interventions in children should be guided by a health care provider with knowledge and expertise in growth and development in children. The most effective dietary approach has been appropriate reduction of energy intake along with exercise to increase energy expenditure. Specific recommendations need to be individualized, and continued evaluation is crucial for long-term success. Individualized plans need to be based on assessment of food preferences, timing and location of meals and snacks, food preparation, and willingness to change behaviors. Drug therapy to reduce weight (i.e., anti-obesity agents) is not recommended in children until more safety and efficacy data are available. Use of very-low-calorie or high-protein diets as well as other fad diets is also not recommended. Quick-fix weight loss programs are unsafe for children and rarely result in long-term weight control. In addition, they do not promote long-term healthy eating behavior. Weight loss programs with the best results have been those combining exercise and dietary components, along with behavior modification. In the 6-year Da Qing IGT and Diabetes Study (18), 126 Chinese men with IGT who were randomized to a program including both dietary and exercise intervention developed type 2 diabetes 32% less

frequently than 133 men in a control group. Although results of other randomized controlled clinical trials of lifestyle interventions to reduce or delay the onset of type 2 diabetes in adults are not yet available, successful programs to promote improved nutrition and increased physical activity are likely to reduce the risk of type 2 diabetes.

Lack of physical activity is strongly associated with the development of obesity, type 2 diabetes, and cardiovascular morbidity and mortality. Despite information on the importance of exercise, only 25% of high school students participate in daily physical education classes, according to a 1995 survey conducted by the Centers for Disease Control and Prevention's Division of Adolescent and School Health (19). Recommendations for increasing physical activity should include encouraging patients to do at least 30 min of physical activity daily, limit sedentary activity, and participate in sports. Specific recommendations need to be individualized to the family and social situation and include safety considerations. Continued follow-up is critical for long-term success.

Primary prevention of type 2 diabetes in children should ideally include a public health approach that targets the general population. Health professionals need to be involved in developing and implementing school- and community-based programs to promote improved dietary and physical activity behaviors for all children and their families. Programs that provide children and their families with the knowledge, attitudes, behavioral skills, and encouragement to consume a healthy diet and engage in regular physical activity may be effective in attenuating the expanding problem of obesity. At the community level, schools, religious organizations, youth and family organizations, and government agencies should assume some responsibility for promoting a healthy lifestyle. School programs should promote healthy food choices and increased physical activity. Planning of effective preventive efforts for populations at risk needs to involve members of the community.

CLINICAL REPORT

Update of Newborn Screening and Therapy for Congenital Hypothyroidism

Guidance for the Clinician in Rendering Pediatric Care

AMERICAN ACADEMY OF PEDIATRICS
Susan R. Rose, MD, and the Section on Endocrinology and Committee on Genetics

AMERICAN THYROID ASSOCIATION
Rosalind S. Brown, MD, and the Public Health Committee

LAWSON WILKINS PEDIATRIC ENDOCRINE SOCIETY

ABSTRACT

Unrecognized congenital hypothyroidism leads to mental retardation. Newborn screening and thyroid therapy started within 2 weeks of age can normalize cognitive development. The primary thyroid-stimulating hormone screening has become standard in many parts of the world. However, newborn thyroid screening is not yet universal in some countries. Initial dosage of 10 to 15 μg/kg levothyroxine is recommended. The goals of thyroid hormone therapy should be to maintain frequent evaluations of total thyroxine or free thyroxine in the upper half of the reference range during the first 3 years of life and to normalize the serum thyroid-stimulating hormone concentration to ensure optimal thyroid hormone dosage and compliance.

Improvements in screening and therapy have led to improved developmental outcomes in adults with congenital hypothyroidism who are now in their 20s and 30s. Thyroid hormone regimens used today are more aggressive in targeting early correction of thyroid-stimulating hormone than were those used 20 or even 10 years ago. Thus, newborn infants with congenital hypothyroidism today may have an even better intellectual and neurologic prognosis. Efforts are ongoing to establish the optimal therapy that leads to maximum potential for normal development for infants with congenital hypothyroidism.

Remaining controversy centers on infants whose abnormality in neonatal thyroid function is transient or mild and on optimal care of very low birth weight or preterm infants. Of note, thyroid-stimulating hormone is not elevated in central hypothyroidism. An algorithm is proposed for diagnosis and management.

Physicians must not relinquish their clinical judgment and experience in the face of normal newborn thyroid test results. Hypothyroidism can be acquired after the newborn screening. When clinical symptoms and signs suggest hypothyroidism, regardless of newborn screening results, serum free thyroxine and thyroid-stimulating hormone determinations should be performed.

INTRODUCTION

Congenital hypothyroidism (CH) is one of the most common preventable causes of mental retardation. In most cases, the disorder is permanent and results from an

TRH—thyrotropin-releasing hormone

abnormality in thyroid gland development (dysgenesis or agenesis) or a defect in thyroid hormonogenesis. Less commonly, the altered neonatal thyroid function is transient, attributable to the transplacental passage of maternal medication, maternal blocking antibodies, or iodine deficiency or excess. In rare cases, CH may result from a pituitary or hypothalamic abnormality (central or secondary/tertiary hypothyroidism). Recent advances in molecular and cell biology have led to improved understanding of normal thyroid physiology and of genes involved in thyroid gland development and disease. In addition, the mechanism and precise temporal sequence of thyroid hormone (TH) modulation of target gene expression are being elucidated.[1–8]

The initial American Academy of Pediatrics recommendation for newborn screening for CH was published in 1993.[9] Screening for CH is one of dozens of newborn screening tests conducted. The rapid advances in our knowledge in the decade since the 1993 publication have prompted reevaluation of the problem and the identification of new questions and concerns.

TH concentrations are low in the fetus during the first half of pregnancy. During this time, the fetus is entirely dependent on maternal TH; its supply to the fetus is controlled by the placenta and the thyroid status of the mother. The fetal hypothalamic-pituitary-thyroid axis begins to function by midgestation and is mature in the term infant at delivery. Despite the critical importance of TH on multiple organ systems, especially the brain, most infants with CH appear normal at birth. The hypothyroid fetus appears to be protected at least in part by placental transfer of maternal TH. This was best illustrated by the demonstration that cord blood thyroxine (T_4) concentration at birth in infants unable to synthesize T_4 was nonetheless one third to one half that of normal infants.[10] In addition, there is increased intracerebral conversion of T_4 to triiodothyronine (T_3), resulting in increased local availability of T_3 despite the low serum concentrations.[11–13] Indeed, normal or near-normal cognitive outcome is possible in even the most severely affected infants with CH. This is true as long as postnatal therapy is early and adequate and maternal thyroid function is normal. In contrast, when both maternal and fetal hypothyroidism are present, whether attributable to severe iodine deficiency, potent thyrotropin receptor (TSH-R)-blocking antibodies (TRBAbs) (or TSH-blocking immunoglobulins), or maternal-fetal PIT1 deficiency, there is a significant impairment in neurointellectual development despite adequate therapy soon after birth.[6,14,15] Maternal hypothyroidism alone during early gestation can lead to mild but significant cognitive impairment of the offspring.[6,15–19] In this report, attention is focused on the problem of CH alone; identification and treatment of maternal hypothyroidism has been the subject of several recent reviews.[20,21]

Pilot screening programs for CH were developed in Quebec, Canada, and Pittsburgh, Pennsylvania, in 1974 and have now been established in Western Europe, North America, Japan, Australia, and parts of Eastern Europe, Asia, South America, and Central America.[22–24] In North America, more than 5 million newborns are screened and approximately 1400 infants with CH are detected annually. Certainly the main objective of screening, the eradication of mental retardation after CH, has been achieved. In addition to the profound clinical benefit, it has been estimated that the cost of screening for CH is much lower than the cost of diagnosing CH at an older age. This estimate does not include the loss of tax income resulting from impaired intellectual capacity in the untreated but noninstitutionalized person. Newborn screening also has revealed the prevalence of the various causes of CH, including a series of transient disorders found predominantly in preterm infants. The incidence of CH has been found to be 4 to 5 times more common than phenylketonuria, for which screening programs were originally developed. The overall incidence of CH ranges from 1 in 3000 to 1 in 4000 newborn infants.[15,25] The incidence of CH is higher in Hispanic individuals and lower in black individuals.[25] There is a 2:1 incidence in females compared with males, and there is an increased risk in infants with Down syndrome.

Iodine deficiency remains the most common treatable cause of mental retardation worldwide. Associated nutritional deficiencies in selenium and iron may have an effect on neurologic development and on thyroidal response to iodine therapy.[26] Many countries have initiated salt iodination.[25–28] Although North America is usually considered to be an iodine-sufficient area, recent epidemiologic evidence suggests that a number of pregnant women may be iodine deficient.[29] There is also some concern that maternal iodine deficiency may be reappearing in developed countries despite salt iodination because diet-conscious young women may avoid iodine-supplemented salt and breads.[30,31] Iodine supplementation before or during pregnancy will normalize thyroid function in the mother and the newborn.[31,32]

The hypothalamic-pituitary-thyroid axis is finely tuned to maintain a fairly stable concentration of free thyroxine (FT_4) within any individual.[33] Divergence from this individual optimal "set point" because of underfunction of the thyroid gland results in an increase in thyroid-stimulating hormone/thyrotropin (TSH) concentration. The exception to this is when the hypothalamus or pituitary gland is unable to respond (in central hypothyroidism, rare pituitary resistance to FT_4 feedback, or in an occasional child with Down syndrome).

Thus, TSH is elevated if thyroid gland function is impaired and FT_4 decreases from its individual optimal set point, although TSH concentration is not elevated in central hypothyroidism.

Although much has been learned, some questions

remain. These issues include the optimal screening approach and the follow-up of infants with low T_4 and normal TSH concentrations. Finally, continued efforts are ongoing to establish the optimal therapy that leads to maximum potential for normal development for infants with CH.

SCREENING METHOD

Two screening strategies for the detection of CH have evolved: a primary TSH/backup T_4 method and a primary T_4/backup TSH method (Fig 1). In addition, an increasing number of programs use a combined primary TSH plus T_4 approach.

Primary TSH With Backup T_4 Measurements

Most programs in Europe, Japan, Canada, Mexico, and the United States screen by using primary TSH measurements, supplemented by T_4 determinations for infants with elevated TSH values. With this approach, delayed TSH elevation in infants with thyroid-binding globulin (TBG) deficiency, central hypothyroidism, and hypothyroxinemia will be missed. Delayed TSH elevation is particularly common in infants with low birth weight (LBW [<2500g]) and very low birth weight (VLBW [<1500g]). In the Quebec study, 2 cases of permanent CH (of 93 000 infants screened) would have been missed by the primary TSH approach and detected by the primary T_4 approach.[34] The recall rate (notification of a physician to contact the infant's family to arrange for a blood test) with a primary TSH screening approach is approximately 0.05%. At this rate, 2 infants will be recalled for testing for every case detected.

Current TSH assay techniques (enzyme-linked immunoassays, chemiluminescent assays, and fluoroimmunoassays) use nonradioactive labels and have improved sensitivity with the potential for better separation between normal and abnormal TSH concentrations. Thus, many screening programs are considering switching to a primary TSH approach. However, the trend toward early discharge of mothers and infants (before 48 hours of age) presents a problem with the switch to a primary TSH approach because of the normal increase in TSH postnatally. With early hospital discharge, the first screening specimen commonly is obtained before 48 hours of age. Recent data using a sensitive and specific immunofluorometric assay indicate that normal TSH values before 24 hours of age are not as high as those using previous assays and usually less than the cutoff value of 20 to 25 mU/L.[35,36] A 50% reduction in abnormal values occurred when age-adjusted TSH cutoffs were used.[37] Thus, the current experience using newer assays in a primary TSH screening approach in a population of infants discharged after 24 hours of age shows lower patient recall rates with negligible false-negative test results.

Primary T_4 With Backup TSH Measurements

An initial filter-paper blood-spot T_4 measurement is followed by a measurement of TSH for filter-paper specimens with low T_4 values.[9,25] The primary T_4 approach will detect primary hypothyroidism in infants with low or low-normal T_4 with elevated TSH concentrations (prevalence ranging from 1 in 3000 to 1 in 4000 newborn infants). In addition to detecting primary hypothyroidism, the primary T_4/backup TSH approach can also identify infants with TBG deficiency (prevalence ranging from 1 in 5000 to 10 000 newborn infants) and central hypothyroidism (low or low-normal T_4 with normal TSH concentration; prevalence: l in 50 000 newborn infants). Programs that quantify high T_4 values also have the potential to identify infants with hyperthyroxinemia (1 in 20 000 to l in 40 000 newborn infants). This approach, however, will miss the condition in an infant with an initially normal T_4 concentration and delayed increase in TSH. To ensure identification of infants with CH who have low-normal T_4 values, most screening programs use a T_4 concentration cutoff of <10th percentile for the days' assay. Comparison of the primary T_4 versus primary TSH screening approach was conducted in Quebec (1983).[34] One case (of 93 000 infants screened) would have been missed by the primary T_4 approach and detected by the primary TSH approach.[34]

Programs using a primary T_4 with secondary TSH approach will follow-up on infants with a low T_4 and elevated TSH screening result. The recall rate for primary hypothyroidism in these screening programs is approximately 0.05%, similar to that in primary TSH screening programs.[38] However, some primary T_4 screening programs also report low T_4 results below an absolute cutoff (eg, 3.0 μg/dL [39 nmol/L]) in infants even if the TSH was normal. The recall rate (and therefore the false-positive rate) will be higher (approaching 0.30%) with this practice. For example, in a 1990 study in California, which did not report low T_4 results, the recall rate was 0.08%. In contrast, a study performed in Oregon, which reported infants with 2 low T_4 results <3rd percentile, the recall rate was 0.30%.[39] This means that up to 12 normal infants may be recalled for testing for every 1 case of hypothyroidism.

Combined Primary TSH Plus T_4 Measurements

Methods for the simultaneous measurement of T_4 and TSH are available (DELFIA data). This represents the ideal screening approach, especially once it is possible for FT_4 to be measured accurately and cost-effectively in the eluates from filter-paper blood spots. Until T_4 and TSH determinations can be performed practically for all infants, physicians should be aware of the potential limitations of each method of screening for CH.

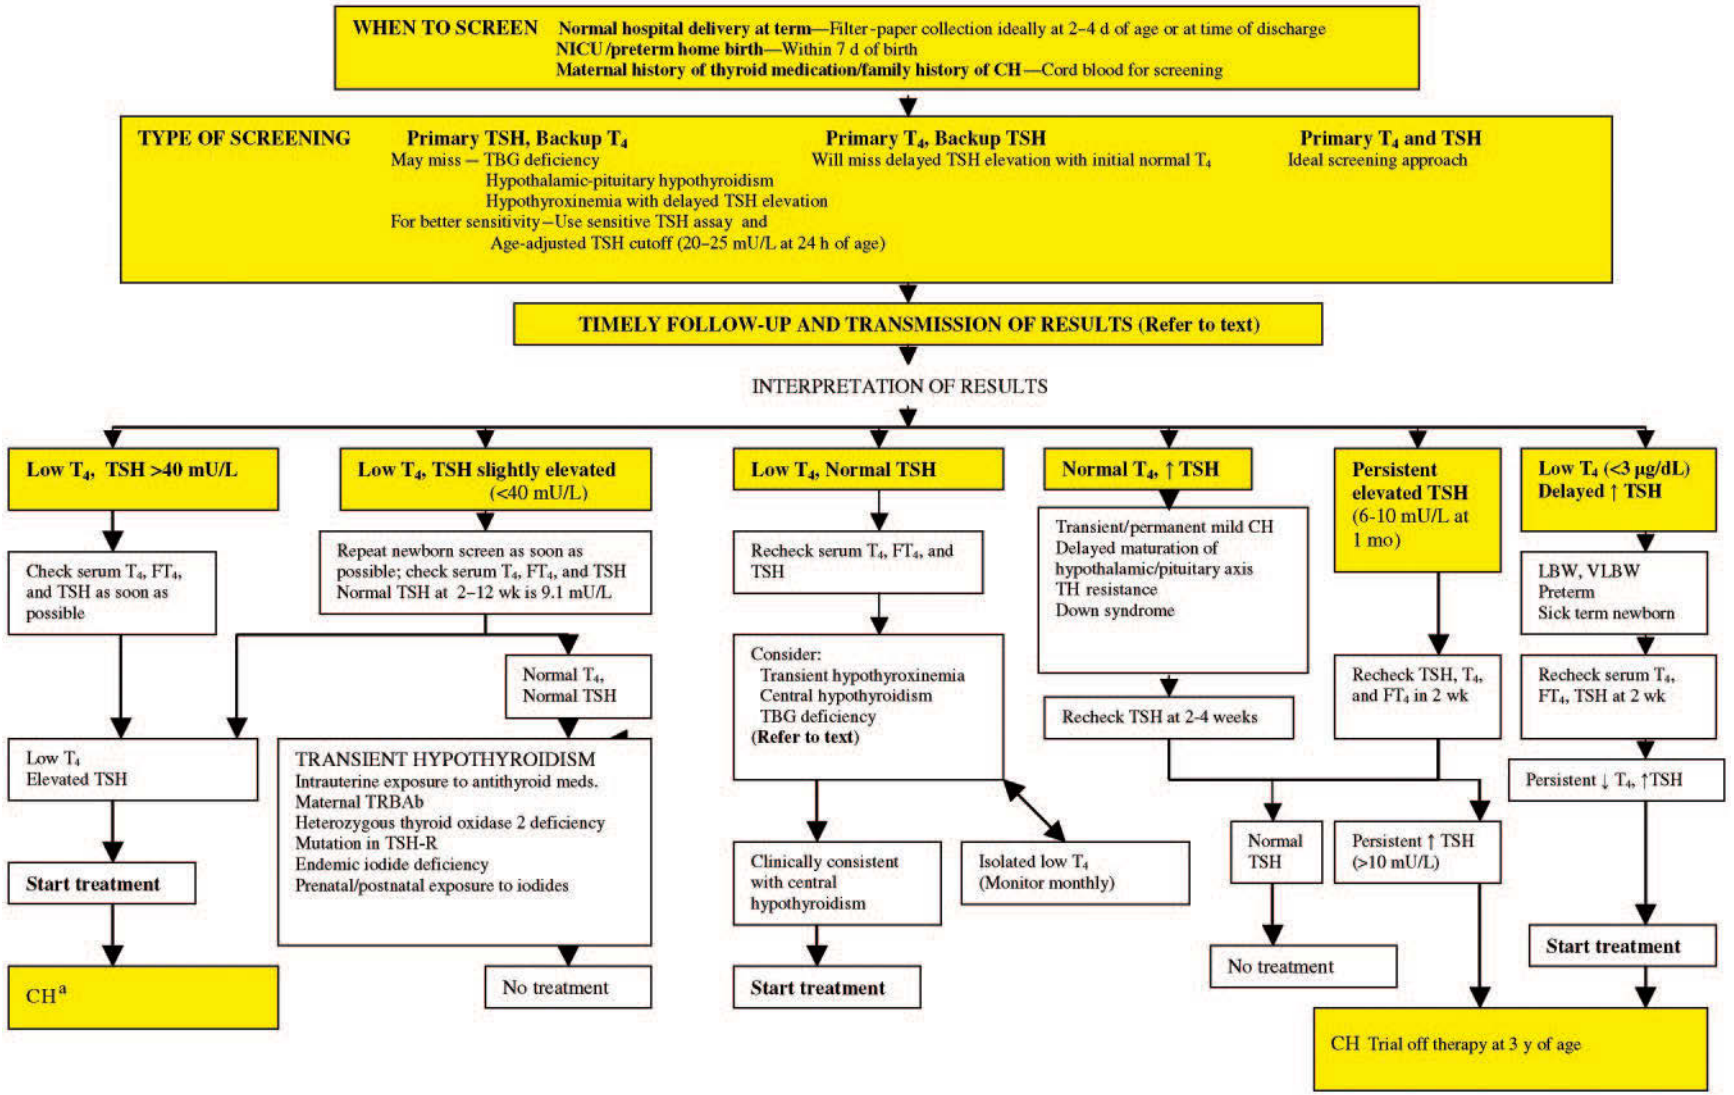

FIGURE 1
Newborn screening for CH. [a] Management of CH is summarized in Table 1.

THE SPECIMEN

Every infant should be tested before discharge from the nursery, optimally by 48 hours to 4 days of age. As noted above, specimens collected in the first 24 to 48 hours of life may lead to false-positive TSH elevations when using any screening test approach. However, screening before hospital discharge or before transfusion is preferable to missing the diagnosis of hypothyroidism. False-negative results may occur by screening a very sick newborn or after transfusion. Because newborn blood specimens are used for a variety of screening tests and shared among different laboratories, every effort should be made to collect adequate and sufficient blood in the recommended manner.[39]

It is highly desirable that the blood be collected when the infant is between 2 and 4 days of age, but there are situations in which this is virtually impossible. In infants discharged from the nursery before 48 hours of age, blood should be obtained before discharge. In instances such as home births or in the case of a critically ill or preterm neonate, blood should be obtained by 7 days of age, recognizing that samples obtained after 4 days of age are late for screening of congenital adrenal hyperplasia or metabolic disease. Particular care must be taken with infants in NICUs. In such cases, more urgent medical problems may result in missed newborn screening. When an infant is transferred to another hospital, the first hospital must indicate whether the specimen has been collected. The second hospital should obtain a specimen if there is no proof that blood was collected before the transfer.

Some state screening programs, testing 10% of newborns in the United States, perform newborn screening on specimens routinely collected at 2 time periods. These programs report that CH is detected in approximately 10% of the affected infants only as a result of collection of a second specimen. The additional incidence of CH based on a second screening at 2 weeks of age is approximately 1 in 30 000.[38,40] Infants with CH detected at the later screening time tend to be of LBW or VLBW, with mild or delayed TSH elevations.[41] Whether these cases represent transient or permanent cases is unknown. Some have thyroid dysgenesis (ectopia, aplasia, or hypoplasia) on thyroid scanning. Others appear to have increased uptake and a large thyroid gland, suggestive of dyshormonogenesis.[8] Either these infants have transient disease or their disease is undiagnosed until a later age, when they appear to have acquired hypothyroidism.

Accurate screening results depend on good-quality blood spots. The filter paper designed for newborn screening bears printed circles. Capillary blood samples are placed in these circular areas to fill and saturate them. Spotting blood over a previous blood spot, or double spotting, causes invalid results, and these blood spots should not be used. The recall of an infant for testing because of an unsatisfactory filter-paper specimen causes needless delay in diagnosis and treatment of a newborn with CH. Specimens that are technically unsatisfactory or contain insufficient amounts of blood should not be assayed. Blood samples should be collected on approved filter-paper forms, dried at room temperature, and not subjected to excessive heat. The blood should completely saturate the filter paper and be applied to 1 side only. Filter-paper spots should not be handled, placed on wet surfaces, or contaminated by coffee, milk, or other substances. Any of these have the potential to invalidate the results regardless of the method used. Testing of an unsatisfactory specimen (because of insufficient blood) can result in a false-negative TSH value. False-negative values can also result from human error in the processing of satisfactory specimens or in erroneous reporting of the results.

TEST RESULTS

Transmission of Results and Follow-up Testing

Newborn screening test results must be communicated rapidly back to the physician or hospital identified on the screening filter-paper card. The responsibility for transmission of these results rests with the authority or agency that performed the test. In general, when an abnormal screening result is found, the responsible physician is notified immediately so that he or she can arrange for follow-up testing. Screening test results should be entered into the patient's record. If the informed physician is no longer caring for or cannot locate the infant, he or she should notify the newborn screening laboratory immediately. In such situations, the local health department is often helpful in locating these infants to ensure that they are not lost to follow-up.

Low T_4 and Elevated TSH Values

Any infant with a low T_4 concentration and TSH concentration greater than 40 mU/L* is considered to have primary hypothyroidism. Such infants should be examined immediately and have confirmatory serum testing performed to verify the diagnosis. Treatment with replacement levothyroxine (L-T_4) should be initiated as soon as confirmatory tests have been drawn and before the results of the confirmatory tests are available. (Clinical management of infants with hypothyroidism is described in the following section.) For cases in which the screening TSH concentration is only slightly elevated but less than 40 mU/L, another filter-paper specimen should be obtained for a second newborn screening. Ten percent of infants with confirmed CH have TSH values between 20 and 40 mU/L. It is important that age-appropriate normative values be used. The reference

* All filter-paper TSH [and T_4] levels here are reported as serum equivalents. Some laboratories report screening results per unit of blood, a value that is approximately half the concentration in serum. We recommend that all laboratories report results per unit of serum, because TSH and T_4 are preferentially distributed into the serum.

range for TSH for the most common time of TSH reevaluation (between 2 and 6 weeks of age) is 1.7 to 9.1 mU/L.[42]

Normal T_4 and Elevated TSH Values

Hyperthyrotropinemia is characterized by elevated serum TSH concentrations during the neonatal period despite normal T_4 and FT_4 concentrations. The etiology is probably heterogeneous and can be either a transient or permanent thyroid abnormality[43–46] or delayed maturation of the hypothalamic-pituitary axis. Inactivation mutations in the TSH-R cause compensated, mild (subclinical) primary hypothyroidism in the neonatal period. The incidence of both transient and persistent hyperthyrotropinemia and CH appears to be higher in infants with Down syndrome. In some cases, transient neonatal hyperthyrotropinemia persists until 10 years of age or later.

There is controversy regarding the need for TH therapy in this setting. There have been no long-term studies to evaluate cognitive development in this group of patients. TSH concentration is the most sensitive indicator that the hypothalamic-pituitary axis is sensing less T_4 than the body "perceives" as optimal. Most physicians would consider a persistent basal TSH concentration higher than 10 mU/L (after the first 2 weeks of age) to be abnormal.[42] Therefore, if the TSH elevation persists, the infant should be treated. If such infants are not treated, measurement of FT_4 and TSH should be repeated in 2 and 4 weeks, and treatment should be initiated promptly if the FT_4 and TSH concentrations have not normalized.

The management of infants with TSH elevations between 6 and 10 mU/L that persist after the first month of life is even more controversial. TSH concentrations are slightly higher in the first few months of life. A TSH range of 1.7 to 9.1 mU/L has been reported for children 2 to 20 weeks of age (Quest Diagnostics reference values, Lyndhurst, NJ). Thus, using the adult reference range for TSH will result in treatment of many euthyroid children. Consequently, if a decision is made to treat such children, a trial off therapy at 3 years of age should be performed.

Low T_4 and Normal TSH Values

Infants with normal TSH but low T_4 values (defined as 2 SDs below the mean for the reference range for age, usually below 10 μg/dL in the newborn infant) may have thyroid insufficiency. The low T_4 with normal TSH profile is seen in 3% to 5% of neonates. This pattern may result from hypothalamic immaturity (particularly in preterm infants, 12% of all newborn infants). Low T_4 but normal TSH results are also observed during illness, with protein-binding disturbances such as TBG deficiency (1 in 5000), in central hypothyroidism (1 in 25 000 to 1 in 50 000 newborn infants; see next 3 paragraphs),[47] or with primary hypothyroidism and delayed TSH elevation (1 in 100 000 newborn infants). Newborn infants who are preterm or ill are found with disproportionate frequency among those with this set of laboratory values.[48] In neonates/infants, inhibition of TSH (causing low T_4 concentrations) can result from constant infusions of dopamine or high-dose glucocorticoids.

Transient hypothyroxinemia is seen to some extent in many preterm infants.[36,48] Immaturity of the hypothalamic-pituitary axis may be physiologically normal for the infant's gestational age. Preterm serum T_4 and FT_4 concentrations are lower than those of term infants, but the TSH concentrations are comparable to term infants.[49,50] Serum TBG concentrations are only slightly low in preterm infants and do not account for the degree of hypothyroxinemia. Consequently, the FT_4 is rarely as low as the total T_4. Serum inhibitors of T_4 binding, present in many patients with nonthyroidal illness, may be an additional contributor to the decreased T_4 values.

In contrast to transient hypothyroxinemia, the presence of midline facial abnormalities, hypoglycemia, microphallus, or visual abnormalities should suggest the possibility of a hypothalamic-pituitary abnormality. Septo-optic dysplasia, often associated with pituitary hormone deficiencies, can manifest as central hypothyroidism.[51,52] Genetic mutation in HESX-1 has been described in septo-optic dysplasia. Clinical symptoms of hypopituitarism, such as neonatal hypoglycemia (from growth hormone and adrenocorticotropic hormone deficiencies), polyuria (from antidiuretic hormone deficiency), or small phallus in boys (from gonadotropin deficiencies), along with the presence of blindness, congenital nystagmus, or midline defects of the brain, should alert the physician to suspect the diagnosis of septo-optic dysplasia. Alternatively, multiple pituitary hormone deficiencies suggest a genetic defect in the cascade leading to fetal pituitary formation, such as PROP1, LHX3, and POU1F1.[4,53] DNA screening for these molecular abnormalities could be beneficial in the future for the rapid and accurate detection of these affected infants during the first weeks of life, but is not yet available clinically.

Isolated TSH-releasing hormone (TRH) deficiency may cause low-normal T_4 and low or normal TSH concentrations. Secondary (or central) hypothyroidism may be suspected in infants with low T_4 and FT_4 and low TSH concentrations.[32,43] Mutations have been identified in the β subunit of TSH, TRH gene, and TRH receptor gene.[54,55] Finally, congenital TSH and growth hormone deficiencies may occur as a result of a difficult birth or anoxia.[56]

In programs that report low T_4 with normal TSH results, there is no clear consensus regarding optimal follow-up. Such programs have elected to take no further action, to follow-up with serial filter-paper screening tests until the T_4 value becomes normal, or to request a second blood sample for measurement of FT_4 and TSH

concentrations. Most infants with low T_4 and normal TSH have normal FT_4 values, and subsequent thyroid function test results are normal. Programs that choose to pursue further laboratory testing must weigh the benefit of detecting TBG deficiency or the rare case of hypopituitary-hypothyroidism or delayed TSH increase against the cost and the psychological effect on the family. The responsibility of deciding which course of action to follow rests with the physician providing the care of the infant. Treatment of these infants (with the exception of those with central hypothyroidism or delayed TSH increase) with L-T_4 has not yet been shown to be beneficial.[48,57–59]

Low T_4 and Delayed TSH Increase

Many infants with low T_4 concentrations and normal TSH values on initial screening (l in 100 000 newborn infants) who are subsequently found to have an elevated TSH concentration are LBW, VLBW, or critically ill preterm and term neonates. Serum TSH values in these infants increase during the first few weeks of life to concentrations characteristic of primary hypothyroidism. It is unclear whether infants with this delayed TSH elevation have an abnormality of pituitary-thyroid feedback regulation, transient hypothyroidism (eg, iodine induced), or a mild form of permanent CH. Long-term follow-up of these infants has not been reported. It is important, therefore, that serum FT_4 and TSH be tested in infants with overtly low T_4 concentrations or in any infant with suggestive signs of hypothyroidism. Infants with low T_4 and a delay in elevation of TSH values and those with normal T_4 concentrations and elevated TSH values might be missed on initial screening. Neither a primary T_4/backup TSH nor a primary TSH/backup T_4 screening strategy will detect the rare infant with a normal T_4 at birth but delayed TSH increase. Even in the absence of technical and human errors, 5% to 10% of LBW and VLBW newborn infants with CH may have normal screening hormone concentrations regardless of the approach used.

Some screening programs routinely obtain a second specimen at 2 to 6 weeks of age and/or obtain a serum sample from any infant with 2 successive T_4 values below an absolute cutoff (<3rd percentile). Whatever strategy is used, subsequent testing should be performed on serum during infancy whenever there is a perceived risk of hypothyroidism, as in familial dyshormonogenesis or in infants with clinical suspicion of hypothyroidism. In addition, a second specimen should be drawn at 2 weeks of age in monozygotic twins, because fetal blood mixing may mask the screening test results.[60]

However, a second screen has not become routine because of (1) increased cost, (2) relatively low yield of cases, (3) diversion and dilution of key personnel, (4) inability to implement new programs, and (5) absence of such cases missed in primary TSH screening programs. Finally, the cognitive and developmental prognosis of this cohort is uncertain because the etiology in most cases is unknown and there are no definitive follow-up data.

As an alternative strategy, other programs have attempted to identify high-risk patient groups so that routine rescreening can be targeted to these infants. There is a disproportionate incidence of delayed TSH increase in VLBW infants (incidence of CH: 1 in 250), LBW infants (incidence of CH: 1 in 1589), and neonates in intensive care settings or with cardiovascular abnormalities.[61] Therefore, some screening programs routinely screen again at 2 weeks and 6 weeks of age all VLBW and all LBW infants in the NICU, especially in newborns known to have cardiac disease. It is likely that most of these infants do not have permanent CH. If hyperthyrotropinemia persists at 6 weeks of age, TH replacement should be started, consistent with therapy of other forms of transient CH, and the infant should be retested after 3 years of age (after stopping therapy for 4–6 weeks) (see "Assessment of Permanence of Hypothyroidism").

Transient TSH Elevation

A small number of infants with abnormal screening values will have transient hypothyroidism as demonstrated by normal serum T_4 and TSH concentrations on the confirmatory (follow-up to screening) laboratory tests. Transient hypothyroidism is relatively rare in North America (estimated at 1 in 50 000) in contrast to iodine-deficient areas of the world; it is much more common in preterm infants but may occur in apparently healthy term infants. Transient hypothyroidism may result from intrauterine exposure to maternal antithyroid drugs, maternal TRBAbs, heterozygous thyroid oxidase 2 deficiency, germ-line mutations in the TSH-R, endemic iodine deficiency, or prenatal or postnatal exposure to excess iodides (povidone iodine, iodinated contrast materials).[31,32,43,62,63] Transient iodine-induced CH is not usually evident at birth and, therefore, may not be detected if newborn screening is performed in the first few days postnatally.

Transplacental passage of potent maternal TRBAbs (incidence: 1 in 180 000) is a much less common cause of transient CH but should be suspected if there is a maternal history of autoimmune thyroid disease or if there is a history of previous affected offspring. In this setting, cord serum can be collected and rapidly tested for thyroid abnormalities. The half-life of immunoglobulin G in the neonate is approximately 3 to 4 weeks,[64] and TRBAbs usually disappear from serum of affected infants by 3 to 6 months of age, depending on the antibody potency.

Because the transient nature of the hypothyroidism will not be recognized clinically or through laboratory tests in some infants, initial treatment will be similar to that in any infant with permanent CH. In these cases, it

is important to determine at some later time whether the hypothyroidism is permanent and whether the infant in fact requires lifelong treatment (see "Assessment of Permanence of Hypothyroidism"). However, in the newborn infant with transient hypothyroidism whose mother is receiving an antithyroid drug, the T_4 and TSH values tend to return to normal within 1 to 3 weeks after birth without treatment.

CLINICAL MANAGEMENT OF NEWBORN INFANTS WITH LOW T_4 AND ELEVATED TSH VALUES

Infants with low T_4 and elevated TSH concentrations have CH until proven otherwise. Management should include the following (Table 1):

1. The infant should be seen by his or her physician without delay. Consultation with a pediatric endocrinologist is recommended to facilitate diagnostic evaluation and optimal management.
2. A complete history, including prenatal thyroid status (maternal drugs and medications) and family history should be obtained, and physical examination should be performed.
3. Serum should be obtained for confirmatory measurements of TSH and FT_4. An elevated thyroglobulin concentration may suggest dyshormonogenesis. Care must be taken to compare the serum results to normal TH concentration for age. When there is history of a maternal autoimmune thyroid disorder or a previously affected infant, measurement of TRBAbs in the infant and/or mother may identify a transient form of neonatal hypothyroidism.
4. Education of parents by trained personnel using booklets or visual aids is highly desirable. Education should focus on (*a*) the etiology of CH, (*b*) the lack of correlation of parental lifestyle during pregnancy with causes of the disease, (*c*) the benefit of early diagnosis in preventing mental retardation, (*d*) the appropriate manner in which TH is administered and the substances (eg, soy, iron, calcium, and fiber) that can interfere with TH absorption, (*e*) the importance of adherence to the treatment plan, and (*f*) the importance of periodic follow-up care.
5. Optional diagnostic studies include thyroid ultrasonography or iodine 123 (^{123}I) or sodium technetium 99m pertechnetate (^{99m}Tc) thyroid uptake and/or scan to identify functional thyroid tissue. Although ^{123}I tends to give a more accurate uptake and scan picture, it may not be readily available in all hospitals. ^{99m}Tc is generally more readily available and a much less expensive radioisotope. The half-life of ^{123}I is 13.3 hours, compared with 8 days for iodine 131 (^{131}I). ^{123}I exposes the infant to much lower doses of ionizing radiation compared with ^{131}I (probably one 100th of the ^{131}I dose [H.-M. Park, MD, Professor Emeritus, Radiology, Indiana University, personal communication, September 16, 2004]).

There remains some controversy regarding the risk-benefit ratio of early thyroid scanning of infants with suspected hypothyroidism. For physicians who opt for imaging, the benefits can be summarized as follows:

1. If an ectopic gland is demonstrated, a permanent form of thyroid disease and CH has been established.
2. The absence of thyroid gland uptake is most often associated with thyroid aplasia or hypoplasia. When radioiodine uptake is absent but ultrasonographic examination reveals a normal gland, a TSH-R defect, iodine-transport defect, or maternal transfer of TRBAbs may be present.
3. Normal scan findings (or a goiter) indicate a functioning thyroid gland with regard to iodine uptake and alert the physician to a probable hereditary defect in T_4 synthesis. Measurement of serum thyroglobulin will help to separate thyroglobulin synthetic defects from other causes of hypothyroidism.[65] Exposure to an exogenous goitrogen other than iodine, such as antithyroid drugs, will produce a similar picture. Finally, some infants exposed to maternal TRBAbs may have a normal scan if their hypothyroidism is partially compensated. The identification of a genetically mediated thyroid synthetic enzyme defect is especially important for families planning on having additional children. In such cases, the scan enables the physician to arrange for genetic counseling.
4. Some infants with normal scan findings at birth who do not fall into one of the above categories may have a transient form of hypothyroidism. These infants should undergo a careful follow-up evaluation after 3

TABLE 1 Management of CH

Initial workup
Detailed history and physical examination
Referral to pediatric endocrinologist
Recheck serum TSH and FT_4
Thyroid ultrasonography and/or thyroid scan (see text for recommendations)
Medications
L-T_4: 10–15 μg/kg by mouth once daily
Monitoring
Recheck T_4, TSH
2–4 wk after initial treatment is begun
Every 1–2 mo in the first 6 mo
Every 3–4 mo between 6 mo and 3 y of age
Every 6–12 mo from 3 y of age to end of growth
Goal of therapy
Normalize TSH and maintain T_4 and FT_4 in upper half of reference range
Assess permanence of CH
If initial thyroid scan shows ectopic/absent gland, CH is permanent
If initial TSH is <50 mU/L and there is no increase in TSH after newborn period, then trial off therapy at 3 y of age
If TSH increases off therapy, consider permanent CH

years of age, when it is safe to discontinue treatment temporarily under the conditions described in "Assessment of Permanence of Hypothyroidism."

Treatment need not be delayed to perform the scan. A thyroid scan can be performed within the first few days of treatment, because the elevated TSH found in patients with permanent CH rarely normalizes within this time period. A serum TSH measurement should be obtained at the time of the scan. If L-T_4 therapy has caused the TSH concentration to be <30 mU/L, ultrasonography can still be performed. A scan can be performed after the child is 3 years of age, when TH treatment can be interrupted without danger to the developing central nervous system.

The usual dose of ^{123}I, the preferred isotope, is 0.925 MBq (25 μCi). This represents a small amount of radiation exposure, equivalent to the amount of exposure with 2 to 3 chest radiographs. However, the radiation exposure is potentially 100 times greater if ^{131}I or large doses of isotope are administered. For this reason, the procedure should be performed by experienced personnel with optimal equipment, using the minimally recommended tracer dose.

To avoid unnecessary radiation, some investigators prefer ultrasonography as the initial imaging procedure to identify the presence and location of thyroid tissue.[66–68] However, gray-scale ultrasonography is much less sensitive than scintigraphy in detecting the presence of ectopic thyroid tissue, the most common cause of CH. Recent studies have indicated markedly improved sensitivity of color Doppler ultrasonography in diagnosing ectopic thyroid tissue.[69] If these studies are confirmed, color Doppler ultrasonography may become the optimal imaging procedure for the initial investigation of suspected CH.

TREATMENT

All infants with hypothyroidism, with or without goiter, should be rendered euthyroid as promptly as possible by replacement therapy with TH.[21,70–72] An optimal cognitive outcome depends on both the adequacy and timing of postnatal therapy, particularly in severe cases of CH (T_4 < 5 μg/dL). However, what constitutes optimal TH therapy is not yet certain. The goal of therapy is to normalize T_4 within 2 weeks and TSH within 1 month. An initial dosage of 10 to 15 μg/kg of L-T_4 (depending on the severity of the initial hypothyroidism) has been recommended. When a higher initial dose of L-T_4 (50 μg [ie, 12–17 μg/kg]) is used, the serum T_4 normalizes in 3 days and the TSH returns to the target range by 2 weeks of therapy.[72] In the long run, evaluation of cognitive outcome is important after use of this increased dose. Currently the evidence base does not indicate cognitive benefit from thyroid therapy of hypothyroxinemia of prematurity in the absence of TSH elevation.[48–50,57–59]

Administration of L-T_4 is the treatment of choice. Although T_3 is the more biologically active TH, most brain T_3 is derived from local monodeiodination of T_4, so T_3 should not be used. The pill should be crushed and suspended in a few milliliters of formula, breast milk, or water. Care should be taken to avoid concomitant administration of soy, fiber, or iron. Breastfeeding can continue. Only T_4 tablets should be used; currently there are no liquid formulations licensed by the US Food and Drug Administration. T_4 suspensions that may be prepared by individual pharmacists may lead to unreliable dosage. T_4 is expected to increase to more than 10 μg/dL, FT_4 is expected to increase to more than 2 ng/dL by 2 weeks after initiating therapy, and TSH should normalize by 1 month.[73] FT_4 measurement at 1 week of therapy can confirm whether the serum concentration is increasing appropriately. The L-T_4 dose should be adjusted according to the infant's clinical response and serum FT_4 and TSH concentrations.

During therapy, the serum total T_4 or FT_4 should and might be in the upper half of the reference range (target values depend on the assay method used [T_4: 10–16 μg/dL (130–206 nmol/L); FT_4: 1.4–2.3 ng/dL (18–30 pmol/L)]) during the first 3 years of life with a low-normal serum TSH. The latter may sometimes be delayed because of relative pituitary resistance. In such cases, characterized by a normal or increased serum T_4 and an inappropriately high TSH concentration, the T_4 value is used to titrate the dose. Nonadherence to the treatment is the most common cause of persistent TSH elevation and should be excluded. Those infants with low serum T_4 concentrations (below 10 μg/dL [129 nmol/L]) and a TSH concentration greater than 15 mU/L during the first year of life have lower IQ values than patients whose T_4 concentrations were held constant at higher concentrations.[35] Thereafter, thyroid function test values should be kept at age-appropriate concentrations, which in children differ from those for adults.[74] On TH-replacement therapy, TSH levels should be maintained between 0.5 and 2.0 mU/L during the first 3 years of life.[75] Clinical evaluation of the infant by the practitioner should be conducted at frequent intervals during the first 3 years of age (see "Follow-up"). Because poor compliance and noncompliance have major sequelae, initial and ongoing counseling of parents is of great importance.

Current international organizations such as the American Clinical Laboratory Association recommend that the FT_4, rather than the total T_4, be measured to assess the concentration of the biologically relevant, unbound or free form of circulating T_4.[75] The cost of total T_4 plus TBG or T_3 resin uptake, versus the FT_4 by most methods (excluding the more costly direct dialyzable or ultrafiltration methods), should be comparable. However, although the total T_4 is a robust measure, it should be recognized that most direct FT_4 assays are influenced,

to some extent, by protein binding. Consequently, the FT_4 values obtained vary between assays.

During TH therapy, 4 or more episodes of insufficiently suppressed TSH (>5 mU/L) after the age of 6 months were the most important variables associated with school delay.[75] Usually, these episodes are caused by poor parental compliance or impaired T_4 bioavailability. The latter may be caused by inhibition of T_4 intestinal uptake by specific foods (soy, fiber) and medications (iron, calcium), malabsorption, or increased degradation (anticonvulsants; large hemangiomas with high deiodinase activity). The Food and Drug Administration has deemed several generic L-T_4 products to be equivalent to some currently branded preparations. Any change in source of the L-T_4, especially if not a standard brand, requires retitration of the dose.

FOLLOW-UP

Clinical examination, including assessment of growth and development, should be performed every few months during the first 3 years of life. Infants with CH appear to be at increased risk of other congenital anomalies (approximately 10% of infants with CH, compared with 3% in the general population). Cardiovascular anomalies, including pulmonary stenosis, atrial septal defect, and ventricular septal defect, are the most common.

Infants need to undergo frequent laboratory and clinical evaluations of thyroid function, growth, and development to ensure optimal T_4 dosage and adherence to their therapy regimen. Serum T_4 and TSH measurements should be performed:

1. at 2 and 4 weeks after the initiation of L-T_4 treatment;
2. every 1 to 2 months during the first 6 months of life;
3. every 3 to 4 months between 6 months and 3 years;
4. every 6 to 12 months until growth is completed; and
5. at more frequent intervals when compliance is questioned, abnormal values are obtained, or dose or source of medication has been changed; FT_4 and TSH measurements should be repeated 4 weeks after any change in L-T_4 dosage.

The aim of therapy is to ensure normal growth and development by maintaining the serum total T_4 or FT_4 concentration in the upper half of the reference range in the first year of life, with a serum TSH in the reference range (optimally 0.5–2.0 mU/L).

Some infants will have serum TSH concentrations in the range of 10 to 20 mU/L despite T_4 concentrations in the upper half of the reference range. Rarely, the elevated TSH relative to the FT_4 value is hypothesized to result from in utero hypothyroidism, producing a resetting of the pituitary-thyroid feedback threshold. A failure of the serum FT_4 concentration to increase into the upper half of the reference range by 2 weeks and/or failure of the TSH concentration to decrease to less than 20 mU/L within 4 weeks after initiation of L-T_4 administration should alert the physician that the child may not be receiving adequate L-T_4 regularly. At this point, careful inquiry should be made regarding compliance, dose of medication, and method of administration. When attempting to achieve the optimal concentration of circulating FT_4, physicians should always bear in mind the adverse effects of excessive medication and thus be prepared to monitor blood concentrations of FT_4 at close intervals. Prolonged hyperthyroidism has been associated with premature craniosynostosis.

DEVELOPMENTAL OUTCOME

Growth rate and adult height are normal in children with CH in whom TH therapy is consistently maintained.[68,76,77] The best outcome occurred with TH therapy started by 2 weeks of age at 9.5 μg/kg or more per day, compared with lower doses or later start of therapy.[71] There are only minor differences in intelligence, school achievement, and neuropsychological tests in adults with CH that was treated early with TH compared with control groups of classmates and siblings.[78–82] Residual defects can include impaired visuospatial processing and selective memory and sensorimotor defects. Whether these minor differences are preventable by further optimizing postnatal therapy remains controversial.

In contrast to the excellent outcome in infants with CH that is treated early, the prognosis for normal mental and neurologic performance is less certain for infants with CH that is not detected early by newborn screening. Although physical recovery is good and stature is normal,[77] when replacement therapy is begun later but within the first 2 months of life, infants with severe hypothyroidism at birth and intrauterine hypothyroidism (retarded skeletal maturation at birth) may still have a low-to-normal IQ.[18] Similarly, although more than 80% of infants given replacement therapy before 3 months of age have an IQ greater than 85, 77% of these infants show some signs of minimal brain damage, including impairment of arithmetic ability, speech, or fine motor coordination in later life. Even in early-treated patients with CH, auditory brainstem evoked potentials were abnormal in 25% of 27 children studied. The reason for this is not known but might suggest that prenatal maternal T_4 production does not provide complete protection for the developing central nervous system.[84] In another study, processing of visuospatial relationships remained affected in adolescents with CH.[85] The effect of underlying severity of CH combines with the effects of TH dose and of age at onset of TH therapy.[35] Otherwise, neurologic and intellectual outcome do not correlate well with the degree of T_4 deficiency found in neonatal screening.

Transplacental transfer of maternal T_4 in the first

trimester may protect the brain during early development.[15] For the same reason, maternal hypothyroidism during fetal development can have persistent neurodevelopmental effects on the child.[15,16,19] Serum T_4 concentrations at term in athyreotic infants are 25% to 50% of those in normal neonates. These concentrations, although low, may contribute to fetal brain development. It is thought that the low-to-normal intelligence of patients with CH treated early in life results most commonly from inadequate treatment or poor compliance.

It must be noted that TH treatment regimens used today are more aggressive in targeting early correction of TSH than were the regimens used 20 or even 10 years ago. Thus, newborn infants with CH today may have an even better intellectual and neurologic prognosis than adults with CH who were evaluated in the reports discussed above.

ASSESSMENT OF PERMANENCE OF HYPOTHYROIDISM

CH is permanent if the thyroid scan reveals an ectopic gland or absent thyroid tissue (confirmed by ultrasonographic examination) or if the serum TSH is seen to increase above 10 mU/L after the first year of life, presumably because of insufficient T_4 replacement.

If no permanent cause of CH was found by scan or there was no TSH increase after the newborn period, then L-T_4 administration should be discontinued for 30 days at some point after the child is 3 years of age.[86] After 30 days, serum should be obtained for measurement of FT_4 and TSH values. It is critical that this follow-up laboratory assessment be obtained in a timely manner and that there be no loss of follow-up. If the FT_4 is low and the TSH value is elevated, permanent hypothyroidism is confirmed and TH therapy should be reinstituted. If the FT_4 and TSH concentrations remain in the reference range, euthyroidism is assumed and a diagnosis of transient hypothyroidism recorded. It is important that the child not be lost to follow-up. The physician should monitor the child carefully and repeat the thyroid function tests at the slightest suspicion of recurrence of hypothyroid symptoms. If the results are inconclusive, careful follow-up and subsequent testing will be necessary.

More severely affected children may become clinically hypothyroid when treatment is discontinued for 30 days. An alternative option is to reduce the TH-replacement dosage by half. If after 30 days the TSH is elevated above 20 mU/L, the permanence of hypothyroidism is confirmed and full replacement therapy should be resumed. If the serum TSH value has not increased, then TH treatment should be discontinued for another 30 days with repeated serum FT_4 and TSH determination as described above.

ADMONITION

Finally, physicians cannot and must not relinquish their clinical judgment and experience in the face of normal newborn thyroid test results. Failure of normal development can result from hypothyroidism in infants who had normal T_4 and TSH newborn screening results. Hypothyroidism can manifest or be acquired after the newborn screening. Rarely, the newborn screening test results can be in error, or human error can result in failure to notify the infant's physician of abnormal test results.[87] When clinical symptoms and signs suggest hypothyroidism, regardless of newborn screening results, serum FT_4 and TSH determinations should be performed.

Organizational Principles to Guide and Define the Child Health Care System and/or Improve the Health of all Children

Policy Statement—Ultraviolet Radiation: A Hazard to Children and Adolescents

abstract

FREE

Ultraviolet radiation (UVR) causes the 3 major forms of skin cancer: basal cell carcinoma; squamous cell carcinoma; and cutaneous malignant melanoma. Public awareness of the risk is not optimal, overall compliance with sun protection is inconsistent, and melanoma rates continue to rise. The risk of skin cancer increases when people overexpose themselves to sun and intentionally expose themselves to artificial sources of UVR. Yet, people continue to sunburn, and teenagers and adults alike remain frequent visitors to tanning parlors. Pediatricians should provide advice about UVR exposure during health-supervision visits and at other relevant times. Advice includes avoiding sunburning, wearing clothing and hats, timing activities (when possible) before or after periods of peak sun exposure, wearing protective sunglasses, and applying and reapplying sunscreen. Advice should be framed in the context of promoting outdoor physical activity. Adolescents should be strongly discouraged from visiting tanning parlors. Sun exposure and vitamin D status are intertwined. Cutaneous vitamin D production requires sunlight exposure, and many factors, such as skin pigmentation, season, and time of day, complicate efficiency of cutaneous vitamin D production that results from sun exposure. Adequate vitamin D is needed for bone health. Accumulating information suggests a beneficial influence of vitamin D on many health conditions. Although vitamin D is available through the diet, supplements, and incidental sun exposure, many children have low vitamin D concentrations. Ensuring vitamin D adequacy while promoting sun-protection strategies will require renewed attention to children's use of dietary and supplemental vitamin D. *Pediatrics* 2011;127:588–597

BACKGROUND

Sunlight sustains life on earth. The sun provides warmth, is needed for photosynthesis, drives biorhythms, and promotes feelings of well-being, and sunlight is essential for vitamin D synthesis in skin.

The sun emits ultraviolet ("above violet") radiation (UVR) waves that range from 200 to 400 nm. UVB (290–320 nm) and UVA (320–400 nm) rays penetrate the atmosphere and have the greatest biological significance. Solar radiation that reaches the earth's surface comprises approximately 95% UVA and 5% UVB rays.[1]

Sand, snow, concrete, and water can reflect up to 85% of sunlight, thus intensifying exposure.[2] UVR can penetrate to a depth of 60 cm in water and result in significant exposure. UVA rays are relatively constant throughout the day and the year. UVB rays have greater intensity in summer than in winter, at midday than in morning or late afternoon, in

places closer to the equator, and at high altitudes. UVR can be produced by man-made lamps (eg, sunlamps) and tools (eg, welding tools).

UVR EFFECTS ON THE SKIN

Erythema and sunburn are acute reactions to excessive amounts of UVR. The minimal erythema (or erythemal) dose (the amount of UVR exposure that will cause minimal erythema or slight pinkness of the skin) depends on factors such as skin type and thickness, the amount of melanin in the epidermis and its capacity to produce melanin after sun exposure, and the intensity of the radiation. Tanning is a protective response to sun exposure.[3] Skin aging is the result of chronic unprotected exposure to UVR, which weakens the skin's elasticity and results in sagging cheeks, deeper facial wrinkles, and skin discoloration later in life.

Chemical photosensitivity refers to an adverse cutaneous reaction that results when certain chemicals or drugs are applied topically or taken systemically at the same time that a person is exposed to UVR or visible radiation. The reaction can occur on first exposure to an agent (phototoxicity) or can be an acquired altered reactivity of the skin (photoallergy), usually triggered by exposure to UVA rays, that depends on antigen-antibody or cell-mediated hypersensitivity. Drugs associated with phototoxic reactions include those commonly used by adolescents, such as nonsteroidal anti-inflammatory agents, tetracyclines, and tretinoin; other medications such as phenothiazines, psoralens, sulfonamides, and thiazides; and para-amino benzoic acid (PABA) esters.[4] Sunscreens, fragrances, sulfonamides, and phenothiazines are associated with photoallergy. Many commonly used medications and furocoumarins in plants[5] have photosensitizing properties. Up to 80% of patients with lupus erythematosus have photosensitivity. The threshold ultraviolet dose that triggers reactions is much lower than that for sunburn in these people, and the latency period is between several days and 3 weeks.[6]

Nonmelanoma skin cancer (NMSC) includes basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). In US adults, NMSC is the most common malignant neoplasm, with more than 2 million cases diagnosed each year. Most of these are BCC; SCC occurs less often.[7] NMSC is rarely fatal.[7] NMSC occurs in maximally sun-exposed areas of fair-skinned people and is uncommon in black people. NMSC is rare in children in the absence of predisposing conditions.[8] The incidence of NMSC is increasing in young adults.[9] Sun exposure is the main environmental cause of NMSC; in SCC, cumulative exposure over long periods, resulting in photodamage, is considered important in pathogenesis.

Likewise, the incidence of melanoma continues to increase. Melanoma incidence has been increasing for at least 30 years. Most recently, rapid increases have occured in young white women (3.0% per year since 1992 in ages 15 to 39 years) and white adults older than 65 years.[10] Melanoma represents less than 5% of all skin cancers but causes the most skin cancer deaths. Melanoma can occur in teenagers and young adults; it is the second most common cancer of women in their 20s and the third most common cancer of men in their 20s.[11] Possible factors that contribute to the increased incidence of melanoma include the decrease in the earth's protective ozone layer, changing patterns of dress that favor more skin exposure, more opportunities for leisure activities in sunny areas, and increased exposure to artificial sources of UVR for tanning purposes. If detected when the tumor is thin and small, melanoma has an excellent prognosis. However, metastatic melanoma has no successful treatment options. Prevention and early detection, therefore, are crucial in this disease.

People at highest risk of melanoma have light skin and eyes and sunburn easily. Risk of developing melanoma is increased for people with a first-degree relative who has had melanoma or those with a personal history of previous melanoma. Those who freckle easily and those with a large number of typical or atypical moles (high nevus count) are also at higher risk of cutaneous malignancy. People with xeroderma pigmentosum (a condition in which there is a genetically determined defect in the repair of DNA damaged by UVR) and related disorders are at increased risk of melanoma.

Melanoma is rare in children but can occur. Characteristics of a child's melanoma lesion may differ from those typically found in adults; a child's lesion may be amelanotic (pink, pink-white, or red), may be raised, and may have regular borders. The key to diagnosis of melanoma in children is often the recognition that the lesion is unlike any other lesions on the child.[12]

EVIDENCE THAT UVR CAUSES SKIN CANCER

In 1992, the International Agency for Research on Cancer concluded that "there is sufficient evidence in humans for the carcinogenicity of solar radiation."[1] Since that time, additional research results have supported a strong causal relationship between sunlight exposure and skin cancer. Evidence comes from cellular, biological, and epidemiologic studies. Epidemiologic evidence includes relationship of high ambient solar UVR with higher rates of BCC and SCC[13]; relationship of BCC, SCC, and melanoma rates to race

and pigmentation[7,14]; increased frequency of skin cancers with higher sun-exposure history[15] or artificial UVR exposures from sunbeds or sunlamps[16]; heightened risk of melanoma for those with increased childhood sun-exposure history[17]; and relationship between sun exposure and increasing number of nevi, which may predispose to melanoma. Exposure to UVR contributes to immunosuppression, which is increasingly recognized as important in the development of skin cancer.[18,19]

UVR EFFECTS ON THE EYE

In adults, most UVR (>99%) is absorbed by the anterior structure of the eye, although some reaches the retina.[20] Acute exposure to UVR can result in photokeratitis.[21] Gazing directly into the sun can cause focal burns to the retina (solar retinopathy).[22] Long-term exposure to UVB is associated with an increased risk of cortical and posterior subcapsular cataracts.[23] UVR can contribute to the development of pterygium, corneal degenerative changes, and cancer of the skin around the eye.[20] There is evidence for a probable relationship between UVR exposure and squamous intraepithelial neoplasms of the conjunctiva or cornea.[24]

ARTIFICIAL SOURCES OF UVR

Sunlamps and tanning beds are the main sources of deliberate artificial UVR exposures.[16] The intensity of UVA radiation produced by large, powerful tanning units may be 10 to 15 times higher than that of the midday sun.[25]

Artificial tanning is a common practice among teenagers. Use of a tanning facility at least once in their lives was reported by 24% of non-Hispanic white teenagers 13 to 19 years of age in a US sample.[26] In another national survey, 10% of youths 11 to 18 years of age reported using indoor tanning sunlamps in the previous year.[27] Women and girls constitute the majority of people who artificially tan.[28]

Artificial UVR exposure causes acute effects such as erythema and sunburn. Other frequently reported effects include skin dryness, pruritus, nausea, photodrug reactions, disease exacerbation (eg, systemic lupus erythematosus), and disease induction (eg, polymorphous light eruption). Long-term health effects include skin-aging, effects on the eyes, and carcinogenesis. Use of tanning devices has been associated with an increased incidence of SCC and BCC[16,29] and melanoma.[30]

One commonly held misconception is that a "prevacation tan"—obtained when people visit tanning salons to prepare skin for a sunny vacation—protects against subsequent skin damage. This practice actually leads to extra radiation exposure not only before the vacation but also afterward, because people use fewer sun-protection precautions during the vacation, believing mistakenly that the tan will protect them.[28] A prevacation tan results in minimal protection (a sun-protection factor [SPF] of 3)[25] and affords virtually no protection against sun-induced DNA damage.[16] The evidence does not support a protective effect of the use of tanning beds against damage to the skin from subsequent sun exposure.[16]

The World Health Organization, the American Medical Association, and the American Academy of Dermatology all support legislation to ban the use of artificial tanning devices by people younger than 18 years. In a review, the International Agency for Research on Cancer concluded that young adults should be discouraged from using indoor tanning equipment and that restricted access to tanning beds and sunlamps by minors should be strongly considered.[16] Currently, more than 60% of US states regulate tanning facilities for minors, and regulatory efforts are increasing.[31] Legislative efforts focus on age limitations and written-consent processes. The tanning industry has fought vigorously to allow teenagers access to tanning salons.[32,33]

Artificial "sunless" tanning with spray products in salons or with self-applied products has been advocated by some organizations as an alternative to tanning through exposure to natural or artificial UVR. A survey of young adults 18 to 24 years of age in the United States revealed that 22% had used sunless tanners in the previous 12 months, and another 22% who had not used these products would consider doing so in the next 12 months.[34] Because most sunless tanners do not afford any significant ultraviolet protection, consumers must be advised that sunburn and sun damage may occur unless they use sunscreen and other sun-protection methods. Consumers must also be warned that sunless tanning products that contain added sunscreen provide UVR protection for a few hours after application but that additional protection from the sun must be used during the duration of the artificial tan.

PREVENTION

Leading organizations have recommended a comprehensive set of sun-safe behaviors.[35–37]

UVR-protective messages include the following:

1. Do not burn; avoid suntanning and tanning beds.
2. Wear protective clothing and hats.
3. Seek shade.
4. Use extra caution near water, snow, and sand.
5. Apply sunscreen.
6. Wear sunglasses.

Clothing can be an excellent UVR barrier. In contrast to sunscreen, the photoprotection afforded by clothing does

not diminish throughout the day unless the clothing becomes wet. Clothes that cover more of the body provide more protection; sun-protective styles cover to the neck, elbows, and knees. Wool and synthetic materials, thickly woven fabrics, darker colors, and tightly woven fabrics with chemical enhancement have higher protective values than do corresponding counterparts.[38] The ultraviolet protection factor (UPF) is a system used to rate a fabric's ability to block UVR from passing through the fabric and reaching the skin. The UPF value can be from 15 to ≥50 and is classified as follows: 15 to 24 is rated as "good" UV protection; 25 to 39 is rated as "very good"; and 40 to ≥50 is rated as "excellent."

Seeking shade is somewhat useful, but people can still sunburn, because light is scattered and reflected. A fair-skinned person sitting under a tree can burn in less than an hour. Clouds decrease UVR intensity but not to the same extent that they decrease heat intensity and, thus, may promote a misperception of protection.[39]

Sunscreen is the main form of protection used by the population.[40–43] Sunscreens reduce the intensity of UVR affecting the epidermis, thus preventing erythema and sunburn. Many sunscreen agents approved by the US Food and Drug Administration are organic chemicals that absorb various wavelengths of UVR, primarily in the UVB range; many are also effective in the UVA range.[44] Some agents are not photostable in the UVA range and degrade with sun exposure, so combinations of chemicals are used to enhance protective effects.[45] The 2 inorganic physical sunscreens approved by the US Food and Drug Administration are zinc oxide and titanium dioxide. These sunscreens prevent penetration of skin by UVB and UVA. Infrequently, topical sunscreen agents (especially chemical screening agents) can have adverse effects, including erythema, itching, burning, or stinging. Allergic contact dermatitis and photoallergic and phototoxic reactions occur rarely.[44]

SPF is a grading system that was developed to quantify the degree of protection from erythema provided by using a sunscreen; the higher the SPF, the greater the protection. For example, a person who would normally experience sunburn in 10 minutes can be protected for approximately 150 minutes (10 × 15) with an SPF-15 sunscreen. SPF pertains only to UVB. Sunscreens do not completely block UVB; for example, an SPF-15 sunscreen will allow approximately one-fifteenth or 6% of UVB photons to penetrate the skin.

In actual use, SPF often is substantially lower than expected because the amount applied to the skin is less than that recommended (2 mg/cm^2).[45] To adequately cover all sun-exposed areas of an average adult wearing a bathing suit, 1 oz (30 mL) of sunscreen would be needed. It is recommended that sunscreen with an SPF of at least 15 be applied liberally 15 to 30 minutes before sun exposure to allow for absorption into the skin and to decrease the likelihood that the sunscreen will be washed off. Furthermore, it is recommended that sunscreens be reapplied every 2 hours and after swimming, sweating, or drying off with a towel.[44] Sunscreen products with a higher SPF provide somewhat greater protection. Products with a higher SPF have been recommended for some people including those who have had skin cancer.[46] For most users, however, proper application and reapplication are more important factors than using a product with a higher SPF.

The regular use of a broad-spectrum sunscreen preparation can prevent solar (actinic) keratoses, which are precursor lesions of SCC.[47,48] One randomized clinical trial revealed that sunscreen also decreases the risk of developing SCC.[49] However, some research has shown that sunscreen users have a higher risk of melanoma and BCC and have more nevi.[50] These observations have led to concerns that people who use sunscreens spend more time in the sun.[51] Two meta-analyses, however, demonstrated that after controlling for skin type and exposure, sunscreen users do not have a higher risk of melanoma.[52,53] No studies have demonstrated that sunscreen use prevents melanoma or BCC. Sunscreen continues to be recommended by the American Academy of Dermatology[54] and many other organizations as part of a total program of protection from the sun.

Sunscreens may be systemically absorbed. In urine samples of a representative sample of the US population older than 6 years, oxybenzone, a commonly used sunscreen agent, was detected in 97% of the samples,[55] which suggests widespread exposure. Concerns have been raised about estrogenic and other systemic effects of oxybenzone and other sunscreen ingredients.[56–58] Sunscreen ingredients have been found in human milk.[59] Because of recent data on bioaccumulation in humans and wildlife, researchers have called for an in-depth analysis of the systemic toxicology of sunscreen ingredients.[57]

Permeability of skin to topically applied products, including sunscreen products, is of concern for young infants, especially preterm infants.[60] The development of the stratum corneum, the part of the epidermis that forms the skin barrier, may not be complete until the first few years of life.[61,62] Issues have arisen regarding the possible increased risk of penetration of ultramicronized physical agents such as zinc oxide and titanium dioxide, which, when micronized, are essentially nano-

particles. To date, no data show toxicity from absorption of sunscreen ingredients in infants and young children. Sunscreen use is advised when other effective means of photoprotection (avoidance, clothing) are not possible. Sunscreen may be used on infants younger than 6 months on small areas of skin if adequate clothing and shade are not available.[63] The known benefits of using sunscreen products for preventing sunburn and SCC, versus the concerns, should be discussed with parents, especially parents of young children.

Sunglasses protect against sun glare and harmful radiation. The latest US standard for sunglasses is voluntary and is not followed by all manufacturers.[64] Major US visual health organizations recommend that sunglasses that absorb 97% or more[65] or 99% or more[20] of the full UVR spectrum be worn. Expensive sunglasses do not necessarily provide better UVR protection; purchasing sunglasses that meet standards for a safe level of UVR should be the goal.

Standard clear window glass absorbs UVB but not UVA wavelengths.[64] Transmission of UVR through automobile glass depends on the type and the tint of the glass.

The UV index predicts the intensity of ultraviolet light for the following day,[66] which allows for the planning of activities. The index is available online for thousands of cities at www.weather.com and through local news media.

VITAMIN D

Sun exposure and vitamin D concentrations are intertwined. Humans get vitamin D from exposure to sun, dietary sources, and vitamin supplements. Vitamin D is essential for normal growth and skeletal development.[67] 25-Hydroxyvitamin D (25[OH]D) concentrations are used to assess vitamin D status; at concentrations of less than 50 nmol/L (20 ng/mL), children are at increased risk of rickets.[68] Relationships between 25(OH)D status and markers of functional outcomes in children vary according to age, race, environment, and genetic predisposition.[68–70] Children at higher risk of low 25(OH)D concentrations include breastfed infants, obese children, children with dark skin pigmentation, and children with many other conditions.[67,71,72] The benefits of vitamin D sufficiency in adults include improved bone health, prevention of fractures, better muscle health, and reduced risk of falling in older people. The nonskeletal actions and health benefits of vitamin D are becoming increasingly understood.[67,73,74] Areas of investigation include the relationship of vitamin D concentrations to risks of cancer, heart disease, multiple sclerosis, and glucose dysregulation.[72] Of particular note is that low vitamin D concentration in prenatal or childhood periods may increase the risk of type 1 diabetes mellitus.[75,76]

Hypovitaminosis D is common among US children.[77,78] Approximately 30% of US teenagers and young adults have 25(OH)D deficiency (ie, 25[OH]D $<$ 50 nmol/L).[79] For younger US children, the prevalence of 25(OH)D deficiency is somewhat less ($\sim$15% for children 6–11 years of age and $\sim$8% for children 1–5 years of age).[79]

Vitamin D concentrations increase with sun exposure. Vitamin D synthesis depends on factors including age, skin pigmentation, amount of skin exposed, time of year, and time of day. It has been stated that at least 20% of the body surface needs to be exposed to UVB for vitamin D concentrations to increase.[67] At latitudes above 35°N and below 35°S, cutaneous vitamin D production is negligible in winter months. One author has called for "sensible sun exposure" (ie, exposure of arms and legs for 5–30 minutes, depending on the time of day, season, latitude and skin pigmentation, between 10 AM and 3 PM twice weekly) to maintain vitamin D concentrations and avoid deficiency.[73,80] In contrast, the American Academy of Dermatology has stated that most people obtain enough vitamin D through incidental exposure during daily activities and that maximum production of vitamin D occurs after only brief exposure to UVR; this amount of time is 2 to 5 minutes of midday exposure for a light-skinned person living in New York, NY, or Boston, MA. Although they agree that vitamin D is important for good health, leaders in skin cancer prevention oppose intentional sun exposure to induce vitamin D production, because UVR is a known human carcinogen.[81,82] There have been no studies of children suggesting a level of sun exposure that would negate the need to comply with dietary vitamin D recommendations. Given the high prevalence of hypovitaminosis D, it seems clear that renewed attention must be paid to evaluating the adequacy of dietary and supplemental vitamin D intake and how much, if any, unprotected sun exposure is beneficial. The American Academy of Pediatrics recommends vitamin D supplementation of 400 IU (10 μg) per day for all breastfed infants and nonbreastfed infants, children, and adolescents who receive less than 400 IU of vitamin D daily in their diets.[71] Most children in the United States receive less than 400 IU of vitamin D daily.[83] Because most vitamin D is endogenously produced after sun exposure, even this degree of supplementation may be insufficient. In young white adults, the supplemental dose of vitamin D required over the winter months at or above 51° latitude for 97.5% of the sample to maintain a 25(OH)D concentration of more than 50 nmol/L was 1120 IU of vitamin D per day and was 1644 IU of vitamin D per day to maintain a 25(OH)D concentration of more than 80 nmol/L.[84] An updated report on

vitamin D from the Institute of Medicine was released in November 2010.[85]

THE PEDIATRICIAN'S ROLE

The US Preventive Services Task Force determined that clinician counseling may have an effect on parents' use of sunscreen for their children but not for using other sun-protection measures.[86] The task force noted that only limited data exist about potential harm of counseling or of specific skin-protection behaviors. Harm includes the possibility that skin cancer counseling that focuses on sunscreen use may result in a false sense of security and more time spent in the sun because users do not sunburn.[51]

The US Preventive Services Task Force concluded that evidence is insufficient to recommend for or against routine screening for skin cancer in adults by using a total-body skin examination for the early detection of cutaneous melanoma, BCC, or SCC.[87] Early detection, however, is recommended by skin cancer authorities as a measure to increase survival rates.[88] Because most melanomas occur in adults, no official recommendations for early detection have been made for children and adolescents. Because melanoma occurs in teenagers and is a common cancer among young adults, it seems prudent to recommend that clinicians caring for these groups include a skin examination as part of a complete physical examination.

PREVENTION PROGRAMS

The Centers for Disease Control and Prevention has published guidelines to protect schoolchildren from excessive sun exposure in schools.[36] Efforts to teach children how to protect themselves from UVR are effective when implemented in primary schools and in recreational settings.[89] The SunWise program, developed by the US Environmental Protection Agency, is a brief, standardized sun-protection education program for use in schools.[90] SunWise has been shown to promote improvement in knowledge, intentions to play in the shade and to use sunscreen, and attitudes regarding healthiness of a tan[91]; SunWise also is cost-effective.[92]

Multicomponent, community-wide approaches have been recommended by health education experts[93] and can be effective. A randomized controlled trial of the SunSafe project, an intervention in New England, involved schools, child care settings, primary care offices, and beach settings. SunSafe was effective in changing sun-protection practices observed at community beaches in children 2 to 10 years of age.[94,95] In adolescence, when sun protection begins to decline, a multicomponent program slowed the deterioration of teenagers' sun-safety practices.[96]

PUBLIC HEALTH CAMPAIGNS

Australia, the country with the highest incidence of skin cancer in the world, has been in the forefront of the public health response to this disease. SunSmart, a population-based skin cancer–prevention program deployed in Australia since 1988, incorporates substantial public education efforts as well as structural and environmental change strategies in schools, workplaces, local government, and pools. Sun protection and sunburn showed substantial general improvement over time but have stalled in recent years.[97] Challenges to effective skin cancer–prevention campaigns include (1) the possible conflict between sun-protection messages to avoid or limit time outdoors during peak sun hours and health-promotion messages to promote physical activity; (2) uncertainty about how much sun exposure is needed for adequate vitamin D synthesis, which possibly results in deliberate and excessive UVR exposure; (3) the finding that skin cancer risk behaviors cluster with other risky behaviors such as smoking and risky drinking; and (4) the benefits of the tanning industry from selling carcinogenic UVR.[98] These challenges suggest that it is uncertain whether primary prevention efforts to reduce skin cancer through UVR protection will be successful.

RECOMMENDATIONS FOR PEDIATRICIANS

1. Pediatricians should incorporate advice about UVR exposure into health-supervision practices. Advice includes avoiding sunburning and suntanning, wearing clothing and hats with brims, and applying sunscreen. When feasible, outdoor activities should be planned to limit exposure to peak-intensity midday sun (10 AM to 4 PM). Sunglasses should be worn when working, driving, participating in sports, taking a walk, running errands, or doing anything in the sun.[21]
2. Sunscreen should be used when a child or adolescent might sunburn. Sunscreen with an SPF of 15 or higher should be applied every 2 hours and after swimming, sweating, or drying off with a towel. People may wish to avoid using sunscreens that contain oxybenzone, which may have weak estrogenic effects when absorbed through the skin. However, using sunscreen is recommended to decrease the known risks of sun exposure and sunburning, both of which raise the risk of developing skin cancer.
3. Advice about UVR exposure is important for all children and especially for children at high risk of developing skin cancer: children with light skin, those with nevi

and/or freckling, and those with a family history of melanoma.

4. Skin cancer prevention is a lifelong effort. Although time is at a premium for most pediatricians, an important aim is to incorporate UVR exposure advice into at least 1 health-maintenance visit per year, beginning in infancy. Not all children sunburn, but all are at risk of adverse effects of UVR exposure on the eyes and immune system. In northern states, advice can be given in the spring and summer. Advice can also be given before anticipated sunny vacations. "Teachable moments" may be found during visits for sunburns.
5. Outdoor physical activity should be strongly encouraged; messages should be framed in the context of promoting outdoor physical activity in a sun-safe manner.
6. Sun-protection practices tend to wane in early childhood. In later childhood, it may be advisable for pediatricians to discuss sun protection with children and parents together beginning at 9 or 10 years of age, thus encouraging joint responsibility for ensuring that the child is protected.
7. Infants require special advice. Infants younger than 6 months of age should be kept out of direct sunlight and covered with appropriate protective clothing and hats. Parents may apply sunscreen when sun avoidance is impossible and, then, only on exposed areas. Preterm infants, because of a thinner stratum corneum, may have a higher susceptibility to the absorption of sunscreen ingredients.
8. Pediatricians should gain familiarity with chemical photosensitizing agents.[99] People who take medications or use topical agents known to be sensitizing should do their best to limit sun exposure and avoid all UVA from artificial sources. They should wear fully protective clothing and apply sunscreen with a high SPF that also blocks UVA wavelengths when sun exposure is inevitable.
9. Guidelines regarding vitamin D supplementation for breastfed and formula-fed infants and other children should be followed. All infants, children, and adolescents should receive at least 400 IU of vitamin D daily. If a child is at risk of hypovitaminosis D because of low intake or other factors, laboratory evaluations of the adequacy of his or her 25(OH)D concentration should be considered.
10. Deliberate UVR exposure to artificial sources and overexposure to sun with the goal of increasing vitamin D concentrations, or for other reasons, is to be avoided. UVR exposure raises skin cancer risk. Guidance should be given about vitamin D adequacy obtained through the diet and supplements.
11. When feasible, pediatricians should advocate for adoption of sun-protective policies such as shaded playgrounds, outdoor time before 10 AM, and allowing hats at schools and child care facilities.
12. Pediatricians should support and advocate for legislation to ban access to tanning parlors for children younger than 18 years.

RECOMMENDATIONS FOR GOVERNMENT

1. Federal, state, and local governments should mount campaigns to raise awareness about the dangers of exposure to artificial sources of UVR and overexposure to sun. These campaigns should include messages directed at children, adolescents, and parents.
2. Federal, state, and local governments and local school districts should support and disseminate successful programs such as the Environmental Protection Agency's SunWise program.
3. Federal, state, and local governments should work toward passing legislation to ban minors' access to tanning salons. Governments should work to ensure that such legislation is enforced.

abstract

FREE

Sunlight sustains life on earth. Sunlight is essential for vitamin D synthesis in the skin. The sun's ultraviolet rays can be hazardous, however, because excessive exposure causes skin cancer and other adverse health effects. Skin cancer is a major public health problem; more than 2 million new cases are diagnosed in the United States each year. Ultraviolet radiation (UVR) causes the 3 major forms of skin cancer: basal cell carcinoma; squamous cell carcinoma; and cutaneous malignant melanoma. Exposure to UVR from sunlight and artificial sources early in life elevates the risk of developing skin cancer. Approximately 25% of sun exposure occurs before 18 years of age. The risk of skin cancer is increased when people overexpose themselves to sun and intentionally expose themselves to artificial sources of UVR. Public awareness of the risk is not optimal, compliance with sun protection is inconsistent, and skin-cancer rates continue to rise in all age groups including the younger population. People continue to sunburn, and teenagers and adults are frequent visitors to tanning parlors. Sun exposure and vitamin D status are intertwined. Adequate vitamin D is needed for bone health in children and adults. In addition, there is accumulating information suggesting a beneficial influence of vitamin D on various health conditions. Cutaneous vitamin D production requires sunlight, and many factors complicate the efficiency of vitamin D production that results from sunlight exposure. Ensuring vitamin D adequacy while promoting sun-protection strategies, therefore, requires renewed attention to evaluating the adequacy of dietary and supplemental vitamin D. Daily intake of 400 IU of vitamin D will prevent vitamin D deficiency rickets in infants. The vitamin D supplementation amounts necessary to support optimal health in older children and adolescents are less clear. This report updates information on the relationship of sun exposure to skin cancer and other adverse health effects, the relationship of exposure to artificial sources of UVR and skin cancer, sun-protection methods, vitamin D, community skin-cancer–prevention efforts, and the pediatrician's role in preventing skin cancer. In addition to pediatricians' efforts, a sustained public health effort is needed to change attitudes and behaviors regarding UVR exposure. *Pediatrics* 2011;127:e791–e817

BACKGROUND

Sunlight sustains life on earth. The sun provides warmth, is needed for photosynthesis, drives biorhythms, and promotes feelings of well-being, and sunlight is essential for vitamin D synthesis in skin.

The sun emits electromagnetic radiation that ranges from short-wavelength, high-energy x-rays to long-wavelength, lower-energy radio waves. Ultraviolet ("above-violet") radiation (UVR) waves range from 200 to 400 nm. UVR waves are longer than x-rays and shorter than visible light (400–700 nm) and infrared ("below-red" or "heat") radiation (>700 nm). UVR is subdivided into UVC (200–290 nm), UVB (290–320 nm), and UVA (320–400 nm, further subdivided into UVA2 [320–340 nm]) and UVA1[340–400 nm]). UVC rays possess the highest energy but do not penetrate the atmosphere. Thus, middle-wavelength (UVB) and long-wavelength (UVA) UVR, visible light, and infrared radiation have the greatest biological significance.

Solar radiation that reaches the earth's surface constitutes approximately 95% UVA and 5% UVB.[1] Most UVB radiation is absorbed by stratospheric ozone, but ozone absorbs little or no UVA or visible light. The ozone layer does not have uniform thickness; ozone concentration tends to increase toward the poles but is thinning in some areas.[2] Ozone depletion has a significant effect on the amount of UVB that reaches the earth.[2] Chlorofluorocarbons used as aerosol propellants and in refrigeration and air conditioning can destroy ozone.

UVR that passes through the stratosphere (10–50 km above sea level) is scattered by molecules such as oxygen and nitrogen. It then passes through the troposphere (0–10 km above sea level), where it is absorbed and scattered by pollutants, such as soot, and attenuated by clouds. Clouds reduce the intensity of UVR but not to the same extent that infrared intensity is reduced; the sensation of heat is diminished, which results in the potential for overexposure.

The intensity of UVB radiation varies; it has greater intensity in summer than in winter, at midday than in morning or late afternoon, in places closer to the equator, and at higher altitudes. Sand, snow, concrete, and water can reflect up to 85% of sunlight, thus intensifying exposure.[3] Water is not a good photoprotectant, because UVR can penetrate to a depth of 60 cm, which results in a significant exposure. In contrast to the variability of UVB radiation, UVA radiation is relatively constant throughout the day and the year.

UVR can be produced by man-made lamps (eg, sunlamps) and tools (eg, welding tools), but the sun is the primary source of UVR for most people.[4] UVR has been used for decades to treat skin diseases, especially psoriasis.[1]

UVR EFFECTS ON THE SKIN

The skin is the organ most exposed to environmental UVR and to associated sequelae. Exposure to UVR may result in erythema and sunburn, tanning, skin aging, photosensitivity, and carcinogenesis (nonmelanoma skin cancer [NMSC] and cutaneous malignant melanoma).

Erythema and Sunburn

Erythema and sunburn are acute reactions to excessive amounts of UVR. Exposure to solar radiation causes vasodilatation and increases the volume of blood in the dermis, which results in erythema. The minimal erythema (or erythemal) dose (the amount of UVR exposure that will cause minimal erythema or slight pinkness of the skin) depends on factors such as (1) skin type, (2) skin thickness, (3) the amount of melanin in the epidermis, (4) melanin production after sun exposure, and (5) the intensity of the radiation. A classification system of 6 skin types ranging from light to dark (Table 1) takes into account a person's expected sunburn and suntan tendency.[5]

The ability of UVR to produce erythema depends on the radiation wavelength expressed as the erythema "action spectrum" (the rate of a physiologic activity plotted against wavelength of light showing which wavelength of light is most effectively used in a specific chemical reaction). The action spectrum for erythema and sunburn is mainly in the UVB range.[6]

TABLE 1 Classification of Sun-Reactive Skin Types[5]

Skin Type	History of Sunburning or Tanning
I	Always burns easily, never tans
II	Always burns easily, tans minimally
III	Burns moderately, tans gradually and uniformly (light brown)
IV	Burns minimally, always tans well (moderate brown)
V	Rarely burns, tans profusely (dark brown)
VI	Never burns, deeply pigmented (black)

Tanning

Tanning is a protective response to sun exposure.[7] Immediate tanning (or immediate pigment-darkening) results from oxidation of existing melanin after exposure to visible light and UVA. Immediate pigment-darkening becomes visible within several minutes and usually fades within 1 to 2 hours. Delayed tanning occurs when new melanin is formed after UVB exposure. Delayed tanning becomes apparent 2 to 3 days after exposure, peaks at 7 to 10 days, and may persist for weeks or months. According to recent evidence, the tanning response means that DNA damage has occurred in skin.[8]

Skin-Aging (Photoaging)

Chronic unprotected exposure to UVR weakens the skin's elasticity and results in sagging cheeks, deeper facial wrinkles, and skin discoloration. Photoaged skin is characterized by alterations of cellular components and of the extracellular matrix. There is accumulation of disorganized elastin and of fibrillin (its microfibrillar component in the deep dermis) and a severe loss of interstitial collagens, the major

structural proteins of the dermal connective tissue. These changes result primarily from exposure to UVR-generated reactive oxygen species that deplete and damage the skin's enzymatic and nonenzymatic antioxidant defense systems.[9,10]

Photosensitivity

Chemical photosensitivity refers to an adverse cutaneous reaction that results when certain chemicals or drugs are applied topically or taken systemically at the same time that a person is exposed to UVR or visible radiation. Phototoxicity is a form of chemical photosensitivity that does not depend on an immunologic response; the reaction can occur on first exposure to an agent. Most phototoxic agents are activated in the range of 320 to 400 nm (the UVA range). Drugs associated with phototoxic reactions include those commonly used by adolescents, such as nonsteroidal anti-inflammatory agents; tetracyclines and tretinoin; other medications such as phenothiazines, psoralens, sulfonamides, and thiazides; and para amino benzoic acid (PABA) esters.[11] Photoallergy is an acquired altered reactivity of the skin, usually triggered by exposure to UVA, that depends on antigen-antibody or cell-mediated hypersensitivity. Photoallergic reactions involve an immunologic response to a chemical or drug that is altered by UVR. PABA-containing sunscreens, fragrances, sulfonamides, and phenothiazines are associated with photoallergic reactions.[11] The consequences of exposure to a photosensitizing agent can be uncomfortable, serious, or life-threatening. People who take medications or use topical agents known to be sensitizing should do their best to limit sun exposure and avoid UVA from artificial sources. They should wear fully protective clothing and apply sunscreen with a high sun-protection factor (SPF) when some light exposure is inevitable.[12]

Plants that contain furocoumarins may lead to phototoxic reactions or phytophotodermatitis. These commonly encountered plants include anise, diseased celery, dill, fennel, fig, lemon, lime, mustard, parsnip, parsley, and chrysanthemums. Phytophotodermatitis can occur through ingestion of plants or, more commonly, through topical contact.[13]

Up to 80% of patients with lupus erythematosus have photosensitivity. The threshold UVR dose that triggers cutaneous or systemic reactions is much lower than that for sunburn. Many patients are not aware of the association of flares with UVR exposure, because the latency period between exposure and skin eruptions can range from several days to 3 weeks.[14]

Carcinogenesis

Nonmelanoma Skin Cancer

NMSC includes basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). In the US adult population, NMSC is the most common malignant neoplasm, with more than 2 million cases diagnosed each year. Most of these are BCC, SCC occurs less often.[15] The rate of NMSC has been increasing in the United States, but the exact number is not precisely known, because physicians are not required to report NMSC to cancer registries. NMSC is rarely fatal; nevertheless, it is estimated that each year, approximately 2000 people die of NMSC.[15]

In general, NMSC occurs in maximally sun-exposed areas of fair-skinned people. NMSC is uncommon in black people and people with increased natural pigmentation. The head and neck region is the most common site for BCC and SCC; 80% to 90% of cases occur in this area in the general population. NMSC is more common in people older than 50 years, and the incidence in this age group is increasing rapidly.[16–18] People with immune suppression, including organ transplant recipients, also are at higher risk. Genetically based conditions, such as basal cell nevus syndrome, xeroderma pigmentosum (a condition in which there is a genetically determined defect in the repair of DNA damaged by UVR),[19] and albinism, are risk factors for the accelerated development of NMSC. Treatment with UVR for psoriasis also increases risk.[19] NMSC is extremely rare in children in the absence of predisposing conditions.[20]

The incidence of NMSC is increasing in young adults. Researchers examined the gender- and age-specific incidence of BCC and SCC in a young (<40-year-old), primarily white and middle-class population within Olmsted County, Minnesota, by using comprehensive medical records available through the Rochester (MN) Epidemiology Project.[21] Over the period of 1976–2003, the incidence of BCC increased significantly among young women, and the incidence of SCC increased significantly among both men and women.

A trend toward a greater number of BCC cases occurring on the torso in younger patients has been reported.[21–23] This change in location supports the possibility that excessive outdoor tanning, use of tanning booths, or both give rise to BCC. Tanning-bed use has been shown to be a risk factor for NMSC in young women.[24]

Sun exposure is the main environmental cause of NMSC. Cumulative exposure over long periods, which results in photodamage, is considered important in the pathogenesis of SCC.

Melanoma

Melanoma is primarily a disease of the skin. Primary extracutaneous sites include the eye, mucous membranes,

gastrointestinal tract, genitourinary tract, leptomeninges, and lymph nodes. Ninety-five percent of melanomas occur in the skin.[25] If detected when the tumor is thin and small, cutaneous malignant melanoma has an excellent prognosis. However, metastatic melanoma has no successful treatment options. Prevention and early detection, therefore, are crucial in this disease.

Many authorities have stated that the incidence of cutaneous malignant melanoma (hereafter referred to as "melanoma") has reached epidemic proportions. Possible factors contributing to the increased incidence of melanoma include the decrease in the earth's protective ozone layer, changing patterns of dress that favor more skin exposure, more opportunities for leisure activities in sunny areas, and increased exposure to artificial sources of UVR for tanning purposes.

In the United States, melanoma is the fifth most common cancer in men and the sixth most common in women.[26] The incidence of melanoma is increasing rapidly in the United States.[27] In 1935, the lifetime risk for a person in the United States developing invasive melanoma was 1 in 1500. In 2007, this risk was 1 in 63 for invasive melanomas and 1 in 33 when in situ melanomas were included. Worldwide, melanoma is increasing faster than any other malignancy.[28] Melanoma represents fewer than 5% of all skin cancers but is the cause of almost all skin-cancer deaths. The American Cancer Society predicted that approximately 68 130 new melanoma cases would be diagnosed in 2010, with 8700 deaths.[29]

Melanoma is more likely to occur in males and at older ages but also occurs in teenagers and young adults. It is the second most common cancer of women in their 20s and the third most common cancer of men in their 20s.[30] Melanoma incidence is increasing in young women aged 15 to 39 years.[31] People at highest risk have light skin and eyes and sunburn easily. Risk of developing melanoma is increased at older ages, in people who have already had melanoma, or in people who have had a first-degree relative with melanoma. Melanomas frequently are found in people with xeroderma pigmentosum and related disorders. In a large case-control study from the Netherlands, the risk of developing melanoma was increased in women who had used estrogens (either as oral contraceptives or hormone-replacement therapy) for more than half a year.[32]

Melanoma is rare in children, but it does occur. Studies have documented an increase in the incidence in children and adolescents, even in the absence of predisposing conditions such as xeroderma pigmentosum. From 1973 to 2001, the incidence of melanoma in US children younger than 20 years increased 2.9% annually.[33] An increase in incidence was noted in Sweden during 1973–1992,[34] but incidence then decreased.[35] Ferrari et al[36] reviewed a 25-year experience with 33 Italian children with melanoma who were 14 years or younger at presentation. The children's lesions were not typical of melanoma lesions in adults. Melanoma lesions in adults generally follow the "ABCDEs": they are asymmetric (A), have irregular borders (B), variegated color (C), and diameter (D) larger than 6 mm (the size of a pencil eraser), and change or evolve (E).[37] In the Ferrari et al[36] series, however, many lesions in children were amelanotic (pink, pink-white, or red) and tended to be raised and to have regular borders. The key to diagnosis for these children was the recognition that the melanoma lesions were unlike any other lesions on the child.

EVIDENCE THAT UVR CAUSES SKIN CANCER

In 1992, the International Agency for Research on Cancer (IARC) reviewed the evidence for the carcinogenicity of solar radiation. They concluded that "[t]here is sufficient evidence in humans for the carcinogenicity of solar radiation. Solar radiation causes cutaneous malignant melanoma and non-melanocytic skin cancer.[1]" Since that time, evidence has strengthened the link between sunlight exposure and skin cancer.

Cellular Studies

UVB is absorbed by and can directly damage DNA, which ultimately leads to the development of skin cancer.[38] The genotoxic effects of solar UVB radiation are mainly mediated by direct absorption in the epidermis of photons by DNA, which results primarily in cyclobutane pyrimidine dimers (formed between adjacent pyrimidine bases located on the same DNA strand) and pyrimidine (6-4) pyrimidone photoproducts.[7] Incorrect repair of these lesions results in the formation of mutations in epidermal cells, which causes the development of cancer.[7,39]

UVA penetrates more deeply into the skin than does UVB, including reaching the basal layer of the epidermis and dermal fibroblasts.[38] UVA causes oxidative damage to DNA that is potentially mutagenic.[7]

Biological Evidence

Biological evidence suggests that sunlight exposure is important in the pathogenesis of melanoma. Results of studies in opossums suggest that portions of the UVA spectrum may play a role in the pathogenesis of melanoma[40] and that portions of the UVA and UVB spectrums promote development of carcinomas in mice.[41] Melanoma can be induced by UVB and UVA radiation in certain fish.[42] Research ethics make it

impossible to determine directly which wavelengths result in skin cancer in humans.

Melanoma has been induced in human newborn foreskins grafted onto immunologically tolerant animals exposed to UVR.[43] Melanomas and NMSC are often found in people with xeroderma pigmentosum and related disorders.[44]

Epidemiologic Evidence

Latitude or Estimated Ambient Solar UVR

The rates of BCC and SCC increase with increasing ambient solar UVR. There is a direct relationship between the incidence of NMSC and latitude; higher rates are found closer to the equator (where the amount of sunlight is greater).[28] The relationship of melanoma with latitude is not as clear as that for NMSC.[28]

Race and Pigmentation

BCC and SCC occur primarily in white people.[15] Incidence and mortality rates of melanoma are highest in white people (Table 2).[27] There is, in general, an inverse relationship between skin-cancer incidence and the skin pigmentation of people in various countries in the world. Superficial epidermal melanin decreases the transmission of UVR, which may protect the deeper basal layer melanocytes and several layers of keratinocytes from sunlight-induced changes that lead to their malignant transformation.[7]

Melanin, a dark pigment produced by melanocytes, accounts for most of the variation in human skin appearance. Melanin that is genetically determined is termed "constitutive" melanin pigmentation. When this basic pigmentation is increased by exposure to UVR, it is termed "inducible" or "facultative" melanin pigmentation. Melanin is thought to have evolved as an optical and chemical photoprotective filter that functions as a natural "sunscreen" to regulate UVR penetration into skin. In early human evolution, the more highly melanized skins of people indigenous to the tropics afforded better protection against the deleterious effects of UVR. A dark epidermis protected sweat glands from UVR-induced injury and ensured the integrity of somatic thermoregulation. Highly melanized skin also protected against UVR-induced photolysis of folate, a metabolite essential for normal development of the embryonic neural tube.[45] As people migrated outside the tropics to northern areas, a lighter skin color was needed as an adaptation to promote maintenance of UVR-induced synthesis of vitamin D_3 in areas of lower UVR exposure.[45] As the pace of human migrations quickened in recent centuries, however, populations have found themselves in UVR-irradiation patterns to which they are poorly adapted. Cultural practices, such as sunbathing and covering up for religious reasons, exacerbate or mitigate the mismatch in degree of melanin protection to UVR exposures.[45]

TABLE 2 Melanoma Incidence and Mortality Rates According to Race/Ethnicity[27]

Race/Ethnicity	Men, Rate per 100 000 Men		Women, Rate per 100 000 Women	
	Incidence	Mortality	Incidence	Mortality
White	28.9	4.4	18.7	2.0
Black	1.1	0.5	1.0	0.4
Asian/Pacific Islander	1.6	0.5	1.3	0.3
American Indian/Alaska Native	3.9	1.6	2.8	0.9
Hispanic	4.6	0.9	4.7	0.6

History of Sun Exposure

The pattern of sun exposure is important in the etiology of BCC, SCC, and melanoma skin cancers. Personal sun exposure is usually characterized by (1) total sun exposure, (2) occupational exposure (which signifies a more chronic exposure), and (3) nonoccupational or recreational exposure (which signifies intermittent exposure).[46] SCC is significantly associated with estimated total sun exposure and with occupational exposure. Chronic exposure to UVB is now considered the main environmental cause of SCC. SCC seems to be most straightforwardly related to the total sun exposure: these tumors occur on skin areas that are most regularly exposed (face, neck, and hands), and the risk rises with the lifelong accumulated dose of UVR.[47] BCC and melanoma are significantly associated with intermittent sun exposure (ie, sunburning or "brutal" exposure), whereas SCC does not show this relationship. Melanoma is more strongly associated with intermittent sun exposures than is BCC.[46]

Childhood Sun Exposure

Childhood and adolescence are often considered to contain "critical periods of vulnerability" when people are especially susceptible to effects of toxic exposures. Approximately 25% of lifetime sun exposure occurs before 18 years of age.[48] Sun exposure and blistering sunburns during youth may be more intense than later in life because of youths' behavior. Exposure may result in alteration of melanocyte DNA and an increase in the risk of malignant degeneration in nevi as children age.

Sunlight exposure during childhood and adolescence is generally considered to confer increased risk of melanoma compared with exposure at older ages. This issue was reviewed in an analysis of epidemiologic studies categorized into 2 groups.[49] The first

group contained 20 ecologic studies (ie, studies in which the unit of observation is the population or community) relating the risk of melanoma to places of residence. These studies were conducted on the basis of the fact that ambient solar radiation increases with proximity to the equator and included studies of migrants to locations with markedly different levels of sunlight. The second group consisted of case-control studies in which measures of sun exposure between people with melanoma and those without were compared.

In the first group, most studies revealed that people who migrated from "low" to "high" areas of ambient solar radiation had decreasing melanoma risk with arrival at older ages, whereas those who arrived in childhood (younger than 10 years) or adolescence (younger than 15 years) had similar risks as people who were native-born. The 1 study that investigated age-specific "high-to-low" migration demonstrated higher risk in people born in a sunny area or having had more than 1 year living in a sunny area before 10 years of age.[49] The results of most studies of the age of migration, therefore, supported the "critical-period" hypothesis.

Ten case-control studies that examined melanoma risks associated with personal sun exposure during 2 or more age periods were evaluated in the second group. Findings of these studies differed widely without consistent associations with childhood sun exposure. Three studies reported significantly increased risks of melanoma associated specifically with episodes of sunburns during childhood, whereas 1 Swedish study found no effect of childhood sunburn but reported significantly higher risks associated with adulthood sunburns. The remaining 5 studies reported similar risks of melanoma regardless of whether sunburn occurred during childhood or adulthood. The summary odds ratios associated with sunburn during childhood and adulthood were 1.8 (95% confidence interval: 1.6–2.2) and 1.5 (95% confidence interval: 1.3–1.8), respectively, although there was significant heterogeneity among the studies for the estimates of childhood sunburn. The authors underscored the lack of reliability of recalling personal sun exposure as a reason for the inconsistencies between the migrant and case-control studies and considered the evidence from the migrant studies to be of higher quality.[49] In a large multicenter case-control study, the authors concluded that excessive UVR exposure later in life may be as important a risk for melanoma as UVR exposure earlier in life.[50] There was a similar upward gradient of melanoma risk related to sunburns during childhood (defined as age $\leq$ 15 years) and adulthood (defined as age $>$ 15 years). More than 5 sunburns doubled the melanoma risk irrespective of whether those sunburns occurred in childhood or adulthood.[50]

There is biological plausibility to support the heightened susceptibility of young melanocytes. Peak melanocytic activity occurs in early life as demonstrated by the steady acquisition of nevi during childhood and adolescence. Freckling is also prominent at these ages; freckles in children often appear abruptly after high-dose sun exposure and are thought to represent clones of mutated melanocytes. The presence of freckles is associated with an increased risk of melanoma.[7] Young melanocytes may be especially vulnerable to the adverse effects of solar radiation. Sunlight may have both early and late effects on the development of melanoma (akin to cancer "initiation," "promotion," and "progression"[51]), and the biological effectiveness of sunlight in initiating melanoma is greatest during the period of peak melanocytic activity. Populations exposed to high sunlight levels in childhood will have more people with more initiated melanocytes than populations of those who experienced lower sunlight levels. This "melanoma potential" is retained when people move to a different environment.[49]

Nevi

Acute sun exposure is implicated in the development of nevi (moles) in children. The number of nevi increases with age[52]; nevi occur with more frequency on sun-exposed areas, and the number of nevi on exposed areas increases with the total cumulative sun exposure during childhood and adolescence.[53] Children with light skin who tend to burn rather than tan have more nevi at all ages, and children who have more severe sunburns have more nevi.[52]

There is a relationship between the number and type of melanocytic nevi and the development of melanoma. The presence of congenital melanocytic nevi (CMN) (pigment cell malformations formed during gestation and visible at or shortly after birth) increases melanoma risk. In a review of 14 studies—case series with adequate follow-up periods—investigators found an overall risk of melanoma arising in CMN of 0.7%, which was lower than expected. Melanoma risk strongly depended on the size of the CMN and was highest in nevi designated as garment nevi (defined as nevi situated on the trunk that measure $>$40 cm in largest diameter or expected to reach this size in adulthood). The mean age at melanoma diagnosis (15.5 years) and median age of diagnosis (7 years) underscored the maximum risk in childhood and adolescence.[54]

Dysplastic melanocytic nevi typically are 5 mm or larger in diameter; usually have fuzzy, irregular borders; and

have variegated color. Dysplastic nevi are considered precursor lesions that increase melanoma risk.[55] The familial dysplastic nevus syndrome is a disorder with the following features: (1) a distinctive appearance of abnormal melanocytic nevi; (2) unique histologic features of the nevi; (3) autosomal dominant pattern of inheritance; and (4) hypermutability of fibroblasts and lymphoblasts. Fibroblasts and lymphoblasts from patients with this syndrome are abnormally sensitive to UV damage, and people with this syndrome are at markedly higher risk of developing melanoma.[56] Certain families with germ-line mutations in *CDKN2A*, *CDK4*, and other genes are at increased risk of developing dysplastic nevi and melanoma.[57]

History of Exposure to Artificial UVR

Exposure to tanning beds and sunlamps, which produce primarily UVA, is associated with increased risk of developing BCC, SCC, and melanoma.

UVR EFFECTS ON THE EYE

In adults, more than 99% of UVR is absorbed by the anterior structure of the eye, although some of it reaches the retina.[58] Acute exposure to UVR can result in photokeratitis.[59] Gazing directly into the sun (as can occur during an eclipse) can cause focal burns to the retina (solar retinopathy).[60]

Exposure to solar UVB radiation is associated with an increased risk of cataracts.[61] UVR can contribute to the development of pterygium, corneal degenerative changes, and cancer of the skin around the eye.[58] There is evidence for a probable relationship between UVR exposure and squamous intraepithelial neoplasms of the conjunctiva or cornea, but there is insufficient evidence to determine if there is a relationship between UVR exposure and the development of macular degeneration.[62] Melanoma of the uveal tract, the most common primary intraocular malignant neoplasm in adults, is associated with light skin color, blond hair, and blue eyes. There is contradictory evidence regarding the role of UVR in causing uveal melanoma.[63,64]

UVR EFFECTS ON THE IMMUNE SYSTEM

Exposure to UVR contributes to immunosuppression, which is increasingly recognized as important in the development of skin cancer. UVR exposure is thought to have 2 effects: skin-cancer induction and immune suppression.[65] Experiments in mice chronically exposed to UVR have shown that tumors induced by UVR are highly antigenic and are recognized and rejected by animals with normal immune systems. The tumors grow progressively, however, when transplanted into mice with immune systems that are compromised.[65] UVR exposure induces "systemic" immune suppression so that exposure on 1 body site suppresses the immune response when the antigen is introduced at a distant site that was not irradiated. Soluble factors implicated in systemic immune suppression include platelet-activating factor (PAF), prostaglandin E2 (PGE2), *cis*-urocanic acid, histamine, interleukin 4, interleukin 10, and α-melanocyte-stimulating hormone.[65]

Skin cancers are common in people exposed to immunosuppressive agents, which further illustrates the role of the immune system. In people who have had renal transplants, lifelong immunosuppressive treatment needed for adequate graft function leads to a reduction of immunosurveillance and an increased risk of various cancers. With increased duration of transplantation, skin cancer is now one of the commonest causes of death in renal transplant recipients. Twenty years after transplantation, approximately 40% to 50% of white recipients in Western countries and 70% to 80% of those in Australia will have developed at least 1 NMSC (mostly SCC).[66] People who have had renal transplants also have an increased incidence of melanoma.[67] Because ongoing immunosurveillance has been lacking, skin cancers in people who have received organ transplants are likely to behave aggressively with a higher rate of local recurrence and a greater tendency to be invasive and metastatic.[66]

ARTIFICIAL SOURCES OF UVR

People may be exposed to artificial sources of UVR in several ways, including as treatment for medical conditions (such as psoriasis), in occupational settings (such as welding), and for cosmetic purposes. Sunlamps and tanning beds are the main sources of artificial UVR used for deliberate purposes.[68] Artificial tanning is a relatively new phenomenon that results in potentially large exposures to UVA and UVB. The "tanning industry" has grown quickly; it takes in $5 billion in annual revenue, up from $1 billion in 1992.[69] Each day, more than 1 million people tan in one of 50 000 tanning facilities in the United States.[69] Indoor tanning also is popular in northern Europe and is gaining popularity in Australia.[68]

Artificial tanning is a common practice among teenagers. In a national sample of non-Hispanic white teenagers 13 to 19 years of age in the United States, 24% of respondents—representing 2.9 million teenagers—reported using a tanning facility at least once in their lives.[70] In another national survey, 10% of youth 11 to 18 years of age reported using indoor tanning beds or sunlamps in the previous year.[71] Women and girls represent the majority of people who artificially tan. Of the 1 million people daily who are tanning-salon customers, 70% are females 16 to 49 years of age.[69] Twenty-eight per-

cent of white US teenaged girls interviewed in 1996 had used tanning salons 3 or more times during their lives.[70] Tanning-bed use increases with age, from 7% among 14-year-old girls to 16% among 15-year-old girls and to 35% among 17-year-old girls.[72]

Tanning-bed use by adolescent girls is often associated with other unhealthy behaviors. In 1 study, frequent tanning-bed use was associated with smoking cigarettes, binge-drinking, being highly concerned about weight, and other risk behaviors.[73]

Evidence That Tanning May Be Addictive

Exposure to UVR from sunlight or tanning parlors may be addictive. Beachgoers aged 18 years and older in Galveston, Texas, were interviewed using questions to evaluate dependence on tanning. Subjects completed surveys that included a tanning-specific modification of a screening instrument for alcoholism and questions to evaluate criteria for tanning-specific substance-related disorder. Of 145 subjects, 26 (18%) screened positive on both measures, and 63 (43%) screened positive on 1 measure. The authors concluded that those who chronically and repeatedly expose themselves to UVR to tan may have a type of UVR substance-related disorder.[74] In a study of 14 adults, tanners overwhelmingly preferred UVR-emitting beds when asked to choose blindly between UVR-emitting and non–UVR-emitting tanning beds. A more relaxed and less tense mood was reported after UVR exposure compared with after non-UVR exposure.[75] In another study, the opioid antagonist naloxone was given to 8 frequent salon tanners and 8 people who were infrequent tanners. Withdrawal-like symptoms were induced in 4 of 8 frequent salon tanners; no symptoms occurred in the 8 infrequent tanners. It is conjectured that ultraviolet light exposure results in induction of cutaneous endorphins; thus, endorphin release may play a role in driving UVR-exposure behavior. If cutaneous endorphins are induced, an endorphin blockade would be expected to block the effect.[76] A recent study assessed the prevalence of addiction to indoor tanning among college students and its association with substance use and symptoms of anxiety and depression. Two written measures, the CAGE (cut down, annoyed, guilty, eye-opener) Questionnaire, used to screen for alcoholism, and the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR) criteria for substance-related disorders were modified to evaluate study participants for addiction to indoor tanning. Self-report measures of anxiety, depression, and substance use were administered. Among the 229 study participants who had tanned indoors, 70 (30.6%) met CAGE criteria and 90 (39.3%) met DSM-IV-TR criteria for addiction to indoor tanning. Indoor tanners reported significantly greater symptoms of anxiety and greater use of alcohol, marijuana, and other substances than those who did not meet these criteria. Depressive symptoms did not significantly vary according to indoor-tanning-addiction status.[77]

Effects of Artificial UVR on Human Skin

Tanning beds primarily emit UVA radiation, although a small amount (<5%) is in the UVB range.[68] In terms of biological activity, the intensity of UVA radiation produced by large, powerful tanning units may be 10 to 15 times higher than that of the midday sun. Frequent indoor tanners may receive 1.2 to 4.7 times the annual dose of UVA than is received from the sun, in addition to doses from sun exposure.[68] This intensity of exposure is not found in nature and is a new phenomenon in people.[78]

Artificial UVR exposure has been shown repeatedly to induce erythema and sunburn. Erythema or burning effects were reported by 18% to 55% of users of indoor tanning equipment in Europe and North America.[68] Although UVB is much more potent than UVA in causing sunburn, high fluxes of UVA can cause erythema in people who are sensitive to sunlight. In people who tan easily, exposure to tanning appliances will lead first to immediate pigment-darkening. A more permanent tan will occur with accumulated exposure, depending on individual tanning ability and the amount of UVB present in the light spectrum of the tanning lamps. Immediate pigment-darkening has no photoprotective effect against UVR-induced erythema or sunburn. In addition, the permanent tan induced by UVA and UVA-induced skin-thickening provides little photoprotection.

Other frequently reported effects of artificial tanning include skin dryness, pruritus, nausea, photodrug reactions, disease exacerbation (eg, systemic lupus erythematosus), and disease induction (eg, polymorphous light eruption). Long-term health effects include skin-aging, effects on the eye (eg, cataract formation), and carcinogenesis.

In 1992, the IARC[1] classified the "use of sunlamps and sunbeds" as "probably carcinogenic to humans." In 2000, the National Institutes of Health stated that "exposure to sunlamps or sunbeds is known to be a human carcinogen, based on sufficient evidence of carcinogenicity from studies in humans, which indicate a causal relationship between exposure to sunlamps or sunbeds and human cancer."[79]

A case-control study demonstrated a significant association between using any tanning device and the incidence

of SCC and BCC.[80] A prospective cohort study of 106 379 women in Scandinavia examined melanoma risk in females who reported having used a sunbed or sunlamp. A 55% increase in melanoma risk was found in women who reported having used a tanning device at least once per month in at least 1 of the 3 decades between 10 and 39 years of age, compared with those who had never or rarely used a tanning device during those 3 decades.[81]

In 2006, the IARC published an updated analysis of studies of the carcinogenicity of artificial UVR with regard to melanoma, SCC, and BCC.[68] On the basis of 19 studies, any previous use of sunbeds was positively associated with melanoma (summary relative risk: 1.15 [95% confidence interval: 1.00–1.31]), although there was no consistent evidence of a dose-response relationship. First exposure to sunbeds before 35 years of age significantly increased the risk of melanoma on the basis of 7 studies (summary relative risk: 1.75 [95% confidence interval: 1.35–2.26]). The summary relative risk of 3 studies of SCC showed an increased risk. Studies did not support an association for BCC. The evidence did not support a protective effect of the use of sunbeds against damage to the skin from subsequent sun exposure.

Biological evidence supports the epidemiologic studies. The skin of volunteers exposed to UVA lamps used in tanning appliances showed DNA damage.[68] The IARC concluded that young adults should be discouraged from using indoor tanning equipment and that restricted access to sunbeds by minors should be strongly considered.

Tanning-Industry Response

The tanning industry has fought vigorously to allow teenagers access to tanning salons and promotes the purported health benefits and safety of artificial tanning. The Indoor Tanning Association, an industry group founded in 1999, promotes "a responsible message about moderate tanning and sunburn prevention."[82] Their mission is to "protect the freedom of individuals to acquire a suntan, via natural or artificial light."[83] The Indoor Tanning Association claims that "controlled" salon tanning is safer than "uncontrolled" beach tanning; this concept is not supported by laboratory, behavioral, or epidemiologic data.[78] Another commonly held misconception is that getting a "prevacation tan"—when people visit tanning salons to prepare skin for a sunny vacation—will protect against subsequent skin damage during the vacation. This practice actually leads to extra radiation exposure not only before the vacation but also afterward, because people use fewer sun-protection precautions during the vacation because of a mistaken belief that the tan will protect them.[69] A prevacation tan results in minimal protection (an SPF of 3),[78] which provides virtually no protection against sun-induced DNA damage.[68]

Antitanning Legislation and Recommendations

Because of mounting evidence about the carcinogenicity of artificial UVR, support for regulations to limit teenagers' access to tanning facilities has been widespread. The World Health Organization,[84] the American Medical Association,[85] and the American Academy of Dermatology[86] all support legislation to ban the use of artificial tanning devices by people younger than 18 years. The IARC review concluded that young adults should be discouraged from using indoor tanning equipment and that restricted access to sunbeds by minors should be strongly considered.[68]

France has banned indoor tanning for people younger than 18 years since 1997; indoor tanning for those younger than 18 years also is prohibited in the province of New Brunswick, Canada.[87] Currently (as of February 2011), more than 60% of US states regulate tanning facilities for minors.[88] Some states completely ban salon access to children younger than 14 years, whereas other states ban access to adolescents 15 or 16 years of age. Some states require written parental consent or written consent with the parent present at the facility or a doctor's prescription. In California, where tanning-salon use is banned for children younger than 14 years, recent legislation made annual signed parental consent required for tanning-facility use by adolescents 14 to 17 years of age.[89] During the 2010 legislative session, 20 states introduced bills to regulate tanning facilities for minors.[88,*]

The Indoor Tanning Association has fought against legislative initiatives and stated that legislation will harm business[90] and that tanning is an issue of parental rights: "When it involves a suntan, the State has no business inserting itself between child and parent. This notion that government knows more about child rearing than parents is preposterous."[89] Pediatric health advocates have countered this argument by stating that laws to limit minors' access to tanning parlors should be thought of in the same way as laws that limit youth access to tobacco.[87,89] All states prohibit the purchase of tobacco products by those younger than 18 years; some prohibit tobacco sales to those younger than 19 years.[87] Tanning legislation is often not enforced.[91]

Artificial Tanners (Spray Tans and Sunless Tanning Lotions)

Several organizations have suggested that people who wish to obtain the look of a tanned skin use artificial (or "sunless") tanning products to substitute

*For more information on current state laws that restrict the use of tanning beds by children and teenagers, please contact the AAP Division of State Government Affairs.

for tanning obtained by going outside or at tanning salons. Sunless tanners contain dihydroxyacetone, a chemical that reacts with amino acids in the stratum corneum to form brown-black compounds—melanoidins—that deposit in skin. Dihydroxyacetone is a mutagen that induces DNA strand breaks in certain strains of bacteria; it has not been shown to be carcinogenic in animal studies.[92]

Dihydroxyacetone is the only color additive approved by the US Food and Drug Administration (FDA) for use as a tanning agent.[93] Dihydroxyacetone-containing tanning preparations may be applied to the consumer's bare skin by misters at sunless tanning booths. Bronzers are water-soluble dyes that temporarily stain the skin. Bronzers are easily removed with soap and water.

The prevalence of sunless tanner use in Australia has ranged from 9% to 22%[94]; 28% of women between 18 and 24 years of age reported using sunless tanners.[95] A survey of young adults 18 to 24 years of age in the United States revealed that 22% had used sunless tanners in the previous 12 months, and another 22% who had not used these products would consider doing so in the next 12 months.[94] Sunless-tanning-product users were more likely to be female, to be younger, and to report having sunburned during the previous summer than potential users or nonusers.

Dihydroxyacetone-induced tans become apparent within 1 hour; maximal darkening occurs within 8 to 24 hours. Most users report that color disappears over 5 to 7 days. Because neither dihydroxyacetone nor melanoidins afford any significant UV protection, consumers must be advised that sunburn and sun damage may occur unless they use sunscreen and other sun-protection methods. Consumers must also be warned that any sunless products that contain added sunscreen provide UVR protection only during the first few hours after application and that additional sun protection must be used during the duration of the artificial tan.

PREVENTION

The incidence of skin cancer continues to rise despite public health efforts to increase awareness of sun-safety measures. Children and teenagers continue to sunburn: in 1 large study of more than 10 000 white teenagers 12 to 18 years of age, most respondents (83% [$n = 8355$]) reported sunburning at least once, and 36% of children reported 3 or more burns during the previous summer.[72] Only one-third of respondents reported routine use of sunscreen during the past summer. Sunburning during the summer was reported in a nationwide survey of youth, although many reported using sunscreen before their most serious sunburn.[96] Among adolescents 16 to 18 years of age, the prevalence of sunburn and the average number of days spent at the beach increased between surveys conducted in 1998 and 2004.[97]

It has been estimated that sun avoidance could reduce the number of lifetime NMSC cases by almost 80%.[98] Although other risk factors (eg, precursor lesions, older age, race, previous melanoma, and family history) are more closely associated with melanoma than sunburns, exposure to UVR is the only risk factor that is avoidable. Leading organizations (the American Cancer Society,[99] Centers for Disease Control and Prevention,[100] Healthy People,[101] National Council on Skin Cancer Prevention[102]) have recommended sun-safe behaviors. UVR-protective messages include:

1. Do not burn; avoid suntanning and tanning beds.
2. Wear protective clothing and hats.
3. Seek shade.
4. Use extra caution near water, snow, and sand.
5. Apply sunscreen.
6. Wear sunglasses.

Clothing and Hats

Clothing can be an excellent UVR barrier, because it offers a simple and practical means of sun protection. In contrast to sunscreens, the photoprotection afforded by clothing does not diminish throughout the day unless the clothing becomes wet. Infants and children may be dressed in cool, comfortable clothing and wear hats with brims. One study revealed that wearing clothing decreases the development of nevi.[103] Protective factors in clothing include fabric type, thickness, color, and chemical enhancement.[2] Wool and synthetic materials such as polyester are more protective, whereas cotton, linen, acetate, and rayon are less protective. A tighter weave lets in less sunlight than a looser weave. Darker colors are more protective than lighter ones. Clothes that cover more of the body provide more protection; sun-protective styles cover to the neck, elbows, and knees. Treating fabrics with chemical absorbers or washing them with optical brighteners increases UVR protectiveness.

In 1996, Australia and New Zealand established standards for the UVR protectiveness of clothing. The United States developed standards in 2001. The ultraviolet protection factor (UPF) measures a fabric's ability to block UVR from passing through the fabric and reaching the skin. The UPF is classified from 15 to $\geq$50 as follows: 15 to 24 is rated as "good"; 25 to 39 is rated as "very good"; and 40 to $\geq$50 is rated as "excellent." Although garments with a UPF above 50 may be labeled "UPF 50+," these garments may not offer substantially more protection than those with a UPF of 50. Any garment

with a UPF lower than 15 should not be labeled as "sun protective" or "UV protective."[104] Denim provides a UPF of 1700.[2] Typical summer cotton T-shirts provide a UPF of 5 to 9. The UPF of fabrics can be increased by shrinking and decreased by stretching. If cotton fabrics get wet, the UPF decreases. The US Federal Trade Commission monitors advertising claims about sun-protective clothing.[105]

Hats provide variable sun protection for the head and neck, depending on the brim width, material, and weave. A wide-brimmed (3-in) hat provides an SPF of 7 for the nose, 3 for the cheek, 5 for the neck, and 2 for the chin. Medium-brimmed (1- to 3-in) hats provide an SPF of 3 for nose, 2 for the cheek and neck, and none for the chin. A narrow-brimmed hat provides an SPF of 1.5 for the nose but little protection for the chin and neck.[2]

Shade

Infants younger than 6 months should be kept out of direct sunlight. Whenever possible, children's outdoor activities should be planned to minimize peak-intensity midday sun (10 AM to 4 PM). Seeking shade is somewhat useful, but people can still sunburn, because light is scattered and reflected. A fair-skinned person sitting under a tree can burn in less than an hour. Shade provides relief from heat and possibly provides a false sense of security about UVR protection. Clouds decrease UVR intensity but not to the same extent that they decrease heat intensity and, thus, may promote a misperception of protection.[6]

Sunscreen

Sunscreen is the main form of protection used by the population, including parents who use sunscreen to protect children.[106–109] Sunscreens reduce the intensity of UVR affecting the epidermis, thus preventing erythema and sunburn. Most FDA-approved sunscreen agents are organic chemicals that absorb various wavelengths of UVR, primarily in the UVB range; others are effective in the UVA range.[110] Some agents are not photostable in the UVA range and degrade with sun exposure. Combinations of chemicals are needed to provide broad-spectrum protection and increase photostability.[110]

The 2 FDA-approved inorganic physical sunscreens are zinc oxide and titanium dioxide, which prevent penetration of skin by UVB, UVA1, and UVA2. Physical sunscreens are usually white or tinted after application; some newer formulations are less visible on the skin but may be less effective.[110] Physical sunscreens are useful for people with photosensitivity disorders and other conditions that require protection from full-spectrum UVR.[3] Table 3 lists the FDA-approved sunscreen agents.

SPF is a grading system developed to quantify the degree of protection from erythema provided by using a sunscreen; the higher the SPF, the greater the protection. For example, a person who would normally experience sunburn in 10 minutes can be protected up to approximately 150 minutes (10 × 15) with an SPF-15 sunscreen. SPF pertains only to UVB. The SPF is determined indoors according to a standard protocol that uses artificial light sources and application of a defined amount of sunscreen (2 mg/cm^2). An SPF-2 sunscreen applied at this thickness blocks approximately 50% of UVB radiation; an SPF-10 blocks 90%; an SPF-15 blocks 94%; and an SPF-30

TABLE 3 FDA-Approved Sunscreens[110,115]

Sunscreen	Range of protection	Comments
Organic		
PABA derivatives	UVB	—
PABA[a]		
Padimate O (octyl dimethyl PABA)		
Cinnamates	UVB	—
Octinoxate (octyl methoxycinnamate)		
Cinoxate		
Salicylates	UVB	—
Octisalate (octyl salicylate)		
Homosalate		
Trolamine salicylate[a]		
Benzophenones	UVB, UVA2	Penetrates skin; estrogenicity in animal studies
Oxybenzone (benzophenone 3)		
Sulisobenzone (benzophenone 4)		
Dioxybenzone (benzophenone 8)[a]		
Others		
Octocrylene	UVB	In combination with other sunscreen agents, improves product photostability
Ensulizole (phenylbenzimidazole sulfonic acid)	UVB	—
Avobenzone (butyl methoxybenzoyl methane, Parsol 1789)	UVA1, UVA2	Photolabile; efficacy decreases by ~60% after 60 min of exposure
Ecamsule (terephthalylidene dicamphor sulfonic acid)	UVB, UVA2	Photostable; particularly effective for UVA2; approved by the FDA in 2007
Meradimate (menthyl anthranilate)[a]	UVA2	—
Inorganic		
Titanium dioxide	UVB, UVA2/UVA1	—
Zinc oxide	UVB, UVA2/UVA1	—

Note that other agents are approved for use in the European Union.
[a] These agents are rarely used in sunscreen formulations.

blocks 97%. However, sunscreens block the pre-D_3 effective radiation more effectively than the erythemally effective radiation.[111]

In actual use, the SPF often is substantially lower than expected, because the amount applied to the skin is less than half the recommended amount (2 mg/cm^2).[112] To adequately cover all sun-exposed areas of an average adult wearing a bathing suit, 1 oz (30 mL) of sunscreen would be needed. It is recommended that sunscreen with an SPF of at least 15 be applied liberally 15 to 30 minutes before sun exposure to allow for absorption into the skin and to decrease the likelihood that the sunscreen will be washed off. Furthermore, it is recommended that sunscreens be reapplied every 2 hours and after swimming, sweating, or drying off with a towel.[110] Sunscreen products with a greater SPF provide somewhat greater protection. Products with a higher SPF have been recommended for some people, including those who have had skin cancer.[113] For most users, however, proper application and reapplication are more important factors than using a product with a higher SPF.

The formulating, testing, and labeling of sunscreen products is regulated by the FDA. The FDA has approved 17 sunscreen chemicals for use in the United States. Several more are available in the European Union. Four chemicals effective in the UVA range have been approved for use in the United States, although others are available in the European Union. In May 1999, the FDA published its final rule for over-the-counter sunscreen products that protect against UVB. Regulations concerning UVA were delayed until reliable testing methods could be developed. In August 2007, the FDA proposed new sunscreen regulations that focused on manufacturing, testing, and labeling of UVA sunscreens using a 4-star rating system that would rate product protection from "low" (1 star) to "highest" (4 stars).[114] The FDA also proposed that the "sun-protection factor" be changed to "UVB sunburn-protection factor."[115] The proposed grading system would divide sunscreens into 4 protection categories: low (SPF-2–SPF-15); medium (SPF-15 to lower than SPF-30); high (SPF-30–SPF-50); and highest (higher than SPF-50). Manufacturers would be unable to label their products with specific SPF values higher than 50, because the FDA believes that there are no data showing accuracy and reproducibility of SPF determinations higher than 50.[115] The proposed FDA rule had not been finalized as of February 2011.

The regular use of a broad-spectrum sunscreen preparation can prevent solar (actinic) keratoses, which are precursor lesions of SCC.[116,117] One randomized clinical trial revealed that sunscreen also decreases the risk of developing SCC.[118] The role of sunscreen in preventing BCC and melanoma has not been fully elucidated. No studies have demonstrated that sunscreen use prevents melanoma or BCC. Some research has revealed that sunscreen users have a higher risk of melanoma and BCC and more nevi.[103] These observations have led to concern that people who use sunscreens also spend more time in the sun because they do not sunburn.[119] The American College of Preventive Medicine found "insufficient evidence to recommend for or against sunscreen use. Nonmelanoma skin cancers may be reduced with regular, daily sunscreen use. There is insufficient evidence that chemical sunscreens protect against malignant melanoma and they may, in fact, increase risk."[120] Two reviews, however, did not support the association between sunscreen use and an increased risk of melanoma.[121,122] Sunscreen continues to be recommended by the American Academy of Dermatology[123] and many other organizations as part of a total program of sun protection.

Sunscreens may be systemically absorbed. In 1 study, sunscreen products were studied in vitro to assess the extent of absorption after application to excised human skin. Half of the products were marketed specifically for children. Of the 5 chemical sunscreen ingredients present in the products, only oxybenzone (benzophenone 3) penetrated skin.[124] In another report, researchers from the Centers for Disease Control and Prevention examined more than 2500 urine samples collected during 2003–2004 for oxybenzone. The samples selected were representative of the US population aged 6 years and older as part of the National Health and Nutrition Examination Survey (NHANES), an ongoing survey that assesses the health and nutritional status of the US civilian population. The analysis found oxybenzone in 97% of the samples,[125] which suggests widespread exposure to the population. Females and non-Hispanic white people had the highest concentrations regardless of age. Data are not available for children younger than 6 years.

Results of animal studies have shown alterations in liver, kidney, and reproductive organs in rats given oral or transepidermal doses of oxybenzone.[126] A study of 6 commonly used UVB and UVA sunscreens was conducted to determine estrogenicity in vivo and in vitro. Five of the 6 sunscreen ingredients (benzophenone 3, homosalate, 4-methyl-benzylidene camphor [4-MBC], octyl methoxycinnamate [OMC] and octyl-dimethyl-PABA) increased cell proliferation in breast cancer cells, and the sixth sunscreen ingredient, butyl-methoxydibenzoylmethane (avobenzone), was inactive. In the in vivo analysis, rats fed the sunscreen ingre-

dients OMC, 4-MBC, and benzophenone 3 showed dose-dependent increases in uterine weight. Epidermal application of 1 of the products (4-MBC) also increased uterine weight.[127] Researchers investigating human prenatal exposures to phthalate and phenol metabolites and their relationship to birth weight found that higher maternal concentrations of benzophenone 3 were associated with a decrease in birth weight in girls but a greater birth weight in boys.[128] A study in young men and postmenopausal women given generous daily applications of benzophenone 3, OMC, and 4-MBC revealed detectable levels of these chemicals in plasma and urine.[129] There were no effects on serum concentrations of reproductive hormones related to sunscreen exposure in men or women. The authors concluded that although the data showed skin penetration of these sunscreen chemicals, there did not seem to be an effect on the hypothalamic-pituitary-gonadal axis. Caution, however, was suggested for children. Researchers in Europe investigated analyzed samples of human milk for the presence of sunscreens and other chemicals with possible endocrine activity. Mothers were asked about their use of sunscreens and cosmetics that contained sunscreen ingredients (benzophenone 2, benzophenone 3, 3-benzylidene camphor, 4-MBC, OMC, homosalate, octocrylene, and octyl-dimethyl PABA). Responding to questionnaires, 78.8% of the women reported using products that contained sunscreens; 76.5% of human milk samples contained these chemicals. There was a high correlation reported between mothers' use of these chemicals and their concentrations in human milk. The authors concluded that except for lipsticks (the ingestion of which is probably important), their results agree with studies in animals and humans showing dermal absorption of sunscreens. Given that some of these chemicals have endocrine activity in animals, the authors suggested that exposure could be lessened if mothers abstained from using these products during their children's sensitive life stages.[130]

Sunscreens are lipophilic and can bioaccumulate in the environment. Sunscreen ingredients have been identified in fish.[127] Because of recent data on bioaccumulation in humans and wildlife, researchers have called for an in-depth analysis of the systemic toxicology of sunscreen ingredients.[127] Sunscreen ingredients are not listed as known or suspected human carcinogens.[131]

Sunscreen products that contain zinc and titanium oxides are increasingly manufactured by using nanotechnology—the design and manipulation of materials on atomic and molecular scales. Nanoscale particles are measured in nanometers, or billionths of a meter. Using nanoscale particles renders products that contain zinc and titanium oxides nearly transparent and increases cosmetic acceptability. Concerns have been raised, however, about the dearth of safety information available about nanoscale ingredients, including the effect on skin that is damaged by sunburn.[132] There are no data available about the effects of these products on infants and children. Advocacy groups have called on the FDA to require more testing and increased regulatory oversight.

To our knowledge, toxicity in infants and children from absorption of sunscreen ingredients has not been reported. Permeability of skin to topically applied products is, however, of concern for infants and young children, especially preterm infants, in whom the stratum corneum of the epidermis is thinner and a less effective barrier than that of term newborn infants and adults. Well-known toxicity from percutaneous absorption in infants and children include the adverse effects of alcohol, boric acid (in diaper powder), hexachlorophene (in antiseptic cleansers), and mercuric chloride (in diaper rinses).[133] Risks from cutaneous exposure to environmental toxicants and chemicals may be heightened in children compared with adults for reasons that include differing behavior patterns; anatomic and physiologic differences in absorption, metabolism, distribution, and excretion; and developmental differences of vital organs that may result in different end organ effects.[133] Infants have a greater ratio of surface area to body weight compared with older children and adults, which allows infants to percutaneously absorb proportionately greater quantities of topical medications or other preparations.[134]

The development of barrier function of infant skin has been investigated. The skin barrier limits water loss, protects the body from entry by toxic substances, and resists mechanical trauma.[135] Vernix caseosum provides a barrier during fetal life. Once the vernix is removed after birth, the stratum corneum of the epidermis provides protection. It was previously thought that the stratum corneum assumed adult function in the first few weeks of life. Accumulating research suggests, however, that the stratum corneum continues to develop through the early years of life. One study[136] assessed the dynamic transport and distribution of water in the stratum corneum in infants (3–12 months of age) and adults (14–73 years of age) by measuring transepidermal water loss (TEWL) ("insensible water loss," a measure of the amount of water that passively diffuses through the epidermis), capacitance (a measure of skin hydration), rates of absorption and desorption, and concentration of water and natural moisturizing factor (NMF) in the skin. Infants' skin had greater hydration, greater TEWL, greater water ab-

sorption and desorption, and lower concentration of NMF. NMFs normally take up water; lower levels may contribute to faster water desorption, which possibly affects barrier function. The authors concluded that the unique properties of infant skin continue to persist at least through the first 12 months of life. In an Italian study,[137] TEWL, capacitance, and pH were measured in 70 infants (8–24 months of age) without skin disease and 30 healthy adult women (25–35 years of age). TEWL measurements did not differ between the infants and adults. Capacitance values and pH were higher in infants. The authors concluded that, despite the similarities in TEWL, differences found in capacitance and pH indicated functional immaturity, possibly resulting in increased permeability.

Infrequently, topical sunscreen agents can have adverse effects, including erythema, itching, burning, or stinging. Allergic contact dermatitis and photoallergic and phototoxic reactions occur rarely.[110]

It is generally recommended that infants younger than 6 months be kept out of direct sunlight. The Australasian College of Dermatologists recommends the use of a sunscreen for infants when exposure to the sun cannot be prevented by other avoidance measures: "Shade, clothing and broad rimmed hats are the best sun protection measures for infants. Sunscreens should be applied to areas of the skin not protected by clothing."[138] The American Academy of Pediatrics (AAP) has stated that sunscreen may be used on infants younger than 6 months on small areas of skin if adequate clothing and shade are not available.[139]

Sunscreens may increase absorption of the insect repellent DEET (*N,N*-dimethyl-metatoluamide), especially when DEET is applied first.[140] Products that combine a sunscreen agent with an insect repellent such as DEET are available. Using individual DEET and sunscreen products at the same time is an acceptable practice, but the use of combination products is not recommended. A sunscreen should be reapplied after swimming or sweating, whereas insect repellent generally does not need to be reapplied.[141] Furthermore, concerns have been raised about potential toxicity of percutaneously absorbed repellents in children, especially with repeated application.[142]

Window Glass

Standard clear window glass absorbs wavelengths below 320 nm (UVB). UVA, visible light, and infrared radiation are transmitted through standard clear window glass. Large window areas are now commonly part of residential and commercial architectural design. Modern windows increasingly incorporate energy-efficient glazes that decrease heat gain and loss through windows. Many of these energy-efficient glazes provide some UVR protection, but only a few provide full UVR protection.[143]

Transmission of UVR through automobile glass depends on the type and the tint of the glass. Because of safety reasons, all windshields are made of laminated glass, a product made stronger through bonding with a tough, clear plastic. Laminated glass filters out most UVA. Side and rear windows, however, are usually made from nonlaminated glass, which allows significant UVA exposure, especially UVA1. Tinted glass removes more UVA than does clear glass; it is possible for automobile owners to add tinted window films to side and rear windows to reduce transmission of light, UVR, and heat.[143] The parts of a driver's or passenger's body closest to a window receive the most radiation. Individuals with photosensitivity disorders can experience exacerbations of their disease while riding in a car.[143] Most states do not allow plastic films with less than 35% visible light transmittance. The minimum allowable visible light transmission levels for side and rear windows are determined by each state[143] and are available from the International Window Film Association.[144]

It has been hypothesized that the increase in melanoma in indoor workers (but not outdoor workers) during the last century may be a result of their exposure to UVA passing through windows.[145] These researchers agree that overexposure to UVB initiates melanoma but that increased UVA exposures (which can cause mutations and break down cutaneous vitamin D_3) and low vitamin D_3 concentrations in the skin promote melanoma.

Sunglasses

Sunglasses protect against sun glare and harmful radiation. The first sunglass standard was published in Australia in 1971; standards were subsequently adopted in Europe and the United States. The latest US sunglass standard was published in 2001 by the American National Standards Institute. This standard is voluntary and is not followed by all manufacturers.[143]

Major US visual health organizations recommend that sunglasses that absorb 97% to 100%[146] or 99% to 100%[59] of the full UV spectrum (up to 400 nm) should be worn. Expensive sunglasses do not necessarily provide better UVR protection. Purchasing sunglasses that meet standards for a safe level of UVR should be the goal. Wearing a hat with a brim can greatly reduce the UVR exposure to the eyes and surrounding skin. It is recommended that people wear sunglasses outdoors when working, driving, participating in sports, taking a walk, or running errands.[147]

Sunglasses for infants and children are available.

The UV Index

The UV index was developed in 1994 by the National Weather Service in consultation with the US Environmental Protection Agency and the Centers for Disease Control and Prevention. The UV index predicts the intensity of UV light for the following day on the basis of the sun's position, cloud movements, altitude, ozone data, and other factors.[148] It is conservatively calculated on the basis of effects on skin types that burn easily. Higher numbers predict more intense UV light during midday of the following day: 0 to 2, minimal; 3 to 4, low; 5 to 6, moderate; 7 to 9, high; and 10 or higher, very high. Sun-protection strategies should be applied at even minimal levels of the UV index, and increasing stringency should be used as the UV index increases (eg, avoiding outdoor exposures from 10 AM to 4 PM if the UV index is 7 or higher). The index is available online for thousands of cities at www.weather.com. It is printed in the weather section of many daily newspapers and reported through weather reports of local radio, television, and weather stations. The UV index can be used to plan outdoor activities.

VITAMIN D

Sun exposure and vitamin D concentrations are intricately intertwined. Thus, effects of limiting sun exposure on vitamin D status must be understood and addressed.

Metabolism

Humans get vitamin D from exposure to sun, dietary sources (such as fortified milk and oily fish), and vitamin supplements. After sunlight exposure, 7-dehydrocholesterol in the skin is converted to previtamin D_3; previtamin D_3 is then converted to vitamin D_3 (cholecalciferol). Vitamin D from the skin and diet is metabolized primarily in the liver to 25-hydroxyvitamin D (25[OH]D), which is used to determine a patient's vitamin D status; 25(OH)D is metabolized in the kidneys to its active form, 1,25-dihydroxyvitamin D, also known as calcitriol.

Vitamin D synthesis in skin depends on skin type. A person with skin type I who burns easily after a first moderate UVR exposure will rapidly achieve maximal vitamin D synthesis. In contrast, a person with skin type VI will have relatively limited vitamin D synthesis, because UVR will be absorbed by melanin rather than other cellular targets.[149] Because excess previtamin D_3 or vitamin D_3 is destroyed by sunlight, exposure to sunlight does not cause vitamin D intoxication.[150] The action spectrum that induces cutaneous vitamin D_3 synthesis is in the UVB range.[151]

Vitamin D Health Effects

Vitamin D is essential for normal growth and skeletal development.[152] At a 25(OH)D concentration lower than 50 nmol/L (<20 ng/mL), children are at increased risk of developing rickets[153]; concentrations below this amount are considered to be deficient. In adults, a 25(OH)D concentration of 80 nmol/L (32 ng/mL) is generally recognized as the threshold of an optimal level, and a concentration of 50 to 79 nmol/L is considered "insufficient."[150,154,155] The AAP recommends that pregnant women maintain a 25(OH)D concentration of 80 nmol/L or higher.[156]

The benefits of vitamin D in adults are many and include improved bone health, prevention of fractures, better muscle health, and reduced risk of falling in older people.[150] The actions of vitamin D that extend beyond bone mineral metabolism are increasingly being understood. Many human tissues, including brain, prostate, breast, and colon, as well as immune cells, have vitamin D receptors, and some have enzymes capable of producing 1,25-dihydroxyvitamin D from circulating vitamin D.[157] 1,25-Dihydroxyvitamin D controls more than 200 genes, including those responsible for regulating cellular proliferation, differentiation, apoptosis, and angiogenesis.[150] These cell-regulation actions are found at 25(OH)D concentrations higher than 75 nmol/L.[152]

Relationships between 25(OH)D status and markers of functional outcomes in children and adolescents vary according to age, race, environment, and genetic predisposition.[153,158,159] A study of bone health in Australian adolescent boys identified a 25(OH)D concentration of at least 43 to 55 nmol/L as optimal.[160] Several studies reviewed by Wagner et al[156] noted associations of low 25(OH)D concentration with increased parathyroid hormone and reduced bone metabolism. Hypovitaminosis D may reduce maximum peak bone mass in pubertal girls.[161] A subsequent study supported these associations for girls,[162] but another study reported a larger gain in bone area and bone mineral content for children with lower 25(OH)D concentration.[163] In a randomized controlled trial, vitamin D supplementation in girls 10 to 17 years of age was associated with higher lean mass and higher bone mineral content.[164] Authors of a study of girls 11 to 15 years of age reported calcium absorption to be unrelated to 25(OH)D status and to vary according to race; relationships between 25(OH)D status and parathyroid hormone were also found to vary according to race.[165] In observational studies (ie, studies in which people are observed or certain outcomes are measured), higher intakes of vitamin D via food in pregnancy and supplementation in infancy were associated with a lower risk of type 1 diabetes in children.[166,167]

Ecologic studies have revealed a lower incidence of breast, colon, and prostate cancers in areas of higher sun ex-

posure.[150,168–170] A recent meta-analysis of observational studies provided evidence of a decreased risk of colorectal cancer and colorectal adenoma associated with higher serum 25(OH)D concentrations.[171] The analysis also found nonsignificant reduced risk of breast cancer and no evidence for association of vitamin D and prostate cancer. Two double-blind placebo-controlled randomized trials with vitamin D supplementation at 400 IU (10 μg)/day failed to demonstrate effects on colorectal[172] or breast cancer[173] incidence, which suggests that ecologic studies may not adequately control for confounding variables[171] or that vitamin D supplementation needs to be substantially higher to achieve a protective effect.[168,171] Low vitamin D status also is directly associated with increased all-cause mortality; reasons for this association merit further examination.[171]

Ecologic studies have revealed a lower risk of multiple sclerosis in areas of high sun exposures[174]; dietary vitamin D lowers risk of multiple sclerosis,[175] possibly through regulating genetic susceptibility.[176] People with low vitamin D concentrations are at higher risk of insulin resistance and the metabolic syndrome,[177] future abnormal glucose regulation,[178] periodontal disease,[179] diminished heart health,[180] and other conditions. To date, however, the relationships between vitamin D supplementation and cancer risks have not been evaluated by randomized controlled trials providing vitamin D at doses that would be high enough to achieve 25(OH)D concentrations similar to those thought to provide protective effects. Until such data are available, questions will remain about the influence of confounding factors (eg, diet, latitude, skin melanin) on previously reported cancer-related outcomes. New randomized controlled trials are needed to guide the development of guidelines for vitamin D supplementation in relationship to cancer prevention[171] and other outcomes.

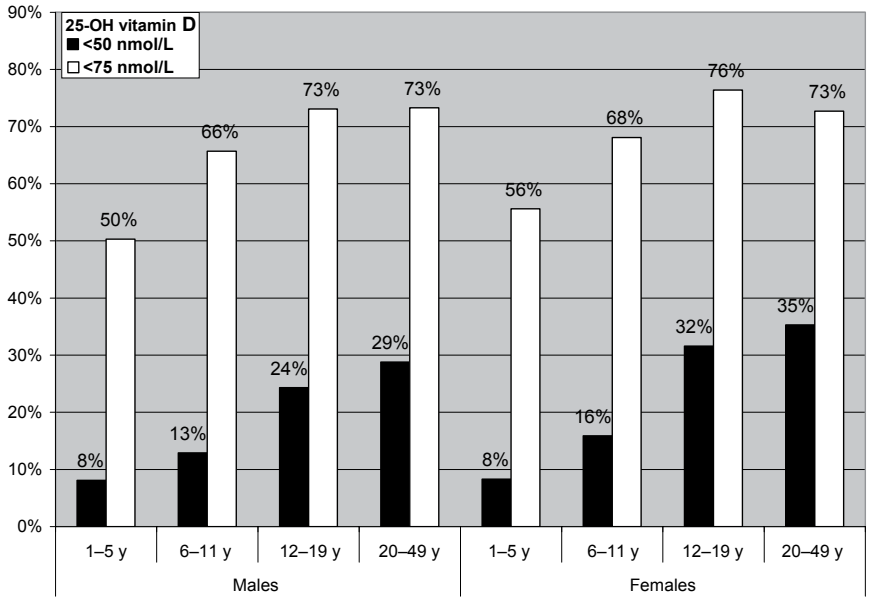

FIGURE 1
Prevalence of serum 25(OH)D concentrations below selected thresholds according to age and gender: NHANES 2000–2004.[183]

Prevalence of Hypovitaminosis D

Hypovitaminosis D is common among US children.[181,182] Data from the 2000–2004 NHANES indicate that approximately 30% of US teenagers and young adults have 25(OH)D deficiency (ie, 25[OH]D < 50 nmol/L), as do approximately 15% of children 6 to 11 years of age and 8% of children 1 to 5 years of age (Fig 1).[183] Because NHANES data are collected in the South in winter months and the North in the summer, these national data may underestimate seasonal variations in 25(OH)D concentrations. The prevalence of hypovitaminosis D is high among samples of women in many areas including Australia,[184] Bangladesh, and Hong Kong, where cutaneous vitamin D synthesis can take place year-round.[185,186]

Risk Factors for Vitamin D Deficiency

Risk factors for hypovitaminosis D in US youth include increasing age, low vitamin D intake, dark skin, winter season, and higher BMI.[181] 25(OH)D deficiency is common in populations such as infants born to mothers at high risk of hypovitaminosis D; breastfed infants; children with sickle cell disease, type 1 diabetes, malabsorption, or obesity; and those who take medications such as anticonvulsants or glucocorticoids. In US non-Hispanic white adults, 25(OH)D concentrations were 5 to 9 nmol/L higher in 1988–1994 compared with 2000–2004; increasing BMI, decreased milk intake, and increased use of sun-protection methods between study periods seemed to be factors accounting for approximately 20% of the difference.[183]

Sun-Exposure Considerations

Many factors influence the efficiency of vitamin D production resulting from sunlight exposures. The amount of skin exposed to the sun results in differences in vitamin D synthesis. In a 1985 study of young infants in Cincinnati, Ohio, who were fully clothed (without hats) and exclusively breastfed, it was determined that 2 hours of sun expo-

sure weekly were needed to maintain 25(OH)D concentrations higher than 27.5 nmol/L, compared with infants who were wearing only a diaper, for whom only 30 minutes/week of sun exposure were required.[187]

It has been stated that at least 20% of the body surface needs to be exposed to UVB for vitamin D concentrations to increase.[152] Dark-skinned people require exposures approximately 5 to 10 times as long as do light-skinned people to achieve similar levels of cutaneous vitamin D production.[188] At latitudes above 35°N (eg, north of Memphis, TN; Kyoto, Japan; and Cyprus) and below 35°S (eg, south of Adelaide, South Australia; and Montevideo, Uruguay), UVB photons do not penetrate to the earth's surface in winter months, which makes cutaneous vitamin D production negligible in those months. Because of the scatter of UVB, sun exposure outside the peak sun hours of 10 AM to 3 PM in the spring, summer, and fall has limited impact on cutaneous vitamin D synthesis.[188] It has been stated that brief exposures to high overhead sunlight have maximum vitamin D benefit with most limited erythema risk.[111]

One author has recommended that children and healthy adults practice "sensible sun exposure" (ie, exposure of arms and legs for 5–30 minutes, depending on the time of day, season, latitude, and skin pigmentation, between 10 AM and 3 PM twice weekly) as a way to maintain vitamin D concentrations and avoid deficiency.[150] This same author recommended that, after such exposure, a sunscreen with an SPF-15 or greater can be applied if the person wishes to remain outdoors.[189] In contrast, the American Academy of Dermatology has stated that maximum production of vitamin D occurs after only brief exposure to UVR; this amount of time is 2 to 5 minutes of midday summer exposure for a light-skinned person living in New York, New York, or Boston, Massachusetts. Although leaders in skin-cancer prevention agree that vitamin D is important for good health, they oppose intentional sun exposure to induce vitamin D production, because UVR is a known human carcinogen.[151,190] There are no studies of children suggesting a level of sun exposure that would negate the need to comply with dietary vitamin D recommendations. Thus, use of deliberate sun exposure to maintain vitamin D sufficiency is not recommended. Given the high prevalence of hypovitaminosis D, however, it seems clear that renewed attention must be paid to evaluating the adequacy of dietary and supplemental vitamin D intake and how much, if any, unprotected sun exposure is beneficial. It is important to keep in mind that infants younger than 6 months should be kept out of direct sunlight as much as possible.

Dietary and Supplemental Vitamin D Recommendations

Many children get less than 400 IU (10 μg) of vitamin D daily from their diets. Approximately 22% of US children 1 to 8 years of age, 50% of girls 9 to 18 years of age, and 35% of boys 9 to 18 years of age get less than 200 IU (5 μg) of vitamin D daily from food or supplements.[191] No primary care–based studies have examined the sensitivity of evaluations of dietary vitamin D intake or sunlight-exposure assessments to determine vitamin D adequacy in children.

The main source of vitamin D is exposure to sunlight,[192–195] which makes it difficult to establish a dietary requirement that has broad generalizability, especially because of the many variables (eg, skin pigmentation, body mass, season, outdoor exposure, clothing, sunscreen use, etc) associated with differences in vitamin D concentrations.[156] In a 1997 report, the Institute of Medicine recommended an adequate intake level for vitamin D of 200 IU/day.[196] An updated report on vitamin D from the Institute of Medicine was released in November 2010.[197] However, because 200 IU/day of vitamin D is insufficient to maintain a 25(OH)D concentration higher than 50 nmol/L, the AAP and others currently recommend that exclusively and partially breastfed infants receive supplements of 400 IU/day of vitamin D shortly after birth and continue to receive these supplements until they are weaned and consume 1000 mL/day or more of vitamin D–fortified formula or vitamin D–fortified milk.[152,156] This level of supplementation in a breastfed infant will generally achieve a 25(OH)D concentration of more than 70 nmol/L and prevent vitamin D deficiency rickets.[151] All nonbreastfed infants who ingest less than 1000 mL/day of vitamin D–fortified formula should receive a vitamin D supplement of 400 IU/day. Formulas for term infants sold in the United States generally provide approximately 400 IU of vitamin D per L, and the majority of vitamin D–only and multivitamin liquid supplements provide 400 IU per dose. The AAP also recommends that older children and adolescents who do not obtain 400 IU/day through vitamin D–fortified milk and foods should take a 400-IU vitamin D supplement daily. The effect of such routine supplementation on 25(OH)D status in children and adolescents has not yet been evaluated. The extent to which 25(OH)D increases with supplementation will vary depending on the amount of vitamin D synthesized over the summer months and the dosage and duration of use.[198] Children at high risk of vitamin D deficiency, such as those with chronic fat malabsorption and those who chronically take antiseizure medications, may need vitamin D doses higher than 400 IU/day,[156] and studies that have tested supplementation in special populations have used

much larger doses safely.[199,200] Treatment of hypovitaminosis D in infants and toddlers is safely done with 2000 IU of vitamin D daily for 6 weeks.[201]

Influence of Vitamin D Supplementation

Several studies have evaluated the influence of the amount of vitamin D supplementation on 25(OH)D levels. In adults, daily supplementation with 400 IU of vitamin D increases 25(OH)D concentration by 7.0 nmol/L.[202] Supplementation of a pregnant woman with 400 IU of vitamin D, as in prenatal vitamins, has little effect on her 25(OH)D concentration.[160] For adult men at latitude 41°N, the amount of supplemental vitamin D (in addition to dietary vitamin D) needed to maintain baseline 25(OH)D concentration over the winter was 500 IU/day.[202] In a sample of young, healthy adults living at ≥51° latitude, the vitamin D supplemental requirement (in addition to dietary vitamin D) for 97.5% of the sample to maintain a 25(OH)D concentration higher than 25 nmol/L was 348 IU of vitamin D per day; the supplemental dose of vitamin D required to maintain a 25(OH)D concentration higher than 50 nmol/L for 97.5% of the sample was 1120 IU of vitamin D per day and was 1644 IU of vitamin D per day to maintain a 25(OH)D concentration higher than 80 nmol/L.[203] The Institute of Medicine report released in November 2010 provided an extensive review of the effects of vitamin D supplementation.[197]

Influence of Sun Protection on 25(OH)D

A few studies of adults, but none of children, have examined associations with sun protection or sunscreen use and 25(OH)D concentrations. Higher use of sun protection was associated with statistically significantly lower 25(OH)D concentrations in non-Hispanic white adult subjects in the 2000–2004 NHANES, compared with similar subjects in the 1988–1994 NHANES.[183] Other studies of adults found expected relationships between reported levels of sun exposure and 25(OH)D concentration but no association between reported sunscreen use and 25(OH)D concentration.[204,205] Authors of a small, controlled trial that involved 24 elderly adult sunscreen users and 19 controls over 2 years reported that lower 25(OH)D concentration in sunscreen users did not result in increases in parathyroid hormone or increases in bone biological markers.[206] Sunscreen users generally apply insufficient amounts to meet the expected SPF level. Sunscreen efficacy also depends on uniform application to exposed body parts, the sunscreen's durability and substantivity (a measure of the sunscreen's ability to be adsorbed by or adhered to the skin while swimming, bathing, or perspiring), and reapplication. Thus, evaluation of sunscreen use without also considering other sun-protection measures may not accurately indicate risk of low 25(OH)D status.

PEDIATRICIAN COUNSELING

Pediatricians can play important roles in counseling about sun protection. In a 2003 report, the US Preventive Services Task Force (USPSTF) determined that clinician counseling may have an effect on parents' use of sunscreen for their children but not for using other sun-protection measures such as wearing protective clothing, reducing excessive sun exposure, avoiding sunlamps/tanning beds, or practicing skin self-examination. The USPSTF noted that only limited data exist about potential harm of counseling or of specific skin-protection behaviors.[207] Harm could include the possibility that focusing on sunscreen use may result in a false sense of security and more time spent in the sun because users do not sunburn.[119] Other harmful outcomes include the possibility that vitamin D deficiency results from sunscreen use; according to the USPSTF, a randomized controlled trial in people older than 40 years found that sunscreen use over the summer had no effect on 25(OH)D concentrations.[207] There are concerns that sun avoidance may result in reduced physical activity levels among children and negative effects on mental health; there have been no studies regarding the effects of protection behaviors on these outcomes.[207]

In a survey of children's caregivers attending a university-based clinic in Florida, only 30% of caregivers reported having been counseled by their physician about sun protection. Caregivers who were counseled had greater sun-protection knowledge, were more likely to report regular use of sun protection for their child, and were more likely to report teaching their child about sun protection.[208] In surveys of Massachusetts and Texas pediatricians, approximately three-quarters of them indicated that they recommended safe sun practices or sunscreen use to a majority of their patients. However, the messages they presented included a limited number of the available sun-protection strategies.[209,210] Counseling regarding sun protection is prioritized lower than counseling on other safety issues.[209,211] Time constraints are often mentioned as a main barrier to providing counseling.[211] A "teachable moment" may arise when the child or adolescent presents with a sunburn.

EARLY DETECTION

The US Preventive Services Task Force concluded that evidence is insufficient to recommend for or against routine screening for skin cancer in adults by using a total-body skin examination for the early detection of cutaneous melanoma, BCC, or SCC in people without a

history of skin cancer or otherwise at high risk.[212] However, because early detection increases survival rates,[213,214] it has been recommended that complete cutaneous examinations be performed by physicians and other health care providers, coupled with periodic self-examination of the skin by the individual person.[214] Skin lesions with malignant features noted in physical examinations should be biopsied. There are no recommendations on skin-cancer screening in children. Because melanoma occurs in teenagers and is a common cancer among young adults, it seems prudent to recommend that clinicians caring for these groups include a skin examination as part of a complete physical examination.

PREVENTION IN SCHOOLS

The Centers for Disease Control and Prevention has published guidelines to protect schoolchildren from excessive sun exposure in schools. Recommendations include reducing skin-cancer risks through policies; creation of physical, social, and organizational environments that facilitate protection from UVR; education of young people; professional development of staff; involvement of families; work by nurses and other school health services staff; and program evaluation.[100] Authors of a systematic review published in 2004 (search updated to June 2000) concluded that efforts to teach children how to protect themselves from UVR were effective when implemented in primary schools and in recreational settings. There was insufficient evidence, however, about the effectiveness of implementation in other settings.[215]

Schools have a role in determining children's attitudes and behaviors. The SunWise Program, developed by the Environmental Protection Agency, is a brief, standardized sun-protection education program.[216] It is the first environmental education program for sun safety designed to teach children in elementary and middle schools (and their caregivers) how to protect themselves from overexposure to the sun. The SunWise program has been shown to promote improvement in knowledge, intentions to play in the shade and to use sunscreen, and attitudes regarding healthiness of a tan.[217] A recent study of the SunWise program demonstrated that every federal dollar invested in it generates $2 to $4 in public health benefits.[218]

COMMUNITY-BASED PROGRAMS

Multicomponent community-wide approaches have been recommended by health education experts[219] and can be effective. Several community-directed campaigns have addressed sun protection in younger children. A randomized controlled trial of the SunSafe project, an intervention in New England, involved schools, child care settings, primary care offices, and beach settings. The SunSafe program was effective in changing sun-protection practices observed at community beaches for children 2 to 10 years of age.[220,221]

Use of sun-protection practices begins to decline in early adolescence[222] as media and peer influences on teen attitudes and behaviors increase and parental influences decrease.[223] A randomized controlled trial of the SunSafe program was conducted in 5 intervention and 5 control communities to assess the impact of a sun education program in the middle school years. The SunSafe in the Middle School Years program augmented the original program by involving sports teams and peer-led activities. After 2 years of intervention, adolescents in intervention communities had less of the expected deterioration in sun-safety practices compared with adolescents in control communities.[224]

Other interventions were not effective. Australian adults who received solar UV forecasts and supporting communications did not implement markedly enhanced personal sun-protection practices.[225] A randomized trial of an educational intervention to reduce sunburn rates and improve sun-protection behavior in schoolchildren showed no difference in sunburn episodes between the study and control groups.[226]

PUBLIC HEALTH CAMPAIGNS

Australia, the country with the highest incidence of skin cancer in the world, has been in the forefront of the public health response to this disease. SunSmart, a population-based skin-cancer–prevention program run by the Australian state of Victoria since 1988, incorporates substantial public education efforts as well as structural and environmental change strategies in schools, workplaces, local government settings, and pools. Paid television advertising has been part of a strategy of public education. The authors of a recent assessment of the SunSmart program concluded that sun-protection methods and rates of sunburn showed substantial general improvement over time but stalled in recent years. Most initial gains were sustained over 15 years of assessments, but there was no further progress with regard to sunburn, sunscreen use, body exposure, and attitudes.[227]

In a 2008 editorial, Martin Weinstock, MD, an internationally known dermatologist and researcher, concluded that data suggest that public health efforts at skin-cancer prevention are inadequate.[228] Four challenges to effective skin-cancer prevention campaigns were identified. First, sun-protection messages to avoid or limit time during peak sun hours may conflict with health-promotion messages regarding physical activity. This potential conflict may be resolved by following the "slip, slop, slap" motto of the Australians to slip on a shirt, slop on sunscreen, and slap on a hat—a message consistent with conducting outdoor physical activity in a sun-protective manner. Next, there is controversy about how much

sun exposure is needed for vitamin D synthesis, which possibly results in excessive exposure to sun and deliberate exposure to artificial UVR. Third, it has been reported that skin-cancer risk behaviors cluster with other risky behaviors, such as smoking and risky drinking. A greater understanding of these behaviors may help with interventions. Fourth, the increasingly profitable tanning industry benefits from unrestrained selling of UVR. These challenges suggest that it is uncertain whether primary prevention efforts to reduce skin cancer through UVR protection will be successful.

RESEARCH NEEDS

Outstanding research questions exist in many areas, including relationships of sunscreen use to melanoma and BCC; safety of absorbed ingredients in sunscreens; effects of long-term use of sunscreen, especially when this practice begins early in life; the role of vitamin D in preventing cancer and other health conditions; the relationship of 25(OH)D to functional outcomes for children; developing and assessing strategies for estimating vitamin D status during a clinical encounter; determining how much sun exposure and vitamin D supplementation is "enough" depending on a person's age and gender, his or her geographic location, the season of the year, and other factors; effects of long-term use of vitamin D supplementation at various levels; and utility of routine counseling on sun-avoidance strategies in clinical encounters.

CONCLUSIONS

UVR is a known human carcinogen and has numerous other adverse health effects. Skin-cancer rates have reached epidemic proportions, and skin cancers occur in young people and sometimes result in death. Excessive exposure to UVR during childhood and adolescence is thought to confer an increased risk of developing skin cancer.

Morbidity and deaths from skin cancer are preventable. Pediatricians may play an important role in providing education about skin-cancer prevention to patients and their parents, yet many do not take opportunities to do so. Pediatricians are urged to provide advice on hundreds of topics,[229] so it may be impractical to expect pediatricians to discuss skin-cancer prevention and sun protection during every health-maintenance visit. It is, however, reasonable to expect that skin-cancer prevention be discussed on at least a few visits during the course of a pediatrician's long-term relationship with a child and his or her family. Because parents' comprehensive sun-protection practices for children start to decline when children are very young,[230] it is important to begin discussions early in the child's life. Discussions are especially important for children at high risk of developing skin cancer—children with light skin, those with nevi and/or freckling, and those with a family history of melanoma. Melanoma is rare in children, but moles are not rare. Education can include a discussion of moles and the need to be aware of changes in them. As children approach puberty, it is important to include information about the dangers of artificial tanning. Pediatricians also have an important role as advocates in helping to support legislation to ban minors' access to tanning salons.

Lifelong sun protection is recommended beginning at an early age. Although sunscreen is the most commonly used method of sun protection, patients should be counseled to not overly rely on sunscreen. A complete program of sun protection includes wearing clothing and hats, timing activities to minimize peak hours of the sun, and wearing sunglasses. Advice should be framed in the context of promoting regular outdoor play and other physical activity.

Vitamin D is available through foods, supplements, and incidental sun exposure. Because current intake levels of vitamin D by children and adolescents may not prevent vitamin D deficiency, it is recommended that all infants, children, and adolescents receive 400 IU of vitamin D per day. Additional vitamin D supplementation and laboratory evaluations of vitamin D status may be needed for some children in some areas. Overexposure to UVR from sunlight and exposure to UVR from artificial sources raise the risk of skin cancer, photoaging, and other adverse effects and should be avoided.

DEDICATED TO THE HEALTH OF ALL CHILDREN™

POLICY STATEMENT

Underinsurance of Adolescents: Recommendations for Improved Coverage of Preventive, Reproductive, and Behavioral Health Care Services

Organizational Principles to Guide and Define the Child Health Care System and/or Improve the Health of All Children

Committee on Adolescence and Committee on Child Health Financing

ABSTRACT

The purpose of this policy statement is to address the serious underinsurance (ie, insurance that exists but is inadequate) problems affecting insured adolescents' access to needed preventive, reproductive, and behavioral health care. In addition, the statement addresses provider payment problems that disproportionately affect clinicians who care for adolescents.

Among adolescents with insurance, particularly private health insurance, coverage of needed services is often inadequate. Benefits are typically limited in scope and amount; certain diagnoses are often excluded; and cost-sharing requirements are often too high. As a result, underinsurance represents a substantial problem among adolescents and adversely affects their health and well-being.

In addition to underinsurance problems, payment problems in the form of inadequate payment, uncompensated care for confidential reproductive services, and the failure of insurers to recognize and pay for certain billing and diagnostic codes are widespread among both private and public insurers. Payment problems negatively affect clinicians' ability to offer needed services to adolescents, especially publicly insured adolescents. *Pediatrics* 2009;123:191–196

SCHIP—State Children's Health Insurance Program

INTRODUCTION

Having health insurance has been associated with better access and utilization of health care, whereas uninsured families are more likely to report experiencing "unmet" health care needs for their children and adolescents.[1,2] In 2006, 13.8% of adolescents 13 through 18 years of age and 28.4% of older adolescents aged 19 through 21 were uninsured.[3] Adolescents at greatest risk of being uninsured are older, are Hispanic, and have low household income. The problems of uninsured adolescents have been a long-standing concern of the American Academy of Pediatrics (AAP) and the subject of several policy statements[4–6] and ongoing state and federal advocacy efforts.

Having health insurance that provides comprehensive and affordable coverage for preventive, behavioral, and reproductive care is particularly important for adolescents, because the major causes of morbidity and mortality in this age group are related to injuries from motor vehicle crashes, suicide, interpersonal violence, alcohol and drug use, and risky sexual behaviors. This policy statement presents a series of recommended strategies to address the serious underinsurance and payment problems affecting insured adolescents and the clinicians who care for them.

INSURANCE COVERAGE

There are no reliable national estimates on the extent of underinsurance among adolescents. Still, the literature on adolescent health care expenditures and private health insurance benefits reveal some important findings. With respect to health care expenditures, nearly 40% of adolescents' health care is paid out-of-pocket. Higher out-of-pocket liabilities are reported among adolescents with private insurance, those in fair to poor overall health, and those with disabilities.[7]

With respect to private health insurance coverage, benefits are often not well matched to meet the needs of adolescents. In a study examining the extent of private health insurance coverage available to hypothetical adolescents

with various conditions or illnesses, substantial levels of underinsurance were found. The specific adolescent conditions that were examined included injuries resulting from motor vehicle crashes, pregnancy and sexually transmitted infections (STIs), major depressive disorder, anorexia nervosa, and bipolar and substance abuse disorders. Overall, physical therapy, occupational therapy, and nutritional counseling, as well as behavioral or mental health therapies, were least likely to be covered at the levels recommended by medical experts to treat adolescents.[8] Additional insurance gaps relate to the refusal by many insurance companies to provide coverage for preexisting conditions when adolescents make transitions from one plan to another.

PROVIDER PAYMENT

In addition to underinsurance, payment problems in the form of inadequate payment, uncompensated care for confidential reproductive services, and rejection by insurers of certain billing and diagnostic codes disproportionately affect clinicians who care for teenagers. For example, fee-for-service Medicaid programs administered by states paid below Medicare reimbursement rates for 70% of the Current Procedural Terminology (CPT) codes in most commonly used in pediatric practices. Overall, Medicaid payments averaged only 80% of Medicare rates.[9] Within Medicaid risk-based managed care systems, capitated rates of payment to cover 13- to 18-year-olds are often substantially lower than those to cover children 12 years old or younger and individuals older than 18 years, thus, penalizing physicians who see a large number of adolescents. Medicaid and State Children's Health Insurance (SCHIP) rates and, to a lesser extent, private health insurance rates do not cover the time needed to serve adolescents.[10] Importantly, research has shown that differences in preventive health care visits by adolescents are linked to physician payment rates.[11]

Providers also report that they are unable to get paid for confidential reproductive, mental health, and substance abuse evaluation and treatment services and for non–face-to-face services such as telephone calls and e-mails. Unfortunately, few insurers have adjusted their administrative and billing systems to protect adolescent confidentiality, and most states do not have fee-for-service payment mechanisms or carve-outs to reimburse providers for this important care. In addition, few public or private insurers reimburse CPT billing codes related to health education and chronic care management, and many also restrict coverage of certain diagnostic *International Classification of Diseases, Ninth Revision* (ICD-9) codes.[8,12]

Adolescent medicine specialists are often not recognized by insurers as both primary care providers and specialists. Adolescent medicine is a specialty recognized by the American Board of Pediatrics, American Board of Family Medicine, and American Board of Internal Medicine and by all state medical organizations as both a primary care specialty and medical subspecialty. Thus, referrals to an adolescent medicine specialist made by other primary care providers often cannot occur when the adolescent medicine specialist also provides primary care services to other patients.

To the extent that these insurance gaps and payment problems represent significant financial losses to the providers caring for adolescents, these issues also represent a very real deterrent to providers expanding their practices to include more adolescents. Moreover, these coverage and payment issues impose significant financial barriers and hardships on adolescents and their families.

PREVENTIVE CARE

The AAP recommends the following strategies to address underinsurance and payment problems among adolescents:

- All insurance plans, including newer consumer-driven health plans, should cover annual preventive health care visits and recommended immunizations for adolescents consistent with national medical guidelines.[13–15]
- Copayments, coinsurance, and deductibles should be eliminated for preventive care visits and immunizations to reduce barriers to adolescents seeking such care.[4,14,16]
- When health problems are identified during the adolescent preventive care visit, insurers should recognize the —25 modifier CPT code to allow for same-day treatment of issues that would otherwise require another separate health care visit.[17] This represents an important window of opportunity for addressing problems in a timely, convenient manner and to reduce the risk of loss to follow-up.
- Insurers' claims systems should recognize and pay for preventive medicine codes for health and behavior assessment and counseling, risk screening, and intervention, which are more frequently needed and appropriate for adolescents.[17]
- Insurers should recognize that physicians trained in adolescent medicine may provide services as both primary care providers and specialists. Adolescent medicine subspecialists should be allowed to provide primary care for teenagers, particularly for those with more complicated problems such as chronic illnesses/disabilities, reproductive health concerns, and mental health/substance abuse conditions. This strategy would allow effective management of both the clinical needs and the health care costs of complicated adolescent patients.
- Insurers should reimburse physicians at higher rates for services provided during nontraditional hours (after 5 PM and on weekends) to increase access to care in the medical home and reduce emergency department and urgent care facility utilization.

The AAP recommends that adolescents have an annual preventive health care visit that includes disease detection and prevention, health promotion, and anticipatory guidance that addresses physical growth and development, social and academic competence, emotional well-being, risk reduction, and violence and in-

jury prevention.[13] This visit should also allow time to provide health guidance to parents, including a discussion of the ongoing psychosocial and physical changes in their adolescents along with ways to support them to adopt healthier lifestyles. In 1997, the National Committee for Quality Assurance, through its Health Employer Data and Information System (HEDIS), affirmed the importance of annual visits for adolescents by adding this yearly visit to its measurements.[18] In addition, the current vaccine financing system and its gaps in coverage need to be addressed, because many underinsured adolescents are unable to access publicly funded vaccines in either the private or public sectors.[16] Unfortunately, a sizeable proportion of Medicaid and private insurers fail to cover annual preventive benefits for adolescents, and almost all insurers exclude coverage for preventive counseling and also do not reimburse providers if more than 1 ambulatory service occurs on the same day.[8,12] Moreover, with the exception of separate SCHIP programs, few private insurers exempt preventive care from deductibles and other forms of cost sharing.

Even when preventive care is covered, low fees paid by Medicaid and SCHIP programs as well as most private health insurance plans fail to adequately cover the work required to perform a comprehensive adolescent preventive health care visit.[10]

The implications of inadequate coverage, significant cost sharing, and low payment rates are numerous: reduced access to preventive health care services to teenagers, including limited or no ongoing preventive counseling; inadequate compliance with recommended AAP guidelines; substitution of brief sports physicals for comprehensive examinations; financial losses for providers who elect to provide comprehensive preventive care services despite inadequate payment; and significant out-of-pocket payments for families. Research suggests that even modest cost sharing makes it less likely that teenagers from low-income families will get effective medical care.[19]

REPRODUCTIVE CARE

The AAP recommends the following strategies to protect teenagers' access to reproductive health care and to ensure adequate payment for comprehensive reproductive care, including confidential care:

- Insurers should cover all contraceptives, including emergency contraception and treatment of STIs, just as they do other medications.
- Copayments, coinsurance, and deductibles for reproductive health care visits and contraceptives should be reduced or eliminated.
- Policies that recognize the rights of adolescents to obtain confidential reproductive health care should be developed by insurers, their governing organizations, and physician offices.
- A unique coding and billing strategy should be implemented by insurers to protect the rights of teenagers to access confidential reproductive health care services.
- Explanations of benefits and other receipts for reproductive care services used by adolescents ideally should not be sent to parents.
- Insurers should recognize that physicians trained in adolescent medicine may provide services as both primary care providers and specialists. Allowing adolescent medicine specialists to provide reproductive health care for teenagers within the context of primary care or consultative services would be a management strategy that serves the needs of the patients clinically and provides cost-effective treatment.
- Incentives should be offered for increased availability of after-hours care in the medical home in the form of higher payments for visits after 5 PM and on weekends.

The AAP recommends that adolescents receive confidential counseling about sexual development, sexuality, and responsible personal decision-making.[20–22] In addition, the AAP recommends that sexually active teenagers receive reproductive health care, which includes appropriate genitourinary and gynecologic evaluations; counseling about contraceptive options, including abstinence; and counseling to prevent, screen for, and treat STIs, including HIV.[13,21] Although parental involvement is desired and encouraged, many sexually active teenagers will not seek reproductive health care services if parental consent is required.[23,24] All states allow minors to obtain confidential screening and treatment for STIs, and many states allow minors to receive contraceptive services without parental notification.[25,26] Yet, coverage of contraceptive services is often limited in Medicaid, SCHIP, and private health insurance plans. Insurance coverage for contraception is highest in states with mandates to cover such services.[27,28]

Coverage of reproductive services, however, is limited in many public and private insurance plans. Routine gynecologic examinations, which are part of the routine preventive care visit for adolescents, are subject to the same limits as the preventive care benefit previously described. Also, a sizeable proportion of insurance plans treat contraceptives differently from other medications by limiting or failing to provide contraceptive coverage even when prescribed for the treatment of menstrual or other gynecologic disorders.[8] In addition, health education and counseling about sexuality, sexual activity and contraception, pregnancy and STI prevention, and reproductive health services for adolescents are seldom covered.

Copayments, coinsurance, and deductibles are routinely applied for both reproductive care visits and contraceptives under private insurance plans.[29] There are many negative implications of these cost-sharing obligations, limitations of coverage, and failure to adopt confidential protections and billing arrangements, including lost opportunities for prevention and early intervention, financial disincentives for pediatricians to provide reproductive health care, and disruptions in continuity of care when adolescents are forced to seek reproductive care outside their primary care medical home. Programs that have been successful in providing reproductive care ser-

vices to teenagers have been funded by public insurance, have ensured confidentiality, and have removed cost barriers.[10,30]

In addition, the extended time and expertise required to provide routine pelvic examinations for teenagers is not recognized. Providing adequate information and education to the adolescent experiencing her first pelvic examination or to the adolescent with previous negative experiences requires more time. Providing contraceptive counseling and prescriptions may represent the first experience of obtaining medication in a confidential setting, thus requiring more time from health care providers and personnel to provide instructions regarding access to and proper use of medication. However, unlike adult gynecology codes, there is no separate billing code for routine gynecologic examinations. The adolescent gynecologic examination is incorporated into the preventive visit code.

BEHAVIORAL HEALTH CARE

The AAP recommends the following strategies for reducing underinsurance and payment problems that adversely affect adolescents' access to early and ongoing mental health and substance abuse prevention and treatment services. Unfortunately, coverage and payment of mental health and substance abuse services for all individuals is seriously flawed. These pervasive failures especially affect adolescents, because their main health issues are behavioral in nature.

- Insurers should cover comprehensive mental health and substance abuse services that are sufficient in amount, duration, and scope to effectively identify and treat such disorders in adolescents.[14]
- Parity in insurance coverage should be established between medical services and mental health and substance abuse services. Coverage of adolescent mental health and substance abuse disorders should be the same as coverage of other adolescent chronic health conditions and disabilities.[31,32]
- Insurers should eliminate condition exclusions for enrollees with mental health and substance abuse disorders.
- Insurers should provide coverage for the care of youth with behavioral disorders affecting physical health, such as eating disorders, which should not be categorized exclusively as mental health disorders.[33]
- All adolescents should have access to the annual adolescent preventive health care visit as a venue for screening for mental health problems and initiating treatment, as recommended in *Bright Futures*.[13,34]
- When health problems are identified during the adolescent preventive care visit, insurers should recognize the —25 modifier CPT code to allow for same-day treatment of issues that would otherwise require another separate health care visit.[17]
- Insurers should recognize codes for providing care for adolescents in various settings, including telephone management and counseling, team conferences, and health and behavior assessment and intervention.[17]
- Insurers should recognize screening codes (V codes) that allow for early identification and treatment of adolescents at risk of mental health and substance abuse disorders.
- Insurers should recognize that physicians trained as adolescent medicine specialists may provide services as both primary care providers and specialists. Allowing adolescent medicine specialists to provide care for mental health problems and substance use problems within the context of primary care or consultative services would be a management strategy that serves the needs of the patient clinically and provides cost-effective treatment.
- Purchasers and payers should be encouraged to establish pilot projects that integrate mental health programs into primary care and other programs, such as reproductive, school health, and community-based programs. Care in these venues improves access and reduces the stigma associated with mental health care.[35]

The AAP recommends that adolescents receive behavior risk assessment and health education at least annually, usually within the context of the preventive health care visit,[23] including screening specifically for substance abuse, depression, anxiety, and other mental health disorders. The role of the pediatrician is critically important in providing early identification and referral to mental health and substance abuse treatment clinicians and in establishing collaborative relationships with these professionals to clarify their respective roles in treatment, coordination, and exchange of information.

Evidence indicates that most psychiatric disorders present during childhood or adolescence.[36] Yet, all too often, adolescents' mental health and substance abuse problems go undiagnosed and untreated. According to the US Surgeon General, 80% of adolescents who need mental health treatment are not receiving care, ultimately at a huge cost to society. This lack of treatment results in worsening symptoms, disability, difficulties with interpersonal relationships, and poor school performance.[37,38] Childhood and adolescent mental disorders typically persist into adulthood; 74% of 21-year-olds with mental disorders had previous problems.[38,39] It has been estimated that for 15- to 44-year-olds, psychiatric illnesses are associated with >50% of disability-adjusted life-years, a measure of the number of expected years of life lost (to death) or lived with disability.[36]

Problems with insurance coverage, payment, and provider availability have all been associated with restricted access to behavioral health care. With respect to mental health and substance abuse benefits, most private insurers and some SCHIP plans limit outpatient benefits, unlike for other ambulatory services. Inpatient benefits are similarly restricted, and authorization for inpatient care among most insurers and managed care plans is extremely limited. In addition, benefit restrictions, as well as condition and treatment exclusions

(such as self-inflicted injuries and family therapy) and high cost-sharing levels, are applied.[29]

Low payment rates and service carve-out arrangements further limit mental health and substance abuse treatment access. Many payers, especially Medicaid and SCHIP plans, reimburse clinicians at extremely low rates.[9] Not surprisingly, a large proportion of mental health clinicians no longer participate in either public or private plans, which makes the already small number of qualified clinicians even smaller.[10] This lack of available mental health providers often leaves primary care physicians to manage adolescents with very difficult, complex problems and disorders. Moreover, assessment, treatment, and collaborative care provided by pediatricians and adolescent medicine specialists are often rejected because of mental health service carve-out arrangements and exclusion of these physicians as participating providers. As a result, adolescents and their families delay seeking care, incur high out-of-pocket-costs, and fail to complete the recommended course of treatment.

SUMMARY

Improvements in the quality of health insurance coverage for adolescents and the adequacy of provider payment for preventive, reproductive, and behavioral health care are critically important for advancing adolescents' access to health care and improving their health and well-being.

ABSTRACT

Children who have suffered early abuse or neglect may later present with significant behavior problems including emotional instability, depression, and a tendency to be aggressive or violent with others. Troublesome behaviors may persist long after the abusive or neglectful environment has changed or the child has been in foster care placement. Neurobiological research has shown that early abuse results in an altered physiological response to stressful stimuli, a response that deleteriously affects the child's subsequent socialization. Pediatricians can assist caregivers by helping them recognize the abused or neglected child's altered responses, formulate more effective coping strategies, and mobilize available community resources. *Pediatrics* 2008;122:667–673

All clinical reports from the American Academy of Pediatrics automatically expire 5 years after publication unless reaffirmed, revised, or retired at or before that time.

The guidance in this report does not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

Key Words
child abuse, posttraumatic stress disorder, foster care

Abbreviations
PTSD—posttraumatic stress disorder
HPA—hypothalamic-pituitary axis

INTRODUCTION

Early maltreatment can significantly alter a child's normal developmental arc and leave the victim with significant long-term impairments. Health care professionals who provide care for maltreated children must consider the consequences of previous abuse for the child's ongoing development and adaptation when faced with a variety of long-term behavior problems regardless of whether children reside with their birth families, foster families, or adoptive families.

An increasing body of evidence documents the robust relationship between adverse experiences in early childhood and a host of complications, both medical and psychological, that manifest throughout childhood and later in adult life. The Adverse Childhood Events Studies have demonstrated that child abuse, neglect, and other circumstances that disrupt the parent-child relationship are significantly associated with many leading causes of adult death, such as stroke, cancer, and heart disease, and with heavy health service utilization. These disparate consequences, including depression and suicide, hypertension and diabetes, cigarette smoking, alcohol and other substance abuse, and fractured bones, bear compelling testimony to the vulnerability of children to stressful experience.[1]

Pediatricians see children before, during, and after adverse events. In the office, clinicians deal daily with children who are suffering the effects of trauma, including separation and loss, physical and sexual abuse, parental neglect, and witnessing violence. Many of these children, especially those for whom the stress is particularly severe, chronic, or pervasive, will have difficulty overcoming their persistent physiological and psychological responses to their earlier stress. Lingering symptoms of posttraumatic stress disorder (PTSD) or disrupted attachment can present as difficulties with sleep, anxiety, oppositional behavior, violent behaviors, and school failure.[2,3]

The child's problematic behavior may continue long after abuse or neglect have ceased, despite consistent and attentive parenting by foster or adoptive parents or birth parents who have successfully changed their own behaviors. Desperate caregivers may seek the pediatrician's help in diagnosing and treating a suspected "medical condition" or "chemical imbalance." Unless health care professionals recognize the relationships of these common behavior problems to their remote antecedents, their interventions will be at best inefficient and at worst ineffective or even counterproductive. The primary health care professional holds the first, perhaps most critical link for caregivers and

children: to help them understand that the child's unsatisfactory response to stress may have originated as a biologically based adaptation to the child's abnormal world and that persisting problem behaviors are the consequence. Pediatricians can help caregivers understand that there are healthy strategies and interventions that can help children reduce these excessive responses to environmental stress and assist children in resuming a normal developmental trajectory.

WHEN TRAUMATIC STRESS WILL NOT GO AWAY

Children who have survived acute events such as house fires, automobile accidents, major medical illness, or natural disasters frequently complain of disordered sleep, intrusive "flashback" memories, and altered emotional responses to everyday situations. These are classic symptoms that arise from experiencing a single traumatic life event. Such severe stress reactions are particularly common after incidents of interpersonal violence (such as domestic violence, child abuse, and terrorism). In cases of child abuse or neglect or other exposure to violence, in which the stresses are often prolonged and unavoidable, long-term stress reactions are common and can be especially devastating. In patients suffering from the aftereffects of significant early stress, the offending stimulus, sometimes minor, seems to echo the previous abuse and to produce an equivalent, dramatic emotional reaction that is often inappropriate to the provocation. Stimuli that produce such reactions are known as traumatic reminders and may take many forms. Reaction to an old trauma may be brought forth by a smell, sound, or other sensory input or may be triggered by an action, place, or date. In this reaction, the brain is engaging in what seems to be an exaggerated form of pattern recognition, a common form of learning in which similar patterns of stimuli call forth a similar neuroendocrine (and, thus, behavioral) response.[4,5]

Symptoms can be grouped into 3 main behavioral clusters: (1) reexperiencing through intrusive thoughts, dreams, and "flashback" recollections; (2) avoidance of reminders and numbing of responsiveness, including social withdrawal, restricted range of affect, and constriction of play; and (3) physiological hyperarousal in the form of hypervigilance and exaggerated startle response, attention and concentration problems, and sleep disturbance. When disordered stress responses persist long after the trauma, the condition is termed PTSD.[6,7] It is uncertain why some children develop PTSD after trauma but others do not, although severity and chronicity of the initiating stress seem to play a part, as do such host factors as social support and genetic variation.[2]

Diagnostic criteria for PTSD are the same in children as in adults. These may be summarized as: (A) exposure to a traumatic event that involved serious threat of death accompanied by intense fear and horror; (B) a tendency to persistently reexperience the traumatic event (through intrusive thoughts, dreams, and "flashback" recollections); (C) numbing of general responsiveness; and avoidance of stimuli that trigger this reexperience (seen as social withdrawal, restricted range of affect, and constriction of play); and (D) persistent symptoms of arousal (hypervigilance, exaggerated startle, and other physiological measures), (E) duration of above symptoms for more than 1 month and causing clinically significant distress or impaired functioning.[6] In children, these characteristics may manifest in developmentally different ways, such as traumatic play or extreme emotional lability, with "hair-trigger" explosive responses to minor provocations.[8–11]

Research has shown anatomical changes correlated with a history of PTSD symptoms, including smaller brain volumes and size differences in limbic structures.[12–14] Similarly, end-organ responses along the hypothalamic-pituitary axis (HPA) are altered by prolonged exposure to cortisol, a glucocorticoid critical to the body's stress response. Abuse victims have demonstrated abnormalities of the HPA response.[14–18] These observations underscore the premise that the exaggerated behavioral responses seen in complex PTSD have strong—and durable—anatomical and physiological underpinnings. Indeed, complex traumatic stress suffered early in life may be thought of as having both behavioral and developmental consequences.

Caregivers of a child with very difficult behaviors need to hear that the fault is neither entirely theirs nor entirely the child's. They need to learn that their child is dealing with a physiological response unfamiliar to them and to learn new and more effective ways of responding themselves. Although love and consistency are essential, they are not always enough.

THE SIGNIFICANCE OF EARLY STRESS: PSYCHOLOGY OR PHYSIOLOGY?

It is hardly remarkable that the seeds of adult dysfunction are sown in early childhood stress. We have long known, for example, of the lifelong effects of early malnutrition or of exposures to toxins such as lead or alcohol. What is remarkable, however, is the realization that many of the dysfunctional behaviors have their origins not in some random organic dysfunction but, rather, in the otherwise healthy brain's physiological adaptations to the abnormal world in which the developing child finds himself or herself. These adaptations, although initially useful, have not prepared the child for existence in the larger, more normal world outside the home. Behaviors that may have been useful, even life-saving, in a violent or neglectful home (such as hypervigilance or extreme passivity) become the problem behaviors identified at school or in child care (often interpreted as "attention deficit" or "daydreaming"). Once clearly established and internalized, however, the child's typical response to a stimulus (his or her definition of "normal") can be very hard to change.

The past 2 decades have seen remarkable progress in the understanding of neurodevelopment.[19,20] Once thought of as an enigmatic "black box," the brain is now seen as a complex of specialized, interactive organs, constantly developing through interaction with the environment and each other. Nowhere is this development more dramatic than in the first 3 years of life as the young brain undergoes sweeping structural change as it senses and adapts to the environment in which it finds

itself. Neurons develop myelin sheaths and proliferate, developing myriad connections with others throughout the cranium. With experience, some are strengthened, developing more connections with other neurons. Others are cut back through a process known as apoptosis, the "pruning" of unused connections. Significant apoptosis is seen as early as 4 years of age, continuing until the typical adult brain has lost nearly half of the neuronal connections it possessed at age 3.

It is now understood that this pruning is experience dependent—use strengthens neural pathways, and idleness marks others for demolition. As neurophysiologists remark, "neurons that fire together wire together." Although the 3-year-old's brain is optimized for learning, an adult's brain becomes optimized for performance. Use and disuse of specific pathways alter the neuronal structure through a variety of mechanisms, including changes in sensitivity and the number of synaptic connections.

These changes act to adapt the brain structurally to its environment. By allowing experience to alter its structure, the brain can grow to become the best brain for a child's given surroundings. It is, in other words, learning. A more visually complex environment, for example, may favor a larger visual cortex, whereas a child born blind might devote more cortical area to hearing. Similarly, a brain grown in a more threatening world may benefit from a highly developed fight-or-flight response, with appropriate modifications to the limbic system and HPA.[16,21] For instance, the amygdala, a vital part of the limbic system and necessary in emotional regulation, demonstrates a biphasic response to circulating stress hormones.[22] It becomes more sensitive to stress initially but shrinks when chronically exposed to high circulating concentrations of the stress hormone cortisol, adapting by becoming less sensitive. The hippocampus, a cortical region essential to the proper encoding and retrieval of memory, is similarly affected.[23] These structural changes, by affecting the brain's (and, thus, the individual's) response to stimuli, result in an altered behavioral response to stress.[10,16] The more chronic the stress, the more likely and longer lived the physiological changes.

WAR OF THE WORLDS

Unfortunately for the child, a brain specifically adapted for one type of extreme environment is seldom optimized to perform in another. This, in itself, would not be an insurmountable problem. However, children raised in abusive, violent, or neglectful homes are often denied the very tools that would help them adapt to new and different surroundings. Abused or neglected children often suffer impairments in their language abilities and cognitive skills.[24] One recent study found 36% of preschoolers in foster care to be developmentally delayed and found no difference between the developmental effects associated with reported physical abuse, sexual abuse, or neglect.[25] These deficiencies may reflect prenatal insults or postnatal contributors, such as malnutrition or toxic exposures, but almost certainly correlate with inadequate parental care during sensitive periods in early brain development, providing children with less exposure to language and fewer opportunities for cognitive development.

One of the most important tasks of early childhood is learning to discriminate states of affect.[26] Lacking good models, abused and neglected children may grow up unable to explain (or, indeed, to understand) the difference between such feelings as sadness and anger. In extreme cases, this is termed alexithymia (an inability to "read" emotion). Without this important perception, the ability to perceive the intentions of others, or to monitor one's own response, is lost and social learning is severely impaired.

The brain is most easily altered, or adapted, early in its life. Although there are thought to be few true "critical periods" after which alterations become impossible, early childhood may be thought of as a "sensitive period" for many forms of cognitive—and most emotional—learning, after which it becomes difficult to establish new patterns of thinking or reacting.[19,20] Thus, the abused or neglected child is asked to adapt to a new and different world but is given inadequate neural and behavioral tools with which to do so.

POSITIVE FEEDBACK (OF THE NEGATIVE KIND)

A child's hypervigilance and inability to regulate emotional states after maltreatment can result in challenging behaviors in interactions with others. Victims of previous abuse or neglect are far more often identified as "problem children" than are their peers and show higher rates of diagnosis with attention problems and violent and oppositional behaviors.[27] Caregivers and teachers often respond to these behaviors in the traditional fashion: warnings become more brusque (and often louder) and discipline more strict (and often more punitive).

Although such responses from adults usually gain the desired result in normal children, they become problematic when the listener is hypervigilant for threats and has difficulty controlling his or her own emotions. To a child who is physiologically adapted to a high-threat environment, a minor slight or stern admonition can sound like the prelude to real danger. When the child's exaggerated emotional response calls forth an even stronger response, the child may mistakenly assume that his or her initial reaction was warranted. Such responses inadvertently confirm the child's mistaken impression that the world in general is a high-threat environment. This is, in effect, positive feedback in that it reinforces the preceding behavior—behavior that has negative consequences for the child and for all those around him or her. With reinforcement, neural adaptation (learning) continues. Thus, although maltreated children's threat-adapted neuroanatomy can be said to determine their behavior, that behavior (via the responses of those around them) would be expected, in turn, to determine the further growth of their anatomy.

ATTACHMENT ISSUES

The child's sense of the parents' availability and responsiveness to protect him or her and see to his or her needs—a building block of secure attachment[28]—is a

critical mediator of developmental success, especially under conditions of traumatic stress.[29] An attentive caregiver may help the child learn the give-and-take nature of social communication and teaches the child to recognize and regulate his or her own emotions in a continuous "dance" of interaction.[30,31] With such a benefactor, the infant is secure to learn and explore. When the parent is frankly abusive, the resultant attachment can be confused and disorganized, but even less-severe mistreatment can affect attachment. When the caregiver is absent, preoccupied, or inconsistent, it also becomes difficult for the infant to feel safe. Observers describe neglected infants as more demanding, anxious, or more difficult to console, and they can present special challenges to their already compromised parents. Unless the cycle is broken, the challenged parents are likely to respond with anger or by further distancing themselves from the demanding child, and another positive feedback cycle begins to reinforce maladaptive behaviors.

INTERVENTIONS

Across this continuum of outcome possibilities, current caregivers—be they birth parents, foster parents, or adoptive parents—are almost certain to face major challenges in appropriately responding to the child's mental and physical health needs. A previously neglectful birth parent who has stopped using drugs or left a violent domestic situation may now be able to be consistent and attentive but may find the child unresponsive to his or her best efforts. When a previously maltreated child presents with behavior problems, especially when those problems are resistant to intervention, maladaptive physiological responses may contribute to a child's presentation. In fostering or newly adoptive parenting situations, it is not enough to merely provide a loving and consistent environment; the new parents must be helped to see that the child who has suffered abuse or neglect might indeed see, and respond to, that environment differently than might another child who has not suffered abuse.[32] Too often, maladaptive physiological responses are misinterpreted by teachers and parents and the child is dismissed as willfully "mean" or "disrespectful" and punished accordingly, which reinforces the response.

As abused children grow and develop, earlier trauma is revisited and reconsidered. Often, a child who has learned to live with these abnormal responses will experience added challenges in addressing them as an adolescent. Physiological changes and the onset of formal operational thought can complicate adjustment issues, and problematic behavior can resurface in new and often more dangerous forms. Here again, caregivers need preparation to help children respond constructively.

Therapy must be directed to reshaping the child's perceptions and emotional responses while helping the caregivers address their own behaviors. Failure to do so can result in serious long-term consequences that range from violent behavior to dangerous risk taking to impaired domestic relationships.[33,34]

A child's primary health care professional plays a critical role in identifying for caregivers and children the psychological and biological signs and symptoms of child traumatic stress. A careful psychosocial history should be taken whenever a child presents with behavioral symptoms, with attention paid to early abuse, neglect, or abandonment, especially during the first 3 years of life. Domestic violence, drug abuse, or parental mental health diagnoses are "red flags" that should raise concerns. If an accentuated stress response is suspected, the physician can help caregivers understand that the child's problems are more than simple "defiance" or willful misbehavior. Guidance can include discouraging aggressive responses to aggressive behaviors, including corporal punishment, and explaining how noise and anger can further aggravate the child's runaway stress reaction. Furthermore, physicians can clearly state that there are evidence-based treatments that mental health professionals use to help children and adolescents with traumatic stress reactions and assist them in resuming a more normal developmental path. This information can be shared with the caregivers, starting them on the road to better understanding and ability to obtain trauma-specific services. It is important for parents to know that treatment research has demonstrated that one of the most important factors influencing children's psychological adjustment is the degree of support they receive from their parents and other guardians.[35,36]

The best available evidence from controlled trials supports treating child abuse trauma reactions and related symptoms with trauma-specific psychotherapy that emphasizes cognitive-behavioral approaches. Cognitive-behavioral approaches used in treating abused children include education about child abuse and common reactions of children; teaching safety skills, stress-management techniques, and emotion-regulation skills; facilitating a coherent narrative of the traumatic event; and assisting appropriate emotional and cognitive processing (correcting untrue or distorted ideas about how and why the trauma occurred). Dyadic or conjoint parent work is emphasized as well, recognizing that the child's caregivers bear responsibility for continuing the work of therapy on a day-to-day basis.[37–40] This is especially important with younger and preverbal children.

Some children may not be ready immediately to construct a narrative about their trauma. When coping skills have been put into place, however, conversation between the child and a skilled therapist about the trauma has been a critical ingredient in studies that have provided the strongest research evidence. In fact, studies of adult rape victims have suggested not only that telling the story of the trauma is critical to treatment but also that organization of the trauma narrative and a client's emotional engagement in talking about his or her story can predict symptom reduction.[41,42] Art therapy may be a venue for some children to express their experiences nonverbally.[43]

Given the biological nature of the stress response, medications are often considered to assist children in regulating symptoms of physiological hyperarousal (such as nightmares, sleep difficulties, and high anxiety) and can be prescribed by child psychiatrists, pediatric primary health care professionals, or other pediatric medical subspecialists such as developmental/behavioral pediatricians. Pharmacologic approaches should be considered whenever the behaviors symptomatic of the uncontrolled stress response

interfere with the child's ongoing socialization. The evidence base for psychopharmacologic approaches to treating children and adolescents who suffer from PTSD symptoms is emerging, and although medication can often help ameliorate the stress response in youth, it is important to note that the research on these psychopharmacologic approaches lags behind the research in adults.[44] The same can be said about the promising efforts to prevent PTSD pharmacologically by using medications to blunt the acute stress response.[45–47] Such prevention, of course, would be more feasible after a single trauma, such as a criminal act, than for chronic stress. However effective in reducing symptoms, psychopharmacologic intervention should be considered an adjunct to, rather than a substitute for, psychotherapy.

Effective intervention may involve a variety of professionals working together. A skilled therapist can help the child learn to recognize and regulate his or her emotions and can help the family to respond in a way that makes the situation better instead of worse. Neuropsychological testing can aid in identifying the child's cognitive strengths and weaknesses, helping to anticipate future difficulties and indicating possible solutions, particularly in the area of school performance. Psychiatric or pediatric physicians may prescribe medications to help control extreme behaviors, and educators can tailor educational interventions that respect the child victim's special challenges. Social service workers can help the family obtain needed respite care or other support. By providing a "medical home" for the child, the pediatrician can serve as the facilitator for the intervention team.

CONCLUSIONS

In pediatric office practice, physicians and nurses are often asked to treat common behavioral problems. Children with a history of abuse, neglect, or abandonment may present to the pediatrician with symptoms including anger, aggressive behaviors, depression, or difficulties sustaining attention. In many cases, the children are no longer exposed to direct threat but present with residual behaviors that can be linked to neurophysiological responses to previous maltreatment. When the children are in foster or adoptive care or when a birth parent's circumstances have improved, caregivers may be attentive and consistent in their attempts to address a child's maladaptive behaviors but still find typical behavior-modification strategies unsuccessful. In many cases, the child's exaggerated reactions to stressful stimuli can cause the caregivers to act in ways that reinforce the child's misbehavior.

When attentive and consistent parenting seems ineffective, the physician would do well to remember that early maltreatment (physical or sexual abuse, neglect, or exposure to violence and fear) can deprive the child of the tools needed to adapt to a larger social environment. In addition to denying the developing child necessary social interactions, early maltreatment can alter the normal child's neural physiology, significantly changing the expected responses to stress and affecting the child's ability to learn from experience.

The pediatrician can assist directly and in cooperation with other professionals. Pediatricians should continue to advocate for timely evaluation of children entering the foster care system, as recommended by the American Academy of Pediatrics.[48] Given the risks posed by early neglect and abuse, these examinations should include developmental and cognitive screening in addition to the usual medical assessment,[49] although many foster children do not receive these comprehensive evaluations.[50] Ongoing education for the caregivers of previously maltreated children, especially for foster parents, is essential and can be better guided by the results of a comprehensive evaluation.

Using their therapeutic relationship with the child and family, physicians can work to educate the caregivers, helping them understand that their child's behavioral responses may well be different from those of other children in the same situation and that the differences may reflect a physiological difference rather than willful misbehavior or an egregious failure on the part of the caregivers. If such timely educational interventions can change caregivers' perceptions, they can relieve stress and begin to stabilize the family, with the ultimate goal of decreasing turnover in foster care. A change in perception might also open the door to ongoing counseling on referral from the primary health care professional.

Although many patients with a significant history of trauma will need to be followed by mental health professionals, the pediatrician still plays an important role in management. By providing a medical home, the pediatrician can work longitudinally with caregivers and continue to treat symptoms that are obstructing therapy. Pediatricians can facilitate access to community resources, work closely with the child's school to address behavioral challenges to learning, and help coordinate care among specialists in other disciplines.

ABSTRACT

Unrecognized congenital hypothyroidism leads to mental retardation. Newborn screening and thyroid therapy started within 2 weeks of age can normalize cognitive development. The primary thyroid-stimulating hormone screening has become standard in many parts of the world. However, newborn thyroid screening is not yet universal in some countries. Initial dosage of 10 to 15 μg/kg levothyroxine is recommended. The goals of thyroid hormone therapy should be to maintain frequent evaluations of total thyroxine or free thyroxine in the upper half of the reference range during the first 3 years of life and to normalize the serum thyroid-stimulating hormone concentration to ensure optimal thyroid hormone dosage and compliance.

Improvements in screening and therapy have led to improved developmental outcomes in adults with congenital hypothyroidism who are now in their 20s and 30s. Thyroid hormone regimens used today are more aggressive in targeting early correction of thyroid-stimulating hormone than were those used 20 or even 10 years ago. Thus, newborn infants with congenital hypothyroidism today may have an even better intellectual and neurologic prognosis. Efforts are ongoing to establish the optimal therapy that leads to maximum potential for normal development for infants with congenital hypothyroidism.

Remaining controversy centers on infants whose abnormality in neonatal thyroid function is transient or mild and on optimal care of very low birth weight or preterm infants. Of note, thyroid-stimulating hormone is not elevated in central hypothyroidism. An algorithm is proposed for diagnosis and management.

Physicians must not relinquish their clinical judgment and experience in the face of normal newborn thyroid test results. Hypothyroidism can be acquired after the newborn screening. When clinical symptoms and signs suggest hypothyroidism, regardless of newborn screening results, serum free thyroxine and thyroid-stimulating hormone determinations should be performed.

INTRODUCTION

Congenital hypothyroidism (CH) is one of the most common preventable causes of mental retardation. In most cases, the disorder is permanent and results from an

Key Words
congenital hypothyroidism, thyroid hormone, thyroid-stimulating hormone, newborn screening

Abbreviations
CH— congenital hypothyroidism
TH—thyroid hormone
T_4—thyroxine
T_3—triiodothyronine
TSH-R—thyrotropin receptor
TRBAb—thyrotropin receptor-blocking antibody
FT_4—free thyroxine
TSH—thyroid-stimulating hormone
TBG—thyroid-binding globulin
LBW—low birth weight
VLBW—very low birth weight
L-T_4—levothyroxine
TRH—thyrotropin-releasing hormone

abnormality in thyroid gland development (dysgenesis or agenesis) or a defect in thyroid hormonogenesis. Less commonly, the altered neonatal thyroid function is transient, attributable to the transplacental passage of maternal medication, maternal blocking antibodies, or iodine deficiency or excess. In rare cases, CH may result from a pituitary or hypothalamic abnormality (central or secondary/tertiary hypothyroidism). Recent advances in molecular and cell biology have led to improved understanding of normal thyroid physiology and of genes involved in thyroid gland development and disease. In addition, the mechanism and precise temporal sequence of thyroid hormone (TH) modulation of target gene expression are being elucidated.[1–8]

The initial American Academy of Pediatrics recommendation for newborn screening for CH was published in 1993.[9] Screening for CH is one of dozens of newborn screening tests conducted. The rapid advances in our knowledge in the decade since the 1993 publication have prompted reevaluation of the problem and the identification of new questions and concerns.

TH concentrations are low in the fetus during the first half of pregnancy. During this time, the fetus is entirely dependent on maternal TH; its supply to the fetus is controlled by the placenta and the thyroid status of the mother. The fetal hypothalamic-pituitary-thyroid axis begins to function by midgestation and is mature in the term infant at delivery. Despite the critical importance of TH on multiple organ systems, especially the brain, most infants with CH appear normal at birth. The hypothyroid fetus appears to be protected at least in part by placental transfer of maternal TH. This was best illustrated by the demonstration that cord blood thyroxine (T_4) concentration at birth in infants unable to synthesize T_4 was nonetheless one third to one half that of normal infants.[10] In addition, there is increased intracerebral conversion of T_4 to triiodothyronine (T_3), resulting in increased local availability of T_3 despite the low serum concentrations.[11–13] Indeed, normal or near-normal cognitive outcome is possible in even the most severely affected infants with CH. This is true as long as postnatal therapy is early and adequate and maternal thyroid function is normal. In contrast, when both maternal and fetal hypothyroidism are present, whether attributable to severe iodine deficiency, potent thyrotropin receptor (TSH-R)-blocking antibodies (TRBAbs) (or TSH-blocking immunoglobulins), or maternal-fetal PIT1 deficiency, there is a significant impairment in neurointellectual development despite adequate therapy soon after birth.[6,14,15] Maternal hypothyroidism alone during early gestation can lead to mild but significant cognitive impairment of the offspring.[6,15–19] In this report, attention is focused on the problem of CH alone; identification and treatment of maternal hypothyroidism has been the subject of several recent reviews.[20,21]

Pilot screening programs for CH were developed in Quebec, Canada, and Pittsburgh, Pennsylvania, in 1974 and have now been established in Western Europe, North America, Japan, Australia, and parts of Eastern Europe, Asia, South America, and Central America.[22–24] In North America, more than 5 million newborns are screened and approximately 1400 infants with CH are detected annually. Certainly the main objective of screening, the eradication of mental retardation after CH, has been achieved. In addition to the profound clinical benefit, it has been estimated that the cost of screening for CH is much lower than the cost of diagnosing CH at an older age. This estimate does not include the loss of tax income resulting from impaired intellectual capacity in the untreated but noninstitutionalized person. Newborn screening also has revealed the prevalence of the various causes of CH, including a series of transient disorders found predominantly in preterm infants. The incidence of CH has been found to be 4 to 5 times more common than phenylketonuria, for which screening programs were originally developed. The overall incidence of CH ranges from 1 in 3000 to 1 in 4000 newborn infants.[15,25] The incidence of CH is higher in Hispanic individuals and lower in black individuals.[25] There is a 2:1 incidence in females compared with males, and there is an increased risk in infants with Down syndrome.

Iodine deficiency remains the most common treatable cause of mental retardation worldwide. Associated nutritional deficiencies in selenium and iron may have an effect on neurologic development and on thyroidal response to iodine therapy.[26] Many countries have initiated salt iodination.[25–28] Although North America is usually considered to be an iodine-sufficient area, recent epidemiologic evidence suggests that a number of pregnant women may be iodine deficient.[29] There is also some concern that maternal iodine deficiency may be reappearing in developed countries despite salt iodination because diet-conscious young women may avoid iodine-supplemented salt and breads.[30,31] Iodine supplementation before or during pregnancy will normalize thyroid function in the mother and the newborn.[31,32]

The hypothalamic-pituitary-thyroid axis is finely tuned to maintain a fairly stable concentration of free thyroxine (FT_4) within any individual.[33] Divergence from this individual optimal "set point" because of underfunction of the thyroid gland results in an increase in thyroid-stimulating hormone/thyrotropin (TSH) concentration. The exception to this is when the hypothalamus or pituitary gland is unable to respond (in central hypothyroidism, rare pituitary resistance to FT_4 feedback, or in an occasional child with Down syndrome).

Thus, TSH is elevated if thyroid gland function is impaired and FT_4 decreases from its individual optimal set point, although TSH concentration is not elevated in central hypothyroidism.

Although much has been learned, some questions

remain. These issues include the optimal screening approach and the follow-up of infants with low T_4 and normal TSH concentrations. Finally, continued efforts are ongoing to establish the optimal therapy that leads to maximum potential for normal development for infants with CH.

SCREENING METHOD

Two screening strategies for the detection of CH have evolved: a primary TSH/backup T_4 method and a primary T_4/backup TSH method (Fig 1). In addition, an increasing number of programs use a combined primary TSH plus T_4 approach.

Primary TSH With Backup T_4 Measurements

Most programs in Europe, Japan, Canada, Mexico, and the United States screen by using primary TSH measurements, supplemented by T_4 determinations for infants with elevated TSH values. With this approach, delayed TSH elevation in infants with thyroid-binding globulin (TBG) deficiency, central hypothyroidism, and hypothyroxinemia will be missed. Delayed TSH elevation is particularly common in infants with low birth weight (LBW [<2500g]) and very low birth weight (VLBW [<1500g]). In the Quebec study, 2 cases of permanent CH (of 93 000 infants screened) would have been missed by the primary TSH approach and detected by the primary T_4 approach.[34] The recall rate (notification of a physician to contact the infant's family to arrange for a blood test) with a primary TSH screening approach is approximately 0.05%. At this rate, 2 infants will be recalled for testing for every case detected.

Current TSH assay techniques (enzyme-linked immunoassays, chemiluminescent assays, and fluoroimmunoassays) use nonradioactive labels and have improved sensitivity with the potential for better separation between normal and abnormal TSH concentrations. Thus, many screening programs are considering switching to a primary TSH approach. However, the trend toward early discharge of mothers and infants (before 48 hours of age) presents a problem with the switch to a primary TSH approach because of the normal increase in TSH postnatally. With early hospital discharge, the first screening specimen commonly is obtained before 48 hours of age. Recent data using a sensitive and specific immunofluorometric assay indicate that normal TSH values before 24 hours of age are not as high as those using previous assays and usually less than the cutoff value of 20 to 25 mU/L.[35,36] A 50% reduction in abnormal values occurred when age-adjusted TSH cutoffs were used.[37] Thus, the current experience using newer assays in a primary TSH screening approach in a population of infants discharged after 24 hours of age shows lower patient recall rates with negligible false-negative test results.

Primary T_4 With Backup TSH Measurements

An initial filter-paper blood-spot T_4 measurement is followed by a measurement of TSH for filter-paper specimens with low T_4 values.[9,25] The primary T_4 approach will detect primary hypothyroidism in infants with low or low-normal T_4 with elevated TSH concentrations (prevalence ranging from 1 in 3000 to 1 in 4000 newborn infants). In addition to detecting primary hypothyroidism, the primary T_4/backup TSH approach can also identify infants with TBG deficiency (prevalence ranging from 1 in 5000 to 10 000 newborn infants) and central hypothyroidism (low or low-normal T_4 with normal TSH concentration; prevalence: l in 50 000 newborn infants). Programs that quantify high T_4 values also have the potential to identify infants with hyperthyroxinemia (1 in 20 000 to l in 40 000 newborn infants). This approach, however, will miss the condition in an infant with an initially normal T_4 concentration and delayed increase in TSH. To ensure identification of infants with CH who have low-normal T_4 values, most screening programs use a T_4 concentration cutoff of <10th percentile for the days' assay. Comparison of the primary T_4 versus primary TSH screening approach was conducted in Quebec (1983).[34] One case (of 93 000 infants screened) would have been missed by the primary T_4 approach and detected by the primary TSH approach.[34]

Programs using a primary T_4 with secondary TSH approach will follow-up on infants with a low T_4 and elevated TSH screening result. The recall rate for primary hypothyroidism in these screening programs is approximately 0.05%, similar to that in primary TSH screening programs.[38] However, some primary T_4 screening programs also report low T_4 results below an absolute cutoff (eg, 3.0 μg/dL [39 nmol/L]) in infants even if the TSH was normal. The recall rate (and therefore the false-positive rate) will be higher (approaching 0.30%) with this practice. For example, in a 1990 study in California, which did not report low T_4 results, the recall rate was 0.08%. In contrast, a study performed in Oregon, which reported infants with 2 low T_4 results <3rd percentile, the recall rate was 0.30%.[39] This means that up to 12 normal infants may be recalled for testing for every 1 case of hypothyroidism.

Combined Primary TSH Plus T_4 Measurements

Methods for the simultaneous measurement of T_4 and TSH are available (DELFIA data). This represents the ideal screening approach, especially once it is possible for FT_4 to be measured accurately and cost-effectively in the eluates from filter-paper blood spots. Until T_4 and TSH determinations can be performed practically for all infants, physicians should be aware of the potential limitations of each method of screening for CH.

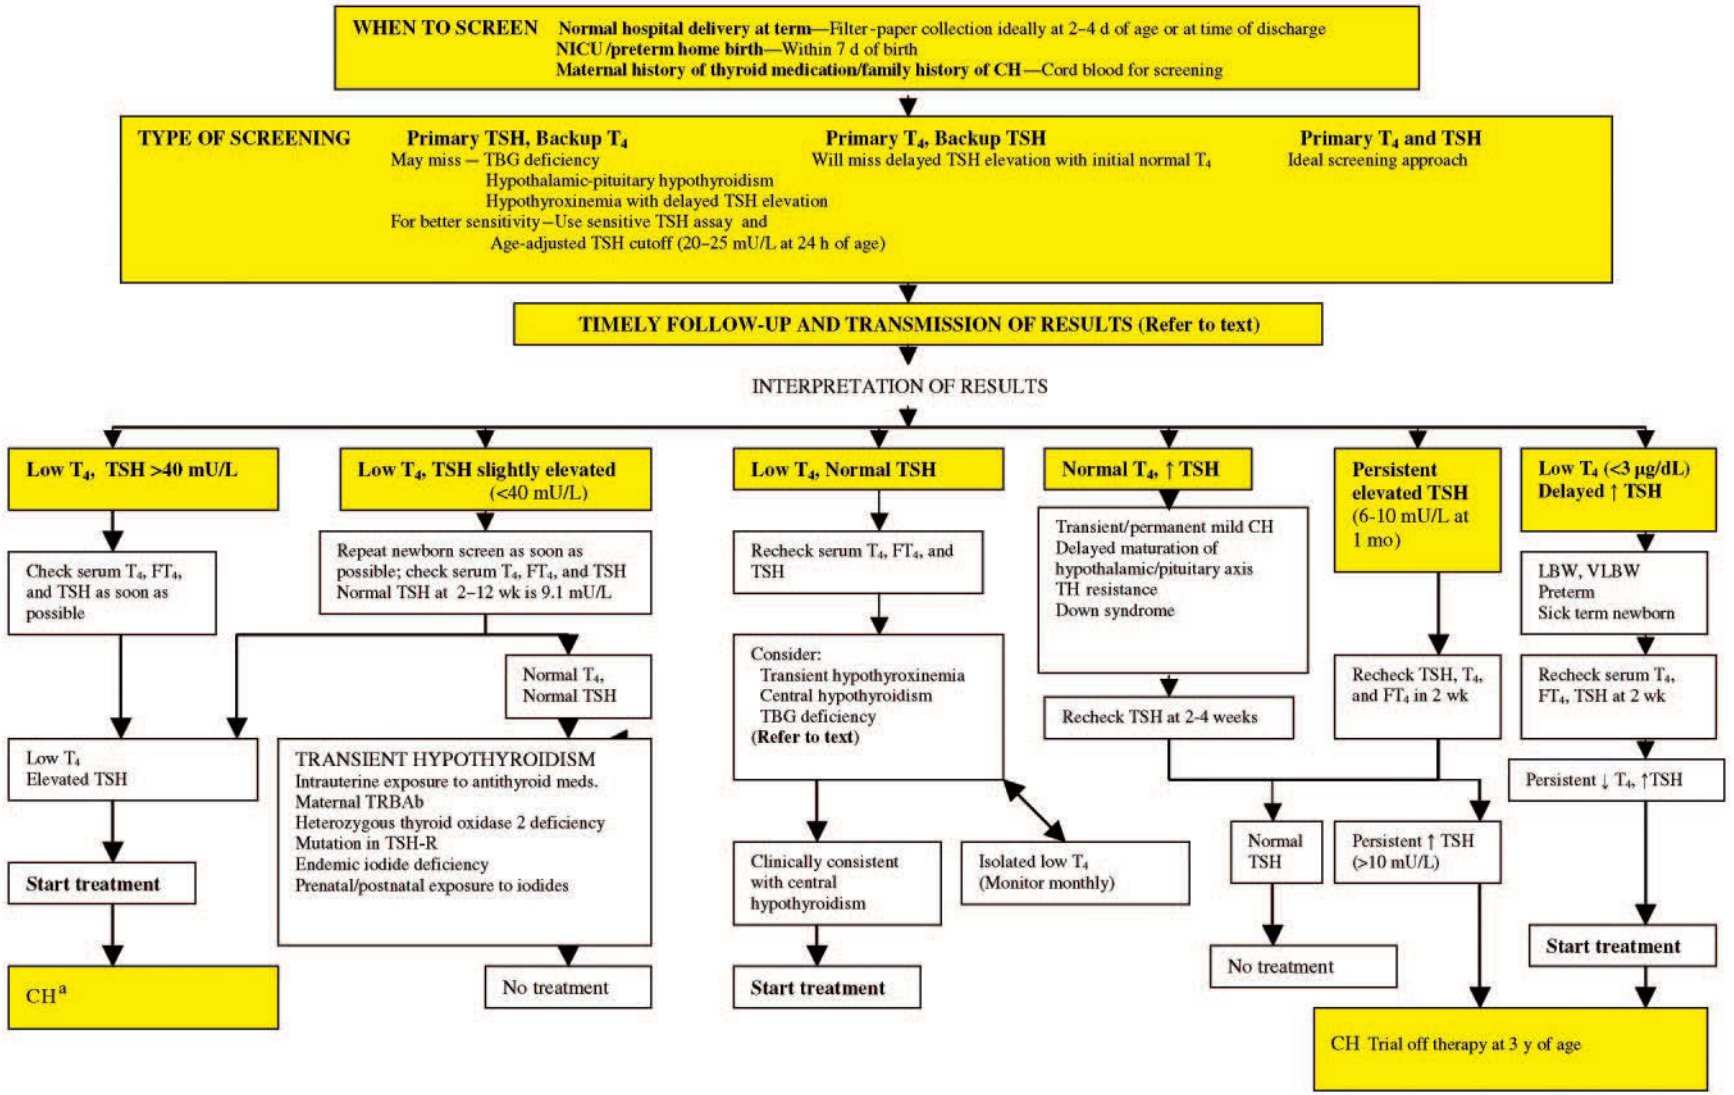

FIGURE 1
Newborn screening for CH. [a] Management of CH is summarized in Table 1.

THE SPECIMEN

Every infant should be tested before discharge from the nursery, optimally by 48 hours to 4 days of age. As noted above, specimens collected in the first 24 to 48 hours of life may lead to false-positive TSH elevations when using any screening test approach. However, screening before hospital discharge or before transfusion is preferable to missing the diagnosis of hypothyroidism. False-negative results may occur by screening a very sick newborn or after transfusion. Because newborn blood specimens are used for a variety of screening tests and shared among different laboratories, every effort should be made to collect adequate and sufficient blood in the recommended manner.[39]

It is highly desirable that the blood be collected when the infant is between 2 and 4 days of age, but there are situations in which this is virtually impossible. In infants discharged from the nursery before 48 hours of age, blood should be obtained before discharge. In instances such as home births or in the case of a critically ill or preterm neonate, blood should be obtained by 7 days of age, recognizing that samples obtained after 4 days of age are late for screening of congenital adrenal hyperplasia or metabolic disease. Particular care must be taken with infants in NICUs. In such cases, more urgent medical problems may result in missed newborn screening. When an infant is transferred to another hospital, the first hospital must indicate whether the specimen has been collected. The second hospital should obtain a specimen if there is no proof that blood was collected before the transfer.

Some state screening programs, testing 10% of newborns in the United States, perform newborn screening on specimens routinely collected at 2 time periods. These programs report that CH is detected in approximately 10% of the affected infants only as a result of collection of a second specimen. The additional incidence of CH based on a second screening at 2 weeks of age is approximately 1 in 30 000.[38,40] Infants with CH detected at the later screening time tend to be of LBW or VLBW, with mild or delayed TSH elevations.[41] Whether these cases represent transient or permanent cases is unknown. Some have thyroid dysgenesis (ectopia, aplasia, or hypoplasia) on thyroid scanning. Others appear to have increased uptake and a large thyroid gland, suggestive of dyshormonogenesis.[8] Either these infants have transient disease or their disease is undiagnosed until a later age, when they appear to have acquired hypothyroidism.

Accurate screening results depend on good-quality blood spots. The filter paper designed for newborn screening bears printed circles. Capillary blood samples are placed in these circular areas to fill and saturate them. Spotting blood over a previous blood spot, or double spotting, causes invalid results, and these blood spots should not be used. The recall of an infant for testing because of an unsatisfactory filter-paper specimen causes needless delay in diagnosis and treatment of a newborn with CH. Specimens that are technically unsatisfactory or contain insufficient amounts of blood should not be assayed. Blood samples should be collected on approved filter-paper forms, dried at room temperature, and not subjected to excessive heat. The blood should completely saturate the filter paper and be applied to 1 side only. Filter-paper spots should not be handled, placed on wet surfaces, or contaminated by coffee, milk, or other substances. Any of these have the potential to invalidate the results regardless of the method used. Testing of an unsatisfactory specimen (because of insufficient blood) can result in a false-negative TSH value. False-negative values can also result from human error in the processing of satisfactory specimens or in erroneous reporting of the results.

TEST RESULTS

Transmission of Results and Follow-up Testing

Newborn screening test results must be communicated rapidly back to the physician or hospital identified on the screening filter-paper card. The responsibility for transmission of these results rests with the authority or agency that performed the test. In general, when an abnormal screening result is found, the responsible physician is notified immediately so that he or she can arrange for follow-up testing. Screening test results should be entered into the patient's record. If the informed physician is no longer caring for or cannot locate the infant, he or she should notify the newborn screening laboratory immediately. In such situations, the local health department is often helpful in locating these infants to ensure that they are not lost to follow-up.

Low T_4 and Elevated TSH Values

Any infant with a low T_4 concentration and TSH concentration greater than 40 mU/L* is considered to have primary hypothyroidism. Such infants should be examined immediately and have confirmatory serum testing performed to verify the diagnosis. Treatment with replacement levothyroxine (L-T_4) should be initiated as soon as confirmatory tests have been drawn and before the results of the confirmatory tests are available. (Clinical management of infants with hypothyroidism is described in the following section.) For cases in which the screening TSH concentration is only slightly elevated but less than 40 mU/L, another filter-paper specimen should be obtained for a second newborn screening. Ten percent of infants with confirmed CH have TSH values between 20 and 40 mU/L. It is important that age-appropriate normative values be used. The reference

* All filter-paper TSH [and T_4] levels here are reported as serum equivalents. Some laboratories report screening results per unit of blood, a value that is approximately half the concentration in serum. We recommend that all laboratories report results per unit of serum, because TSH and T_4 are preferentially distributed into the serum.

range for TSH for the most common time of TSH reevaluation (between 2 and 6 weeks of age) is 1.7 to 9.1 mU/L.[42]

Normal T_4 and Elevated TSH Values

Hyperthyrotropinemia is characterized by elevated serum TSH concentrations during the neonatal period despite normal T_4 and FT_4 concentrations. The etiology is probably heterogeneous and can be either a transient or permanent thyroid abnormality[43–46] or delayed maturation of the hypothalamic-pituitary axis. Inactivation mutations in the TSH-R cause compensated, mild (subclinical) primary hypothyroidism in the neonatal period. The incidence of both transient and persistent hyperthyrotropinemia and CH appears to be higher in infants with Down syndrome. In some cases, transient neonatal hyperthyrotropinemia persists until 10 years of age or later.

There is controversy regarding the need for TH therapy in this setting. There have been no long-term studies to evaluate cognitive development in this group of patients. TSH concentration is the most sensitive indicator that the hypothalamic-pituitary axis is sensing less T_4 than the body "perceives" as optimal. Most physicians would consider a persistent basal TSH concentration higher than 10 mU/L (after the first 2 weeks of age) to be abnormal.[42] Therefore, if the TSH elevation persists, the infant should be treated. If such infants are not treated, measurement of FT_4 and TSH should be repeated in 2 and 4 weeks, and treatment should be initiated promptly if the FT_4 and TSH concentrations have not normalized.

The management of infants with TSH elevations between 6 and 10 mU/L that persist after the first month of life is even more controversial. TSH concentrations are slightly higher in the first few months of life. A TSH range of 1.7 to 9.1 mU/L has been reported for children 2 to 20 weeks of age (Quest Diagnostics reference values, Lyndhurst, NJ). Thus, using the adult reference range for TSH will result in treatment of many euthyroid children. Consequently, if a decision is made to treat such children, a trial off therapy at 3 years of age should be performed.

Low T_4 and Normal TSH Values

Infants with normal TSH but low T_4 values (defined as 2 SDs below the mean for the reference range for age, usually below 10 μg/dL in the newborn infant) may have thyroid insufficiency. The low T_4 with normal TSH profile is seen in 3% to 5% of neonates. This pattern may result from hypothalamic immaturity (particularly in preterm infants, 12% of all newborn infants). Low T_4 but normal TSH results are also observed during illness, with protein-binding disturbances such as TBG deficiency (1 in 5000), in central hypothyroidism (1 in 25 000 to 1 in 50 000 newborn infants; see next 3 paragraphs),[47] or with primary hypothyroidism and delayed TSH elevation (1 in 100 000 newborn infants). Newborn infants who are preterm or ill are found with disproportionate frequency among those with this set of laboratory values.[48] In neonates/infants, inhibition of TSH (causing low T_4 concentrations) can result from constant infusions of dopamine or high-dose glucocorticoids.

Transient hypothyroxinemia is seen to some extent in many preterm infants.[36,48] Immaturity of the hypothalamic-pituitary axis may be physiologically normal for the infant's gestational age. Preterm serum T_4 and FT_4 concentrations are lower than those of term infants, but the TSH concentrations are comparable to term infants.[49,50] Serum TBG concentrations are only slightly low in preterm infants and do not account for the degree of hypothyroxinemia. Consequently, the FT_4 is rarely as low as the total T_4. Serum inhibitors of T_4 binding, present in many patients with nonthyroidal illness, may be an additional contributor to the decreased T_4 values.

In contrast to transient hypothyroxinemia, the presence of midline facial abnormalities, hypoglycemia, microphallus, or visual abnormalities should suggest the possibility of a hypothalamic-pituitary abnormality. Septo-optic dysplasia, often associated with pituitary hormone deficiencies, can manifest as central hypothyroidism.[51,52] Genetic mutation in HESX-1 has been described in septo-optic dysplasia. Clinical symptoms of hypopituitarism, such as neonatal hypoglycemia (from growth hormone and adrenocorticotropic hormone deficiencies), polyuria (from antidiuretic hormone deficiency), or small phallus in boys (from gonadotropin deficiencies), along with the presence of blindness, congenital nystagmus, or midline defects of the brain, should alert the physician to suspect the diagnosis of septo-optic dysplasia. Alternatively, multiple pituitary hormone deficiencies suggest a genetic defect in the cascade leading to fetal pituitary formation, such as PROP1, LHX3, and POU1F1.[4,53] DNA screening for these molecular abnormalities could be beneficial in the future for the rapid and accurate detection of these affected infants during the first weeks of life, but is not yet available clinically.

Isolated TSH-releasing hormone (TRH) deficiency may cause low-normal T_4 and low or normal TSH concentrations. Secondary (or central) hypothyroidism may be suspected in infants with low T_4 and FT_4 and low TSH concentrations.[32,43] Mutations have been identified in the β subunit of TSH, TRH gene, and TRH receptor gene.[54,55] Finally, congenital TSH and growth hormone deficiencies may occur as a result of a difficult birth or anoxia.[56]

In programs that report low T_4 with normal TSH results, there is no clear consensus regarding optimal follow-up. Such programs have elected to take no further action, to follow-up with serial filter-paper screening tests until the T_4 value becomes normal, or to request a second blood sample for measurement of FT_4 and TSH

concentrations. Most infants with low T_4 and normal TSH have normal FT_4 values, and subsequent thyroid function test results are normal. Programs that choose to pursue further laboratory testing must weigh the benefit of detecting TBG deficiency or the rare case of hypopituitary-hypothyroidism or delayed TSH increase against the cost and the psychological effect on the family. The responsibility of deciding which course of action to follow rests with the physician providing the care of the infant. Treatment of these infants (with the exception of those with central hypothyroidism or delayed TSH increase) with L-T_4 has not yet been shown to be beneficial.[48,57–59]

Low T_4 and Delayed TSH Increase

Many infants with low T_4 concentrations and normal TSH values on initial screening (l in 100 000 newborn infants) who are subsequently found to have an elevated TSH concentration are LBW, VLBW, or critically ill preterm and term neonates. Serum TSH values in these infants increase during the first few weeks of life to concentrations characteristic of primary hypothyroidism. It is unclear whether infants with this delayed TSH elevation have an abnormality of pituitary-thyroid feedback regulation, transient hypothyroidism (eg, iodine induced), or a mild form of permanent CH. Long-term follow-up of these infants has not been reported. It is important, therefore, that serum FT_4 and TSH be tested in infants with overtly low T_4 concentrations or in any infant with suggestive signs of hypothyroidism. Infants with low T_4 and a delay in elevation of TSH values and those with normal T_4 concentrations and elevated TSH values might be missed on initial screening. Neither a primary T_4/backup TSH nor a primary TSH/backup T_4 screening strategy will detect the rare infant with a normal T_4 at birth but delayed TSH increase. Even in the absence of technical and human errors, 5% to 10% of LBW and VLBW newborn infants with CH may have normal screening hormone concentrations regardless of the approach used.

Some screening programs routinely obtain a second specimen at 2 to 6 weeks of age and/or obtain a serum sample from any infant with 2 successive T_4 values below an absolute cutoff (<3rd percentile). Whatever strategy is used, subsequent testing should be performed on serum during infancy whenever there is a perceived risk of hypothyroidism, as in familial dyshormonogenesis or in infants with clinical suspicion of hypothyroidism. In addition, a second specimen should be drawn at 2 weeks of age in monozygotic twins, because fetal blood mixing may mask the screening test results.[60]

However, a second screen has not become routine because of (1) increased cost, (2) relatively low yield of cases, (3) diversion and dilution of key personnel, (4) inability to implement new programs, and (5) absence of such cases missed in primary TSH screening programs. Finally, the cognitive and developmental prognosis of this cohort is uncertain because the etiology in most cases is unknown and there are no definitive follow-up data.

As an alternative strategy, other programs have attempted to identify high-risk patient groups so that routine rescreening can be targeted to these infants. There is a disproportionate incidence of delayed TSH increase in VLBW infants (incidence of CH: 1 in 250), LBW infants (incidence of CH: 1 in 1589), and neonates in intensive care settings or with cardiovascular abnormalities.[61] Therefore, some screening programs routinely screen again at 2 weeks and 6 weeks of age all VLBW and all LBW infants in the NICU, especially in newborns known to have cardiac disease. It is likely that most of these infants do not have permanent CH. If hyperthyrotropinemia persists at 6 weeks of age, TH replacement should be started, consistent with therapy of other forms of transient CH, and the infant should be retested after 3 years of age (after stopping therapy for 4–6 weeks) (see "Assessment of Permanence of Hypothyroidism").

Transient TSH Elevation

A small number of infants with abnormal screening values will have transient hypothyroidism as demonstrated by normal serum T_4 and TSH concentrations on the confirmatory (follow-up to screening) laboratory tests. Transient hypothyroidism is relatively rare in North America (estimated at 1 in 50 000) in contrast to iodine-deficient areas of the world; it is much more common in preterm infants but may occur in apparently healthy term infants. Transient hypothyroidism may result from intrauterine exposure to maternal antithyroid drugs, maternal TRBAbs, heterozygous thyroid oxidase 2 deficiency, germ-line mutations in the TSH-R, endemic iodine deficiency, or prenatal or postnatal exposure to excess iodides (povidone iodine, iodinated contrast materials).[31,32,43,62,63] Transient iodine-induced CH is not usually evident at birth and, therefore, may not be detected if newborn screening is performed in the first few days postnatally.

Transplacental passage of potent maternal TRBAbs (incidence: 1 in 180 000) is a much less common cause of transient CH but should be suspected if there is a maternal history of autoimmune thyroid disease or if there is a history of previous affected offspring. In this setting, cord serum can be collected and rapidly tested for thyroid abnormalities. The half-life of immunoglobulin G in the neonate is approximately 3 to 4 weeks,[64] and TRBAbs usually disappear from serum of affected infants by 3 to 6 months of age, depending on the antibody potency.

Because the transient nature of the hypothyroidism will not be recognized clinically or through laboratory tests in some infants, initial treatment will be similar to that in any infant with permanent CH. In these cases, it

is important to determine at some later time whether the hypothyroidism is permanent and whether the infant in fact requires lifelong treatment (see "Assessment of Permanence of Hypothyroidism"). However, in the newborn infant with transient hypothyroidism whose mother is receiving an antithyroid drug, the T_4 and TSH values tend to return to normal within 1 to 3 weeks after birth without treatment.

CLINICAL MANAGEMENT OF NEWBORN INFANTS WITH LOW T_4 AND ELEVATED TSH VALUES

Infants with low T_4 and elevated TSH concentrations have CH until proven otherwise. Management should include the following (Table 1):

1. The infant should be seen by his or her physician without delay. Consultation with a pediatric endocrinologist is recommended to facilitate diagnostic evaluation and optimal management.
2. A complete history, including prenatal thyroid status (maternal drugs and medications) and family history should be obtained, and physical examination should be performed.
3. Serum should be obtained for confirmatory measurements of TSH and FT_4. An elevated thyroglobulin concentration may suggest dyshormonogenesis. Care must be taken to compare the serum results to normal TH concentration for age. When there is history of a maternal autoimmune thyroid disorder or a previously affected infant, measurement of TRBAbs in the infant and/or mother may identify a transient form of neonatal hypothyroidism.
4. Education of parents by trained personnel using booklets or visual aids is highly desirable. Education should focus on (*a*) the etiology of CH, (*b*) the lack of correlation of parental lifestyle during pregnancy with causes of the disease, (*c*) the benefit of early diagnosis in preventing mental retardation, (*d*) the appropriate manner in which TH is administered and the substances (eg, soy, iron, calcium, and fiber) that can interfere with TH absorption, (*e*) the importance of adherence to the treatment plan, and (*f*) the importance of periodic follow-up care.
5. Optional diagnostic studies include thyroid ultrasonography or iodine 123 (^{123}I) or sodium technetium 99m pertechnetate (^{99m}Tc) thyroid uptake and/or scan to identify functional thyroid tissue. Although ^{123}I tends to give a more accurate uptake and scan picture, it may not be readily available in all hospitals. ^{99m}Tc is generally more readily available and a much less expensive radioisotope. The half-life of ^{123}I is 13.3 hours, compared with 8 days for iodine 131 (^{131}I). ^{123}I exposes the infant to much lower doses of ionizing radiation compared with ^{131}I (probably one 100th of the ^{131}I dose [H.-M. Park, MD, Professor Emeritus, Radiology, Indiana University, personal communication, September 16, 2004]).

There remains some controversy regarding the risk-benefit ratio of early thyroid scanning of infants with suspected hypothyroidism. For physicians who opt for imaging, the benefits can be summarized as follows:

1. If an ectopic gland is demonstrated, a permanent form of thyroid disease and CH has been established.
2. The absence of thyroid gland uptake is most often associated with thyroid aplasia or hypoplasia. When radioiodine uptake is absent but ultrasonographic examination reveals a normal gland, a TSH-R defect, iodine-transport defect, or maternal transfer of TRBAbs may be present.
3. Normal scan findings (or a goiter) indicate a functioning thyroid gland with regard to iodine uptake and alert the physician to a probable hereditary defect in T_4 synthesis. Measurement of serum thyroglobulin will help to separate thyroglobulin synthetic defects from other causes of hypothyroidism.[65] Exposure to an exogenous goitrogen other than iodine, such as antithyroid drugs, will produce a similar picture. Finally, some infants exposed to maternal TRBAbs may have a normal scan if their hypothyroidism is partially compensated. The identification of a genetically mediated thyroid synthetic enzyme defect is especially important for families planning on having additional children. In such cases, the scan enables the physician to arrange for genetic counseling.
4. Some infants with normal scan findings at birth who do not fall into one of the above categories may have a transient form of hypothyroidism. These infants should undergo a careful follow-up evaluation after 3

TABLE 1 Management of CH

Initial workup
Detailed history and physical examination
Referral to pediatric endocrinologist
Recheck serum TSH and FT_4
Thyroid ultrasonography and/or thyroid scan (see text for recommendations)
Medications
L-T_4: 10–15 μg/kg by mouth once daily
Monitoring
Recheck T_4, TSH
2–4 wk after initial treatment is begun
Every 1–2 mo in the first 6 mo
Every 3–4 mo between 6 mo and 3 y of age
Every 6–12 mo from 3 y of age to end of growth
Goal of therapy
Normalize TSH and maintain T_4 and FT_4 in upper half of reference range
Assess permanence of CH
If initial thyroid scan shows ectopic/absent gland, CH is permanent
If initial TSH is <50 mU/L and there is no increase in TSH after newborn period, then trial off therapy at 3 y of age
If TSH increases off therapy, consider permanent CH

years of age, when it is safe to discontinue treatment temporarily under the conditions described in "Assessment of Permanence of Hypothyroidism."

Treatment need not be delayed to perform the scan. A thyroid scan can be performed within the first few days of treatment, because the elevated TSH found in patients with permanent CH rarely normalizes within this time period. A serum TSH measurement should be obtained at the time of the scan. If L-T_4 therapy has caused the TSH concentration to be <30 mU/L, ultrasonography can still be performed. A scan can be performed after the child is 3 years of age, when TH treatment can be interrupted without danger to the developing central nervous system.

The usual dose of ^{123}I, the preferred isotope, is 0.925 MBq (25 μCi). This represents a small amount of radiation exposure, equivalent to the amount of exposure with 2 to 3 chest radiographs. However, the radiation exposure is potentially 100 times greater if ^{131}I or large doses of isotope are administered. For this reason, the procedure should be performed by experienced personnel with optimal equipment, using the minimally recommended tracer dose.

To avoid unnecessary radiation, some investigators prefer ultrasonography as the initial imaging procedure to identify the presence and location of thyroid tissue.[66–68] However, gray-scale ultrasonography is much less sensitive than scintigraphy in detecting the presence of ectopic thyroid tissue, the most common cause of CH. Recent studies have indicated markedly improved sensitivity of color Doppler ultrasonography in diagnosing ectopic thyroid tissue.[69] If these studies are confirmed, color Doppler ultrasonography may become the optimal imaging procedure for the initial investigation of suspected CH.

TREATMENT

All infants with hypothyroidism, with or without goiter, should be rendered euthyroid as promptly as possible by replacement therapy with TH.[21,70–72] An optimal cognitive outcome depends on both the adequacy and timing of postnatal therapy, particularly in severe cases of CH (T_4 < 5 μg/dL). However, what constitutes optimal TH therapy is not yet certain. The goal of therapy is to normalize T_4 within 2 weeks and TSH within 1 month. An initial dosage of 10 to 15 μg/kg of L-T_4 (depending on the severity of the initial hypothyroidism) has been recommended. When a higher initial dose of L-T_4 (50 μg [ie, 12–17 μg/kg]) is used, the serum T_4 normalizes in 3 days and the TSH returns to the target range by 2 weeks of therapy.[72] In the long run, evaluation of cognitive outcome is important after use of this increased dose. Currently the evidence base does not indicate cognitive benefit from thyroid therapy of hypothyroxinemia of prematurity in the absence of TSH elevation.[48–50,57–59]

Administration of L-T_4 is the treatment of choice. Although T_3 is the more biologically active TH, most brain T_3 is derived from local monodeiodination of T_4, so T_3 should not be used. The pill should be crushed and suspended in a few milliliters of formula, breast milk, or water. Care should be taken to avoid concomitant administration of soy, fiber, or iron. Breastfeeding can continue. Only T_4 tablets should be used; currently there are no liquid formulations licensed by the US Food and Drug Administration. T_4 suspensions that may be prepared by individual pharmacists may lead to unreliable dosage. T_4 is expected to increase to more than 10 μg/dL, FT_4 is expected to increase to more than 2 ng/dL by 2 weeks after initiating therapy, and TSH should normalize by 1 month.[73] FT_4 measurement at 1 week of therapy can confirm whether the serum concentration is increasing appropriately. The L-T_4 dose should be adjusted according to the infant's clinical response and serum FT_4 and TSH concentrations.

During therapy, the serum total T_4 or FT_4 should and might be in the upper half of the reference range (target values depend on the assay method used [T_4: 10–16 μg/dL (130–206 nmol/L); FT_4: 1.4–2.3 ng/dL (18–30 pmol/L)]) during the first 3 years of life with a low-normal serum TSH. The latter may sometimes be delayed because of relative pituitary resistance. In such cases, characterized by a normal or increased serum T_4 and an inappropriately high TSH concentration, the T_4 value is used to titrate the dose. Nonadherence to the treatment is the most common cause of persistent TSH elevation and should be excluded. Those infants with low serum T_4 concentrations (below 10 μg/dL [129 nmol/L]) and a TSH concentration greater than 15 mU/L during the first year of life have lower IQ values than patients whose T_4 concentrations were held constant at higher concentrations.[35] Thereafter, thyroid function test values should be kept at age-appropriate concentrations, which in children differ from those for adults.[74] On TH-replacement therapy, TSH levels should be maintained between 0.5 and 2.0 mU/L during the first 3 years of life.[75] Clinical evaluation of the infant by the practitioner should be conducted at frequent intervals during the first 3 years of age (see "Follow-up"). Because poor compliance and noncompliance have major sequelae, initial and ongoing counseling of parents is of great importance.

Current international organizations such as the American Clinical Laboratory Association recommend that the FT_4, rather than the total T_4, be measured to assess the concentration of the biologically relevant, unbound or free form of circulating T_4.[75] The cost of total T_4 plus TBG or T_3 resin uptake, versus the FT_4 by most methods (excluding the more costly direct dialyzable or ultrafiltration methods), should be comparable. However, although the total T_4 is a robust measure, it should be recognized that most direct FT_4 assays are influenced,

to some extent, by protein binding. Consequently, the FT_4 values obtained vary between assays.

During TH therapy, 4 or more episodes of insufficiently suppressed TSH (>5 mU/L) after the age of 6 months were the most important variables associated with school delay.[75] Usually, these episodes are caused by poor parental compliance or impaired T_4 bioavailability. The latter may be caused by inhibition of T_4 intestinal uptake by specific foods (soy, fiber) and medications (iron, calcium), malabsorption, or increased degradation (anticonvulsants; large hemangiomas with high deiodinase activity). The Food and Drug Administration has deemed several generic L-T_4 products to be equivalent to some currently branded preparations. Any change in source of the L-T_4, especially if not a standard brand, requires retitration of the dose.

FOLLOW-UP

Clinical examination, including assessment of growth and development, should be performed every few months during the first 3 years of life. Infants with CH appear to be at increased risk of other congenital anomalies (approximately 10% of infants with CH, compared with 3% in the general population). Cardiovascular anomalies, including pulmonary stenosis, atrial septal defect, and ventricular septal defect, are the most common.

Infants need to undergo frequent laboratory and clinical evaluations of thyroid function, growth, and development to ensure optimal T_4 dosage and adherence to their therapy regimen. Serum T_4 and TSH measurements should be performed:

1. at 2 and 4 weeks after the initiation of L-T_4 treatment;
2. every 1 to 2 months during the first 6 months of life;
3. every 3 to 4 months between 6 months and 3 years;
4. every 6 to 12 months until growth is completed; and
5. at more frequent intervals when compliance is questioned, abnormal values are obtained, or dose or source of medication has been changed; FT_4 and TSH measurements should be repeated 4 weeks after any change in L-T_4 dosage.

The aim of therapy is to ensure normal growth and development by maintaining the serum total T_4 or FT_4 concentration in the upper half of the reference range in the first year of life, with a serum TSH in the reference range (optimally 0.5–2.0 mU/L).

Some infants will have serum TSH concentrations in the range of 10 to 20 mU/L despite T_4 concentrations in the upper half of the reference range. Rarely, the elevated TSH relative to the FT_4 value is hypothesized to result from in utero hypothyroidism, producing a resetting of the pituitary-thyroid feedback threshold. A failure of the serum FT_4 concentration to increase into the upper half of the reference range by 2 weeks and/or failure of the TSH concentration to decrease to less than 20 mU/L within 4 weeks after initiation of L-T_4 administration should alert the physician that the child may not be receiving adequate L-T_4 regularly. At this point, careful inquiry should be made regarding compliance, dose of medication, and method of administration. When attempting to achieve the optimal concentration of circulating FT_4, physicians should always bear in mind the adverse effects of excessive medication and thus be prepared to monitor blood concentrations of FT_4 at close intervals. Prolonged hyperthyroidism has been associated with premature craniosynostosis.

DEVELOPMENTAL OUTCOME

Growth rate and adult height are normal in children with CH in whom TH therapy is consistently maintained.[68,76,77] The best outcome occurred with TH therapy started by 2 weeks of age at 9.5 μg/kg or more per day, compared with lower doses or later start of therapy.[71] There are only minor differences in intelligence, school achievement, and neuropsychological tests in adults with CH that was treated early with TH compared with control groups of classmates and siblings.[78–82] Residual defects can include impaired visuospatial processing and selective memory and sensorimotor defects. Whether these minor differences are preventable by further optimizing postnatal therapy remains controversial.

In contrast to the excellent outcome in infants with CH that is treated early, the prognosis for normal mental and neurologic performance is less certain for infants with CH that is not detected early by newborn screening. Although physical recovery is good and stature is normal,[77] when replacement therapy is begun later but within the first 2 months of life, infants with severe hypothyroidism at birth and intrauterine hypothyroidism (retarded skeletal maturation at birth) may still have a low-to-normal IQ.[18] Similarly, although more than 80% of infants given replacement therapy before 3 months of age have an IQ greater than 85, 77% of these infants show some signs of minimal brain damage, including impairment of arithmetic ability, speech, or fine motor coordination in later life. Even in early-treated patients with CH, auditory brainstem evoked potentials were abnormal in 25% of 27 children studied. The reason for this is not known but might suggest that prenatal maternal T_4 production does not provide complete protection for the developing central nervous system.[84] In another study, processing of visuospatial relationships remained affected in adolescents with CH.[85] The effect of underlying severity of CH combines with the effects of TH dose and of age at onset of TH therapy.[35] Otherwise, neurologic and intellectual outcome do not correlate well with the degree of T_4 deficiency found in neonatal screening.

Transplacental transfer of maternal T_4 in the first

trimester may protect the brain during early development.[15] For the same reason, maternal hypothyroidism during fetal development can have persistent neurodevelopmental effects on the child.[15,16,19] Serum T_4 concentrations at term in athyreotic infants are 25% to 50% of those in normal neonates. These concentrations, although low, may contribute to fetal brain development. It is thought that the low-to-normal intelligence of patients with CH treated early in life results most commonly from inadequate treatment or poor compliance.

It must be noted that TH treatment regimens used today are more aggressive in targeting early correction of TSH than were the regimens used 20 or even 10 years ago. Thus, newborn infants with CH today may have an even better intellectual and neurologic prognosis than adults with CH who were evaluated in the reports discussed above.

ASSESSMENT OF PERMANENCE OF HYPOTHYROIDISM

CH is permanent if the thyroid scan reveals an ectopic gland or absent thyroid tissue (confirmed by ultrasonographic examination) or if the serum TSH is seen to increase above 10 mU/L after the first year of life, presumably because of insufficient T_4 replacement.

If no permanent cause of CH was found by scan or there was no TSH increase after the newborn period, then L-T_4 administration should be discontinued for 30 days at some point after the child is 3 years of age.[86] After 30 days, serum should be obtained for measurement of FT_4 and TSH values. It is critical that this follow-up laboratory assessment be obtained in a timely manner and that there be no loss of follow-up. If the FT_4 is low and the TSH value is elevated, permanent hypothyroidism is confirmed and TH therapy should be reinstituted. If the FT_4 and TSH concentrations remain in the reference range, euthyroidism is assumed and a diagnosis of transient hypothyroidism recorded. It is important that the child not be lost to follow-up. The physician should monitor the child carefully and repeat the thyroid function tests at the slightest suspicion of recurrence of hypothyroid symptoms. If the results are inconclusive, careful follow-up and subsequent testing will be necessary.

More severely affected children may become clinically hypothyroid when treatment is discontinued for 30 days. An alternative option is to reduce the TH-replacement dosage by half. If after 30 days the TSH is elevated above 20 mU/L, the permanence of hypothyroidism is confirmed and full replacement therapy should be resumed. If the serum TSH value has not increased, then TH treatment should be discontinued for another 30 days with repeated serum FT_4 and TSH determination as described above.

ADMONITION

Finally, physicians cannot and must not relinquish their clinical judgment and experience in the face of normal newborn thyroid test results. Failure of normal development can result from hypothyroidism in infants who had normal T_4 and TSH newborn screening results. Hypothyroidism can manifest or be acquired after the newborn screening. Rarely, the newborn screening test results can be in error, or human error can result in failure to notify the infant's physician of abnormal test results.[87] When clinical symptoms and signs suggest hypothyroidism, regardless of newborn screening results, serum FT_4 and TSH determinations should be performed.

FREE

Physicians should always communicate the scope and nature of the physical examination to be performed to the pediatric patient and his or her parent. This statement addresses the use of chaperones and issues of patient comfort, confidentiality, and privacy. The use of a chaperone should be a shared decision between the patient and physician. In some states, the use of a chaperone is mandated by state regulations. *Pediatrics* 2011;127:991–993

BACKGROUND

An appropriate physical examination is usually a critical component of a visit to a pediatrician by an infant, child, adolescent, or young adult and represents efficient, sensitive, and effective health care. The extent of the physical examination is determined by both the reason for the visit and diagnostic considerations raised during the taking of the history.

The purpose and scope of the physical examination should be made clear to the parents as well as the patient if he or she is old enough to understand. If any part of the examination may be physically or psychologically uncomfortable, every effort should be made to support the patient and parent, including the use of measures to preserve privacy, such as gowns and drapes.

In the medical office setting, the physical examination of an infant, toddler, or child should always be performed in the presence of a parent or guardian. If a parent or guardian is unavailable or the parent's presence will interfere with the physical examination, such as in a possible case of abuse or parental mental health issues, a chaperone should be present during the physical examination.

If the patient is an adolescent or young adult and the examination requires inspection or palpation of anorectal or genital areas and/or the female breast, a chaperone is recommended. The presence of a chaperone may be useful to reinforce the professional nature of the interaction and content of the examination and to provide a witness in case of misunderstanding.[1] In general, it is wise for male clinicians to have a chaperone during female breast, anorectal, and genital examinations. However, even same-sex examinations can be misunderstood and can benefit from chaperoning. The patient's wishes and comfort should determine the sex of the chaperone.[2] If the patient chooses to have a chaperone, the chaperone should preferably be a nurse or medical assistant. Family members or friends should not be used as chaperones unless specifically requested by the patient and, if at all possible, only in the presence of an additional chaperone who is not a

family member or friend.[3] The name of the chaperone should be documented in the medical record.

The patient or physician might consider the presence of a chaperone problematic in a variety of circumstances. A patient may feel that his or her privacy and confidentiality may be compromised. A patient may experience embarrassment and increased vulnerability with another party present during the examination. Pediatricians could have concerns that providing a chaperone would require additional staff or that they would not have a chaperone of the desired gender available. In these situations, the use of a chaperone may not be possible.

The use of a chaperone should be a shared decision between the patient and physician. The patient's preference should be given the highest priority when deciding on the use of a chaperone.[4–7] If the patient declines the use of a chaperone, the pediatrician should document this fact in the medical record. Regardless of whether a chaperone is used, the physician should review the scope and findings of the examination with the patient and parents at completion of the examination. This review should be documented in the medical record.

In certain situations, a physician may request the presence of a chaperone, particularly when a patient or parent is exhibiting mental health issues; has developmental issues; or displays anxiety, tension, or reluctance toward examination. If the explanation of the scope and confidentiality of the examination does not resolve the tension or conflict, the use of a chaperone during the examination is appropriate.[8] The pediatrician needs to communicate with the patient and parent why a chaperone is required in this situation. For the rare situation in which the patient refuses an appropriate chaperone and the physician is concerned that providing the examination might result in false allegations or medicolegal risk, the physician is not obligated to provide further treatment.[9] If a patient request for a chaperone is not able to be accommodated, the patient may refuse to receive further treatment. If care is not provided, the physician must discuss with the patient the risks of not receiving further care and offer alternatives, including being examined by another provider or seeking care elsewhere. This discussion should be documented in the medical record.

Pediatricians should develop and follow a clear policy for the office or clinic setting regarding the presence of a chaperone during parts of the physical examination. This policy should include respect for privacy and confidentiality by the chaperone.[10] Pediatricians should document in the medical record if they are unable to adhere to the policy or state medical board regulations regarding the use of a chaperone.

RECOMMENDATIONS

1. Communication in advance regarding the components of the physical examination is of critical importance. Effective communication will help ensure that there is no misunderstanding about the reasons for and conduct of the examination.
2. If the patient is an adolescent or young adult and the examination requires inspection or palpation of anorectal or genital areas and/or the female breast, a chaperone is recommended. However, the use of a chaperone should be a shared decision between the patient and physician.
3. If a medical chaperone is indicated and the patient refuses, the patient or parent should be given alternatives, including seeking care elsewhere.
4. Pediatricians should develop policy about the use of chaperones in the office or clinic setting and document in the medical record if they are unable to adhere to the policy or state medical board regulations.

Committee on Drugs

Use of Codeine- and Dextromethorphan-Containing Cough Remedies in Children

ABSTRACT. Numerous prescription and nonprescription medications are currently available for suppression of cough, a common symptom in children. Because adverse effects and overdosage associated with the administration of cough and cold preparations in children have been reported, education of patients and parents about the lack of proven antitussive effects and the potential risks of these products is needed.

INDICATIONS AND CONTRAINDICATIONS

Cough is a reflex response to mechanical, chemical, or inflammatory irritation of the tracheobronchial tree mediated by sensory neurons in the airways reflexly through neurons in the brainstem. Cough serves as a physiologic function to clear airways of obstructive or irritating material or to warn of noxious substances in inspired air.[1]

In some pathologic states (eg, asthma, bronchopulmonary dysplasia, cystic fibrosis, and a variety of inflammatory conditions), excessive and/or abnormal airway secretions may be produced. The cough reflex serves to maintain airway patency by clearing these secretions. Clearing of pathologic tracheobronchial secretions is essential to patient management and may be enhanced by chest physiotherapy. Cough suppression may adversely affect patients with these conditions by promoting pooling of secretions, airway obstruction, secondary infection, and hypoxemia.

Many common respiratory conditions in which cough is prominent (eg, respiratory viral infections) are self-limited (lasting a few days). Cough may be an expression of airway reactivity or asthma. The cough that is associated with these conditions may be satisfactorily managed with fluids and increased ambient humidity (especially of value with croup). When cough is persistent, it is usually secondary to infection, allergy (including asthma), environmental irritants (eg, cigarette smoke, dust particles) or, occasionally, a foreign body. Therapy should be directed at the underlying condition for lasting benefit.

ANTITUSSIVE AGENTS

Most cough suppressant preparations are marketed as mixtures of dextromethorphan or codeine with antihistamines, decongestants, expectorants, and/or antipyretics. Some nonprescription preparations substitute diphenhydramine or eucalyptus oil in place of codeine or dextromethorphan. Prescription medications may substitute other narcotic agents (hydrocodone or hydromorphone) for codeine and may be more addictive than codeine.[2,3] In addition, many of these cough products are elixirs, which may contain up to 25% alcohol by volume.[3]

The over-the-counter availability of numerous cough and cold preparations promotes the perception that such medications are safe and efficacious. Although codeine and dextromethorphan are efficacious for cough suppression in adults,[1] similar efficacy has not been demonstrated in children. Taylor et al[4] conducted a randomized, controlled trial of codeine, dextromethorphan, and placebo in children with acute nocturnal cough without evidence of chronic underlying lung disease (asthma, cystic fibrosis, or bronchopulmonary dysplasia). Neither dextromethorphan nor codeine in the dosages used was significantly more effective than placebo in reduction of acute cough. Studies using larger dosages have not been performed. Other studies focusing exclusively on children with cough have not been placebo-controlled trials.[5–7] To our knowledge, studies of the use of other purportedly antitussive agents in children, such as diphenhydramine, have not been reported in the literature.

Demonstration of the efficacy of antitussive preparations in children is lacking, and these medications may be potentially harmful.[8] Decongestant (sympathomimetic) components of these mixtures administered to children have been associated with irritability, restlessness, lethargy, hallucination, hypertension, and dystonic reactions.[8] The clearance and metabolism of the components of cough mixtures may vary with age[9] and disease state.[10,11] Great variability in the enterohepatic circulation of these drugs is noted in adults, which affects drug response, especially with repeated dosing.[3] The relative immaturity of hepatic enzyme systems that metabolize drugs in young children may enhance the risk of adverse effects of such medications, especially in infants younger than 6 months.[9] Metabolism and/or toxicity also may be altered by concurrent use of medications such as acetaminophen.[12] Unfortunately, the dosing guidelines for these agents are based on extrapolation from adult data without consideration of their potentially unique metabolism and disposition in children.

Codeine

In adults, codeine and dextromethorphan have been shown to suppress both artificially induced and

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

PEDIATRICS (ISSN 0031 4005).

disease-related cough, mainly through central nervous system mechanisms.[13] A linear relationship has been shown to exist between a codeine dosage in the range of 7.5 to 60 mg/d and a decrease in the frequency of chronic cough.[14] Complete suppression of cough was not achieved in these trials, even at the highest daily dose of codeine.

Dosage

Pharmacokinetic studies of codeine therapy in children are lacking. The published dosage recommendation for codeine in children is 1 mg/kg/d in four divided doses, not to exceed 60 mg/d.[12] To our knowledge, no well-controlled studies have documented the safety and efficacy of this dosage.

Adverse Reactions and Overdosage

The principal clinical manifestations of codeine toxicity are respiratory depression and obtundation.[14,15] In children, antitussive dosages of 3 to 5 mg/kg/d have produced somnolence, ataxia, miosis, vomiting, rash, facial swelling, and pruritis. Respiratory depression requiring mechanical ventilation occurred in 3% of children receiving dosages greater than 5 mg/kg/d; two of these patients died.[16] Dosages of codeine less than 2 mg/kg are unlikely to be associated with significant adverse reactions. Reports of adverse reactions to codeine are based on single dose ingestions; the repetitive administration of codeine for therapeutic purposes may be associated with adverse symptoms at doses lower than a single dose of 5 mg/kg. In adults, glucuronide conjugation in the liver apparently inactivates codeine, but 10% of an oral dose is demethylated to form morphine, which is believed by some to be the active form of the drug.[17] The hepatic glucoronidation pathway is incompletely developed in infants, which places them at particular risk for adverse dose-related effects. Furthermore, alteration of hepatic enzyme pathways by illness or concurrent drug therapy (such as acetaminophen) may further alter metabolism of this drug and increase the risk of drug toxicity.[10,11]

Other narcotic antitussives that are available in cough preparations, such as hydrocodone and hydromorphone, have no demonstrated advantage as antitussive agents compared with codeine, have similar adverse effects, and have a greater risk of dependency.[12] Hydrocodone and hydromorphone are classified as Schedule III drugs under the Controlled Substances Act.

Dextromethorphan

The addictive potential of codeine encouraged the marketing of dextromethorphan in a variety of cough and cold preparations. Although dextromethorphan is chemically derived from the opiates, it has no analgesic or addictive properties. The cough suppression potency of dextromethorphan in adults is nearly equal to that of codeine.[2] The drug, like codeine, acts on the central nervous system to elevate the threshold for coughing.[2]

Dosages

Pharmacokinetic studies and demonstrations of the efficacy of cough suppression in children are lacking. Dosages of dextromethorphan of equal antitussive potency to codeine produce comparable levels of central nervous system depression in adults.[15] The recommended dosage in children is similar to that for codeine (ie, 1 mg/kg/d divided into 3 to 4 doses).[3]

Adverse Reactions and Overdosage

Acute overdosage of cough mixtures containing dextromethorphan has resulted in behavioral disturbances, including respiratory depression.[8]

CONCLUSIONS AND RECOMMENDATIONS

1. No well-controlled scientific studies were found that support the efficacy and safety of narcotics (including codeine) or dextromethorphan as antitussives in children. Indications for their use in children have not been established.
2. Suppression of cough in many pulmonary airway diseases may be hazardous and contraindicated. Cough due to acute viral airway infections is short-lived and may be treated with fluids and humidity.
3. Dosage guidelines for cough and cold mixtures are extrapolated from adult data and clinical experience, and thus are imprecise for children. Adverse effects and overdosage associated with administration of cough and cold preparations in children are reported. Further research on dosage, safety, and efficacy of these preparations needs to be done in children.
4. Education of patients and parents about the lack of proven antitussive effects and the potential risks of these products is needed.

CLINICAL REPORT

The Use of Complementary and Alternative Medicine in Pediatrics

Guidance for the Clinician in Rendering Pediatric Care

Kathi J. Kemper, MD, MPH, Sunita Vohra, MD, Richard Walls, MD, PhD, the Task Force on Complementary and Alternative Medicine, the Provisional Section on Complementary, Holistic, and Integrative Medicine

ABSTRACT

The American Academy of Pediatrics is dedicated to optimizing the well-being of children and advancing family-centered health care. Related to these goals, the American Academy of Pediatrics recognizes the increasing use of complementary and alternative medicine in children and, as a result, the need to provide information and support for pediatricians. From 2000 to 2002, the American Academy of Pediatrics convened and charged the Task Force on Complementary and Alternative Medicine to address issues related to the use of complementary and alternative medicine in children and to develop resources to educate physicians, patients, and families. One of these resources is this report describing complementary and alternative medicine services, current levels of utilization and financial expenditures, and associated legal and ethical considerations. The subject of complementary and alternative medicine is large and diverse, and consequently, an in-depth discussion of each method of complementary and alternative medicine is beyond the scope of this report. Instead, this report will define terms; describe epidemiology; outline common types of complementary and alternative medicine therapies; review medicolegal, ethical, and research implications; review education and training for complementary and alternative medicine providers; provide resources for learning more about complementary and alternative medicine; and suggest communication strategies to use when discussing complementary and alternative medicine with patients and families. *Pediatrics* 2008;122:1374–1386

INTRODUCTION

The National Center for Complementary and Alternative Medicine (NCCAM) of the National Institutes of Health (NIH) defines complementary and alternative medicine (CAM) as a group of diverse medical and health care systems, practices, and products that are not presently considered to be part of conventional Western medicine.[1] Complementary medicine is used in conjunction with conventional medicine; for example, massage, guided imagery, and acupuncture may be used in addition to analgesic medications to help decrease pain. Alternative medicine is used in place of conventional Western medicine; for example, some adolescents use herbs rather than antidepressant medications to treat depression.

The distinction between CAM and mainstream medicine has lessened as many practices have undergone rigorous research and have been integrated increasingly into mainstream care. For example, guided imagery and massage have been proven to be effective in the treatment of pain and are now included in many tertiary care settings.[2–5] Since the American Academy of Pediatrics (AAP) convened the Task Force on Complementary and Alternative Medicine in 2000 and since the creation of the NCCAM, these complexities inherent in the definition of CAM have become more problematic. Given the wide usage and general understanding of the term "CAM," it will be used throughout this report. However, the term "CAM" has been replaced increasingly with "holistic" or "integrative" medicine. Holistic medicine refers to patient-centered care that includes consideration of biological, psychological, spiritual, social, and environmental aspects of health. Integrative medicine is relationship-based care that combines mainstream and complementary therapies for which there is some high-quality scientific evidence of safety and effectiveness to promote health for the whole person in the context of his or her family and community.[1] Integrative medicine also reaffirms the importance of the relationship between the practitioner and the patient, emphasizes wellness and the inherent drive toward healing, and focuses on the whole person, using all appropriate therapies to achieve the patient's goals for health and healing.[6]

The AAP Provisional Section on Complementary, Holistic, and Integrative Medicine, established in 2005, also contributed extensively to this report.

Epidemiology

The use of CAM in Western medicine has grown dramatically in recent decades. Many CAM therapies, such as herbal remedies, are mainstream or traditional in many parts of the world. The World Health Organization estimates that most of the world's population regularly uses "traditional medicine" such as traditional Chinese medicine (TCM), Ayurvedic medicine, and Native American healing practices.

In the United States, more than one third of adults have used CAM.[7] The total number of visits to CAM providers increased by 47.3%, from 420 million visits in 1990 to 629 million visits in 1997.[8] The number of visits to CAM providers in 1997 exceeded the total number of visits to primary care physicians in the same year.[8] Estimated expenditures for CAM services for adults increased by 45.2% between 1990 and 1997, with a conservative estimate of $21.2 billion spent in 1997. Of that total, out-of-pocket expenses were estimated to be $12.2 billion. This figure exceeded the 1997 out-of-pocket expenditures for all US hospitalizations.[8] More recent studies have described CAM use among adults as high as 62%,[9] with 41% of adults using 2 or more CAM therapies in a 12-month period.[10]

Children and adolescents also are using CAM therapies increasingly. Weighted estimates of the amount paid for pediatric expenditures on CAM visits and remedies were $127 million and $22 million, respectively.[11] An analysis of the 1996 US Medical Expenditure Panel Survey indicated that only 2% of the pediatric population uses CAM.[12] However, an early study of Canadian children reported 11% use of professionally provided CAM therapies, with chiropractic, homeopathy, naturopathy, and acupuncture accounting for 84% of CAM use.[13] Approximately 20% to 40% of healthy children seen in outpatient pediatric clinics[14–17] and more than 50% of children with chronic, recurrent, and incurable conditions use CAM, almost always in conjunction with mainstream care.[18–20] The use of CAM is considerably higher in certain groups of children, including children with special health care needs[21] and homeless adolescents, who have a reported use as high as 70%.[22] Use tends to be most common among patients with asthma,[23–25] attention-deficit/hyperactivity disorder,[26–28] autism,[29–31] cancer,[32–36] cerebral palsy,[37] cystic fibrosis,[38] inflammatory bowel disease,[39,40] and juvenile rheumatoid arthritis.[41] Presently, there is little research on the effectiveness of most CAM therapies for many of these conditions.[42] The NCCAM funds various studies, but to date, they have not addressed the pediatric population as a priority focus area for research.

Most pediatric patients who receive complementary therapies also receive conventional care.[13] This fact underscores the importance of pediatricians being aware of the necessity to have an open, respectful relationship and clear communication with families. A 2001 policy statement from the AAP Committee on Children With Disabilities, "Counseling Families Who Choose Complementary and Alternative Medicine for Their Child With Chronic Illness or Disability,"[43] recognized that the use of CAM is increasing and provides information and guidance for pediatricians when counseling families about CAM.

Patients' Characteristics and Reasons for Using CAM

Children who use CAM are more likely to be seeing their pediatrician for an illness, take medication on a regular basis, and have ongoing medical problems.[14] Approximately half of parents/caregivers of children who used CAM saw a CAM provider for themselves. The majority (66%) of parents/caregivers of CAM users had not informed their child's doctor of the use of CAM for their child.[14] There has been no consistent connection between CAM use and parent income, children's gender, or usual source of care,[13,14,16–19,44] and there have been mixed findings connecting CAM use and parent education level, family ethnicity, insurance coverage, and child's age.[13,16–19,44,45]

There are various reasons for the growing use of CAM. Many users of CAM reported use "not so much as a result of being dissatisfied with conventional medicine, but largely because they found these health care alternatives to be more congruent with their own values, beliefs, and philosophical orientations toward health and life."[46] Parents' reasons for seeking care for their children from CAM providers included, in decreasing order of frequency, word of mouth, particular treatment was considered effective, fear of drug adverse effects, dissatisfaction with conventional medicine, and the need for more personal attention.[13] In addition, many cultural groups may use CAM because of cultural values and beliefs.

Insurance Coverage

Many insurers offer coverage for CAM services. A 1996 survey of managed care organizations reported that 70% of surveyed plans have experienced an increased demand from members for CAM services and that 58% intended to offer some services within the next 2 years.[47] A 2004 Kaiser Family Foundation employer survey revealed that 87% of covered employees had chiropractic coverage, and 47% had acupuncture coverage.[48] The Landmark Report II on Health Maintenance Organizations and Alternative Care reported that 67% of health maintenance organizations offer some type of alternative care.[49] In addition, many Medicaid programs pay for the use of some CAM services. Of 46 reporting states, 36 (78.3%) Medicaid programs provide coverage for at least 1 alternative therapy,[50] most commonly chiropractic care (reimbursed by 33 programs), biofeedback (reimbursed by 10 programs), acupuncture (reimbursed by 7 programs), and hypnotherapy and naturopathy (reimbursed by 5 programs each).[50] Because state Medicaid benefits packages change frequently, pediatricians are encouraged to become familiar with their state's list of covered services.

Some states require coverage for CAM services. In 1996, Blue Cross of Washington launched a plan called AlternaPath in response to the passing of a Washington state law in the same year mandating that all commercial health insurance companies cover the services provided by every category of licensed provider.[51] Currently, most states require coverage of chiropractic care, and more than 50% of all health maintenance organizations cover these services.[47] Although very few states mandate coverage of acupuncture or massage therapy, these services are quickly becoming part of many insurers' benefit plans. The scope of services covered by insurers varies considerably; most coverage is disease-treatment oriented, with limited (either by scope or by number) visits allowed per diagnosis. Many plans offer a separate rider for purchase by either the employer or employee at an additional cost, and other plans offer CAM coverage as an embedded benefit to everyone in the program. Another type of program is an affinity discount network, in which certain CAM providers are designated as members of the network. Members of the program pay providers directly at a discounted fee.[52]

In a 1998 survey, the most common treatment modality covered by insurance plans was chiropractic care, with coverage ranging from 41% to 65%. By contrast, homeopathic treatments were covered by only 4% to 11% of all plans; acupuncture was covered by 9% to 19%; biofeedback was covered by 4% to 10%; and massage therapy was covered by 6% to 10%.[52]

Despite the public's increasing use of CAM therapies and willingness to pay out-of-pocket for these services, health insurers have had difficulty including them in their plans because of variation in credentialing, difficulties with accounting, and because there are so few *Current Procedural Terminology* (CPT) codes that cover these services.[52] Although there are CPT codes that cover some CAM techniques, CAM providers may find them difficult to implement because of philosophical differences with a system that singles out disease states or organs from the whole person. Some CAM providers use a separate coding system of more than 4000 codes for CAM procedures and supplies, known as the alternative billing concept or "ABC" codes.[53]

Government Response

The Office of Alternative Medicine was established as part of the NIH by congressional mandate in 1992. In 1998, the Office of Alternative Medicine became the NCCAM. The NCCAM has increased its fiscal-year appropriations from $50 million in 1998 to an estimated $123 million in 2006.[1] Total funding by all institutes and centers of the NIH for research and training on CAM and the training of investigators to study CAM exceeded $225 million in 2006, with additional funding being provided by other agencies and philanthropic foundations.[1] Of the approximately 360 NCCAM-funded research projects in 2006, fewer than 5% were related to pediatrics, including research on the effects of massage for preterm infants, probiotics, omega-3 fatty acids, and food allergies.[1] In 2007 and 2008, the AAP Provisional Section on Complementary, Holistic, and Integrative Medicine urged the NCCAM to consider increasing their priorities and funding for pediatric research, education, and information dissemination (Harry Gewanter, MD, verbal communication).

In 2000, the US President and Congress assembled and mandated the White House Commission on Complementary and Alternative Medicine Policy to make administrative and legislative recommendations to maximize the benefits of CAM for Americans. Comprising 20 physicians and other clinicians, CAM providers, and other experts, the commission was charged with developing a report to address the following:

- education and training of clinicians;
- research to increase knowledge regarding CAM;
- provision of reliable information to clinicians and the public; and
- guidelines for appropriate access to and delivery of CAM.

In March 2002, the commission issued its report, which addressed these charges and examined the relevance of CAM to national efforts to promote health, and created a central coordinating office. The report included 29 recommendations and more than 100 action items for federal agencies, Congress, state government, and other groups.[54]

In 2005, at the request of the NIH and the Agency for Healthcare Research and Quality, the Institute of Medicine released the report *Complementary and Alternative Medicine in the United States*. The report assessed what is known about Americans' reliance on CAM therapies and assisted the NIH in developing research methods and setting priorities for evaluating such products and therapies.[55]

The US Food and Drug Administration (FDA) also has weighed in on CAM-related issues. The Dietary Supplements Health and Education Act of 1994 (DSHEA) amended previous FDA statutes to encompass dietary supplement–specific provisions, including the definition of a "dietary supplement," product safety, nutritional statements and claims, ingredient and nutritional labeling, good manufacturing procedures, and the classification of "new" dietary ingredients.[56]

Under the DSHEA, a dietary supplement is:

- a product (other than tobacco) intended to supplement the diet that bears or contains 1 or more of the following ingredients: a vitamin, a mineral, an herb or other botanical, or an amino acid;
- intended for ingestion in pill, capsule, tablet, or liquid form;
- not used as a conventional food or as the sole item of a meal or diet; and
- labeled as a dietary supplement.

This classification of dietary supplements is specifically separate from food or drug categories and, as such, lies outside the jurisdiction of many of the safety and regulatory rules that cover food and drugs.[56]

According to the DSHEA, manufacturers bear the burden of proof of ingredient safety of dietary supplements. However, unlike pharmaceutical preparations, dietary supplements can be marketed without proven safety or efficacy. A manufacturer does not have to provide the FDA with the evidence on which it relies to substantiate safety or effectiveness before or after it markets its products. For new ingredients, the manufacturer is only required to provide evidence to the FDA that the product is "reasonably expected to be safe."[56]

Manufacturers of supplements are not required to report any data on adverse events to the FDA. The FDA can demonstrate that a supplement is unsafe only after it reaches the market. The FDA must prove that the product is unsafe before it can restrict a product's use or take other legal action. The FDA largely relies on the MedWatch voluntary reporting system to collect safety data on dietary supplements.[57]

The DSHEA also regulates third-party literature regarding dietary supplements. Informational materials (ie, articles, fact sheets, etc) may be displayed in commercial retail sites provided they are displayed separately from the product, do not contain false or misleading information, and do not promote a specific brand of supplement. Most important, the DSHEA regulates the labeling of dietary supplements. Under this provision, any claims to prevent, treat, or cure a specific disease are expressly prohibited (unless approved by the FDA). Labels can include statements describing the supplement's effects on the "structure and function" or general "well-being" of the body as long as they are truthful and bear the statement, "This statement has not been evaluated by the Food and Drug Administration. This product is not intended to diagnose, treat, cure, or prevent any disease."[56]

Finally, like food products, dietary supplements are allowed to have suggested dosages on the label and must bear nutritional labeling. The label must include the name and quantity of each dietary ingredient, and if the ingredient is botanical in origin, the label must state the part of the plant from which the ingredient is derived.[56]

Physician Awareness, Attitude, and Perception

In 1995, the American Medical Association passed a resolution suggesting that its 300 000 members become better informed regarding the practices and techniques of CAM.[57] Many primary care physicians, including pediatricians, recommend and refer patients for complementary therapies.[58,59] In the 2001 AAP Periodic Survey 49, "Complementary and Alternative Therapies in Pediatric Practice," pediatricians reported that they recognize patients' frequent use of CAM therapies and expressed a strong desire for additional education on CAM topics.[60] Topics of greatest immediate interest included herbs, dietary supplements, special diets, and exercise. More than one third of the pediatricians reported that they or their families used some type of CAM therapy. Of those reporting CAM use, 70% used massage therapy, 21% received chiropractic care, 13.5% consulted a spiritual or religious healer, and 13% had used acupuncture.[60]

TABLE 1 **The Kemper Model of Holistic Care**

Component	Example
Biochemical	Medications, dietary supplements, vitamins, minerals, herbal remedies
Lifestyle	Nutrition; exercise/rest; environmental therapies such as heat, ice, music, vibration, and light; mind-body therapies (behavior management, meditation, hypnosis, biofeedback, counseling)
Biomechanical	Massage and bodywork, chiropractic and osteopathic adjustments, surgery
Bioenergetic	Acupuncture, radiation therapy, magnets, Reiki, healing touch, qi gong, therapeutic touch, prayer, homeopathy

A growing number of pediatric generalists and subspecialists have begun to offer complementary therapies and advice as part of their practice. In addition, there is a growing number of academic pediatric integrative medicine programs and new initiatives to promote systematic sharing, support, and dissemination of information to improve collaborative and comprehensive care. These initiatives include the AAP Provisional Section on Complementary, Holistic, and Integrative Medicine[61]; the International Pediatric Integrative Medicine Network; and the Pediatric Complementary and Alternative Medicine Research and Education Network.[62] However, these initiatives may be insufficient to ensure consistent, quality education across the spectrum of medical education. Standardized curricula or content specifications for physician education on CAM therapies should be considered for medical school, residency, and continuing medical education activities.

COMMON CAM THERAPIES

As a means of understanding and integrating different modalities encompassing complementary and mainstream therapies, the Kemper model of holistic care (Table 1) has been widely accepted.[63] This paradigm integrates complementary and mainstream therapies into a coherent construct of treatment options.[63] Another model for understanding CAM therapies has been developed by the NCCAM. This framework focuses on CAM rather than integration of therapies. The most common CAM therapies used by infants, children, and adolescents within the NCCAM framework follow. A complete description of all therapies and scientific evidence regarding each of them is beyond the scope of this report.

Biologically Based Practices (Use of Vitamins, Herbs, Other Dietary Supplements, Diets, and Foods)

According to the NCCAM, biologically based practices include the use of botanicals, animal-derived extracts, vitamins, minerals, fatty acids, amino acids, proteins, prebiotics and probiotics, whole diets, and functional foods.[1] Of these, multivitamins are the most frequently used CAM products by children, with up to 41% reported usage.[14,15] Among teenagers who use CAM, nearly 75% use herbs and other dietary supplements.[64] Controlled studies have investigated the use of dietary

supplements for various conditions including asthma, upper respiratory infections, diarrhea, depression, anxiety, and attention-deficit/hyperactivity disorder.[65–67] Several studies are in progress, and the research literature is expanding rapidly. For example, the use of probiotics was considered complementary in the mid-1990s but has become mainstream practice in the 21st century as many gastroenterologists recommend and use them in daily practice for patients with inflammatory bowel disease.

There are a number of excellent review articles on the use of herbal products in pediatric populations[64–66,68,69] as well as data on potentially toxic herbal products and herb-drug interactions.[70–79] Because of regulations differing from those governing the use of pharmaceuticals, there are concerns about the purity and potency of herbal products and other dietary supplements sold in the United States. Product quality is influenced by many factors, including which portion of the plant is used (ie, root, stem, leaves, flowers), the time of harvest (ie, young versus old plants), the handling of the product, and proper identification of the plant. Furthermore, labeling is often inaccurate.[80–82] To conduct research, the quality of product must be guaranteed, and to compare clinical trials, the similarity of product must be ensured.

Dietary therapies such as the ketogenic diet in the treatment of seizure disorders[83] have become an accepted practice for some health conditions. However, the popularity of other diets has risen to a new level as the prevalence of obesity and metabolic syndrome has increased and traditional exercise and diet "prescriptions" have failed. The macronutrient content of these popular diets varies widely.[1]

Manipulative and Body-Based Practices

As defined by the NCCAM, manipulative and body-based practices include chiropractic and osteopathic manipulation, massage therapy, reflexology, Rolfing, Bowen technique, and Trager approach.[1]

Chiropractic care is one of the most common professionally provided CAM practices. It focuses on the relationship between body structure (primarily that of the spine) and bodily function and how that relationship affects health. With more than 50 000 chiropractors licensed in the United States, the number of children visiting chiropractors is substantial and increasing.[84] Recent studies have confirmed that up to 14% of all chiropractic visits were for pediatric patients[14,15] and that chiropractors were the most common CAM providers visited by children and adolescents.[14] Few randomized, controlled trials (RCTs) have demonstrated significant clinical benefits of chiropractic practices among pediatric patients[85]; additional studies are needed, and parents need to be cautioned not to rely on chiropractic care as the primary treatment for serious conditions such as cancer. Although anecdotal data suggest that severe complications are possible with chiropractic treatment of infants and children, such adverse effects seem to be rare.[86] Further systematic studies are needed to determine the costs, benefits, and safety of this widely used practice.

Massage is another common manipulative practice that is frequently provided at home by parents and by licensed massage therapists and nurses in clinical settings. Massage is now routine practice in many NICUs to promote growth and development in preterm infants.[2–4] Massage also has been demonstrated to be beneficial in alleviating symptoms from asthma, insomnia, colic, cystic fibrosis, and juvenile rheumatoid arthritis.[87–92]

Mind-Body Medicine

As defined by the NCCAM, mind-body medicine includes diverse practices such as relaxation, visual imagery, tai chi, qi gong, yoga, meditation, prayer, hypnosis, biofeedback, diaphragmatic breathing, progressive muscle relaxation, and cognitive-behavioral therapies. Many of these practices, particularly prayer, are commonly used among adults.[11] In children, popular techniques include prayer, progressive relaxation exercises, meditation, biofeedback, and hypnosis.[14,15] Hypnotherapy encourages the child to use his or her imagination to improve health and health behaviors.

Guided imagery, hypnosis, and biofeedback have been shown to be effective adjuncts to medical therapy for such common conditions as chronic, acute, and recurrent pain; anxiety and stress disorders; enuresis; encopresis; sleep disorders; autonomic nervous system dysregulation; habitual disorders; attention and learning disorders; asthma; cancer; and diabetes.[5] These therapies generally have few or no adverse effects.[5]

Spiritual healing includes prayer and is the most prevalent complementary therapy in the United States.[9] Spiritual healing is sometimes included under the rubric of mind-body therapies and sometimes under the rubric of biofield or bioenergetic therapies.[1] Eighty-two percent of Americans believe in the healing power of personal prayer, 73% believe that praying for someone else can help cure their illness, and 77% believe that God sometimes intervenes to cure people who have a serious illness.[93] Prayer is used by up to two thirds of parents for their children.[14,15]

Studies have suggested that spiritual/religious beliefs and practices may contribute to decreased stress and increased sense of well-being and enhanced immune system functioning.[93] RCTs of the clinical therapeutic effects of prayers in pediatrics are lacking. Some states have pursued legal measures against parents seeking to use prayer or spiritual healing as an alternative to conventional medical therapy for children with serious medical problems such as cancer. However, most families view spiritual healing as a personal practice that is complementary to medical care rather than a replacement for it.

Biofield Therapies

According to the NCCAM, biofield therapies are "intended to affect energy fields that purportedly surround and penetrate the human body." These therapies "manipulate biofields by applying pressure and/or manipulating the body by placing the hands in, or through, these fields."[1] Biofield techniques include acupuncture,

homeopathy, polarity therapy, magnet therapy, Japanese Reiki and Johrei, Chinese qi gong, therapeutic touch, healing touch, and spiritual healing.

Perhaps the best known of the noninvasive biofield therapies is therapeutic touch, which is taught in more than 80 nursing schools and provided in numerous hospitals in the United States. Therapeutic touch is a form of energy medicine that has been developed by nurses on the basis of the premise that healing is promoted when the body's energies are in balance. Nurse-healers are trained to identify and treat energy imbalances to improve the patient's well-being.[94]

Studies on the effectiveness of biofield therapies in pediatric populations have been limited, but the therapies are generally safe.[95,96]

Acupuncture

Acupuncture has been one component of TCM, which also includes herbal remedies, diet, massage, and lifestyle. Today, acupuncture describes a family of procedures involving stimulation of anatomic points on the body by a variety of techniques. American practices of acupuncture incorporate medical traditions from China, Japan, Korea, and other countries. The acupuncture technique that has been most studied scientifically involves penetrating the skin with thin, solid, metallic needles that are manipulated by hand or by electrical stimulation.[1] Variants of needle therapy include stimulation of acupuncture points by vigorous massage (shiatsu), heat (moxibustion), lasers, magnets, gentle massage or pressure (acupressure), or electrical currents.

Acupuncture is used by an increasing number of pediatric patients. A meta-analysis of the use of acupuncture in the treatment of recurrent headaches suggested potential benefit.[97] Additional applications for acupuncture may include nausea, pain, and allergy.[98–101]

Whole or Traditional Medical Systems

Whole medical systems involve complete systems of theory and practice that have evolved independently from or parallel to conventional Western medicine.[1] They include homeopathy, naturopathic medicine, TCM, Ayurvedic medicine (India's traditional system of medicine), and healing systems of American Indian/Alaska Native, African, Middle Eastern, Tibetan, and other indigenous populations.

Homeopathy

Developed by Samuel Hahnemann in 1790, homeopathy is based on the theory that "like cures like," meaning that small, highly diluted quantities of medicinal substances are given to cure symptoms, when the same substances given at higher or more concentrated doses would actually cause those symptoms.[1] Unlike classic pharmacology, homeopathy follows the theory that the greater the dilution, the greater the potency of the product. In the United States, an estimated 3000 clinicians, including physicians, nurses, chiropractors, naturopaths, and dentists, use homeopathy in their practices.[101] A range of 2% to 10% of children use homeopathic remedies, most often for respiratory problems, teething, otitis media, and other conditions related to the ears, neck, and throat.[14,15]

SPECIAL POPULATIONS

Adolescents

Numerous reports have described the frequent use of CAM by adolescents.[44,102–106] In Seattle, Washington, 70% of homeless adolescents reported using some form of CAM,[22] and among 9th- and 12th-grade students in Massachusetts, herbal remedies were used by up to 20% of respondents.[107] In a survey of New York teenagers, the most frequently used therapies were massage, prayer or faith healing, herbs, vitamins, performance-enhancing supplements, and special exercises.[105] Many adolescents use supplements to improve their body image or athletic performance. As many as 4.5% of boys and 0.8% of girls in secondary school used creatine[108]; of those, 73% were student athletes.

In general, adolescents seem to be more open than adults are to using CAM therapies, and adolescents are more inclined to use CAM if their parents also use these therapies.[103] Adolescence is characterized by increasing cognition, independence, increased desire for privacy and autonomy, and higher incidence of risky behavior. In addition, as they begin to take responsibility for their own health needs, adolescents also may use CAM therapies as self-treatment. The Internet is also becoming a larger influence on the lives of teenagers. Many dietary supplements are promoted on the Internet and promise relief of adolescent concerns such as acne and obesity, or they promise enhanced energy and sports performance. Some pediatricians refer patients to CAM providers or provide complementary therapies themselves, integrating them into conventional medical practice.

Children With Chronic Illness or Disability

Children with special health care needs are frequent users of CAM. The rate of CAM use for this population is estimated to be 30% to 70%.[21,29–41] In a recent survey of families of children with developmental disabilities, families wanted their clinicians to be able to counsel them about CAM options.[109] An overview of these issues and recommendations for counseling children with special health care needs and their families is outlined in a 2001 AAP Committee on Children With Disabilities statement, "Counseling Families Who Choose Complementary and Alternative Medicine for Their Child With Chronic Illness or Disability."[43]

Ethnic and Cultural Groups

Use of CAM therapies varies among different ethnic and cultural groups. Excluding prayer, CAM is used less commonly by Hispanic and black individuals than by white individuals, and its use by Hispanic and black people is less likely to be disclosed to clinicians.[110] Families of different cultural backgrounds use different herbs, over-the-counter remedies, and other items traditionally used for cooking as home remedies.[111,112] Many ethnic and cultural groups also use traditional

healing practices such as TCM, Ayurvedic medicine, and American Indian/Alaska Native healing practices, which can include a variety of diverse therapies and native healers within a coherent cultural belief system.[113,114] Use of these remedies is often integrated with conventional medicine but may not be reported unless the clinician specifically inquires about them.[110]

RESEARCH ISSUES

Although many CAM therapies have not yet been evaluated formally in children, a 2002 review identified more than 1400 RCTs and 47 systematic reviews of pediatric CAM.[115] Formal evaluation has suggested that the quality of RCTs of CAM is as good as that of RCTs of conventional medicine,[116] and the quality of systematic reviews of CAM exceeds that of systematic reviews of conventional medicine.[117] It should be noted that publication bias in CAM research is opposite that of conventional medicine; that is, negative studies are more likely to be published in well-known journals, and positive studies are more likely to be published in foreign-language journals.[118] Those interested in promoting an evidence-based approach to the use of CAM therapies must be cognizant of the bias created by applying language restrictions in their search strategy. Other approaches to evidence-based CAM include *n*-of-1 evaluation, whereby methodologic rigor (eg, blinding, randomization) is combined with an individualized approach fundamental to many CAM therapies.[119]

There are some unique considerations when examining the efficacy of CAM, including heterogeneity of both products and practices. Lack of regulation of many commonly used practices exacerbates heterogeneity, making treatment effect difficult to measure. The relative lack of CAM expertise in conventional institutions results in inadequate peer review and undue difficulties when attempting to obtain institutional review board approval to study CAM in children.

Although CAM use is common in children, there have been few reports of serious adverse effects. Most current safety data come from case reports. Some population-based surveillance studies to monitor adverse events have been conducted in adults receiving acupuncture, and the resulting data are reassuring.[120] The need for rigorous safety evaluation is questioned by some who perceive "natural" to be equivalent to "safe." More complete data about safety in children would require prospectively gathered, population-based studies, which are expensive to conduct.

There are numerous challenges inherent in all clinical research, and these difficulties are compounded when performing research in children and on therapies based on different cultural concepts of what causes or constitutes disease and health. The NCCAM has identified women and minority populations as priority groups for federally funded research on CAM, but it has not yet added pediatrics to this priority listing.

EDUCATION AND TRAINING

The number of CAM providers is increasing. The number of CAM providers in the United States is projected to increase 88% between 1994 and 2010, compared with a 16% increase in the number of physicians. However, few CAM providers undergo extensive education or training specific to pediatric populations. For example, although chiropractic training typically lasts 4 years, pediatric certification in chiropractic requires only a 10-module, 120-hour certification program.[121] Naturopathic training at the 4 US colleges also typically requires 2000 hours of training over 4 years, which includes clerkships in dermatology, family medicine, psychiatry, medicine, radiology, pediatrics, obstetrics and gynecology, neurology, surgery, and ophthalmology.[122] Some CAM training programs do not offer any specific training for diagnosing or treating pediatric patients.

Many CAM providers seek additional training in pediatrics.[123] Likewise, many physicians seek additional training in CAM. As of 1998, 64% of US medical schools reported having CAM curricula,[124] and 18 of the 19 colleges of osteopathic medicine offered CAM instruction.[125] These programs have a wide range of content and quality. Although many medical schools and residency programs offer survey courses on CAM,[126,127] the extent to which pediatric residencies and postgraduate courses address educational needs about CAM are unknown.[128–131] However, there have been significant gains in the growth of academic integrative medicine since the establishment of the Consortium for Academic Health Centers for Integrative Medicine in 2000. There are also well-established training programs for physicians in specific modalities such as hypnosis and acupuncture.

LICENSING

Licensure of CAM providers varies significantly from state to state. Licensing does not mean that CAM providers can practice medicine. In some states, CAM providers must have clients sign a form acknowledging that they understand the provider is not a physician and not practicing medicine. As of the writing of this report, chiropractic medicine is licensed in all states, acupuncture and massage therapy are licensed in more than half of the states, and naturopathy and homeopathy are licensed in less than one third of the states. Lobbying efforts by CAM providers to win licensure and expanded scopes of practice are ongoing in many states. It is essential for physicians to understand local and state statutes and regulations governing specific therapeutic modalities. If a CAM provider is unlicensed, then he or she may be engaged in the unauthorized practice of medicine, and if a physician refers a patient to an unlicensed provider, the referring physician may be liable for negligent referral. If a CAM provider is licensed, then he or she must be practicing within his or her "scope of practice" as defined by local and state statutes and regulatory boards.[132] Similar to physician licensing, licensing information about other health care professionals is maintained by state licensing boards.

MEDICOLEGAL AND ETHICAL CONSIDERATIONS

Medicolegal

CAM poses a challenging risk-management issue with the potential for either a medical malpractice lawsuit, disciplinary proceedings from state licensing boards, or fraud and abuse actions from federal or state regulators.[133,134] The use of some types of CAM in adults has been judicially held to be below the standard of care constituting medical negligence[135]; that is, use of complementary therapies in and of themselves does not constitute negligence. In terms of practicing within the standard of care, more clinicians are willing to offer CAM, and more insurers are willing to pay for it.[136]

Clinicians need to be aware of individual state laws relating to CAM, because medicine is regulated by state rather than federal laws.[137] In its database of closed pediatric malpractice claims from 1985–2005, the Physicians Insurers Association of America reported that the average indemnity payment for all CAM claims was $358 333, which was 37.1% higher than the average for all pediatric claims ($261 321).[138] A proposed risk-management model limits liability for the use of CAM if the physician is recommending, accepting, or avoiding CAM depending on availability of evidence relating to safety and/or efficacy.[139]

Some CAM modalities may need to be included in discussions about informed consent for treatment. The informed-consent process may potentially require a discussion about possible risks of CAM, notwithstanding the ability of a patient to acquire CAM without the involvement of the pediatrician (eg, dietary supplements and their interaction with prescribed medication). Case law has placed a burden on clinicians to at least discuss viable options of treatment even though he or she may be unwilling to offer the therapy.[140]

Pediatricians need to be aware of the use of alternative therapies as a substitute for conventional medical care for children with life-threatening conditions and whether they believe such treatment is reportable under state abuse and neglect laws. Another legal duty of pediatricians relates to the assurance that seeking reimbursement for CAM therapy does not trigger a potential violation of fraud and abuse laws for therapy deemed "medically unnecessary." It is prudent to be cautious about any representations or guarantees.

Ethics

There are several ethical challenges to integrating CAM into mainstream pediatric practice. There is a lack of systematic pediatric education about the safety and effectiveness of CAM therapies; uncertainty about the scope of practice, licensing requirements, and credentialing of nonphysician CAM providers; concerns about patient safety and legal liability when recommending CAM therapies or therapists; and uncertainty about how to translate principles of medical ethics into CAM.[141]

The first guideline of ethical practice is to seek reliable, evidence-based information about the safety and effectiveness of specific therapies and therapists. Indeed, the 2001 AAP policy statement "Counseling Families Who Choose Complementary and Alternative Medicine for Their Child With Chronic Illness or Disability" recommended that pediatricians seek information, evaluate the scientific merits of specific therapeutic approaches, and identify risks or potential harmful effects.[43]

It is also prudent to apply common sense to balancing risks and benefits when making therapeutic decisions (see Fig 1).[142] The specific ethical questions in clinical practice vary in different clinical situations. If a therapy is both safe and effective, the pediatrician is ethically obligated to recommend and encourage its use as he or she would for any other such therapy in conventional care.

Factors to be included in a risk/benefit analysis when considering CAM therapies include the severity and acuteness of illness; curability with conventional care; degree of invasiveness; toxicities and adverse effects of conventional treatment; quality of evidence for efficacy and safety of the complementary therapy; and the family's understanding of the risks and benefits of CAM treatment, voluntary acceptance of those risks, and persistence of the family's intention to use CAM therapy.[139] Thus, the level of evidence required for evaluating efficacy can be small when there is little to no risk of harm from a therapy, especially when other therapies are likely to be futile. Likewise, the level of evidence for efficacy required to endorse a particular complementary therapy would be quite high when that therapy is risky and safer, more effective therapies are available.

Situation-specific variables can also affect ethical decision-making. Situation-specific variables include the patient's and parents' personal beliefs, cultural values and practices, and therapeutic goals; the type and severity of illness; and the lack of efficacy and safety data in a specific patient. Even when such data are known for other populations, application of population data to individual pediatric patients requires inference and implies some degree of uncertainty. The tolerance of the patient, family, and clinician for uncertainty varies from one situation to another.[139]

Finally, clinicians should be aware of the 4 basic principles of biomedical ethics: (1) respect for patients' autonomy; (2) nonmaleficence (avoiding harm); (3) beneficence (putting the patient's interest and well-being first); and (4) justice (fairness in providing access to essential care).[139]

CONCLUSIONS

Pediatricians and other clinicians who care for children have the responsibility to advise and counsel patients and families about relevant, safe, effective, and age-appropriate health services and therapies regardless of whether they are considered mainstream or CAM. In the 2001 AAP Periodic Survey of Fellows, 73% of pediatricians agreed that it is the role of pediatricians to provide patients/families with information about all potential treatment options for the patient's condition, and 54% agreed that pediatricians should consider the use of all potential therapies, not just those of mainstream medicine, when treating patients.[60] Because most families use CAM services without spontaneously reporting this use to their clinician, pediatricians can best provide appropriate advice and counseling if they regularly inquire about all the therapies the family is using to help the child.[143,144]

Pediatricians should seek continued and updated knowledge about therapeutic options available to their patients, whether they are mainstream or CAM, and about the specific services used by individual patients to ensure that issues of safety, appropriateness, and advisability of CAM can be addressed. Only then can pediatricians appreciate the concerns of their patients and families and offer them the thoughtful and knowledgeable guidance they may require.

Finally, if the pediatrician confirms that the patient is seeing a CAM provider, the pediatrician can (with the permission of the patient and family) include the CAM provider in overall care-coordination activities.

TIPS ON TALKING WITH PATIENTS

- Ask about the different therapies received by your patients. Patients and parents often do not tell their clinicians about CAM use, because many of them believe that it is not relevant or not within the clinician's interest or expertise.[143,144] By asking routinely, pediatricians can learn whether a child is receiving complementary therapies. This knowledge is essential for the pediatrician to evaluate and counsel about potential adverse effects and to enhance the probability of correctly attributing improvements or adverse effects to the specific intervention. Questions that include examples are often helpful in jogging memories and enhancing disclosure. Thus, rather than asking whether a patient is using any "alternative" therapies, the pediatrician might ask whether the patient is using any "vitamins, herbs, supplements, teas, home remedies, back rubs, chiropractic, acupuncture, or other services to enhance health." It is also often useful to ask how the patient manages stress; examples here may include exercise, prayer, music, or talking with friends or trusted adults.
- Respect the family's perspectives, values, and cultural beliefs in open, ongoing communication centered on the patient's well-being. Recognize cultural or educational differences. Demonstrate respect for families and their values. Work together with the parents as a team to consider and evaluate all appropriate treatments. This may require discussing an array of treatment options. By actively listening to families and patients, pediatricians can become important allies in examining all potential treatment options for children. Maintaining a dialogue to promote the best interests of the child is critical to the integrity of the medical home.
- Monitor the patient's response to treatment and establish measurable outcomes for evaluation. Measurable outcomes such as specific goals for symptom relief can be established. The *primum non noceri* ("first do no harm") concept is central to all clinical practice. If there is a lack of response or untoward response, the therapy needs to be reevaluated.
- Maintain current knowledge of popular complementary therapies and evidence-based resources about them. Become familiar with the definitions, terms, and uses of CAM and learn about specific CAM therapies patients are using. Pediatricians are encouraged to educate themselves about the modalities and professionals that are available in their practice area. Provide evidence-based information about relevant therapies, available from the NCCAM, the Consortium of Academic Health Centers for Integrative Medicine member institutions, and an increasing number of publications in peer-reviewed publications and professional review articles.

ACKNOWLEDGMENTS

Robert Pendergrast, MD, Provisional Section on Complementary, Holistic, and Integrative Medicine member-at-large, and Hilary McClafferty, MD, Provisional Section on Complementary, Holistic, and Integrative Medicine editor, contributed extensively to this report. Kellie Waters, MD, FRCPC, of the Complementary and Alternative Research and Education (CARE) Program (Department of Pediatrics, University of Alberta, Edmonton, Alberta, Canada) also contributed to this report. The Committee on Medical Liability and Risk Management developed the medicolegal text of the report. Committee on Fetus and Newborn

Use of Inhaled Nitric Oxide

ABSTRACT. Approval of inhaled nitric oxide by the US Food and Drug Administration for hypoxic respiratory failure of the term and near-term newborn provides an important new therapy for this serious condition. This statement addresses the conditions under which inhaled nitric oxide should be administered to the neonate with hypoxic respiratory failure.

ABBREVIATIONS. ECMO, extracorporeal membrane oxygenation; iNO, inhaled nitric oxide; FDA, US Food and Drug Administration.

Hypoxic respiratory failure in neonates born at or near term may be caused by such conditions as primary persistent pulmonary hypertension, respiratory distress syndrome, aspiration syndromes, pneumonia or sepsis, and congenital diaphragmatic hernia. Conventional therapies, which have not been validated by randomized controlled trials, include administration of high concentrations of oxygen, hyperventilation, high-frequency ventilation, the induction of alkalosis, neuromuscular blockade, and sedation.[1] Despite aggressive conventional therapy, neonatal respiratory failure was associated with a high rate of mortality before the development of extracorporeal membrane oxygenation (ECMO).[2,3] Survival and short-term morbidity rates have been superior in term and near-term infants (≥34 weeks' gestation) treated with ECMO compared with conventional therapy[4]; however, questions remain about the long-term safety of ECMO.

Inhaled nitric oxide (iNO) is a selective pulmonary vasodilator for which the mechanism of action involves guanylyl cyclase activation leading to production of cyclic guanosine monophosphate and subsequent smooth muscle relaxation.[5–7] Although several studies have suggested that iNO improves oxygenation,[8–14] the US Food and Drug Administration (FDA) evaluated 2 large randomized multicenter controlled trials of term and near-term neonates with hypoxic respiratory failure that demonstrated improved outcome with iNO therapy. The Neonatal Inhaled Nitric Oxide Study Group trial documented that iNO reduced the need for ECMO[15] without increasing neurodevelopmental, behavioral, or medical abnormalities at 2 years of age.[16] These results were strengthened by the Clinical Inhaled Nitric Oxide Research Group trial, in which iNO reduced the need for ECMO and the incidence of chronic lung disease.[17] iNO was not effective for infants with congenital diaphragmatic hernia.[18]

The limited data to date on hypoxic preterm neonates suggest that low-dose iNO improves oxygenation but does not improve survival.[14,19] Additional large randomized trials of iNO in premature neonates are required because they may experience more toxic effects than term and near-term infants.[14,19,20]

It is critical that infants with hypoxic respiratory failure in whom conventional ventilator therapy fails or is predicted to fail be cared for in institutions that have **immediate availability** of personnel, including physicians, nurses, and respiratory therapists, who are qualified to use multiple modes of ventilation and rescue therapies. Radiologic and laboratory support required to manage the broad range of needs of these infants is also essential.

iNO should be administered using FDA-approved devices that are capable of administering iNO in constant concentration ranges in parts per million or less throughout the respiratory cycle. Infants who receive iNO therapy should be monitored according to institutionally derived protocols designed to avoid the potential toxic effects associated with iNO administration. These effects include methemoglobinemia (secondary to excess nitric oxide concentrations), direct pulmonary injury (attributable to excess levels of nitrogen dioxide), and ambient air contamination.

In the trials of iNO therapy reported to date, the indication for use has been failure of ventilatory therapy. ECMO, a therapy of proven efficacy, usually is initiated if iNO therapy fails. Therefore, institutions that offer iNO therapy generally should have ECMO capability; if a center lacks ECMO capability, it should work in collaboration with an ECMO center to prospectively establish appropriate iNO failure criteria and mechanisms for the timely transfer of infants to the collaborating ECMO center. The diversity of geography, climate, and transport capabilities necessitates that the "timely transfer" be dictated by the location-specific transport limitations as well as the severity of the infant's illness. Because hypoxic respiratory failure is often rapidly progressive and abrupt discontinuation of iNO may lead to worsening oxygenation,[21] the risk of delayed provision of ECMO must be considered carefully when determining the appropriate time of transfer.

Plans for the care and referral of these infants should incorporate the following recommendations.

RECOMMENDATIONS

1. Infants with progressive hypoxic respiratory failure should be cared for in centers with the expertise and

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

experience to provide multiple modes of ventilatory support and rescue therapies or be transferred in a timely manner to such an institution.
2. iNO therapy should be given using the indications, dosing, administration, and monitoring guidelines outlined on the product label (http://www.fda.gov). An echocardiogram to rule out congenital heart disease is recommended. Center-specific criteria for treatment failure should be developed to facilitate timely consideration of alternative therapies.
3. iNO therapy should be directed by physicians qualified by education and experience in its use and offered only at centers that are qualified to provide multisystem support, generally including on-site ECMO capability.
4. Generally, iNO should be initiated in centers with ECMO capability. If iNO is offered by a center without ECMO capability, for geographic or other compelling reasons, mutually acceptable treatment failure criteria and mechanisms for timely transfer of infants to a collaborating ECMO center should be established prospectively. Transfer must be accomplished without interruption of iNO therapy.
5. Centers that provide iNO therapy should provide comprehensive long-term medical and neurodevelopmental follow-up.
6. Centers that provide iNO therapy should establish prospective data collection for treatment time course, toxic effects, treatment failure, use of alternative therapies, and outcomes.
7. Administration of iNO for indications other than those approved by the FDA or in other neonatal populations, including compassionate use, remains experimental. As such, iNO should be administered according to a formal protocol that has been approved by the FDA and the institutional review board and with informed parental consent.

Committee on Nutrition

The Use and Misuse of Fruit Juice in Pediatrics

ABSTRACT. Historically, fruit juice was recommended by pediatricians as a source of vitamin C and an extra source of water for healthy infants and young children as their diets expanded to include solid foods with higher renal solute. Fruit juice is marketed as a healthy, natural source of vitamins and, in some instances, calcium. Because juice tastes good, children readily accept it. Although juice consumption has some benefits, it also has potential detrimental effects. Pediatricians need to be knowledgeable about juice to inform parents and patients on its appropriate uses.

ABBREVIATIONS. FDA, Food and Drug Administration; AAP, American Academy of Pediatrics.

INTRODUCTION

In 1997, US consumers spent almost $5 billion on refrigerated and bottled juice.[1] Mean juice consumption in America is more than 2 billion gal/y or 9.2 gal/y per person.[2] Children are the single largest group of juice consumers. Children younger than 12 years account for only about 18% of the total population but consume 28% of all juice and juice drinks.[3] By 1 year of age, almost 90% of infants consume juice. The mean daily juice consumption by infants is approximately 2 oz/d, but 2% consume more than 16 oz/d, and 1% of infants consume more than 21 oz/d.[2,4,5] Toddlers consume a mean of approximately 6 oz/d.[2] Ten percent of children 2 to 3 years old and 8% of children 4 to 5 years old drink on average more than 12 oz/d.[2] Adolescents consume the least, accounting for only 10% of juice consumption.

DEFINITIONS

To be labeled as a fruit juice, the Food and Drug Administration (FDA) mandates that a product be 100% fruit juice. For juices reconstituted from concentrate, the label must state that the product is reconstituted from concentrate. Any beverage that is less than 100% fruit juice must list the percentage of the product that is fruit juice, and the beverage must include a descriptive term, such as "drink," "beverage," or "cocktail." In general, juice drinks contain between 10% and 99% juice and added sweeteners, flavors, and sometimes fortifiers, such as vitamin C or calcium. These ingredients must be listed on the label, according to FDA regulations.

PEDIATRICS (ISSN 0031 4005).

COMPOSITION OF FRUIT JUICE

Water is the predominant component of fruit juice. Carbohydrates, including sucrose, fructose, glucose, and sorbitol, are the next most prevalent nutrient in juice. The carbohydrate concentration varies from 11 g/100 mL (0.44 kcal/mL) to more than 16 g/100 mL (0.64 kcal/mL). Human milk and standard infant formulas have a carbohydrate concentration of 7 g/100 mL.

Juice contains a small amount of protein and minerals. Juices fortified with calcium have approximately the same calcium content as milk but lack other nutrients present in milk. Some juices have high contents of potassium, vitamin A, and vitamin C. In addition, some juices and juice drinks are fortified with vitamin C. The vitamin C and flavonoids in juice may have beneficial long-term health effects, such as decreasing the risk of cancer and heart disease.[6,7] Drinks that contain ascorbic acid consumed simultaneously with food can increase iron absorption by twofold.[8,9] This may be important for children who consume diets with low iron bioavailability.

Juice contains no fat or cholesterol, and unless the pulp is included, it contains no fiber. The fluoride concentration of juice and juice drinks varies. One study found fluoride ion concentrations ranged from 0.02 to 2.8 parts per million.[10] The fluoride content of concentrated juice varies with the fluoride content of the water used to reconstitute the juice.

Grapefruit juice contains substances that suppress a cytochrome P-450 enzyme in the small bowel wall. This results in altered absorption of some drugs, such as cisapride, calcium antagonists, and cyclosporin.[11–13] Grapefruit juice should not be consumed when these drugs are used.

Some manufacturers specifically produce juice for infants. These juices do not contain sulfites or added sugars and are more expensive than regular fruit juice.

ABSORPTION OF CARBOHYDRATE FROM JUICE

The 4 major sugars in juice are sucrose, glucose, fructose, and sorbitol. Sucrose is a disaccharide that is hydrolyzed into 2 component monosaccharides, glucose and fructose, by sucrase present in the small bowel epithelium. Glucose is then absorbed rapidly via an active-carrier–mediated process in the brush border of the small bowel. Fructose is absorbed by a facilitated transport mechanism via a carrier but not against a concentration gradient. In addition, fructose may be absorbed by a disaccharidase-related transport system, because the absorption of fructose

is more efficient in the presence of glucose, with maximal absorption occurring when fructose and glucose are present in equimolar concentrations.[14] Clinical studies have demonstrated this, with more apparent malabsorption when fructose concentration exceeds that of glucose (eg, apple and pear juice) than when the 2 sugars are present in equal concentrations (eg, white grape juice).[15,16] However, when provided in appropriate amounts (10 mL/kg of body weight), these different juices are absorbed equally as well.[17] Sorbitol is absorbed via passive diffusion at slow rates, resulting in much of the ingested sorbitol being unabsorbed.[18]

Carbohydrate that is not absorbed in the small intestine is fermented by bacteria in the colon. This bacterial fermentation results in the production of hydrogen, carbon dioxide, methane, and the short-chain fatty acids—acetic, propionic, and butyric. Some of these gases and fatty acids are reabsorbed through the colonic epithelium, and in this way, a portion of the malabsorbed carbohydrate can be scavenged.[19] Nonabsorbed carbohydrate presents an osmotic load to the gastrointestinal tract, which causes diarrhea.[20]

Malabsorption of carbohydrate in juice, especially when consumed in excessive amounts, can result in chronic diarrhea, flatulence, bloating, and abdominal pain.[21–27] Fructose and sorbitol have been implicated most commonly,[15,16,28–30] but the ratios of specific carbohydrates may also be important.[31] The malabsorption of carbohydrate that can result from large intakes of juice is the basis for some health care providers to recommend juice for the treatment of constipation.[32]

JUICE IN THE FOOD GUIDE PYRAMID

Fruit is 1 of the 5 major food groups in the Food Guide Pyramid.[33] It is recommended that children consuming approximately 1600 kcal/d (depending on size, 1–4 years old) should have 2 fruit servings and those consuming 2800 kcal/d (depending on size, 10–18 years old) should consume 4 fruit servings. Half of these servings can be provided in the form of fruit juice (not fruit drinks). A 6-oz glass of fruit juice equals 1 fruit serving. Fruit juice offers no nutritional advantage over whole fruit. In fact, fruit juice lacks the fiber of whole fruit. Kilocalorie for kilocalorie, fruit juice can be consumed more quickly than whole fruit. Reliance on fruit juice instead of whole fruit to provide the recommended daily intake of fruits does not promote eating behaviors associated with consumption of whole fruits.

MICROBIAL SAFETY OF JUICE

Only pasteurized juice is safe for infants, children, and adolescents. Pasteurized fruit juices are free of microorganisms. Unpasteurized juice may contain pathogens, such as *Escherichia coli* and *Salmonella* and *Cryptosporidium* organisms.[34] These organisms can cause serious disease, such as hemolytic-uremic syndrome, and should never be given to infants and children. Unpasteurized juice must contain a warning on the label that the product may contain harmful bacteria.[35]

INFANTS

The American Academy of Pediatrics (AAP) recommends that breast milk be the only nutrient fed to infants until 4 to 6 months of age.[36] For mothers who cannot breastfeed or choose not to breastfeed, a prepared infant formula can be used and is a complete source of nutrition. No additional nutrients are needed. There is no nutritional indication to feed juice to infants younger than 6 months. Offering juice before solid foods are introduced into the diet could risk having juice replace breast milk or infant formula in the diet. This can result in reduced intake of protein, fat, vitamins, and minerals such as iron, calcium, and zinc.[37] Malnutrition and short stature in children have been associated with excessive consumption of juice.[4,38]

After approximately 4 to 6 months of age, solid foods can be introduced into the diets of infants. The AAP recommends that single-ingredient foods be chosen and introduced 1 at a time at weekly intervals. Iron-fortified infant cereals or pureed meats are good choices for first weaning foods. Because foods high in iron are recommended as weaning foods, beverages that contain vitamin C do not offer a nutritional advantage for iron-sufficient individuals.

It is prudent to give juice only to infants who can drink from a cup (approximately 6 months or older). Teeth begin to erupt at approximately 6 months of age. Dental caries have also been associated with juice consumption.[39] Prolonged exposure of the teeth to the sugars in juice is a major contributing factor to dental caries. The AAP and the American Academy of Pedodontics recommendations state that juice should be offered to infants in a cup, not a bottle, and that infants not be put to bed with a bottle in their mouth.[40] The practice of allowing children to carry a bottle, cup, or box of juice around throughout the day leads to excessive exposure of the teeth to carbohydrate, which promotes development of dental caries.

Fruit juice should be used as part of a meal or snack. It should not be sipped throughout the day or used as a means to pacify an unhappy infant or child. Because infants consume fewer than 1600 kcal/d, 4 to 6 oz of juice per day, representing 1 food serving of fruit, is more than adequate. Infants can be encouraged to consume whole fruits that are mashed or pureed.

The AAP practice guideline on the management of acute gastroenteritis in young children recommends that only oral electrolyte solutions be used to rehydrate infants and young children and that a normal diet be continued throughout an episode of gastroenteritis.[41] Surveys show that many health care providers do not follow the recommended procedures for management of diarrhea.[42] The high carbohydrate content of juice (11–16 g %), compared with oral electrolyte solutions (2.5–3 g %), may exceed the intestine's ability to absorb carbohydrate, resulting in carbohydrate malabsorption. Carbohydrate malabsorption causes osmotic diarrhea, increasing the severity of the diarrhea already present.[43] Fruit juice is low in electrolytes. The sodium concentration is 1

to 3 mEq/L. Stool sodium concentration in children with acute diarrhea is 20 to 40 mEq/L. Oral electrolyte solutions contain 40 to 45 mEq/L of sodium. As a replacement for fluid losses, juice may predispose infants to development of hyponatremia.

In the past, there was concern that infants who were fed orange juice were likely to develop an allergy to it. The development of a perioral rash in some infants after being fed freshly squeezed citrus juice is most likely a contact dermatitis attributable to peel oils.[44] Diarrhea and other gastrointestinal symptoms observed in some infants were most likely attributable to carbohydrate malabsorption. Although allergies to fruit may develop early in life, they are uncommon.[45]

TODDLERS AND YOUNG CHILDREN

Most issues relevant to juice intake for infants are also are relevant for toddlers and young children. Fruit juice and fruit drinks are easily overconsumed by toddlers and young children because they taste good. In addition, they are conveniently packaged or can be placed in a bottle and carried around during the day. Because juice is viewed as nutritious, limits on consumption are not usually set by parents. Like soda, it can contribute to energy imbalance. High intakes of juice can contribute to diarrhea, overnutrition or undernutrition, and development of dental caries.

OLDER CHILDREN AND ADOLESCENTS

Juice consumption presents fewer nutritional issues for older children and adolescents, because they consume less of these beverages. Nevertheless, it seems prudent to limit juice intake to two 6-oz servings, or half of the recommended fruit servings each day. It is important to encourage consumption of the whole fruit for the benefit of fiber intake and a longer time to consume the same kilocalories.

Excessive juice consumption and the resultant increase in energy intake may contribute to the development of obesity. One study found a link between juice intake in excess of 12 oz/d and obesity.[4] Other studies, however, found that children who consumed greater amounts of juice were taller and had lower body mass index than those who consumed less juice[46] or found no relationship between juice intake and growth parameters.[47] More research is needed to better define this relationship.

CONCLUSIONS

1. Fruit juice offers no nutritional benefit for infants younger than 6 months.
2. Fruit juice offers no nutritional benefits over whole fruit for infants older than 6 months and children.
3. One hundred percent fruit juice or reconstituted juice can be a healthy part of the diet when consumed as part of a well-balanced diet. Fruit drinks, however, are not nutritionally equivalent to fruit juice.
4. Juice is not appropriate in the treatment of dehydration or management of diarrhea.
5. Excessive juice consumption may be associated with malnutrition (overnutrition and undernutrition).
6. Excessive juice consumption may be associated with diarrhea, flatulence, abdominal distention, and tooth decay.
7. Unpasteurized juice may contain pathogens that can cause serious illnesses.
8. A variety of fruit juices, provided in appropriate amounts for a child's age, are not likely to cause any significant clinical symptoms.
9. Calcium-fortified juices provide a bioavailable source of calcium but lack other nutrients present in breast milk, formula, or cow's milk.

RECOMMENDATIONS

1. Juice should not be introduced into the diet of infants before 6 months of age.
2. Infants should not be given juice from bottles or easily transportable covered cups that allow them to consume juice easily throughout the day. Infants should not be given juice at bedtime.
3. Intake of fruit juice should be limited to 4 to 6 oz/d for children 1 to 6 years old. For children 7 to 18 years old, juice intake should be limited to 8 to 12 oz or 2 servings per day.
4. Children should be encouraged to eat whole fruits to meet their recommended daily fruit intake.
5. Infants, children, and adolescents should not consume unpasteurized juice.
6. In the evaluation of children with malnutrition (overnutrition and undernutrition), the health care provider should determine the amount of juice being consumed.
7. In the evaluation of children with chronic diarrhea, excessive flatulence, abdominal pain, and bloating, the health care provider should determine the amount of juice being consumed.
8. In the evaluation of dental caries, the amount and means of juice consumption should be determined.
9. Pediatricians should routinely discuss the use of fruit juice and fruit drinks and should educate parents about differences between the two.

Use of Performance-Enhancing Substances

ABSTRACT. Performance-enhancing substances include dietary supplements, prescription medications, and illicit drugs. Virtually no data are available on the efficacy and safety in children and adolescents of widely used performance-enhancing substances. This statement is intended to provide a generalized but functional definition of performance-enhancing substances. The American Academy of Pediatrics strongly condemns the use of performance-enhancing substances and vigorously endorses efforts to eliminate their use among children and adolescents. ***Pediatrics*** **2005;115:1103–1106;** ***ergogenic, anabolic, performance enhancing, banned substance, athlete, adolescent, sport.***

INTRODUCTION

Performance-enhancing substance use in young people is a concern to pediatricians and society because of potential adverse health consequences and the effects that such practices have on moral development of the individual and on fair athletic competition for all. Health care professionals can play a valuable role in counseling the young person using or contemplating use of performance-enhancing substances by conveying factual information about the proven benefits and medical consequences of these substances and providing advice about healthful eating and training. Attempts to discourage use through scare tactics or by dismissing known performance-enhancing effects of these substances may seriously damage the credibility of the physician and do little to diminish use. Efforts to minimize use of performance-enhancing substances require the pediatrician to have an understanding of the incentives for use, a comprehensive definition of performance-enhancing substances, and familiarity with strategies for prevention.

INCENTIVES FOR THE USE OF PERFORMANCE-ENHANCING SUBSTANCES

The temptation for young people to use performance-enhancing substances should be easily understood by anyone who is familiar with high-level sports in our society. Success (that is, winning) is considered by many to be the most important goal of sports. At the level of professional sports, winning is the ultimate goal. This attitude permeates lower levels of sports as well, down to youth sports. Society rewards success in sports with celebrity, status, and favoritism.

For athletes of all ages, the pursuit of excellence in sports is an endeavor to be admired and encouraged. Success in sports involves obtaining an "edge" over the competition. However, sometimes the drive for success can be so engrossing and so compelling that a young person can easily lose sight of what is fair and right. Some individuals may view the use of performance-enhancing substances as a substitute for hard work. For others, performance-enhancing substances may be considered a necessary adjunct to hard work or part of the price of success. From the user's perspective, the prospects for success in sports often outweigh the prospects for serious medical complications from use of performance-enhancing substances.

For some, winning has a monetary incentive as well. The enormous salaries paid to professional athletes in the United States and elsewhere are powerful inducements for a young person with outstanding athletic talent to try anything to ensure continued athletic success.

Adolescents may be uniquely vulnerable to the lure of performance-enhancing substances. Many adolescents engage in risk-taking behavior and experimentation at a time when they are coping with the developmental tasks of adolescence, including defining their sexual identity, emancipating themselves from their families, achieving a sense of mastery and self-efficacy, and finding a peer group with which they can identify.[1] The adolescent, by nature, feels invincible and often shuns any suggestion that use of a substance for purposes other than legitimate therapy might pose a danger to their health or their eligibility for sports.

Adolescents are also intensely preoccupied with body image. Personal rewards perceived from enhancing size, strength, stamina, or body build can be strong motivators. A significant number of adolescents who are not involved in competitive athletics use performance-enhancing substances.[2]

The child athlete, particularly the adolescent, in today's society is caught in a struggle between ideals highly valued by society but often in direct conflict: the attitude of winning at all costs and the values of fairness and wholesomeness.

doi:10.1542/peds.2005-0085

RATIONALE FOR A BROAD-BASED STATEMENT ON PERFORMANCE-ENHANCING SUBSTANCES AND YOUTH

In the last 2 decades, a considerable amount of research has been conducted with performance-enhancing substances such as creatine, amino acids, androstenedione, and dehydroepiandrosterone. Virtually no experimental research on either the ergogenic effects or adverse effects of performance-enhancing substances has been conducted in subjects younger than 18 years. The amount of scientific data from well-designed studies on the effects of these substances in adults continues to accumulate at such a rate that systematic reviews are soon made obsolete.

This statement is not intended to provide a review of currently available data on performance-enhancing substances. A list of resources for detailed information on specific performance-enhancing substances is provided at the end of this statement. Rather, this statement is intended to convey a more general policy on the basis of the following 3 points. First, the intentional use of any substance for performance enhancement is unfair and, therefore, morally and ethically indefensible. Second, use of any substance for the purpose of enhancing sports performance, including over-the-counter supplements, the composition and quality of which are not under federal regulation, may pose a significant health risk to the young person. Third, use and promotion of performance-enhancing substances tends to devalue the principles of a balanced diet, good coaching, and sound physical training.

CURRENT DEFINITIONS OF PERFORMANCE-ENHANCING SUBSTANCES

Limitations of Current Definitions

Traditionally, sports organizations such as the International Olympic Committee and the National Collegiate Athletic Association have defined performance-enhancing substances as substances that create an unfair competitive advantage. These organizations have produced lists of banned or prohibited drugs that include substances with known performance-enhancing effects as well as substances used by athletes that have been associated with adverse health effects. Detection of illegal or banned substances by drug testing is a critical element of the enforcement and efficacy of these policies. However, current definitions of performance-enhancing substances have contextual limitations. If the substance does not have adverse medical consequences, if the substance is not detectable by drug testing, or if testing for the drug is not performed (so that a potentially dangerous substance or unfair practice may go undetected), then the substance in question would not be included in a list of banned substances.

To date, there is no definition of performance-enhancing substances that applies to all potential users. A definition of a performance-enhancing substance that is applicable to the pediatric age group should not exclude any individual who may have a substance-abuse problem or any substance that cannot be readily detected. With the prohibitive cost of testing and deficiencies associated with a detection-based banned list, widespread drug testing of children and adolescents is unlikely to be effective or practical. A definition of a performance-enhancing substance for the pediatric age group, therefore, must be independent of whether testing of the substance is conducted in that age group. Because new substances for performance enhancement as well as methods for masking the presence of these substances are continually being discovered, a definition of performance-enhancing substances must remain valid in a changing environment.

General Definition of Performance-Enhancing Substances

A performance-enhancing substance is any substance taken in nonpharmacologic doses specifically for the purposes of improving sports performance. A substance should be considered performance enhancing if it benefits sports performance by increasing strength, power, speed, or endurance (ergogenic) or by altering body weight or body composition. Furthermore, substances that improve performance by causing changes in behavior, arousal level, and/or perception of pain should be considered performance enhancing.

Performance-enhancing substances include the following:

- Pharmacologic agents (prescription or nonprescription) taken in doses that exceed the recommended therapeutic dose or taken when the therapeutic indication(s) are not present (eg, using decongestants for stimulant effect, using bronchodilators when exercise-induced bronchospasm is not present, increasing baseline methylphenidate hydrochloride dose for athletic competition)
- Agents used for weight control, including stimulants, diet pills, diuretics, and laxatives, when the user is in a sport that has weight classifications or that rewards leanness
- Agents used for weight gain, including over-the-counter products advertised as promoting increased muscle mass
- Physiologic agents or other strategies used to enhance oxygen-carrying capacity, including erythropoietin and red blood cell transfusions (blood doping)
- Any substance that is used for reasons other than to treat a documented disease state or deficiency
- Any substance that is known to mask adverse effects or detectability of another performance-enhancing substance
- Nutritional supplements taken at supraphysiologic doses or at levels greater than required to replace deficits created by a disease state, training, and/or participation in sports

STRATEGIES FOR PREVENTING USE OF PERFORMANCE-ENHANCING SUBSTANCES

The methods most widely used to prevent use of performance-enhancing substances, namely drug bans and drug testing, are primarily punitive. Drug

bans imposed by organizations that regulate and oversee sports programs at various levels, from the International Olympic Committee to the National Collegiate Athletic Association and state high-school sports associations, effectively make the use of such substances "against the rules." Enforcement of drug bans has necessarily involved the use of drug testing, with positive tests carrying stiff penalties or sanctions including loss of playing privileges, removal of awards or championships from the entire team, loss of scholarships, and restrictions on future regular-season and postseason play.[3] Drug testing and legal sanctions are intended to be deterrents but have little effect on most children and adolescents involved in sports.

Neither the use of drug bans nor the implementation of drug testing provides the young athlete with any framework or guidelines for resolving the conflict between the drive to win and the imperative to do the right thing.

A variety of programs educating young athletes about substance abuse in general and targeting specific performance-enhancing drugs such as anabolic steroids have been tested at the international, collegiate, and even high-school levels.[4] It is unfortunate that few evaluations of these programs have included measurement of continued drug use after the intervention, and programs appropriately studied have not been highly successful in curbing use. One program that combined drug education with training in personal skills to resist the social influences that drive the use of performance-enhancing substances was successful in decreasing the intention to use anabolic steroids among adolescent football players.[5]

Little effort has been made to target adults who are responsible for collegiate, high-school, middle-school, and youth sports programs. Permissiveness often has the same effect as active encouragement when it comes to using performance-enhancing substances. A "don't-ask" attitude should be as intolerable to parents as the provision of performance-enhancing substances to athletes by coaches would be.

IDENTIFICATION OF THE YOUNG PERSON USING PERFORMANCE-ENHANCING SUBSTANCES

Data from epidemiologic studies and case descriptions have provided information about users of performance-enhancing substances that can help pediatricians to identify them. Users of anabolic or androgenic compounds are more likely to be male; are more likely to be involved in sports that demand high levels of strength, power, size, and speed; and are likely to use other illegal substances such as tobacco and alcohol.[5–7] Young people who participate in sports that demand leanness are also more likely to use performance-enhancing substances than are those involved in sports in which leanness is not essential. Young men and women who are not competitive athletes but who are obsessed with body image and who train intensely primarily to improve their physique are also more likely to use performance-enhancing substances. Users of certain performance-enhancing substances might be identified by outward signs such as virilization in females, testicular atrophy in males, and mood changes produced by anabolic steroids. Unfortunately, most young people who use performance-enhancing substances are not readily identified by outward signs. Therefore, it is imperative that all adolescents be asked about use of performance-enhancing substances in the assessment of high-risk behaviors that should be a part of every adolescent health maintenance visit, including sports physicals, camp physicals, and all other scheduled physician-adolescent encounters.

RECOMMENDATIONS

To assist the pediatrician in dealing with users or potential users of performance-enhancing substances, the American Academy of Pediatrics offers the following recommendations:

1. Use of performance-enhancing substances for athletic or other purposes should be strongly discouraged.
2. Parents should take a strong stand against the use of performance-enhancing substances and, whenever possible, demand that coaches be educated about the adverse health effects of performance-enhancing substances.
3. Schools and other sports organizations should be proactive in discouraging the use of performance-enhancing substances, incorporating this message into policy and educational materials for coaches, parents, and athletes.
4. Interventions for encouraging substance-free competition should be developed that are more positive than punitive, such as programs that teach sound nutrition and training practices along with skills to resist the social pressures to use performance-enhancing substances.
5. Colleges, schools, and sports clubs should make use of educational interventions that encourage open and frank discussion of issues related to the use of performance-enhancing substances, with the aim of promoting decisions about personal drug use based on principles of fair competition and character rather than on the fear of getting caught.
6. Coaches at all levels, including youth sports, should encourage wholesome and fair competition by emphasizing healthy nutrition and training practices, taking a strong stand against cheating, and avoiding the "win-at-all-costs" philosophy.
7. Inquiries about the use of performance-enhancing substances should be made in a manner similar to inquiries about use of tobacco, alcohol, or other substances of abuse. Guidelines for patient confidentiality should be followed and explained to the patient.
8. Athletes who admit using performance-enhancing substances should be provided unbiased medical information about benefits, known adverse effects, and other risks. When appropriate, additional testing may be necessary to investigate or rule out adverse medical effects.
9. The pediatric health care professional providing care for an athlete who admits to using a perfor-

mance-enhancing substance should explore the athlete's motivations for using these substances, evaluate other associated high-risk behaviors, and provide counseling on safer, more appropriate alternatives for meeting fitness or sports-performance goals.

10. Nonusers of performance-enhancing substances should have their decisions reinforced while establishing an open channel of communication if questions about performance-enhancing substances arise in the future.
11. Pediatric health care professionals should promote safe physical activity and sports participation by providing or making available sound medical information on exercise physiology, conditioning, nutrition, weight management, and injury prevention and by helping to care for sports-related medical conditions and injuries.

The November 2004 issue of "Sports Shorts" by the American Academy of Pediatrics Section on Sports Medicine and Fitness concerning performance-enhancing substances[8] is available for download and includes guidelines for pediatricians and parents.

CLINICAL REPORT

Use of Soy Protein-Based Formulas in Infant Feeding

Guidance for the Clinician in Rendering Pediatric Care

Jatinder Bhatia, MD, Frank Greer, MD, and the Committee on Nutrition

ABSTRACT

Soy protein-based formulas have been available for almost 100 years. Since the first use of soy formula as a milk substitute for an infant unable to tolerate a cow milk protein-based formula, the formulation has changed to the current soy protein isolate. Despite very limited indications for its use, soy protein-based formulas in the United States may account for nearly 25% of the formula market. This report reviews the limited indications and contraindications of soy formulas. It will also review the potential harmful effects of soy protein-based formulas and the phytoestrogens contained in these formulas.

THE AMERICAN ACADEMY of Pediatrics (AAP) is committed to the use of human milk as the ideal source of nutrition for infant feeding. However, by 2 months of age, the majority of infants in North America are receiving at least some formula. Soy-based infant formulas have been available for almost 100 years.[1] Despite limited indications, soy protein-based formula accounts for approximately 20% of the formula market in the United States. Because an infant formula provides a source of nutrition for an extended interval, its nutritional adequacy must be proven, and the indications for its use must be substantiated and well understood. This statement updates the 1998 AAP review of soy protein-based formulas and addresses the ongoing concern of phytoestrogens in soy formulas.

COMPOSITION

Isolated soy protein-based formulas currently on the market are all free of cow milk protein and lactose and provide 67 kcal/dL. All are iron-fortified and meet the vitamin, mineral, and electrolyte specifications addressed in the 2004 guidelines from the AAP for feeding term infants[2] and established by the US Food and Drug Administration.[3] The protein is a soy isolate supplemented with L-methionine, L-carnitine, and taurine to provide a protein content of 2.45 to 2.8 g per 100 kcal or 1.65 to 1.9 g/dL. The fat content of soy protein-based formulas is derived primarily from vegetable oils. The quantity of specific fats varies by manufacturer and is usually similar to those in the manufacturer's corresponding cow milk-based formula. The fat content ranges from 5.02 to 5.46 g per 100 kcal or 3.4 to 3.6 g/dL. The oils used include soy, palm, sunflower, olein, safflower, and coconut. Docosahexaenoic and arachidonic acids now are added routinely.

In formulas, carbohydrate sources are corn maltodextrin, corn syrup solids, and sucrose, with content ranging from 10.26 to 10.95 g per 100 kcal or 6.9 to 7.4 g/dL. Until 1980, mineral absorption from soy formulas was erratic because of poor stability of the suspensions and the presence of excessive soy phytates.[4] Because soy protein isolate formulas still contain 1.5% phytates, and up to 30% of the total phosphorus is phytate bound, they contain 20% more calcium and phosphorus than cow milk-based formulas and maintain the ratio of calcium to available phosphorus of 1.1 to 2.0:1. With the current formulations, bone mineralization, serum concentrations of calcium and phosphorus, and alkaline phosphatase concentrations in term infants through 12 months of age are equivalent to those observed in infants fed cow milk-based formulas.[5–7] Because soy phytates and fiber oligosaccharides also bind iron and zinc,[9] all soy-based formulas are fortified with iron and zinc.[8,9]

Phytoestrogens in Soy Protein-Based Formulas

Of the many heat-stable factors present in soy formulas, the phytoestrogens are of particular interest in human health. Phytoestrogens consist of several groups of nonsteroidal estrogens, including isoflavones. Isoflavones are commonly found in legumes, with the highest amount found in soybeans.[1,10] Concerns raised in relation to phytoestrogens/isoflavones include their potential negative effects on sexual development and reproduction, neurobehavioral development, immune function, and thyroid function. On the other hand, epidemiologic studies have

suggested a protective effect of isoflavones against a number of adult chronic diseases, including coronary heart disease and breast, endometrial, and prostate cancers.[11,12]

The structural similarity of phytoestrogens with 17-estradiol has prompted studies on the possible effects of soy isoflavones on reproductive function and growth. Numerous toxicity studies in rats have demonstrated some effects on estrogen-related tissues, but overall maternal reproductive function and fetal development were unaffected.[13–15] A recent study of the isoflavone genistein demonstrated adverse consequences of neonatal exposure in mice[16]; however, feeding of soy formula (and not individual components) has not demonstrated these adverse effects in animals.[17]

The possible effects of soy isoflavones on various forms of carcinogen-induced and estrogen-induced tumorigenesis have been investigated in animal models, but no clear conclusion can be drawn.[18,19] Soy diets were reported to stimulate growth of estrogen-dependent mammary tumors in mice in a dose-dependent manner.[20,21] Contrary to these results, phytoestrogens in typical dietary quantities were reported not to have estrogen-like activity in female ovariectomized macaque monkeys, but they antagonized estrogen-induced cellular proliferation in the breast.[22]

In humans, very limited data to date suggest that soy phytoestrogens have a low affinity for human postnatal estrogen receptors and low potency in bioassays.[23] The absorption, distribution, metabolism, and excretion of soy isoflavones vary, depending on age and gender and among cultural groups; interindividual variability has been documented in several studies.[24,25] However, differences in gender have been inconclusive.[26–28] Analysis of maternal and cord plasma and amniotic fluid indicates placental transfer of these compounds after soy consumption; no deleterious effects were discerned in the fetuses of Japanese mothers with relatively high soy consumption.[29]

Isoflavones are excreted in human milk, although the concentration is very low. The concentration of isoflavones in human milk reflects maternal diet, with omnivores demonstrating considerably lower concentrations of isoflavones compared with vegans.[30,31] Setchell and Cassidy[32] estimated that the amount of isoflavones ingested by infants fed soy-based formulas on a body weight basis exceeded those reported to increase the length of the menstrual cycle in adult women. However, an increased incidence of feminization in male infants[33] or an increased incidence of hypospadias in high soy-consuming populations[34] have not been observed. Even in infants fed soy-based formulas exclusively, the sulfate and glucuronide conjugates of phytoestrogens are identified in plasma, although both of these are rapidly excreted.[27] Data on reproductive health in young adults 20 to 34 years of age who had previously participated in a controlled feeding study of soy formula as infants demonstrated a longer duration of menstrual bleeding and greater discomfort in women exposed to soy as infants.[35] We cautioned against overinterpretation of their data, however, because there was no increase in menstrual blood flow in the women exposed to soy formula as infants and no statistically significant differences in >30 other outcome variables measured.[35]

Consumption of soy products by infants with congenital hypothyroidism complicates their management, as evidenced by a prolonged increase in thyroid-stimulating hormone when compared with infants not fed soy formula; the authors of 2 studies suggested closer monitoring and a possible need for an increased dose of levothyroxine.[36,37] In infants receiving replacement hormone, the phytates may interfere with the uptake of exogenous thyroid hormone by binding the thyroxine within the lumen, increasing fecal loss, and reducing the efficacy of oral thyroid hormone.[36,38] In an extensive review of the effects of soy protein and soybean isoflavones, little evidence was found that soy foods or isoflavones adversely affect thyroid function in iodine-replete individuals with euthyroidism.[39] This review also found that, similar to infants, adults with hypothyroidism may need additional doses of thyroid hormone with the concomitant use of soy foods because of the effects on absorption. Trials with dietary soy isoflavones have not reported adverse effects on thyroid function in rats.[40] These data suggest that there is a lack of sufficient evidence suggesting short-term or long-term adverse effects of soy consumption on endocrine function.

In summary, although studied by numerous investigators in various species, there is no conclusive evidence from animal, adult human, or infant populations that dietary soy isoflavones may adversely affect human development, reproduction, or endocrine function.

Aluminum in Soy Protein-Based Formulas

In 1996, the AAP issued a statement (since retired) on aluminum toxicity in infants and children and discussed the relatively high content of aluminum in soy-based formulas.[41] Although the aluminum content of human milk is 4 to 65 ng/mL, that of soy protein-based formula is 600 to 1300 ng/mL.[42,43] Mineral salts used in formula production are the source of the aluminum. Aluminum, which makes up 8% of the earth's crust as the third most common element, has no known biological function in humans.[43] The toxicity of aluminum is traced to increased deposition in bone and in the central nervous system, particularly in the presence of reduced renal function in preterm infants and children with renal failure. Because aluminum competes with calcium for absorption, increased amounts of dietary aluminum from isolated soy protein-based formula may contribute to the reduced skeletal mineralization (osteopenia) observed in preterm infants and infants with intrauterine growth retardation.[44] Term infants with normal renal function do not seem to be at substantial risk of developing aluminum toxicity from soy protein-based formulas.[42]

USE IN TERM AND PRETERM INFANTS

Numerous studies have documented normal growth and development in term neonates fed methionine-supplemented isolated soy protein-based formulas.[42,45–48] Average energy intakes in infants receiving soy protein-based

formulas are equivalent to those achieved with cow milk formulas.[42] In infants fed soy protein-based formulas, the serum albumin concentration, as a marker of nutritional adequacy, is normal,[46,49–51] and bone mineralization is equivalent to that documented with cow milk-based formulas in term infants.[5–7] Literature reviews and clinical studies of infants fed soy protein-based infant formulas raise no clinical concerns with respect to nutritional adequacy, sexual development, thyroid disease, immune function, or neurodevelopment.[1] Additional studies confirm that soy protein-based formulas do not interfere with normal immune responses to oral immunization with poliovirus vaccine.[52,53] The US Food and Drug Administration has approved these formulas as safe for use with infants.

On the other hand, soy protein-based formulas are not recommended for preterm infants. Serum phosphorus concentrations are lower, and alkaline phosphatase concentrations are higher in preterm infants fed soy protein-based formula than they are in preterm infants fed cow milk-based formula.[54,55] As anticipated from these observations, the degree of osteopenia is increased in infants with low birth weight receiving soy protein-based formulas.[50,56] Even with supplemental calcium and vitamin D, radiographic evidence of significant osteopenia was present in 32% of 125 preterm infants fed soy protein-based formula.[56] The cow milk protein-based formulas designed for preterm infants are clearly superior to soy protein-based formula for preterm infants.

USE IN DISORDERS OF CARBOHYDRATE METABOLISM

When strict dietary lactose elimination is required in the management of infants with galactosemia or primary lactase deficiency (extremely rare), soy protein-based formulas are safe and cost-effective. In addition, soy protein-based formulas can be a dietetic alternative for families wishing to avoid feeding their infants formulas containing animal products. Soy protein-based formulas with sucrose as the carbohydrate are contraindicated in sucrase-isomaltase deficiency and in hereditary fructose intolerance.

USE IN ACUTE DIARRHEA AND SECONDARY LACTASE DEFICIENCY

A number of studies have addressed the role of these formulas in the recovery from acute infantile diarrhea complicated by secondary or transient lactase deficiency. However, after immediate rehydration, most infants can be managed successfully with continued breastfeeding or standard cow milk or soy formula.[57,58] In an extensive review, Brown[57] noted that the dietary failure rate of lactose-containing formulas was 22%, whereas that of lactose-free formulas was 12%. In a study comparing human milk, cow milk-based formula, and soy protein-based formula, no difference was found in the rate of recovery from rotavirus or nonrotavirus diarrhea on the basis of nutritional therapy.[49] However, the duration of diarrhea has been reported to be shorter in infants receiving soy protein-based formula,[51,59] and the duration of liquid stools may also be reduced by adding additional soy polysaccharide fiber[60] or by resuming a mixed-staple diet.[61]

Lactose free and reduced lactose-containing cow milk formulas are now available and could be used for circumstances in which elimination or a reduction in lactose in the diet, respectively, is required. Because primary or congenital lactase deficiency is rare, very few individuals would require a total restriction of lactose. Lactose intolerance is more likely to be dose dependent. Thus, the use of soy protein-based lactose-free formulas for this indication should be restricted.

USE IN COLIC AND "FORMULA INTOLERANCE"

Perhaps the most common reason for use of soy formulas by infant care providers is for relief of perceived formula intolerance (spitting, vomiting, fussiness) or symptoms of colic. Colicky discomfort is described by the parents of 10% to 20% of infants during the first 3 months of age.[62] Although many factors have been implicated, parents frequently seek relief by changing infant formulas. Although some calming benefit can be attributed to the sucrose[63,64] and fiber content,[65] controlled trials of cow milk and soy protein-based formulas have not demonstrated a significant benefit from soy.[66,67] The value of parental counseling as to the cause and duration of colic seems greater than the value of switching to soy formula.[68] Because most colicky behavior diminishes spontaneously between 4 and 6 months of age, any intervention at that time can be credited anecdotally.

SEVERE GASTROINTESTINAL REACTIONS TO SOY FORMULA

As with cow milk protein-based formula, severe gastrointestinal reactions to soy protein-based formula have been described for >40 years[69] and encompass the full gamut of disease: enteropathy, enterocolitis, and proctitis. Small-bowel injury, a reversible celiac-like villus injury that produces an enteropathy with malabsorption, hypoalbuminemia, and failure to thrive, has been documented in at least 4 studies.[70–73] In case series of infantile food protein-induced enterocolitis caused by cow milk protein, 30% to 64% of infants had concomitant soy-induced enterocolitis,[74–77] with enterocolitis manifested by bloody diarrhea, ulcerations, and histologic features of acute and chronic inflammatory bowel disease.[69,75,78–80] Afflicted infants have responded to replacing the soy protein-based formula with a hydrolyzed protein formula. It is theorized that the intestinal mucosa damaged by cow milk allows increased uptake and, therefore, increased immunologic response to the subsequent soy antigen. Eosinophilic proctocolitis, a more benign variant of enterocolitis, also has been reported in infants receiving soy protein-based formula.[81,82]

These dietary protein-induced syndromes of enteropathy and enterocolitis, although clearly immunologic in origin, are not immunoglobulin E (IgE)-mediated, reflecting instead an age-dependent transient soy protein hypersensitivity. Because of the reported high frequency of sensitivity to both cow milk and soy antigens in infants, soy protein-based formulas are not indicated in

the management of documented cow milk protein-induced enteropathy or enterocolitis. Hydrolyzed protein formulas should be used for these infants. Most, but not all children, can resume soy protein consumption safely after 5 years of age.

SOY PROTEIN-BASED FORMULAS AND PREVENTION OF ATOPIC DISEASE

Any ingested large molecular weight protein is a potential antigen to the intestinal immune system, including soy protein. In soy protein isolate, 90% of the pulp-derived protein resides in 2 major heat-stable globulins: β-conglycin, with a molecular weight of 180 000; and glycinin, with a molecular weight of 320 000.[83] After enteric digestion, the number of potential antigens generated at the mucosal surface is enormous.[84] As a result, the in vitro demonstration of antigen-specific antibody can be difficult. The antigenicity of soy protein, suspected since 1934,[85] was documented in low-risk infants by Eastham et al in 1982.[86] Intrauterine sensitization has been documented by demonstrating antigen-specific antibody in human amniotic fluid.[87]

Recognizing that soy protein is antigenic does not mean that soy protein is highly allergenic. In a prospective study of healthy infants fed human milk, cow milk formula, or soy protein-based formula, Halpern et al[88] documented true allergic responses in 0.5% and 1.8% of infants to soy formula and cow milk formula, respectively. This frequency is consistent with the summary by Fomon[89] that in 3 decades of study of soy protein-based formulas, <1% of soy formula-fed infants had adverse reactions. In a national survey of pediatric allergists, the occurrence of allergy to cow milk was reported at 3.4%, whereas allergy to soy protein was reported to be 1.1%.[90] Two large studies of infants with atopic dermatitis addressed the frequency with which a double-blind, placebo-controlled challenge with soy protein was positive. Sampson[91] documented a positive soy allergy in 5% of 204 patients, whereas Businco et al[92] implicated soy in 4% of 143 children.

In a recent meta-analysis of 5 randomized or quasi-randomized studies, the authors concluded that feeding with soy formula should not be recommended for the prevention of atopy in infants at high risk of developing allergy.[93] Furthermore, the use of soy protein-based formula during the first 3 months of age does not reduce the frequency of positive antibody responses to cow milk formula introduced later in infancy.[93] When human milk feeding is supplemented with soy formula in infants at high risk, the anticipated frequency of eczema by 2 years of age is not significantly reduced.[94,95] Interpretation of these data are obscured by multiple alterations in the maternal diet and by environmental stimuli. However, isolated soy protein-based formula has no advantage over cow milk-based formula for supplementing the diet of a breastfed infant.

Regarding soy proteins and other food allergies, in 1 partly prospective, partly retrospective study of the risk factors for the development of peanut allergy, feeding of soy milk or soy protein-based formula was associated with the development of peanut allergy (odds ratio: 2.6; 95% confidence interval: 1.3–5.2).[96] However, in a randomized trial of soy formula feeding in infants with cow milk allergy, there was no association between soy formula ingestion with the development of peanut allergy.[97] Thus, the evidence that soy formula feeding increases the risk of developing peanut allergy is contradictory, and additional study is warranted.

Sensitization to soy has been reported in 10% to 14% of infants with cow milk allergy.[98,99] One study documented similar adverse reactions to soy in IgE-associated and non-IgE-associated cow milk allergy (11% vs 9%).[99] A second study evaluated infants and children with IgE-associated cow milk allergy (ages 3–41 months), and 14% (95% confidence interval: 7.7–22.7) were determined to have soy allergy.[98] Thus, although most infants with IgE-mediated cow milk allergy will tolerate soy formula, because of the 10% to 14% crossover rate, the use of an extensively hydrolyzed protein formula rather than a soy formula may be considered in infants allergic to cow milk formula. Although reported in the literature, severe anaphylaxis after soy protein exposure is uncommon, especially in infants.[100,101]

SUMMARY

1. In term infants, although isolated soy protein-based formulas may be used to provide nutrition for normal growth and development, there are few indications for their use in place of cow milk-based formula. These indications include (*a*) for infants with galactosemia and hereditary lactase deficiency (rare) and (*b*) in situations in which a vegetarian diet is preferred.
2. For infants with documented cow milk protein allergy, extensively hydrolyzed protein formula should be considered, because 10% to 14% of these infants will also have a soy protein allergy.
3. Most previously well infants with acute gastroenteritis can be managed after rehydration with continued use of human milk or standard dilutions of cow milk-based formulas. Isolated soy protein-based formulas may be indicated when secondary lactose intolerance occurs.
4. Isolated soy protein-based formula has no advantage over cow milk protein-based formula as a supplement for the breastfed infant, unless the infant has 1 of the indications noted previously.
5. Soy protein-based formulas are not designed for or recommended for preterm infants.
6. The routine use of isolated soy protein-based formula has no proven value in the prevention or management of infantile colic or fussiness.
7. Infants with documented cow milk protein-induced enteropathy or enterocolitis frequently are as sensitive to soy protein and should not be given isolated soy protein-based formula. They should be provided formula derived from hydrolyzed protein or synthetic amino acids.

8. The routine use of isolated soy protein-based formula has no proven value in the prevention of atopic disease in healthy or high-risk infants.

Guidance for the Clinician in Rendering Pediatric Care

CLINICAL REPORT

The Use of Systemic and Topical Fluoroquinolones

John S. Bradley, MD, Mary Anne Jackson, MD, and the COMMITTEE ON INFECTIOUS DISEASES

abstract

FREE

Appropriate prescribing practices for fluoroquinolones are essential as evolving resistance patterns are considered, additional treatment indications are identified, and the toxicity profile of fluoroquinolones in children becomes better defined. Earlier recommendations for systemic therapy remain; expanded uses of fluoroquinolones for the treatment of certain infections are outlined in this report. Although fluoroquinolones are reasonably safe in children, clinicians should be aware of the specific adverse reactions. Use of fluoroquinolones in children should continue to be limited to treatment of infections for which no safe and effective alternative exists. *Pediatrics* 2011;128:e1034–e1045

KEY WORDS

fluoroquinolones, pediatrics, infectious diseases, systemic therapy

ABBREVIATIONS

FDA—Food and Drug Administration
UTI—urinary tract infection
TMP-SMX—trimethoprim-sulfamethoxazole

The guidance in this report does not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

OVERVIEW

Fluoroquinolones are highly active in vitro against both Gram-positive and Gram-negative pathogens and have pharmacokinetic properties that are favorable for treating a wide array of infections. The prototype quinolone antibiotic agent, nalidixic acid, was approved by the US Food and Drug Administration (FDA) for adults in 1964 and generally is considered to be the first generation of such agents. For more than 2 decades, nalidixic acid also has been approved by the FDA and available for children aged 3 months and older. Subsequent chemical modifications of the first quinolone compounds resulted in the development of a series of fluoroquinolone agents with an increased antimicrobial spectrum of activity and better pharmacokinetic tissue-exposure characteristics.

Second-generation agents have a greater Gram-negative spectrum (with activity against *Pseudomonas aeruginosa*) and include ciprofloxacin, levofloxacin, norfloxacin, and ofloxacin. In 2004, ciprofloxacin became the first fluoroquinolone agent approved for use in children 1 through 17 years of age.

Gemifloxacin, a currently marketed third-generation agent, has been approved by the FDA for adults for the treatment of community-acquired pneumonia and acute exacerbations of chronic bronchitis. Compared with earlier agents, gemifloxacin provides substantially increased activity against *Streptococcus pneumoniae* (while retaining activity against many Gram-negative pathogens), *Mycoplasma pneumoniae*, and *Chlamydophila pneumoniae*.

A fourth generation of fluoroquinolones, represented by moxifloxacin, displays increased activity against anaerobes while maintaining the Gram-positive and Gram-negative activity of the third-generation agents. Moxifloxacin also provides excellent activity against many my-

cobacteria including most strains of *Mycobacterium tuberculosis* currently isolated in the United States.

Animal toxicology data available with the first quinolone compounds documented their propensity to create inflammation and subsequent destruction of weight-bearing joints in juvenile animals.[1,2] This observation effectively sidelined further development or large-scale evaluation of this class of antibiotic agents in children.

A policy statement summarizing the assessment of risks and benefits of fluoroquinolones in pediatric patients was published by the American Academy of Pediatrics in 2006.[3] At that time, parenteral fluoroquinolones were believed to be appropriate for the treatment of infections caused by multidrug-resistant pathogens for which no alternative safe and effective parenteral agent existed. For outpatient management, oral fluoroquinolones were reasonable for treatment of infections when the only other options were intravenous treatment with other classes of antibiotic agents.

Since publication of the previous American Academy of Pediatrics policy statement, the clinical value of fluoroquinolones for the treatment of specific infections in children, particularly those caused by Gram-negative pathogens, has been further documented. The use of topical fluoroquinolone therapy for external otitis is now recommended by the American Association of Otolaryngology.[4] In addition, results of the first randomized, prospective studies on the safety of the fluoroquinolones have been reported.[5,6] No published reports exist of physician-diagnosed cartilage damage in children in the United States, either from controlled clinical trials of fluoroquinolones or from unsolicited reporting to the FDA or drug manufacturers. Quinolones that are currently approved by the FDA and available for use in children are nalidixic acid for urinary tract infections (UTIs), ciprofloxacin for inhalational anthrax and complicated UTI and pyelonephritis, and levofloxacin for inhalational anthrax. Only ciprofloxacin and levofloxacin are available in a suspension formulation. Moxifloxacin is currently under investigation for treatment of complicated intraabdominal infections in children.[7] Other systemic quinolones that may be available in other countries but not the United States are not addressed in this report.

SAFETY

Animal Models

The original toxicology studies with quinolones documented cartilage injury in weight-bearing joints in juvenile animals; damage to the joint cartilage was proportional to the degree of exposure.[1,2] Each quinolone may demonstrate a different potential to cause cartilage toxicity.[8] However, given a sufficiently high exposure, cartilage changes will occur in all animal models with all quinolones, including nalidixic acid.

Although initial reports focused on articular cartilage, the results of subsequent studies suggested the possibility of epiphyseal plate cartilage injury,[9] which led to fluoroquinolone clinical study designs that lasted several years to assess growth potential. Recent data suggest that quinolone toxicity occurs as a result of concentrations present in cartilage that are sufficiently high to form chelate complexes with divalent cations, particularly magnesium, that result in impairment of integrin function and cartilage matrix integrity in the weight-bearing joints, which undergo chronic trauma during routine use.[10]

In studies of ciprofloxacin exposure to very young beagle puppies (one of the most sensitive animal models for quinolone toxicity), clinical evidence of arthrotoxicity was observed during a 14-day treatment course at 90 mg/kg per day but not at 30 mg/kg per day. Apparent joint tenderness at the higher exposure resolved 6 weeks after the last dose of ciprofloxacin.

Histopathologic evidence of cartilage injury was noted in virtually all animals given 90 mg/kg per day. At this exposure level, the observed clinical signs all occurred during and shortly after treatment but resolved by 2 months, with no recurrent signs noted during the 5-month follow-up period. In contrast, histopathologic evidence of cartilage injury was observed at 30 mg/kg per day, the dose currently recommended for children. Histopathologic evidence of inflammation occurred in fewer than half the animals at this dose but persisted for 5 months after treatment, at full skeletal maturation.[5,11] The "no-observed-adverse-event level" was 10 mg/kg per day, a dose at which neither clinical nor histopathologic evidence of toxicity was present.

Similar data, which documented a no-observed-adverse-event level of 3 mg/kg per day for intravenous dosing for 14 days (approximately one-quarter the current FDA-approved dose of 16 mg/kg per day for children who weigh $<$50 kg), were documented before FDA approval of levofloxacin for adults. Levofloxacin has virtually 100% bioavailability; total drug exposure is equivalent between intravenous and oral formulations at the same milligram-per-kilogram dose.[12]

Recent data from investigation of a lamb model, felt to approximate human growth rates and activity more closely than juvenile beagle dogs or rats, have been published. This study addressed epiphyseal cartilage and growth velocity after a 14-day drug exposure to either gatifloxacin or ciprofloxacin that was equivalent to that achieved in children receiving thera-

peutic doses. Gross examination of articular cartilage and microscopic examination of epiphyseal cartilage did not reveal abnormalities consistent with cartilage injury or inflammation.[13]

Preclinical toxicology data are available for all FDA-approved fluoroquinolones. These data document differences in the animal species susceptible to cartilage effects as well as differences between each quinolone in the ability to create cartilage toxicity.

Human Studies

At the time of publication of the last American Academy of Pediatrics policy statement, retrospective studies, case-control series, and case reports represented the published data on fluoroquinolone safety in children available in the peer-reviewed literature.[14–17] Some reports included children with cystic fibrosis, who can develop disease-related arthropathy, and some included more toxic fluoroquinolone agents that were never approved in the United States. These data provided conflicting reports regarding the safety of fluoroquinolones in children. The results of 2 large, prospective safety studies are now available for review; 1 study was performed at the request of the FDA by Bayer for ciprofloxacin, and the second study was performed by Johnson & Johnson for levofloxacin as part of their FDA-coordinated program of pediatric drug development.

In 2008, the FDA's analysis of study data for ciprofloxacin in the treatment of complicated UTI and pyelonephritis in children aged 1 through 17 years from 2004 was posted on the FDA Web site.[5] A series of prospective, randomized, double-blinded studies was performed to compare (1) intravenous ceftazidime with intravenous ciprofloxacin, permitting oral step-down therapy, and (2) oral ciprofloxacin with oral cefixime or trimethoprim-sulfamethoxazole (TMP-SMX). These large studies were conducted in several countries (Table 1). Clinical end points were designed to capture any sign of cartilage or tendon toxicity by eliciting a detailed history of a wide variety of complaints referable to bones and joints (Table 2). Comparing complaints and physical findings between the ciprofloxacin-treated group and the group treated with comparator antimicrobial agents, a difference was detected only in the United States. The difference in rates of complaints varied between countries; the lowest

[a] The study was designed to demonstrate that the arthropathy rate for the ciprofloxacin group did not exceed that of the comparator group by more than 6.0%. At both evaluations, the 95% confidence interval indicated that it could not be concluded that ciprofloxacin had findings comparable to those of the comparator.

[b] Events that occurred in 2 or more patients.

[c] A patient with arthropathy may have had more than 1 event.

rates were reported from Mexico (0% ciprofloxacin, 0% comparator), and the highest rates were reported from the United States (21% ciprofloxacin, 11% comparator). The study used a noninferiority design to assess musculoskeletal complaints between the 2 treatment groups across all countries, and as analyzed, the groups were sufficiently different to suggest potential musculoskeletal toxicity with ciprofloxacin (Table 2).

The levofloxacin safety data collection was prospective and randomized but not blinded. The published safety profile of levofloxacin included a large cohort of 2523 children from 3 large multicenter efficacy trials. Data were collected from a community-acquired pneumonia trial in children aged 6 months to 16 years (a randomized 3:1, prospective, comparative trial with 533 levofloxacin-exposed and 179 comparator-exposed evaluable subjects) and from 2 trials that assessed therapy of acute otitis media in children aged 6 months to 5 years (1 open-label noncomparative study with 204 evaluable subjects and another randomized 1:1, prospective, comparative trial with 797 levofloxacin-exposed and 810 comparator-exposed evaluable subjects).[6] In addition, after completion of the treatment trials, all subjects from both treatment arms were also offered participation in an unblinded, long-term, 12-month follow-up study for safety assessments, and 2233 of 2523 families participated. From these trials, a selected group of children who were judged to benefit from additional follow-up because of the presence of tendon/joint abnormalities or failure to achieve expected vertical growth over the year of observation were continued in the musculoskeletal long-term follow-up study, which consisted of yearly visits for 4 additional years.

The definitions of musculoskeletal events for tendinopathy (inflammation or rupture of a tendon as determined by physical examination and/or MRI or ultrasound), arthritis (inflammation of a joint as evidenced by redness and/or swelling of the joint), arthralgia (pain in the joint as evidenced by complaint), and gait abnormality (limping or refusal to walk) were determined before starting the studies. The identity of study medication was known by parents, study personnel, and the subject's care providers as reports of musculoskeletal events and any other adverse events were collected during the follow-up period. An analysis of these events occurred 1, 2, and 12 months after treatment. The analysis of disorders that involved weight-bearing joints revealed a statistically greater rate between the levofloxacin- and comparator-treated groups at 2 months (1.9% vs 0.7%; $P = .025$) and at 12 months (2.9% vs 1.6%; $P = .047$). A history of joint pain accounted for 85% of all events, and there were no findings of joint abnormality when assessed by physical examination. Computed tomography or MRI was performed for 5 of the patients with musculoskeletal symptoms; no signs of structural injury were identified. No evidence of joint abnormalities was observed at 12 months in the levofloxacin group.

A report on the 5-year safety assessment of the 2233 children who received levofloxacin treatment was recently completed by the manufacturer, Johnson & Johnson. Specified criteria for review included (1) documented height that was less than 80% of the expected height increase, (2) abnormal bone or joint findings, and (3) any other concerns for possible tendon/joint toxicity identified by the data safety monitoring board during treatment or in the 12 months after treatment. A total of 174 of 207 (84%) reviewed subjects were identified by the predetermined growth criteria (124 levofloxacin-treated and 83 comparator-treated subjects), and 49% of each group completed the entire 5-year follow-up. Although an increase in musculoskeletal events in the levofloxacin group had been noted 12 months after treatment, the cumulative long-term outcomes of children with musculoskeletal adverse events reported during the 5-year safety study (including ongoing arthropathy, peripheral neuropathy, abnormal bone development, scoliosis, walking difficulty, myalgia, tendon disorder, hypermobility syndrome, and pain in the spine, hip, and shoulder) were slightly higher in the comparator treatment group (2% levofloxacin, 4% comparator). Among all study participants identified by the growth criteria ($n = 174$), equal percentages of children from each treatment group were documented to fall into the previously defined categories at the 5-year visit: no change in height percentile; improvement; or deterioration in growth characteristics. This 5-year follow-up study enrolled 48% of study participants from US sites compared with 20% from US sites enrolled in the original clinical trials (unpublished data on file, J&J protocol LOFBO-LTSS-001, clinical study report, March 23, 2011).

A rare complication associated with quinolone antibiotic agents, tendon rupture, has a predilection for the Achilles tendon (often bilateral) and is estimated to occur at a rate of 15 to 20 per 100 000 treated patients in the adult population. Advanced age, along with antecedent steroid therapy and a particular subset of underlying diseases, including hypercholesterolemia, gout, rheumatoid arthritis, end-stage renal disease/dialysis, and renal transplantation, have been identified as risk factors and prompted an FDA warning about this serious adverse event for all quinolone agents. Achilles tendon rupture in the pediatric popu-

TABLE 3 Rate of FDA-Defined Neurologic Adverse Events by 6 Weeks After Treatment With Ciprofloxacin or Comparator

Neurologic Adverse Events	Ciprofloxacin ($N = 335$), *n* (%)	Comparator ($N = 349$), *n* (%)
Any event	9 (3)	7 (2)
Dizziness	3 (<1)	1 (<1)
Nervousness	3 (<1)	1 (<1)
Insomnia	2 (<1)	0 (0)
Somnolence	2 (<1)	0 (0)
Abnormal dreams	0 (0)	2 (<1)
Convulsion	0 (0)	2 (<1)
Hypertonia	0 (0)	1 (<1)
Abnormal gait	0 (0)	1 (<1)

lation, in general, is extremely rare, and although tendonitis in athletes is observed, this event usually follows overuse. To date, there have been no reports of this rare complication in a pediatric patient who was exposed to a quinolone, which precludes assessment of the risk of this complication in children.

Other potential toxicities of fluoroquinolone-class antibiotic agents do not occur commonly in children but include central nervous system adverse effects (seizures, headaches, dizziness, lightheadedness, sleep disorders), peripheral neuropathy, hypersensitivity reactions, photosensitivity and other rashes, disorders of glucose homeostasis (hypoglycemia and hyperglycemia), prolongation of QT interval, and hepatic dysfunction.

In the prospective ciprofloxacin study requested by the FDA, the rate of neurologic events was similar between ciprofloxacin- and comparator-treated children (Table 3).[5] Reported rates of neurologic events in the levofloxacin safety database were statistically similar between fluoroquinolone- and comparator-treated children.[18,19]

RESISTANCE

Quinolone resistance has been a concern since the first approval of these agents, given the broad spectrum of activity and the large number of clinical indications. Multiple mechanisms of resistance have been described, including mutations that lead to changes in the target enzymes DNA gyrase and DNA topoisomerase, as well as efflux pumps and alterations in membrane porins.[20] Newly described plasmid-encoded quinolone-resistance proteins have the ability to spread rapidly.[21]

Surveillance studies have tracked fluoroquinolone resistance in *S pneumoniae* strains isolated primarily from adult patients with respiratory tract infections and in *Escherichia coli* isolated from adult patients with UTIs. A number of studies also have assessed resistance in other enteric bacilli,[22–25] *Pseudomonas aeruginosa*,[26] *Neisseria gonorrhoeae*,[27] *Neisseria meningitidis*,[28] and *Streptococcus pyogenes*.[29,30] One recent study in North America addressed fluoroquinolone resistance in both Gram-negative and Gram-positive isolates, specifically from children younger than 7 years.[31] Previous concerns that continuing widespread use of respiratory fluoroquinolones would lead to substantial increases in pneumococcal resistance and subsequent lack of usefulness of this class of agents for respiratory tract infections[32–34] have, fortunately, not been confirmed by current published surveillance data, particularly for pneumococcal isolates from children.[31,35,36] The Active Bacterial Core Surveillance of the Centers for Disease Control and Prevention documented virtually no levofloxacin resistance in children younger than 2 years between 1999 and 2004.[37] In large-scale pediatric studies of levofloxacin for acute otitis media, emergence of levofloxacin-resistant pneumococci was not documented in children with persisting pneumococcal colonization after treatment, which suggests that emergence of resistance during treatment is not a common event.[38] Possible reasons for the lack of increasing multidrug-resistant serotypes in both children and adults in populations in North America and Europe include the almost universal use of conjugate pneumococcal vaccine in children since 2000 as well as the lack of widespread use of fluoroquinolones in children.[37,39–41]

In adult patients, *Pseudomonas* resistance to both fluoroquinolones and other antimicrobial agents is problematic.[42] Data on resistance in *E coli* isolated from adults with UTIs who were seen in emergency departments in the EMERGEncy ID NET, a network of 11 geographically diverse university-affiliated institutions, suggest a low but stable rate of resistance of approximately 5%,[24] although in specific locations, rates of resistance for outpatients are closer to 10%.[22,43] Similar published data do not exist for children, although in recent reports that included outpatient data, stratified according to age, the rates of fluoroquinolone resistance in *E coli* in children have been generally well below 3%.[23,43]

For hospitalized children in a major tertiary care pediatric center, only 3% of 271 bloodstream isolates of *E coli* and *Klebsiella* species collected over 4 years (1999–2003) were resistant to fluoroquinolones.[44] With the exception of children with cystic fibrosis, overall resistance in pediatric Gram-negative isolates, including *P aeruginosa*, has been lower than 5%.[31] Data available from 3 large tertiary care children's hospitals document ciprofloxacin resistance for *E coli* to range from 4% to 7% for 2010 (B. Connelly, MD [Cincinnati Children's Hospital and Medical Center, Cincinnati, OH], M. A. Jackson, MD [Mercy Children's Hospital, Kansas City, MO], and J. Bradley, MD [Rady Children's Hospital, San Diego, CA], verbal communication, May 2011), and the rates have seemed stable for the last 3 years.

TABLE 4 Most Common Infections for Which Fluoroquinolones Are Effective Therapy (See Text)

Infection	Primary Pathogen(s)[a]	Fluoroquinolone
Systemic antibiotic requirement[b]		
UTI	*Escherichia coli*	Ciprofloxacin[c]
	Pseudomonas aeruginosa	
	Enterobacter species	
	Citrobacter species	
	Serratia species	
Acute otitis media; sinusitis	*Streptococcus pneumoniae*	Levofloxacin[d]
	Haemophilus influenzae	
Pneumonia	*Streptococcus pneumoniae*	Levofloxacin
	Mycoplasma pneumoniae (macrolides preferred for *Mycoplasma* infections)	
Gastrointestinal infections	*Salmonella* species	Ciprofloxacin[c]
	Shigella species	
Topical antibiotic requirement[e,f]		
Conjunctivitis	*Streptococcus pneumoniae*	Besifloxacin
	Haemophilus influenzae	Levofloxacin
		Gatifloxacin
		Ciprofloxacin
		Moxifloxacin
		Ofloxacin
Acute otitis externa; tympanostomy tube–associated otorrhea	*Pseudomonas aeruginosa*	Ciprofloxacin[g]
	Staphylococcus aureus	Ofloxacin
	Mixed Gram-positive/Gram-negative organisms	

[a] Assuming that the pathogen is either documented to be susceptible or presumed to be susceptible for fluoroquinolones.
[b] If oral therapy is appropriate, use other classes of oral antibiotics if organisms are susceptible.
[c] Dose of ciprofloxacin: oral administration, 20 to 40 mg/kg per day, divided every 12 hours (maximum dose: 750 mg per dose); intravenous administration, 20 to 30 mg/kg per day, divided every 8 to 12 hours (maximum dose: 400 mg per dose).
[d] Dose of levofloxacin: oral or intravenous administration, 16 to 20 mg/kg per day divided every 12 hours (for children 6 months to 5 years of age) or 10 mg/kg per day once daily (for children 5 years of age and older) (maximum dose: 750 mg per dose).
[e] Systemic toxicity of fluoroquinolones is not a concern with topical therapy; use of topical agents should be determined according to suspected pathogens, efficacy for mucosal infection, tolerability, and cost.
[f] Other systemic therapy may be required for more severe infection.
[g] Available with and without corticosteroid.

As fluoroquinolone use in pediatrics increases, it is expected that resistance will increase, as has been documented in adults. Appropriate use of fluoroquinolones in children should limit the development and spread of resistance.

USE OF FLUOROQUINOLONES FOR PEDIATRIC INFECTIONS

Conjunctivitis

An increasing number of topical fluoroquinolones have been investigated and approved by the FDA for treatment of acute conjunctivitis in adults and children older than 12 months, including levofloxacin, moxifloxacin, gatifloxacin, ciprofloxacin, and besifloxacin (Table 4). Conjunctival tissue pharmacokinetic evaluation was conducted in healthy adult volunteers; besifloxacin, gatifloxacin, and moxifloxacin were compared by using conjunctival biopsy. All 3 agents reached peak concentrations after 15 minutes.[45] Bacterial eradication and clinical recovery of 447 patients aged 1 through 17 years with culture-confirmed bacterial conjunctivitis was evaluated in a posthoc multicenter study that investigated besifloxacin and moxifloxacin ophthalmic drops.[46] Although better clinical and microbiological response was noted for besifloxacin compared with placebo, similar outcomes were noted when compared with moxifloxacin. Both agents were reported to be well tolerated. Although drug concentrations are only 1 indicator of potential clinical efficacy, the utility of agents with higher concentrations is tempered by the observation of a potential increase in ocular adverse events, such as eye pain,[45] and slower corneal reepithelialization with specific agents.[47]

External Otitis, Tympanostomy Tube–Associated Otorrhea

Recommendations for optimal care for patients with otitis externa were outlined in a review of 19 randomized controlled trials, including 2 from a primary care setting, which yielded 3382 participants. Topical antibiotic agents containing corticosteroids seemed to be more effective than acetic acid solutions. Aminoglycoside-containing otic preparations were reported to cause ototoxicity if the tympanic membrane was not intact; fluoroquinolone-containing preparations represent a safer alternative for treating both otorrhea associated with tympanic membrane perforation and tympanostomy tube otorrhea. Eleven trials included aural toilet as a routine intervention, but the authors acknowledged that this treatment is not likely to be available in a typical primary care office setting.[48] The paucity of high-quality studies of antimicrobial-based topical therapy limited conclusions in this review. A small, prospective, randomized, open-label study of 50 patients with tympanostomy tube–associated otorrhea or a tympanic membrane perforation resulted in comparable outcomes with either topical antibiotic therapy or topical plus systemic antibiotic agents.[49] For children with severe acute otitis externa, systemically administered antimicrobial agents should be considered in addition to topical therapy.[50]

Which topical antibiotic agent is best for external otitis is unclear. High-quality studies that evaluated quinolone versus nonquinolone topical solutions have been limited. A systematic review of 13 meta-analyses confirmed

that topical antibiotic agents were superior to placebo and noted a statistically significant advantage of quinolone agents over nonquinolone agents in the rate of microbiological cure ($P = .035$), although the clinical import of this advantage is likely of limited value. Safety profiles were similar between groups.[50] A conclusion that quinolone and nonquinolone agents are similar in both microbiological and clinical cure rates was reached in a study of more than 200 children, 90 of whom were evaluated for microbiological response in a multicenter, randomized, parallel-group, evaluator-blinded study that compared once-daily ofloxacin drops to 4-times-daily neomycin sulfate/polymyxin B sulfate/hydrocortisone otic suspension. Microbial eradication was documented in 95% and 94%, respectively; clinical cure was achieved in 96% and 97%, respectively. Treatment was well tolerated with both regimens.[51]

Acute Otitis Media, Sinusitis, and Lower Respiratory Tract Infections

Newer fluoroquinolones display enhanced in vitro activity against *S pneumoniae* compared with ciprofloxacin. The clinical need for such agents to treat respiratory tract infections has largely been driven by the emergence of multidrug-resistant strains of this pathogen. Pharmacokinetic data for children 6 months of age and older are well defined for levofloxacin, the only currently available fluoroquinolone that has been studied for respiratory tract infections in children.[52] The pharmaceutical manufacturer is currently not intending to present data to the FDA to obtain approval for the use of levofloxacin for acute bacterial otitis media or community-acquired pneumonia in children (S. Maldonado, Johnson & Johnson, written communication, May 2011).

Acute Bacterial Otitis Media

Clinical studies of levofloxacin and gatifloxacin have been conducted in children with recurrent or persistent otitis media but not simple acute bacterial otitis media. Although the results of studies of several fluoroquinolones have been reported, only levofloxacin is currently available in the United States. A prospective, open-label, noncomparative study of levofloxacin was performed in 205 children 6 months of age and older, 80% of whom were younger than 2 years. Tympanocentesis was performed at study entry and at least at 3 to 5 days into therapy for children for whom treatment failed or who had persistent effusion. Bacterial eradication of middle-ear pathogens occurred in 88% of children, including 84% infected by pneumococci and 100% infected by *Haemophilus influenzae*. Levofloxacin treatment was well tolerated; vomiting in 4% of the patients was documented as the most common adverse effect.[53] An evaluator-blinded, active-comparator, noninferiority, multicenter study that involved 1305 evaluable children older than 6 months and compared levofloxacin to amoxicillin-clavulanate (1:1) found equivalent clinical cure rates of 75% in each treatment arm. However, because tympanocentesis was not required, microbiological cure rates could not be determined.[19]

Pneumonia

Although initially approved by the FDA for the treatment of pneumonia and acute exacerbation of chronic bronchitis in adults, ciprofloxacin therapy has not been uniformly successful in treatment of pneumococcal pneumonia in adults at dosages initially studied 30 years ago. Failures are most likely a result of the increasing pneumococcal resistance to ciprofloxacin and other fluoroquinolones documented since their first approval.[54] Ciprofloxacin is currently not considered appropriate therapy for community-acquired pneumonia in adults.

Fluoroquinolones with enhanced activity against *S pneumoniae* compared with ciprofloxacin (levofloxacin, moxifloxacin, gemifloxacin) have been used in adults for single-drug treatment of community-acquired pneumonia. These "respiratory tract" fluoroquinolones have demonstrated in vitro activity against the most commonly isolated pathogens: *S pneumoniae*, *Haemophilus influenzae* (nontypeable), and *Moraxella catarrhalis*, as well as *M pneumoniae*, *C pneumoniae*, and *Legionella pneumophila*.[55–57] Although these agents are not the drugs of choice for pneumonia in previously healthy adults, they are recommended for adults with underlying comorbidities and for those who have been exposed to antibiotic agents within the previous 3 months and, therefore, are more likely to be infected with antibiotic-resistant pathogens.[58] Failures in the treatment of pneumococcal pneumonia have been reported with levofloxacin at 500 mg daily as a result of emergence of resistance on therapy or resistance from previous exposures to fluoroquinolones.[59] An increased dose of levofloxacin—750 mg daily, given for 5 days—is currently approved by the FDA for adults with pneumonia. The increase in drug exposure at the higher dose is designed to overcome the most common mechanism for the development of fluoroquinolone resistance.[60]

Of the fluoroquinolones, only levofloxacin has been studied prospectively in children with community-acquired pneumonia; efficacy in a multinational, open-label, noninferiority-design trial compared with standard antimicrobial agents for pneumonia was documented. For children aged 6 months to 5 years, levofloxacin (oral or intravenous) was compared with amoxicillin/

clavulanate (oral) or ceftriaxone (intravenous). For children 5 years of age and older, levofloxacin (oral) was compared with clarithromycin (oral), and levofloxacin (intravenous) was compared with ceftriaxone (intravenous) in combination with either erythromycin (intravenous) or clarithromycin (oral). Clinical cure rates were 94.3% in the levofloxacin-treated group and 94.0% in the comparator group, and there were similar rates of cure in both the younger and older age groups. Microbiological etiologies were investigated, and *Mycoplasma* was the most frequently diagnosed pathogen (by serologic testing), representing 32% of those receiving levofloxacin in both older and younger age groups and approximately 30% of those receiving comparator agents in both age groups. Pneumococci were infrequently documented to be the cause of pneumonia in study patients, representing only 3% to 4% of those who received levofloxacin and 3% to 5% of those receiving comparator. It should be noted that the clinical response rate of 83% in children younger than 5 years diagnosed by serologic testing with *Mycoplasma* infection and treated with amoxicillin/clavulanate was similar to that in children treated with levofloxacin (89%), which indicates a high rate of spontaneous resolution of disease caused by *Mycoplasma* species in preschool-aged children, poor accuracy of diagnosis by serologic testing, or a clinical endpoint evaluation after a treatment course that could not identify possible differences in response that may have been present in the first days of therapy.[18]

Although fluoroquinolones may represent effective therapy, they are not recommended for first-line therapy of respiratory tract infection in children, because other better-studied and safer antimicrobial agents are available to treat the majority of the currently isolated pathogens.

Gastrointestinal Infections

Alghasham and Nahata[61] summarized the results of 12 efficacy trials that used a number of fluoroquinolone agents for infections caused by *Salmonella* and *Shigella* species. However, data from only 2 of the 12 trials that compared fluoroquinolones to nonquinolone agents were reported. Patients were treated for typhoid fever (8 studies, including 7 for multidrug-resistant strains), invasive nontyphoid salmonellosis (1 study), and shigellosis (3 studies). Clinical and microbiological success with fluoroquinolone therapy for these infections was similar for children and adults. A recent report suggested caution in the use of fluoroquinolones in visitors returning from India with typhoid fever, because antimicrobial-resistant *Salmonella typhi* strains, including strains with decreased susceptibility to fluoroquinolones, have been noted.[62]

A prospective, randomized, double-blind comparative trial of acute, invasive diarrhea in febrile children was conducted by Leibovitz et al,[63] who compared ciprofloxacin with intramuscular ceftriaxone in a double-dummy treatment protocol. Two hundred and one children were treated and evaluated for clinical and microbiological cure as well as for safety. Pathogens were isolated in 121 children, most commonly *Shigella* and *Salmonella* species. Clinical and microbiological cure were equivalent between groups. No arthropathy was detected during or up to 3 weeks after completion of therapy.[63]

In the United States, although cases of typhoid fever and invasive salmonellosis are uncommon, there are up to 280 000 cases of shigellosis per year, most of which occur in preschool-aged children with relatively mild disease. Treatment is recommended primarily to prevent spread of infection. Ampicillin and TMP-SMX resistance is increasing, and multidrug-resistant strains are becoming common; the National Antimicrobial Resistance Monitoring System (NARMS) reported that 38% of the strains isolated from 1999–2003 were resistant to both ampicillin and TMP-SMX. A 2005 outbreak of multidrug-resistant *Shigella sonnei* infection involving 3 states was reported in the *Morbidity and Mortality Weekly Report*[64]; 89% of the strains were resistant to both agents, but 100% of the strains were susceptible to ciprofloxacin. Treatment options for multidrug-resistant shigellosis, depending on the antimicrobial susceptibilities of the particular strain, include ciprofloxacin, azithromycin, and parenteral ceftriaxone.

Although ciprofloxacin has been regarded as an effective agent for traveler's diarrhea in the past, resistance rates are increasing for specific pathogens in many parts of the world. Resistance in *Campylobacter* species is particularly problematic in countries such as Taiwan, Thailand, and Sweden, where rates of 57%, 84%, and up to 88%, respectively, have been reported.[65,66]

Urinary Tract Infection

Standard empiric therapy for uncomplicated UTI in the pediatric population continues to be a cephalosporin antibiotic agent, because TMP-SMX- and amoxicillin-resistant *E coli* are increasingly common. The fluoroquinolones remain a potential first-line agent only in the setting of pyelonephritis or complicated UTI when typically recommended agents are not appropriate on the basis of susceptibility data, allergy, or adverse-event history. The previous American Academy of Pediatrics policy statement (2006) supported the use of

ciprofloxacin as oral therapy for UTI and pyelonephritis caused by *P aeruginosa* or other multidrug-resistant Gram-negative bacteria in children aged 1 through 17 years and remains current.[3]

Mycobacterial Infections

The fluoroquinolones are active in vitro against mycobacteria, including *M tuberculosis* and many nontuberculous mycobacteria.[58,67] Increasing multidrug resistance in *M tuberculosis* has lead to the increased use of fluoroquinolones as part of individualized, multiple-drug treatment regimens; levofloxacin and moxifloxacin have demonstrated greater bactericidal activity than has ciprofloxacin.[68] Treatment regimens that include fluoroquinolones for 1 to 2 years for multidrug-resistant and extensively drug-resistant tuberculosis have not been prospectively studied in children. However, the benefit of treatment of tuberculosis with an active compound when other active alternatives are not available is greater than the potential for arthropathy. No joint toxicity has yet been reported in children who have received long-term therapy for tuberculosis, but data on safety have not been collected systematically.

Other Uses

Ciprofloxacin is effective in eradicating nasal carriage of *Neisseria meningitidis* (single dose: 500 mg for adults and 20 mg/kg for children older than 1 month), is preferred in nonpregnant adult women, and can be considered for younger patients as an alternative to rifampin, depending on results of a risk/benefit assessment.

Good penetration into the cerebrospinal fluid by certain fluoroquinolones has been reported, and concentrations often exceed 50% of the corresponding plasma drug concentration. In cases of multidrug-resistant Gram-negative meningitis in which no other agents are suitable, fluoroquinolones may represent the only treatment option.[69]

P aeruginosa can cause skin infections (including folliculitis) after exposure to inadequately chlorinated swimming pools or hot tubs. For children who require systemic therapy, fluoroquinolone agents offer an oral treatment option that may be preferred over parenteral nonfluoroquinolone antimicrobial therapy.

SUMMARY

Use of a fluoroquinolone in a child or adolescent may be justified in special circumstances in which (1) infection is caused by a multidrug-resistant pathogen for which there is no safe and effective alternative and (2) the options for treatment include either parenteral nonfluoroquinolone therapy or oral fluoroquinolone therapy, and oral therapy is preferred. In other clinical situations outlined previously, fluoroquinolones may also represent a preferred option (eg, topical fluoroquinolones in the treatment of tympanostomy tube–associated otorrhea) or an acceptable alternative to standard therapy because of concerns for antimicrobial resistance, toxicity, or characteristics of tissue penetration.

No compelling published evidence to date supports the occurrence of sustained injury to developing bones or joints in children treated with available fluoroquinolone agents; however, FDA analysis of ciprofloxacin safety data, as well as posttreatment and 12-month follow-up safety data for levofloxacin, suggest the possibility of increased musculoskeletal adverse effects in children who receive fluoroquinolones compared with agents of other classes. Many drugs in common pediatric use lack specific FDA approval for children. In the case of fluoroquinolones, as is appropriate with all antimicrobial agents, practitioners should verbally review common, anticipated potential adverse events, and indicate why a fluoroquinolone is the most appropriate antibiotic agent for a child's infection.

Committee on Drugs

Uses of Drugs Not Described in the Package Insert (Off-Label Uses)

ABSTRACT. New regulatory initiatives have been designed to ensure that new drugs and biologicals include adequate pediatric labeling for the claimed indications at the time of, or soon after, approval. However, because such labeling may not immediately be available, off-label use (or use that is not included in the approved label) of therapeutic agents is likely to remain common in the practice of pediatrics. This policy statement was written to address questions practitioners have regarding off-label use. The purpose of off-label use is to benefit the individual patient. Practitioners may use their professional judgment to determine these uses. Practitioners should understand that the Food and Drug Administration does not regulate off-label use.

ABBREVIATIONS. FDA, Food and Drug Administration; IND, investigational new drug; FDAMA, Food and Drug Administration Modernization Act of 1997.

OFF-LABEL USE OF APPROVED DRUGS

Off-label use of an approved drug refers to a use that is not included in the approved label.* Omission of uses for a specific age group or a specific disorder from the approved label means that the evidence required by law to allow their inclusion in the label has not been submitted to the Food and Drug Administration (FDA). This circumstance is often reflected in statements such as "safety and efficacy in pediatric patients have not been established" in the product label. Off-label use does not imply an improper use and certainly does not imply an illegal use or a contraindication based on evidence. Explicit evidence-based warnings and contraindications are provided in product labels. The distinction between lack of FDA approval of a use or dosing regimen and explicit warnings or contraindications against uses is important medically and legally.

The package insert (label) is intended to provide all of the information judged to be necessary for the drug or biological to be used safely and effectively for the approved indication(s). Special groups, however, such as children and pregnant women, have commonly been excluded by disclaimers in the label because substantial evidence of safety and efficacy has not been submitted to the FDA. Three fourths of the prescription drugs currently marketed in the United States lack pediatric use information and are labeled with such disclaimers.[1,2] Most drugs have not been adequately studied in the pediatric population. Recent regulations and legislation have been introduced to improve this situation. A description of these is provided in Appendix 1.

THE FDA AND FEDERAL LAW

The FDA regulates the manufacture, labeling, and promotion of drugs; it does not regulate the use of drugs by physicians (ie, the practice of medicine). The FDA's approval of a new drug is based on data submitted by the manufacturer. The Food, Drug, and Cosmetic Act[3] requires that "substantial evidence," resulting from "adequate and well-controlled investigations" demonstrating that a new drug "will have the effect it purports or is represented to have under the conditions of use prescribed, recommended, or suggested in the proposed labeling," be submitted to and reviewed and approved by the FDA before the drug is marketed in interstate commerce. For biologicals (eg, vaccines) proof of effectiveness consists of "adequate and well-controlled studies" as defined for new drugs in the Code of Federal Regulations.[4] Biologicals are approved under the Public Health Service Act.[5] Given these requirements as well as the rapid pace of medical discovery, it is not surprising that labels do not reflect all possible uses of an agent.

PRACTITIONER RESPONSIBILITY

The practitioner who prescribes a drug is responsible for deciding which drug and dosing regimen the patient will receive and for what purposes. This decision is made on the basis of the information contained in the drug's label or other data available to the prescriber. The off-label use of a drug should be based on sound scientific evidence, expert medical judgment, or published literature. New uses, doses, or indications will not be approved by the FDA until substantial evidence of safety and effectiveness for that indication or age group is submitted to the FDA. This may take years or may never occur, because until recently, there has been little incentive for manufacturers to conduct trials and submit data for new uses in pediatric patients. Practitioners may be concerned that the off-label use of an approved drug may invite a variety of legal actions. To con-

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

*See also Title 21 Section 201.56 (21 CFS 201.56)–General requirements on content and format of labeling for human prescription drugs. The labeling shall contain a summary of the essential scientific information needed for the safe and effective use of the drug. The labeling shall be informative and accurate and neither promotional in tone nor false or misleading in any particular. The labeling shall be based whenever possible on data derived from human experience.

PEDIATRICS (ISSN 0031 4005).

form to accepted professional standards, the off-label use of a drug should be done in good faith, in the best interest of the patient, and without fraudulent intent.

A practitioner may be accountable for the negligent use of any drug in a civil action whether or not the FDA has approved the use of that drug. Labeling is not intended to preclude the practitioner from using his or her best medical judgment in the interest of patients or to impose liability for off-label use. Indeed, the practice of medicine may require a practitioner to use drugs off-label to provide the most appropriate treatment for a patient.

EXPERIMENTATION AND RESEARCH

One frequently asked question is whether an off-label use of an approved drug should be viewed as experimentation requiring formalized institutional review and informed consent. This question reflects a misunderstanding of what constitutes research. The FDA approval process does not determine whether treatment constitutes experimentation and research. According to federal regulations, "Clinical investigation means any experiment in which a drug is administered or dispensed to, or used involving, one or more human subjects. For the purposes of this part, an experiment is any use of a drug except for the use of a marketed drug in the course of medical practice."[6] In most situations, off-label use of medications is neither experimentation nor research. Any medical intervention is based on consent, albeit implied in many instances. Whether institutional review, consultation, or written consent is required for a given intervention depends on the degree of risk or deviation from standard practices and the extent to which research, rather than individual patient care, is involved. The administration of an approved drug in a way that is not approved by the FDA is not research and does not call for special consent or review if it is given in the individual patient's best interest. However, discussion about the off-label status of a drug may, as a matter of professional judgment, be part of the information provided to the patient or parents. Similarly, the degree of acceptance among physicians of an off-label drug treatment may be an important issue to discuss with a patient or family.

There seems to be confusion also about whether an off-label use requires submission of an investigational new drug (IND) application to the FDA. Use of approved drugs in an off-label manner to treat an individual patient does not require an IND application. The IND regulations "do not apply to the use in the practice of medicine for an unlabeled indication."[7] In fact, the IND process regulates interstate shipment of the drug for investigation of an unapproved use in humans. For further description of the IND process, see Appendix 2.

DEVELOPMENT OF DRUG INFORMATION

Physicians who choose to prescribe a medication with limited pediatric data have a public and a professional responsibility to assist in the systematic development of the information about that drug for the benefit of other patients. Practitioners are encouraged to publish experiences that result from such off-label uses of drugs. It is also important that information about adverse events be reported to the drug manufacturer or directly to the FDA. Physicians or other practitioners should report serious adverse events via the FDA's MedWatch program by mail, phone, or Internet (http://www.fda.gov/medwatch). The law requires manufacturers to report all adverse experience reports they receive or are aware of (eg, published literature) to the FDA. Promising new uses for approved drugs might best be reported to the drug sponsor to encourage formal investigation. The full and ultimate role of a drug is rarely evident at the time of its initial approval and labeling. Many of the most important uses and toxicities emerge from postmarketing clinical experience. Although these uses are often discovered through off-label therapeutic use, confirmation of efficacy and safety in formal studies is usually required. In clinical practice, new uses or dosing regimens often become widespread and well accepted long before they are reflected in the labeling.

Expanded indications and new dosing regimens may eventually be supported by objective data that may be incorporated into the approved labeling. For example, postapproval changes in labeling include imipramine hydrochloride for the treatment of enuresis, lidocaine hydrochloride for the treatment of arrhythmias in children, furosemide for use in children, and naloxone hydrochloride for use in infants. Postmarketing safety experience may ultimately lead to restriction of labeled or off-label uses of the drug or eventual withdrawal from the market. Information about the dosage, metabolism, elimination, and adverse effects of drugs in pediatric patients is often not available when the drugs are approved initially. The decision to prescribe an approved drug for an off-label use should be based on all available data.

APPENDICES

Appendix 1. Recent Regulations and Legislation to Increase the Study of Drugs in Pediatric Patients

A regulation published in 1994 (the "1994 Pediatric Final Rule"[8]) that recognizes several methods of establishing substantial evidence to support pediatric labeling remains in effect. These methods include relying in certain cases on efficacy studies performed in adults and other supporting information to adequately label the product for safe and effective use in the pediatric population. The FDA has issued a new regulation (the "1998 Pediatric Final Rule"[9]), which became effective April 1, 1999, that requires pediatric studies of certain new and marketed drugs and biologicals. This rule establishes a presumption that new drugs and biologicals will be studied in pediatric patients unless the requirement is waived. The 1998 Pediatric Final Rule is designed to ensure that new drugs and biologicals contain adequate pediatric labeling for the claimed indications at the time of, or soon after, approval. Under this rule, the FDA can require studies to assess the safe and effective use of the drug or biological in the pediatric population for the claimed indications. This rule also authorizes the FDA to require pediatric studies of marketed drugs and biologicals when there is a compelling need for studies (ie, the product is used in a substantial number of pediatric patients or the product provides a meaningful therapeutic benefit over existing treatments for pediatric patients and, in either case, the absence of adequate labeling could pose significant risks for pediatric patients).

In 1997, a law was enacted (the Food and Drug Administration

Modernization Act of 1997 [FDAMA][10]) that contains provisions establishing economic incentives to drug manufacturers for conducting pediatric studies of drugs for which exclusivity or patent protection is still available.[9] A manufacturer that conducts pediatric studies required by the 1998 Pediatric Final Rule may qualify for economic incentives provided by FDAMA.

All these changes respond to concerns that drugs and biologicals have not been adequately studied in the pediatric population or if studied, the information required to meet the statutory requirement for the product to be declared safe and effective in this population has not been submitted to the FDA. Whereas current prescription product labels do not include adequate pediatric use information, these regulatory measures have been instituted to improve our knowledge base to provide better prescribing information for practitioners who care for pediatric patients.

Appendix 2. The IND Process

An IND application requires submission of a study protocol, labeling of the drug as investigational, submission of drug and investigator information, and an agreement to obtain the consent of subjects (and/or parents), to submit reports of adverse events, and to account for any unused drug after the study. After receipt of an IND application, the FDA reviews the application to determine whether proceeding with the study is safe. Investigational trials involving marketed drugs do not require IND applications if all of the following apply: 1) the investigation is not intended to be reported to the FDA as a well-controlled study to support a new indication or to support any other significant change in the labeling; 2) the investigation is not intended to support a significant change in the product's advertising; 3) the investigation does not involve a route of administration, dosing level, or use in a patient population or other factor that significantly increases the risks (or decreases the acceptability of the risks) associated with the use of the drug; 4) the investigation is conducted in compliance with the requirements for institutional review and informed consent; and 5) the investigation is conducted in compliance with the requirements concerning promotion and charging for investigational drugs.[7]

abstract

A personal health record (PHR) is a repository of information from multiple contributors (eg, patient, family, guardians, physicians, and other health care professionals) regarding the health of an individual. The development of electronic PHRs presents new opportunities and challenges to the practice of pediatrics. This policy statement provides recommendations for actions that pediatricians can take to support the development and use of PHRs for children.

Pediatric health care professionals must become actively involved in developing and adopting PHRs and PHR systems. The American Academy of Pediatrics supports development of:

- educational programs for families and clinicians on effective and efficient use of PHRs;
- incentives to facilitate PHR use and maintenance; and
- child- and adolescent-friendly standards for PHR content, portability, security, and privacy.

Properly designed PHR systems for pediatric care can empower patients. PHRs can improve access to health information, improve coordination of preventive health and health maintenance activities, and support emergency and disaster management activities. PHRs provide support for the medical home for all children, including those with special health care needs and those in foster care. PHRs can also provide information to serve as the basis for pediatric quality improvement efforts.

For PHRs to be adopted sufficiently to realize these benefits, we must determine how best to support their development and adoption. Privacy and security issues, especially with regard to children and adolescents, must be addressed. *Pediatrics* 2009;124:403–409

BACKGROUND

A personal health record (PHR) is a repository of information from multiple sources (eg; patient, family, guardians, physicians, and other health care professionals) about the health and health care of an individual that is controlled by the individual or designated people. Documentation of personal health information for children has traditionally been managed in a variety of formal and informal formats, primarily by their parents. Some parents may use tools such as the compact, form-based booklet "Child Health Record From Infancy to Adulthood"[1] from the American Academy of Pediatrics (AAP). This book facilitates standardized and concise tracking of a child's personal health information, including birth and demographic data, physician contacts, medical and family history, and well-child care information. Use of such tools is variable; some parents record nothing, and others maintain extensive and detailed records. For children with special health care needs, similar tools and forms have been developed to summarize clinically relevant information. Two examples are the emergency information form,[2] developed by the AAP and the American College of Emergency Physicians, and care notebooks and medical care plans/assessment forms[3] from the National Center for Medical Home Incentives for Children With Special Needs, which also use electronic forms that have the potential to become interoperable through standard interfaces.

Problems caused by the lack of availability of paper medical records and the lack of data transferability have been well described.[4] Moving these records into an electronic format that is used universally has been proposed as a way to solve some of these problems. As a result, the focus on electronic PHRs has steadily increased over the past several years, with more than 200 systems available in 2006.[5]

On the federal level, the American Health Information Community, which advises the Secretary of Health and Human Services, selected a "consumer empowerment use case" including a registration summary and medication history as a first step for the Health Information Standards Panel and the Certification Commission for Healthcare Information Technology to standardize the exchange of basic patient data.[6] Many electronic health record (EHR) vendors now offer PHRs as extensions of their products. Health plans, employers, and hospitals are also offering PHRs to their subscribers, employees, and patients, either as stand-alone systems or as part of the institution's information systems. Cooperation among organizations is beginning, with America's Health Insurance Plans (AHIP) designing PHRs for their members with "portability" (ie, the ability to transfer and share information between different insurers). Some companies are offering PHR systems to their employees, and an effort to create a common PHR for multiple employers has been launched. Major vendors in the software industry, seeing the opportunities to expand into health care, are establishing various forms of Internet-based PHRs. Electronic PHRs that are populated by a wide variety of organizations, together with health information exchange solutions, may serve as the backbone of efforts to support improved quality of care and a nationwide health information network.

The technical infrastructure of electronic PHR systems may have many forms. In addition to Web-based systems, information in electronic PHRs may be stored on portable computer drives (such as USB "flash drives"), "smart cards," or other electronic storage devices. Functionally, PHRs are diverse. Some contain tools for managing care, such as delivering electronic test results, providing support for remote monitoring (eg, weight, blood pressure, blood glucose), and providing secure communication services between patient/family and health care professional or access to health-related content. Some PHRs have the ability to transfer information using standardized data formats[7] or to transfer data to a patient-controlled health data record or repository.

Ideally, an electronic PHR prevents duplication and delays in services. It may be part of a comprehensive strategy to empower patients to understand the care they are receiving while fostering a closer collaboration with their health care team. For pediatricians, PHRs can provide pediatricians information on events occurring at home and in school between encounters to supplement secure messaging features that may facilitate doctor-patient communication. PHRs integrated with medical devices may allow for direct, automated reporting of important information for real-time clinical management and for evaluation of clinical outcomes, especially for patients with chronic medical conditions. In addition, improved documentation and reporting of electronic clinical interactions and patient-physician communications can be beneficial for reimbursement. PHRs are increasingly being designed to integrate patient data, communication, and management interventions. They have the potential to provide improvements in quality (ie, safety, timeliness, effectiveness, efficiency, equity, and patient-centeredness, as defined by the Institute of Medicine).[8]

Assurance of consumer control of privacy is essential to the acceptance and adoption of PHRs. With appropriate access controls, patients and families can allow portions of the PHR to be

made available to family members, school nurses, and others, with emergency access ("break-the-glass") functionality for use during medical crises or in disaster situations.

Few, if any, PHRs offer the privacy controls that are necessary for adolescent medical care. Adolescents are typically excluded from PHR use because of the wide variation of state laws regarding access to adolescent medical information and to limitations in the ability of adolescents to enter into contracts independently. In general, adolescents should have access to their records as well as control over who else may access these records. The approach to adolescents could start with parental access for records of young adolescents while parents remain in control. Older adolescents who are authorized to seek care alone may start a separate private PHR for those episodes of care, subject to local mandatory disclosures to their parents. At the appropriate time (to be determined by convention and law), a copy of the parent-maintained PHR should be transferred to adolescent control (although special consideration to issues, such as genetic susceptibility known only to parents, might be withheld until the adolescent reaches the age of majority). Because of laws limiting the authority of adolescents to enter into contracts independently in many states, it is likely that such a separate PHR would need to be a part of the original contract agreed to by their parents.

STATEMENT OF THE PROBLEM

Electronic PHRs have the potential for great impact on the medical care of children, especially children with special health care needs. To realize the potential of PHRs in pediatrics, 2 needs must be addressed: (1) standards for content, information assurance, and data exchange that meet the health needs of children, including adolescents; and (2) incentives for adoption and use by pediatric providers and families. There are still many unanswered questions regarding PHRs, including who will bear the costs of their development and adoption, but key issues for children and adolescents must be clarified, because they are not being addressed in the current development of PHRs.

The Need for Standards

Pediatricians have a critical role in defining content standards for PHR use in child health care. Lack of adequate pediatric-specific content standards for PHRs may result in incomplete products (eg, a PHR that lacks immunization functionality). Content requirements for pediatric EHRs[9] and for emergent care for children with special health care needs[3] have been articulated and may be used as a basis for developing pediatric PHR standards.

In addition to developing minimum content standards, pediatricians should support the creation of data-exchange standards that are detailed enough so that the data can be:

- transmitted and received correctly (ie, technical interoperability [eg, using the ASTM/Health Level 7 Continuity of Care Record/Document format]);
- interpreted correctly after transmission (ie, semantic interoperability [eg, vocabulary standards to allow determination whether "fundus" refers to a part of the eye or of the uterus]); and
- shown and used in the correct context (ie, process interoperability [eg, data are presented via consistent, useful, and efficient user interfaces that fit workflow]).

It is highly desirable for pediatricians to be involved in standardization efforts at all of these levels. If successful, PHRs will have reliable and transportable data that are presented in a consistent interface, resulting in decreased time and errors in use, higher adoption rates, and increased medical quality.

Pediatricians must also play a central role in defining PHR information-assurance standards for PHR use in child health care. Such standards include requirements for PHR confidentiality and access controls, for data and source integrity including audit trails, and for physical and functional availability of PHR content. An example of information assurance relevant to pediatrics is the definition of standards to protect the privacy of adolescents and children in foster care.[10] Other information-assurance standards ensure the integrity of the data and source information (ie, who entered it, including nonrepudiation [the prevention of a user's denial that he or she has entered information]) as they are moved between/among health care professionals, health systems, and electronic health information environments.

The Need for Incentives

Despite the promise of improved care through the adoption and use of electronic PHRs, acceptance by patients, parents, and physicians has been slow. In addition to the lack of pediatric standards for PHRs, the business case for a PHR is currently weak,[11] especially if it is not linked to an EHR (for which pediatric adoption is also low[12]), making financial incentives important. Many PHRs do not currently fit physician workflow, often adding steps to an already onerous information-recording and -transfer process. Other issues that must be addressed include language barriers to PHR use for non–English-speaking families, literacy barriers in patients' understanding of

their health information to make decisions, technology-access (ie, "digital-divide") barriers, and the lack of coordination between Medicaid, State Children's Health Insurance Programs (SCHIPs), private insurers, and employers with respect to PHRs.

A stronger business case from employers and third-party payers is necessary to create financial support for PHRs to help manage employee health and to control costs. Insurers, hospitals, and employers are organizing to support various types of PHRs. Government support is being considered, with legislation introduced on a federal level. To make PHRs a routine part of patient care and quality improvement, incentives to accelerate adoption, such as adjusted reimbursement for the time and work of manual duplicate data entry by pediatricians and their office staff, should be used. A reasonable workaround may be for pediatricians to provide these data to patients for them to enter into their own PHRs or, ideally, to provide automatic electronic updates from an EHR by using standard EHR-PHR interfaces. The financial issues associated with potential duplication of data entry and time spent in review of information in individual patients' PHRs need to be addressed if pediatricians and other health care professionals are expected to fully participate.

SUMMARY/CONCLUSIONS

Electronic PHRs are a platform on which pediatricians can improve the quality of pediatric health care and increase patient/family empowerment—both of which facilitate care that is safer, timelier, and more effective, efficient, equitable, and patient centered. The AAP recognizes the potential of PHRs and supports their adoption and use in pediatric care, especially for children with special health care needs. The AAP also supports efforts to create pediatric-specific standards for PHRs and incentives for their adoption and use in pediatrics.

BASIC PRINCIPLES FOR IDEAL PEDIATRIC PHRs

1. Access—All children should have a single PHR, either paper or electronic, as an essential component of a medical home to document and coordinate care and to improve communication between their families and health care providers. Children should have equal access to a PHR regardless of income or method of health care financing.
2. Information Availability—Personal health information from a PHR should be available at all times, especially in emergent situations or disasters. To support availability, PHR information must be redundant (ie, copies on paper, portable electronic media, secure sites on the Internet, or through centralized electronic data repositories).
3. Data Exchange—PHR data should be interoperable as needed at the request of the patient or patient's medical guardian (ie, it should be easily transferable to and from other PHRs, EHRs, and health information systems, including hospital systems and registries such as those for immunizations, hearing screening, and newborn metabolic testing). PHRs should also include provisions for efficient data entry by health care professionals who do not use an EHR.
4. Content—The following should be contained in PHRs for children:
   - demographic data;
   - insurance information;
   - information on family members and other support providers;
   - summary and linkage to advance directives, power of attorney, and other key documents, such as an individualized education plan (IEP);
   - information on health care professionals and encounter lists, including dental and oral health professionals;
   - problem list, including active conditions and illnesses, chronic health problems (such as mental health issues), emergency care procedures (equipment if needed) and contacts, hospitalizations, surgeries/procedures (and current technology support needs [ventilator, monitor, surgical site care, etc]), and privacy issues of individual problems;
   - allergy, adverse-reaction, and other alert data;
   - list of medications and immunizations and date of last reconciliation;
   - anthropometric data including weight, stature, BMI, and head circumference and developmental milestones;
   - results of laboratory, imaging, and other studies including screening results;
   - family health history;
   - birth history; and
   - information on durable medical equipment and supplies.

Pediatric PHR content standards must be aligned with the special requirements for EHRs for children[9] with regard to presentation of data. All payers who provide PHRs should include the content and functionality described in this policy and in pediatric PHR standards as they are developed.

Given the cumulative nature of information contained in a PHR, a key challenge will be to provide the appropriate types and amounts of useful data to specific profession-

als for specific purposes (health maintenance and "sick" visits by primary care professionals versus follow-up care by specialists or emergency care by emergency medical services providers and emergency physicians). Pediatricians and PHR/EHR vendors should work to develop appropriate standard elements for each type of care and health care professional.

5. Privacy—The personal health information of children must be protected from abuse and unauthorized secondary or commercial uses. Key principles for PHR privacy include:
   - Control. PHR data are owned and controlled by the patient or the patient's parent/guardian, who authorizes access to the PHR. PHR access should include an override function for use by health care professionals in emergent situations (eg, individuals brought unconscious to an emergency department).
   - Protections. PHR data (ie, personal health information) require protections (including federal and local jurisdictional laws for oversight, accountability, disclosure, recovery, and penalties), even if the organization hosting the PHR is not a covered entity under the Health Insurance Portability and Accountability Act (HIPAA).[13]
   - Adolescent rights. Adolescents should have the right to exclude parents from their PHRs when law dictates that they may be treated without parental consent. When these features are used, health care professionals need to know that these exclusions are in place.
   - Facilitated portability in emergent care. Children in foster care have special legal requirements for portability of personal health information that vary by state and jurisdiction (discussion and agreement among pediatric health care professionals, foster care authorities, lawmakers, and vendors is needed to develop standards for the availability of PHR information of children in emergent care).
   - Special protections for specific personal data.
   - Specific health information, such as information about sexually transmitted diseases/HIV status, mental health diagnoses and treatment, genetic susceptibility, artificial procreation arrangements, and social conditions such as a family history of parental incarceration, may require special protections that must be enforced by PHR mechanisms.
6. Data Entry and Integrity—All data, regardless of source, must be auditable as to source, date, and time of the change. PHRs should allow for data entry by patients or parents/guardians that is auditable as to source (including nonrepudiation) and date/time of record modifications. Data from health care professionals and institutions should be subject to review and comment by the patient but should not be modifiable. Health care professionals should not be required to reconcile disagreements between the patient and previous caregivers that are recorded in the PHR (eg, if a patient disagrees with an entry made by a previous physician) except as clinically necessary to provide needed care.
7. Extensible Functionality—Pediatric PHRs may contain functions that add value, including tools that help track and document immunization status, growth (including tools to address obesity), and development. Examples of other functions that PHRs could perform include generating standard reports, such as school and camp forms, using data stored in the PHR. The addition of such functions should be structured in a modular fashion that allows their inclusion without disruption of the structure and/or function of existing PHRs.
8. Continuity—When available, PHRs should be used during all clinical encounters. The health care professional should help the patient update the PHR, including the problem/procedure lists, key measurements, immunizations, and medications that were changed during the encounter. Electronic data should be shared using standard interfaces and printouts produced as needed for patients who do not yet use a PHR.
9. Support for PHR Adoption—Programs should be established to provide incentive payments to health care professionals who use and support patient/family use of electronic PHRs as part of a medical home, including an adjusted reimbursement system that acknowledges the value and services of the medical home.[14] Programs with national demonstrations and educational materials should also be established to meet the need for patient and provider education regarding the benefits and proper use of PHRs.

THE VISION OF PEDIATRIC PHR IMPLEMENTATION

The PHR is a lifelong and comprehensive record for a patient and should be used beginning at birth. Newborn infants should be discharged from hospitals and birthing centers with a PHR containing perinatal information, birth history, and relevant medical informa-

tion, including assessments for jaundice. Such PHRs should be available in secure formats that conform to electronic health standards (such as the ASTM/Health Level 7 Continuity of Care Record/Document) for easy export to a medical home EHR from the hospital or at the first office visit. The PHR should interoperate with immunization and newborn metabolic and hearing screening registries and with other stakeholders in regional health information organizations. The PHR should facilitate coordination of care with other agencies (eg, it should help to automate the periodic health assessments collected by school systems and serve as an accurate collection of information about children in foster care). The childhood portion of the PHR should provide a comprehensive view of all aspects of a child's health status over time, including reporting of growth and development, health maintenance, and relevant issues managed in all clinical care settings. It should facilitate the transition from pediatric to adult health care professionals.

To achieve this vision, pediatric advocacy is necessary in the form of partnerships among professional medical societies (such as the AAP), health care professional organizations, health care information technology vendors, and standards-development organizations to help establish the necessary standards and incentives for widespread PHR use. A strong pediatric presence is also necessary in the legislative arena to ensure the clear and vocal representation of the needs of children and pediatricians in policy development that drive standards and adoption of health information technologies, such as PHRs. Pediatric leadership is needed to lead and to teach patients, families, and health care professionals to use PHRs effectively to promote the good care and good health of children and families.

Finally, to sustain the vision, PHRs must be rigorously evaluated so that their use can be optimized and their value can be documented. Potential metrics include:

- Manual data-entry elimination: Percentage of new patients who do not have to fill out a paper form or questionnaire in the physician's waiting room, because they have a PHR that can be imported electronically into an EHR or practice-management system.
- Availability of basic history data from other professionals: Percentage of well-child visits that begin with a complete immunization summary, growth chart, problem list, and medication list reconciled from a PHR that contains data from other health care professionals.
- Providing families with up-to-date health information: Percentage of well-child visits that end with the parents receiving an updated PHR with immunization, growth, problem, and medication summaries.
- External PHR updates: Percentage of emergency department, inpatient, or referral visits that update a PHR with the date, location, health care professional, problem, medications, test results, or outcomes.
- External PHR use: Percentage of emergency department, inpatient, or referral visits that access a PHR to review patient data at the time of the encounter.
- Hospital-office newborn continuity: Percentage of newborn first office visits that include a PHR with the birth history, birth and discharge weight, hearing test results, hepatitis B immunization data, bilirubin and blood type (if determined), any newborn problems, and newborn screening results as they become available.
- Completeness of medical providers list: Percentage of preterm infants or children with special health care needs (including foster care children) who have a list of all health care professionals in a PHR, including contact information, date of last visit, and date of next appointment (as applicable).
- EHR adoption rates: Percentage of practices with an EHR that offer a patient Web portal to their patients.

POLICY STATEMENT

Ventricular Fibrillation and the Use of Automated External Defibrillators on Children

Organizational Principles to Guide and Define the Child Health Care System and/or Improve the Health of All Children

Committee on Pediatric Emergency Medicine and Section on Cardiology and Cardiac Surgery

ABSTRACT

The use of automated external defibrillators (AEDs) has been advocated in recent years as one part of the chain of survival to improve outcomes for adult cardiac arrest victims. When AEDs first entered the market, they had not been tested for pediatric usage and rhythm interpretation. In addition, the presumption was that children do not experience ventricular fibrillation, so they would not benefit from the use of AEDs. Recent literature has shown that children do experience ventricular fibrillation, which has a better outcome than do other cardiac arrest rhythms. At the same time, the arrhythmia software on AEDs has become more extensive and validated for children, and attenuation devices have become available to downregulate the energy delivered by AEDs to allow their use on children. Pediatricians are now being asked whether AED programs should be implemented, and where they are being implemented, pediatricians are being asked to provide guidance on the use of them on children. As AED programs expand, pediatricians must advocate on behalf of children so that their needs are accounted for. For pediatricians to be able to provide guidance and ensure that children are included in AED programs, it is important for pediatricians to know how AEDs work, be up-to-date on the literature regarding pediatric fibrillation and energy delivery, and understand the role of AEDs as life-saving interventions for children.

INTRODUCTION

Early defibrillation has been shown to be the most effective treatment for adult out-of-hospital cardiac arrest attributable to ventricular fibrillation (VF).[1,2] The likelihood of survival decreases by approximately 7% to 10% with each minute of delay to defibrillation after cardiac arrest. Strategies to decrease the time to defibrillation that have been shown to be effective include the use of an automated external defibrillator (AED) by prehospital care providers and nonmedical personnel.[3–6]

For children, use of defibrillation traditionally has been downplayed, with a focus on early airway and ventilatory assistance as a result of data that showed that asystole was the predominant rhythm and that VF rarely occurred.[7] Although not the most common rhythm, VF does occur in children. In addition, the chance of survival after VF is greater than that from other nonperfusing rhythms, which makes treatment of VF a priority in pediatric resuscitation.[8]

Although the incidence of VF in the pediatric population is low, there is a need for developing strategies to provide early defibrillation to patients younger than 8 years. This strategy may include the need for an AED that is suitable for use in pediatric

patients from birth to 8 years of age with either an attenuated adult-dosage AED tested for efficacy and safety in children or an AED specifically designed for defibrillation of young children and infants. In the absence of either of such devices, standard nonattenuated adult-dosage AEDs should be used on children on the basis of protocols for use developed with medical oversight. Because of the limited data on effective energy dose, emergency medical services (EMS) systems, medical directors, and pediatric researchers should make efforts to gather information regarding pediatric uses of AEDs and report it by using the pediatric Utstein style,[9] which represents an internationally accepted standard method of collecting and reporting respiratory and cardiac arrest and resuscitation data. In addition, because the use of AEDs on children may be a new concept to many responders, EMS and physician leaders should work with professional organizations, community organizations, and researchers to educate their community members regarding the benefits of early pediatric defibrillation and the use of available varieties of AEDs.

The message for the public and for EMS systems is to recognize the existence of VF in infants and children and use methods to treat it as early as possible to improve the survival of children and infants after sudden cardiac arrest. In addition, this possible life-saving therapy should not be withheld purely on the basis of absolute weight and size issues. The key is to pursue a long-term goal of providing devices that will support rapid pediatric and adult defibrillation. This approach would include the ability to treat infants and children without compromising adult care while minimizing training issues and minimizing the use of limited financial and personnel resources.

RECOMMENDATIONS

1. Although the incidence of VF in children is far less than that in adults, the outcome for VF is better than that for other nonperfusing rhythms and is improved with early defibrillation. Therefore, strategies and equipment availability for treatment of pediatric arrest should be focused on shortening the intervals from collapse to recognition of VF and to defibrillation.
2. Although most data available on the correct energy for defibrillation of children are from animal studies, data suggest that the immature heart is less susceptible to energy-related damage and that there is a wide therapeutic range of defibrillation energy doses. In addition, although using a fixed adult-energy AED on some children has a theoretical potential for harm, not treating VF has the proven potential for even greater harm: death of the child. On the basis of this risk/benefit assessment, prehospital programs and public-access AED programs should not withhold defibrillation because of weight or age criteria alone.
3. Children and infants of all ages who suffer VF must be provided defibrillation as soon as possible after arrest. The following approach to achieve this goal should be used:
   a. Immediately provide defibrillation to all infants and children from birth to 8 years of age with either an attenuated adult-dosage AED tested for efficacy and safety in children or an AED specifically designed for defibrillation of young children and infants, depending on which device is available first. In the absence of the devices listed above, standard nonattenuated adult-dosage AEDs should be used on infants and children from birth to 8 years of age. Protocols for use of adult-dosage AEDs should be developed with medical oversight.
   b. For children 8 years of age and older, immediately provide defibrillation with an adult-dosage AED or manual defibrillation.
4. EMS systems must have protocols to allow for pediatric defibrillation in the timeliest fashion and by all levels of responders. These protocols include pediatric AED capability and, in the interim, protocols for the use of an adult AED on infants and children.
5. Although a cost/benefit assessment of public-access defibrillation specifically for children has not been established, when a community or facility chooses to establish a public-access defibrillation program, the AED chosen for that program must have pediatric capability.
6. Although a cost/benefit assessment of school-based AEDs has not been established yet, school systems must, in their assessment of need for an AED, consider the benefit of AED purchase to adult staff members and adult visitors and as another component of school-based emergency care.
7. When determining the need for a school-based AED program, the following factors should direct the decision[10]:
   a. The frequency of cardiac arrest events is such that there is a reasonable probability of AED use within 5 years of rescuer training and AED placement. This probability can be established if 1 cardiac arrest has been known to have occurred at the site within the last 5 years or can be estimated on the basis of population demographics.
   b. There are children attending the school or adults working at the school who are thought to be at high risk of sudden cardiac arrest (eg, children with conditions such as congenital heart disease and a history of abnormal heart rhythms, children with long QT syndrome, children with cardiomyopathy, adults or children who have had a heart transplant, and adults with a history of heart disease).

c. An EMS call-to-shock interval of less than 5 minutes cannot be achieved reliably with conventional EMS services, and a collapse-to-shock interval of less than 5 minutes can be achieved reliably (in >90% of cases) by training and equipping lay people to function as first responders by recognizing cardiac arrest, telephoning 911 (or other appropriate emergency response number), starting cardiopulmonary resuscitation, and attaching and operating an AED.

8. When placed in schools, AEDs must be part of a comprehensive emergency care plan that includes:
   a. pediatric medical oversight;
   b. staff training in basic first aid and cardiopulmonary resuscitation; and
   c. integration with local EMS.
9. Any legislation that mandates placement of an AED also must provide the funding for such devices, including costs of staff training and maintenance of the equipment.
10. AED legislation must allow for pediatric AED usage and liability protection for those who use these devices and for the physicians who provide the medical oversight for these programs.

CLINICAL REPORT

When Is Lack of Supervision Neglect?

Guidance for the Clinician in Rendering Pediatric Care

Kent P. Hymel, MD, and the Committee on Child Abuse and Neglect

ABSTRACT

Occasionally, pediatricians become aware of children who are inadequately supervised. More frequently, pediatricians treat children for traumatic injuries or ingestions that they suspect could have been prevented with better supervision. This clinical report contains guidance for pediatricians considering a referral to a child protective services agency on the basis of suspicion of supervisory neglect.

BACKGROUND

Laws in all 50 states mandate that pediatricians report any suspicion of child abuse or neglect to the appropriate child protective services agency. Barriers to physician reporting include lack of knowledge and training, previous negative experiences with a child protective services agency, fear of damaging the relationship with the child's family, and fear of courtroom testimony.[1] There are no guidelines specifically designed to help pediatricians decide when to report suspected supervisory neglect.

In our society, parents, guardians, baby-sitters, and other designated caregivers* are expected to protect children from harmful people or situations. Nevertheless, epidemiologic studies confirm that many young children are injured in their own homes,[2,3] and inadequate supervision is cited frequently as a contributing cause.[4] The extent to which adequate supervision protects children from injury or inadequate supervision increases injury risk remains largely undefined.[5–11] Furthermore, there are no established standards that define adequate (or inadequate) parental supervision across a wide variety of cultures and specific circumstances.[12,13]

Under what circumstances should a pediatrician report a suspicion of supervisory neglect? Are parents neglectful only when an inadequately supervised child suffers harm? Or, can a parent be considered neglectful before actual harm occurs? There are no easy answers to these questions. Many pediatric injuries occur while a child is being supervised, and many poorly supervised children do not get injured. Injury risks in young children are related to their developmental capabilities.[14] Certainly, the attention, proximity, and/or continuity of adult supervision necessary to protect an active toddler is vastly different from that required to safely monitor a responsible 10-year-old.[5]

The American Academy of Pediatrics believes that supervisory neglect occurs whenever a caregiver's supervisory decisions or behaviors place a child in his or her care at significant ongoing risk for physical, emotional, or psychological harm.[1]

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

* For the purposes of this report, a caregiver is defined as a parent, guardian, or other designated individual who is responsible for the supervision of the children under his or her care.

ADVICE FOR PEDIATRICIANS

1. In some jurisdictions, child protective services agencies promote or enforce age-specific guidelines for the supervision of children. Become aware of these guidelines (if any) in the local community and consider educating parents about them. Jurisdictional laws or guidelines may not reflect best practices for prevention of injuries.
2. Consider every allegation or suspicion of supervisory neglect individually.
3. If the information is available, carefully consider:
   a. whether the child has previously demonstrated an ongoing ability to execute appropriate judgments regarding his or her own behaviors;
   b. whether the child has any physical, developmental, genetic, behavioral, emotional, cognitive, or psychiatric disabilities;
   c. the length of time and the time of day that the child was inadequately supervised;
   d. the caregiver's reasoning and understanding of the situation;
   e. the inherent danger(s) of the child's unsupervised environment (eg, a young child left home alone, unattended in a car or bathtub, or with unrestricted access to a swimming pool);
   f. the child's level of discomfort regarding his or her unsupervised situation;
   g. the specific nature of the child's activities while he or she was left unsupervised (eg, age-appropriate play activities versus accessing pornography on the Internet, vandalism, or shoplifting);
   h. the child's knowledge of emergency telephone numbers† and procedures;
   i. the child's knowledge and use of protocols for safely answering the telephone and/or door when he or she has been left unsupervised;
   j. the child's accessibility to his or her parent or to another, specific, informed individual designated to be his or her caregiver;
   k. past allegation(s) of supervisory neglect or abuse involving the child and/or the child's caregiver;
   l. the physical, emotional, and mental capabilities of the designated caregiver (eg, a young baby-sitter or an elderly grandmother asked to care for too many children simultaneously);
   m. the number, ages, and maturity of the other children under the caregiver's supervision; and
   n. the age-appropriateness of the responsibilities given to the child.
4. Remember that some child injury risks are unpredictable or unavoidable; caregivers may underestimate the supervisory requirements for some children, and even the most careful caregiver may experience a brief lapse of supervisory attention, proximity, and/or continuity that leads to childhood injury. In these circumstances, counseling regarding child supervision may be an appropriate initial intervention.
5. Be mindful of the emotional burden a caregiver endures when a child in his or her care suffers a preventable injury.
6. When a reasonable suspicion exists that a pattern of caregiver decisions or behaviors have placed a child at significant ongoing risk for physical, emotional, or psychological harm, report the incident to the appropriate child protective services agency.

† Emergency telephone numbers include the telephone numbers for the police, fire department, emergency medical services, and the parent (or another designated, responsible individual) to be called in the event of an emergency.

AMERICAN ACADEMY OF PEDIATRICS

Provisional Section on Breastfeeding

WIC Program

ABSTRACT. This policy statement highlights the important collaboration between pediatricians and local Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) programs to ensure that infants and children receive high-quality, cost-effective health care and nutrition services. Specific recommendations are provided for pediatricians and WIC personnel to help children and their families receive optimum services through a medical home.

ABBREVIATIONS. WIC, Special Supplemental Nutrition Program for Women, Infants, and Children; AAP, American Academy of Pediatrics; SCHIP, State Children's Heath Insurance Program.

Since its inception in 1972, the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) has been an important source of nutrition education, supplemental food, and health care referrals for low-income women during and after pregnancy and for infants and children up to age 5 in the United States. Breastfeeding promotion and support are important components of the WIC program.

There has been a steady increase in the number of individuals served, with approximately 47% of infants born in 1998 receiving benefits through the program. Despite this increase, 11% of eligible women, infants, and children still did not participate.[1,2]

Prospective participants in the WIC program must undergo a variety of nutritional screenings to determine eligibility. These include assessments of height, weight, diet, health history, and other indices. Because the WIC program serves a significant number of children younger than 5 years, it is often called on to assess immunization status and screen for child health problems.

The WIC program is an important partner in promoting the health and nutrition of children and their families. Ensuring a medical home[3,4] for all children and using the WIC program as a means to identify children at risk of not receiving comprehensive, coordinated health services should be a priority. A medical home is an approach to providing health care services in a high-quality and cost-effective manner that is accessible, family centered, coordinated, compassionate, culturally competent, and consistent. The medical home should provide continuous comprehensive care, including immunizations, assessment of growth and development, and treatment of acute and chronic illnesses.[3,4] A strong collaboration between pediatricians and the WIC program is a key step in identifying and accessing all of the medical and nonmedical services needed to help children and their families achieve their maximum potential.

The American Academy of Pediatrics (AAP) supports the following recommendations for pediatricians:

1. Pediatricians should disseminate information to all of their potentially eligible patients' families about the nutritional and educational benefits of the WIC program; collaborate with local WIC programs to enhance the treatment, anticipatory guidance, and monitoring of their patients' nutritional status; and promote sound dietary patterns for their patients.
2. Pediatricians should work collaboratively with public health departments and colleagues in related professions to identify and mitigate hindrances to the health and well-being of children in the communities they serve. In many cases, vitally needed services already exist in the community. Pediatricians can play an important role in coordinating and focusing services to realize maximum benefit for all children.[5]
3. Pediatricians, including AAP chapter breastfeeding coordinators, should work collaboratively with state and local WIC agencies to maximize efforts to promote, support, and manage breastfeeding as the preferred feeding method for all infants. Although the WIC program is based on federal regulations, states have the option to develop additional policies. Pediatricians must become knowledgeable about their state and local policies and programs to maximize potential benefits available through the WIC program.
4. Pediatricians should provide information to employers on the improved health of infants who are breastfed, which can result in fewer missed workdays for working mothers and fathers attributable to a child's illness.[6]

The AAP also supports the following recommendations for the WIC program:

1. Breastfeeding should be aggressively promoted among WIC recipients as the preferred feeding method for all infants because of the nutritional value and health benefits of human milk. The AAP recommends that infants be exclusively breastfed for approximately the first 6 months of

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

life. It is further recommended that breastfeeding continue with appropriate food supplementation for at least 12 months and thereafter for as long as mutually desired by the mother and the child.[6]
2. For infants whose mothers do not breastfeed or partially breastfeed, iron-fortified infant formula should be provided through the first year of life. Noncontract formula should be made available through physician prescription for specific medical conditions. Food prescriptions should be nutritionally and culturally appropriate.
3. Hematocrit and hemoglobin screening should be performed consistent with the AAP policy statement "Recommendations for Preventive Health Care."[7] Uniform procedures should be developed to ensure that children who have very low hemoglobin or hematocrit levels are referred to their pediatricians for evaluation before iron treatment is instituted.
4. Breastfeeding women should be certified to receive WIC program benefits for up to 1 year after giving birth. Currently, an infant is certified for the first year of life (up to 12 months). Breastfeeding women, however, have to be recertified 6 months after delivery, with benefits limited to 1 year or less if they stop breastfeeding. It is further recommended that WIC program personnel be encouraged to continue to support breastfeeding women after completion of WIC program benefits.
5. The research component of the WIC program should be expanded to document its effectiveness in the treatment and prevention of nutritional deficiencies in mothers and children.

The AAP supports the following recommendations for a collaborative effort between pediatricians and the WIC program:

1. Pediatricians and WIC breastfeeding coordinators should develop partnership initiatives with local obstetricians, family physicians, hospitals, and other providers of obstetric care to introduce pregnant women to the benefits of breastfeeding.
2. Pediatricians and WIC breastfeeding coordinators should work with local businesses to encourage the establishment of family-friendly work policies and facilities that provide breastfeeding women clean and private places to express and store breast milk.
3. Pediatricians and the WIC program should make special efforts to encourage uninsured WIC recipients and those with nutritional needs to enroll in health programs funded by Medicaid or the State Children's Health Insurance Program (SCHIP).[8] A process should also be established by which families enrolled in separate state programs funded by SCHIP are screened for eligibility for WIC.
4. Although they are important sources of screenings and referrals, local WIC programs are not expected to provide primary care services. Pediatricians and other health care professionals are solely responsible for rendering that care, and outside agencies should develop policies to support the concept of the medical home.[3,4] The WIC program should work collaboratively with the medical home to ensure that patient information is shared and referrals are completed in a timely manner.

The AAP supports the nutrition education, breastfeeding promotion, and food supplementation components of the WIC program and advocates for full funding to support all women, infants, and children who are potentially eligible to receive these benefits.

American Academy of Pediatrics
DEDICATED TO THE HEALTH OF ALL CHILDREN™

POLICY STATEMENT

Year 2007 Position Statement: Principles and Guidelines for Early Hearing Detection and Intervention Programs

Joint Committee on Infant Hearing

THE POSITION STATEMENT

The Joint Committee on Infant Hearing (JCIH) endorses early detection of and intervention for infants with hearing loss. The goal of early hearing detection and intervention (EHDI) is to maximize linguistic competence and literacy development for children who are deaf or hard of hearing. Without appropriate opportunities to learn language, these children will fall behind their hearing peers in communication, cognition, reading, and social-emotional development. Such delays may result in lower educational and employment levels in adulthood.[1] To maximize the outcome for infants who are deaf or hard of hearing, the hearing of all infants should be screened at no later than 1 month of age. Those who do not pass screening should have a comprehensive audiological evaluation at no later than 3 months of age. Infants with confirmed hearing loss should receive appropriate intervention at no later than 6 months of age from health care and education professionals with expertise in hearing loss and deafness in infants and young children. Regardless of previous hearing-screening outcomes, all infants with or without risk factors should receive ongoing surveillance of communicative development beginning at 2 months of age during well-child visits in the medical home.[2] EHDI systems should guarantee seamless transitions for infants and their families through this process.

2007 JCIH POSITION STATEMENT UPDATES

The following are highlights of updates made since the 2000 JCIH statement[3]:

1. Definition of targeted hearing loss
   - The definition has been expanded from congenital permanent bilateral, unilateral sensory, or permanent conductive hearing loss to include neural hearing loss (eg, "auditory neuropathy/dyssynchrony") in infants admitted to the NICU.
2. Hearing-screening and -rescreening protocols
   - Separate protocols are recommended for NICU and well-infant nurseries. NICU infants admitted for more than 5 days are to have auditory brainstem response (ABR) included as part of their screening so that neural hearing loss will not be missed.
   - For infants who do not pass automated ABR testing in the NICU, referral should be made directly to an audiologist for rescreening and, when indicated, comprehensive evaluation including ABR.
   - For rescreening, a complete screening on both ears is recommended, even if only 1 ear failed the initial screening.
   - For readmissions in the first month of life for all infants (NICU or well infant), when there are conditions associated with potential hearing loss (eg, hyper-

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

bilirubinemia that requires exchange transfusion or culture-positive sepsis), a repeat hearing screening is recommended before discharge.

3. Diagnostic audiology evaluation
   - Audiologists with skills and expertise in evaluating newborn and young infants with hearing loss should provide audiology diagnostic and auditory habilitation services (selection and fitting of amplification device).
   - At least 1 ABR test is recommended as part of a complete audiology diagnostic evaluation for children younger than 3 years for confirmation of permanent hearing loss.
   - The timing and number of hearing reevaluations for children with risk factors should be customized and individualized depending on the relative likelihood of a subsequent delayed-onset hearing loss. Infants who pass the neonatal screening but have a risk factor should have at least 1 diagnostic audiology assessment by 24 to 30 months of age. Early and more frequent assessment may be indicated for children with cytomegalovirus (CMV) infection, syndromes associated with progressive hearing loss, neurodegenerative disorders, trauma, or culture-positive postnatal infections associated with sensorineural hearing loss; for children who have received extracorporeal membrane oxygenation (ECMO) or chemotherapy; and when there is caregiver concern or a family history of hearing loss.
   - For families who elect amplification, infants in whom permanent hearing loss is diagnosed should be fitted with an amplification device within 1 month of diagnosis.
4. Medical evaluation
   - For infants with confirmed hearing loss, a genetics consultation should be offered to their families.
   - Every infant with confirmed hearing loss should be evaluated by an otolaryngologist who has knowledge of pediatric hearing loss and have at least 1 examination to assess visual acuity by an ophthalmologist who is experienced in evaluating infants.
   - The risk factors for congenital and acquired hearing loss have been combined in a single list rather than grouped by time of onset.
5. Early intervention
   - All families of infants with any degree of bilateral or unilateral permanent hearing loss should be considered eligible for early intervention services.
   - There should be recognized central referral points of entry that ensure specialty services for infants with confirmed hearing loss.
   - Early intervention services for infants with confirmed hearing loss should be provided by professionals who have expertise in hearing loss, including educators of the deaf, speech-language pathologists, and audiologists.
   - In response to a previous emphasis on "natural environments," the JCIH recommends that both home-based and center-based intervention options be offered.
6. Surveillance and screening in the medical home
   - For all infants, regular surveillance of developmental milestones, auditory skills, parental concerns, and middle-ear status should be performed in the medical home, consistent with the American Academy of Pediatrics (AAP) pediatric periodicity schedule. All infants should have an objective standardized screening of global development with a validated assessment tool at 9, 18, and 24 to 30 months of age or at any time if the health care professional or family has concern.
   - Infants who do not pass the speech-language portion of a medical home global screening or for whom there is a concern regarding hearing or language should be referred for speech-language evaluation and audiology assessment.
7. Communication
   - The birth hospital, in collaboration with the state EHDI coordinator, should ensure that the hearing-screening results are conveyed to the parents and the medical home.
   - Parents should be provided with appropriate follow-up and resource information, and hospitals should ensure that each infant is linked to a medical home.
   - Information at all stages of the EHDI process is to be communicated to the family in a culturally sensitive and understandable format.
   - Individual hearing-screening information and audiology diagnostic and habilitation information should be promptly transmitted to the medical home and the state EHDI coordinator.
   - Families should be made aware of all communication options and available hearing technologies (presented in an unbiased manner). Informed family choice and desired outcome guide the decision-making process.
8. Information infrastructure
   - States should implement data-management and -tracking systems as part of an integrated child health information system to monitor the quality of EHDI services and provide recommendations for improving systems of care.

- An effective link between health and education professionals is needed to ensure successful transition and to determine outcomes of children with hearing loss for planning and establishing public health policy.

BACKGROUND

It has long been recognized that unidentified hearing loss at birth can adversely affect speech and language development as well as academic achievement and social-emotional development. Historically, moderate-to-severe hearing loss in young children was not detected until well beyond the newborn period, and it was not unusual for diagnosis of milder hearing loss and unilateral hearing loss to be delayed until children reached school age.

In the late 1980s, Dr C. Everett Koop, then US Surgeon General, on learning of new technology, encouraged detection of hearing loss to be included in the *Healthy People 2000*[4] goals for the nation. In 1988, the Maternal and Child Health Bureau (MCHB), a division of the US Health Resources and Services Administration (HRSA), funded pilot projects in Rhode Island, Utah, and Hawaii to test the feasibility of a universal statewide screening program to screen newborn infants for hearing loss before hospital discharge. The National Institutes of Health, through the National Institute on Deafness and Other Communication Disorders (NIDCD), issued in 1993 a consensus statement on early identification of hearing impairment in infants and young children.[5] In the statement the authors concluded that all infants admitted to the NICU should be screened for hearing loss before hospital discharge and that universal screening should be implemented for all infants within the first 3 months of life.[4] In its 1994 position statement, the JCIH endorsed the goal of universal detection of infants with hearing loss and encouraged continuing research and development to improve methods for identification of and intervention for hearing loss.[6,7] The AAP released a statement that recommended newborn hearing screening and intervention in 1999.[8] In 2000, citing advances in screening technology, the JCIH endorsed the universal screening of all infants through an integrated, interdisciplinary system of EHDI.[3] The *Healthy People 2010* goals included an objective to "increase the proportion of newborns who are screened for hearing loss by one month, have audiological evaluation by 3 months, and are enrolled in appropriate intervention services by 6 months."[9]

The ensuing years have seen remarkable expansion in newborn hearing screening. At the time of the National Institutes of Health consensus statement, only 11 hospitals in the United States were screening more than 90% of their newborn infants. In 2000, through the support of Representative Jim Walsh (R-NY), Congress authorized the HRSA to develop newborn hearing screening and follow-up services, the Centers for Disease Control and Prevention (CDC) to develop data and tracking systems, and the NIDCD to support research in EHDI. By 2005, every state had implemented a newborn hearing-screening program, and approximately 95% of newborn infants in the United States were screened for hearing loss before hospital discharge. Congress recommended cooperation and collaboration among several federal agencies and advocacy organizations to facilitate and support the development of state EHDI systems.

EHDI programs throughout the United States have demonstrated not only the feasibility of universal newborn hearing screening (UNHS) but also the benefits of early identification and intervention. There is a growing body of literature indicating that when identification and intervention occur at no later than 6 months of age for newborn infants who are deaf or hard of hearing, the infants perform as much as 20 to 40 percentile points higher on school-related measures (vocabulary, articulation, intelligibility, social adjustment, and behavior).[10–13] Still, many important challenges remain. Despite the fact that approximately 95% of newborn infants have their hearing screened in the United States, almost half of newborn infants who do not pass the initial screening do not have appropriate follow-up to either confirm the presence of a hearing loss and/or initiate appropriate early intervention services (see www.infanthearing.org, www.cdc.gov/ncbddd/ehdi, and www.nidcd.nih.gov/health).

State EHDI coordinators report system-wide problems including failure to communicate information to families in a culturally sensitive and understandable format at all stages of the EHDI process, lack of integrated state data-management and -tracking systems, and a shortage of facilities and personnel with the experience and expertise needed to provide follow-up for infants who are referred from newborn screening programs.[14] Available data indicate that a significant number of children who need further assessment do not receive appropriate follow-up evaluations. However, the outlook is improving as EHDI programs focus on the importance of strengthening follow-up and intervention.

PRINCIPLES

All children with hearing loss should have access to resources necessary to reach their maximum potential. The following principles provide the foundation for effective EHDI systems and have been updated and expanded since the 2000 JCIH position statement.

1. All infants should have access to hearing screening using a physiologic measure at no later than 1 month of age.
2. All infants who do not pass the initial hearing screening and the subsequent rescreening should have appropriate audiological and medical evaluations to

confirm the presence of hearing loss at no later than 3 months of age.

3. All infants with confirmed permanent hearing loss should receive early intervention services as soon as possible after diagnosis but at no later than 6 months of age. A simplified, single point of entry into an intervention system that is appropriate for children with hearing loss is optimal.
4. The EHDI system should be family centered with infant and family rights and privacy guaranteed through informed choice, shared decision-making, and parental consent in accordance with state and federal guidelines. Families should have access to information about all intervention and treatment options and counseling regarding hearing loss.
5. The child and family should have immediate access to high-quality technology including hearing aids, cochlear implants, and other assistive devices when appropriate.
6. All infants and children should be monitored for hearing loss in the medical home.[15] Continued assessment of communication development should be provided by appropriate professionals to all children with or without risk indicators for hearing loss.
7. Appropriate interdisciplinary intervention programs for infants with hearing loss and their families should be provided by professionals who are knowledgeable about childhood hearing loss. Intervention programs should recognize and build on strengths, informed choices, traditions, and cultural beliefs of the families.
8. Information systems should be designed and implemented to interface with electronic health charts and should be used to measure outcomes and report the effectiveness of EHDI services at the patient, practice, community, state, and federal levels.

GUIDELINES FOR EHDI PROGRAMS

The 2007 guidelines were developed to update the 2000 JCIH position statement principles and to support the goals of universal access to hearing screening, evaluation, and intervention for newborn and young infants embodied in *Healthy People 2010*.[9] The guidelines provide current information on the development and implementation of successful EHDI systems.

Hearing screening should identify infants with specifically defined hearing loss on the basis of investigations of long-term, developmental consequences of hearing loss in infants, currently available physiologic screening techniques, and availability of effective intervention in concert with established principles of health screening.[15–18] Studies have demonstrated that current screening technologies are effective in identifying hearing loss of moderate and greater degree.[19] In addition, studies of children with permanent hearing loss indicate that moderate or greater degrees of hearing loss can have significant effects on language, speech, academic, and social-emotional development.[20] High-risk target populations also include infants in the NICU, because research data have indicated that this population is at highest risk of having neural hearing loss.[21–23]

The JCIH, however, is committed to the goal of identifying all degrees and types of hearing loss in childhood and recognizes the developmental consequences of even mild degrees of permanent hearing loss. Recent evidence, however, has suggested that current hearing-screening technologies fail to identify some infants with mild forms of hearing loss.[24,25] In addition, depending on the screening technology selected, infants with hearing loss related to neural conduction disorders or "auditory neuropathy/auditory dyssynchrony" may not be detected through a UNHS program. Although the JCIH recognizes that these disorders may result in delayed communication,[26–28] currently recommended screening algorithms (ie, use of otoacoustic emission [OAE] testing alone) preclude universal screening for these disorders. Because these disorders typically occur in children who require NICU care,[21] the JCIH recommends screening this group with the technology capable of detecting auditory neuropathy/dyssynchrony: automated ABR measurement.

All infants, regardless of newborn hearing-screening outcome, should receive ongoing monitoring for development of age-appropriate auditory behaviors and communication skills. Any infant who demonstrates delayed auditory and/or communication skills development, even if he or she passed newborn hearing screening, should receive an audiological evaluation to rule out hearing loss.

Roles and Responsibilities

The success of EHDI programs depends on families working in partnership with professionals as a well-coordinated team. The roles and responsibilities of each team member should be well defined and clearly understood. Essential team members are the birth hospital, families, pediatricians or primary health care professionals (ie, the medical home), audiologists, otolaryngologists, speech-language pathologists, educators of children who are deaf or hard of hearing, and other early intervention professionals involved in delivering EHDI services.[29,30] Additional services including genetics, ophthalmology, developmental pediatrics, service coordination, supportive family education, and counseling should be available.[31]

The birth hospital is a key member of the team. The birth hospital, in collaboration with the state EHDI coordinator, should ensure that parents and primary health care professionals receive and understand the hearing-screening results, that parents are provided with appropriate follow-up and resource information, and

that each infant is linked to a medical home.[2] The hospital ensures that hearing-screening information is transmitted promptly to the medical home and appropriate data are submitted to the state EHDI coordinator.

The most important role for the family of an infant who is deaf or hard of hearing is to love, nurture, and communicate with the infant. From this foundation, families usually develop an urgent desire to understand and meet the special needs of their infant. Families gain knowledge, insight, and experience by accessing resources and through participation in scheduled early intervention appointments including audiological, medical, habilitative, and educational sessions. This experience can be enhanced when families choose to become involved with parental support groups, people who are deaf or hard of hearing, and/or their children's deaf or hard-of-hearing peers. Informed family choices and desired outcomes guide all decisions for these children. A vital function of the family's role is ensuring direct access to communication in the home and the daily provision of language-learning opportunities. Over time, the child benefits from the family's modeling of partnerships with professionals and advocating for their rights in all settings. The transfer of responsibilities from families to the child develops gradually and increases as the child matures, growing in independence and self-advocacy.

Pediatricians, family physicians, and other allied health care professionals, working in partnership with parents and other professionals such as audiologists, therapists, and educators, constitute the infant's medical home.[2] A medical home is defined as an approach to providing health care services with which care is accessible, family centered, continuous, comprehensive, coordinated, compassionate, and culturally competent. The primary health care professional acts in partnership with parents in a medical home to identify and access appropriate audiology, intervention, and consultative services that are needed to develop a global plan of appropriate and necessary health and habilitative care for infants identified with hearing loss and infants with risk factors for hearing loss. All children undergo surveillance for auditory skills and language milestones. The infant's pediatrician, family physician, or other primary health care professional is in a position to advocate for the child and family.[2,16]

An audiologist is a person who, by virtue of academic degree, clinical training, and license to practice, is qualified to provide services related to the prevention of hearing loss and the audiological diagnosis, identification, assessment, and nonmedical and nonsurgical treatment of persons with impairment of auditory and vestibular function, and to the prevention of impairments associated with them. Audiologists serve in a number of roles. They provide newborn hearing-screening program development, management, quality assessment, service coordination and referral for audiological diagnosis, and audiological treatment and management. For the follow-up component, audiologists provide comprehensive audiological diagnostic assessment to confirm the existence of the hearing loss, ensure that parents understand the significance of the hearing loss, evaluate the infant for candidacy for amplification and other sensory devices and assistive technology, and ensure prompt referral to early intervention programs. For the treatment and management component, audiologists provide timely fitting and monitoring of amplification devices.[32] Other audiologists may provide diagnostic and auditory treatment and management services in the educational setting and provide a bridge between the child/family and the audiologist in the clinic setting as well as other service providers. Audiologists also provide services as teachers, consultants, researchers, and administrators.

Otolaryngologists are physicians whose specialty includes determining the etiology of hearing loss; identifying related risk indicators for hearing loss, including syndromes that involve the head and neck; and evaluating and treating ear diseases. An otolaryngologist with knowledge of childhood hearing loss can determine if medical and/or surgical intervention may be appropriate. When medical and/or surgical intervention is provided, the otolaryngologist is involved in the long-term monitoring and follow-up with the infant's medical home. The otolaryngologist provides information and participates in the assessment of candidacy for amplification, assistive devices, and surgical intervention, including reconstruction, bone-anchored hearing aids, and cochlear implantation.

Early intervention professionals are trained in a variety of academic disciplines such as speech-language pathology, audiology, education of children who are deaf or hard of hearing, service coordination, or early childhood special education. All individuals who provide services to infants with hearing loss should have specialized training and expertise in the development of audition, speech, and language. Speech-language pathologists provide both evaluation and intervention services for language, speech, and cognitive-communication development. Educators of children who are deaf or hard of hearing integrate the development of communicative competence within a variety of social, linguistic, and cognitive/academic contexts. Audiologists may provide diagnostic and habilitative services within the individualized family service plan (IFSP) or school-based individualized education plan. To provide the highest quality of intervention, more than 1 provider may be required.

The care coordinator is an integral member of the EHDI team and facilitates the family's transition from screening to evaluation to early intervention.[33] This person must be a professional (eg, social worker, teacher, nurse) who is knowledgeable about hearing loss. The care coordinator incorporates the family's preferences for outcomes into an IFSP as required by federal legisla-

tion. The care coordinator supports the family members in their choice of the infant's communicative development. Through the IFSP review, the infant's progress in language, motor, cognitive, and social-emotional development is monitored. The care coordinator assists the family in advocating for the infant's unique developmental needs.

The deaf and hard-of-hearing community includes members with direct experience with signed language, spoken language, hearing-aid and cochlear implant use, and other communication strategies and technologies. Optimally, adults who are deaf or hard-of-hearing should play an integral part in the EHDI program. Both adults and children in the deaf and hard-of-hearing community can enrich the family's experience by serving as mentors and role models. Such mentors have experience in negotiating their way in a hearing world, raising infants or children who are deaf or hard of hearing, and providing families with a full range of information about communication options, assistive technology, and resources that are available in the community.

A successful EHDI program requires collaboration between a variety of public and private institutions and agencies that assume responsibility for specific components (eg, screening, evaluation, intervention). Roles and responsibilities may differ from state to state. Each state has defined a lead coordinating agency with oversight responsibility. The lead coordinating agency in each state should be responsible for identifying the public and private funding sources available to develop, implement, and coordinate EHDI systems.

Hearing Screening

Multidisciplinary teams of professionals, including audiologists, physicians, and nursing personnel, are needed to establish the UNHS component of EHDI programs. All team members work together to ensure that screening programs are of high quality and are successful. An audiologist should be involved in each component of the hearing-screening program, particularly at the level of statewide implementation and, whenever possible, at the individual hospital level. Hospitals and agencies should also designate a physician to oversee the medical aspects of the EHDI program.

Each team of professionals responsible for the hospital-based UNHS program should review the hospital infrastructure in relationship to the screening program. Hospital-based programs should consider screening technology (ie, OAE or automated ABR testing); validity of the specific screening device; screening protocols, including the timing of screening relative to nursery discharge; availability of qualified screening personnel; suitability of the acoustical and electrical environments; follow-up referral criteria; referral pathways for follow-up; information management; and quality control and improvement. Reporting and communication protocols must be well defined and include the content of reports to physicians and parents, documentation of results in medical charts, and methods for reporting to state registries and national data sets.

Physiologic measures must be used to screen newborns and infants for hearing loss. Such measures include OAE and automated ABR testing. Both OAE and automated ABR technologies provide noninvasive recordings of physiologic activity underlying normal auditory function, both are easily performed in neonates and infants, and both have been successfully used for UNHS.[19,34–37] However, there are important differences between the 2 measures. OAE measurements are obtained from the ear canal by using a sensitive microphone within a probe assembly that records cochlear responses to acoustic stimuli. Thus, OAEs reflect the status of the peripheral auditory system extending to the cochlear outer hair cells. In contrast, ABR measurements are obtained from surface electrodes that record neural activity generated in the cochlea, auditory nerve, and brainstem in response to acoustic stimuli delivered via an earphone. Automated ABR measurements reflect the status of the peripheral auditory system, the eighth nerve, and the brainstem auditory pathway.

Both OAE and ABR screening technologies can be used to detect sensory (cochlear) hearing loss[19]; however, both technologies may be affected by outer or middle-ear dysfunction. Consequently, transient conditions of the outer and middle ear may result in a "failed" screening-test result in the presence of normal cochlear and/or neural function.[38] Moreover, because OAEs are generated within the cochlea, OAE technology cannot be used to detect neural (eighth nerve or auditory brainstem pathway) dysfunction. Thus, neural conduction disorders or auditory neuropathy/dyssynchrony without concomitant sensory dysfunction will not be detected by OAE testing.

Some infants who pass newborn hearing screening will later demonstrate permanent hearing loss.[25] Although this loss may reflect delayed-onset hearing loss, both ABR and OAE screening technologies will miss some hearing loss (eg, mild or isolated frequency region losses).

Interpretive criteria for pass/fail outcomes should reflect clear scientific rationale and should be evidence based.[39,40] Screening technologies that incorporate automated-response detection are necessary to eliminate the need for individual test interpretation, to reduce the effects of screener bias or operator error on test outcome, and to ensure test consistency across infants, test conditions, and screening personnel.[41–45] When statistical probability is used to make pass/fail decisions, as is the case for OAE and automated ABR screening devices, the likelihood of obtaining a pass outcome by chance alone is increased when screening is performed repeatedly.[46–48]

This principle must be incorporated into the policies of rescreening.

There are no national standards for the calibration of OAE or ABR instrumentation. Compounding this problem, there is a lack of uniform performance standards. Manufacturers of hearing-screening devices do not always provide sufficient supporting evidence to validate the specific pass/fail criteria and/or automated algorithms used in their instruments.[49] In the absence of national standards, audiologists must obtain normative data for the instruments and protocols they use.

The JCIH recognizes that there are important issues differentiating screening performed in the well-infant nursery from that performed in the NICU. Although the goals in each nursery are the same, numerous methodologic and technological issues must be considered in program design and pass/fail criteria.

Screening Protocols in the Well-Infant Nursery

Many inpatient well-infant screening protocols provide 1 hearing screening and, when necessary, a repeat screening no later than at the time of discharge from the hospital, using the same technology both times. Use of either technology in the well-infant nursery will detect peripheral (conductive and sensory) hearing loss of 40 dB or greater.[19] When automated ABR is used as the single screening technology, neural auditory disorders can also be detected.[50] Some programs use a combination of screening technologies (OAE testing for the initial screening followed by automated ABR for rescreening [ie, 2-step protocol[5]]) to decrease the fail rate at discharge and the subsequent need for outpatient follow-up.[34,35,37,51–53] With this approach, infants who do not pass an OAE screening but subsequently pass an automated ABR test are considered a screening "pass." Infants in the well-infant nursery who fail automated ABR testing should not be rescreened by OAE testing and "passed," because such infants are presumed to be at risk of having a subsequent diagnosis of auditory neuropathy/dyssynchrony.

Screening Protocols in the NICU

An NICU is defined as a facility in which a neonatologist provides primary care for the infant. Newborn units are divided into 3 categories:

- Level I: basic care, well-infant nurseries
- Level II: specialty care by a neonatologist for infants at moderate risk of serious complications
- Level III: a unit that provides both specialty and subspecialty care including the provision of life support (mechanical ventilation)

A total of 120 level-II NICUs and 760 level-III NICUs have been identified in the United States by survey, and infants who have spent time in the NICU represent 10% to 15% of the newborn population.[54]

The 2007 JCIH position statement includes neonates at risk of having neural hearing loss (auditory neuropathy/auditory dyssynchrony) in the target population to be identified in the NICU,[55–57] because there is evidence that neural hearing loss results in adverse communication outcomes.[22,50] Consequently, the JCIH recommends ABR technology as the only appropriate screening technique for use in the NICU. For infants who do not pass automated ABR testing in the NICU, referral should be made directly to an audiologist for rescreening and, when indicated, comprehensive evaluation, including diagnostic ABR testing, rather than for general outpatient rescreening.

Conveying Test Results

Screening results should be conveyed immediately to families so that they understand the outcome and the importance of follow-up when indicated. To facilitate this process for families, primary health care professionals should work with EHDI team members to ensure that:

- communications with parents are confidential and presented in a caring and sensitive manner, preferably face-to-face;
- educational materials are developed and disseminated to families that provide accurate information at an appropriate reading level and in a language they are able to comprehend; and
- parents are informed in a culturally sensitive and understandable manner that their infant did not pass screening and informed about the importance of prompt follow-up; before discharge, an appointment should be made for follow-up testing.

To facilitate this process for primary care physicians, EHDI systems should ensure that medical professionals receive:

- the results of the screening test (pass, did not pass, or missed) as documented in the hospital medical chart; and
- communication directly from a representative of the hospital screening program regarding each infant in its care who did not pass or was missed and recommendations for follow-up.

Outpatient Rescreening for Infants Who Do Not Pass the Birth Admission Screening

Many well-infant screening protocols will incorporate an outpatient rescreening within 1 month of hospital discharge to minimize the number of infants referred for follow-up audiological and medical evaluation. The out-

patient rescreening should include the testing of both ears, even if only 1 ear failed the inpatient screening.

Outpatient screening at no later than 1 month of age should also be available to infants who were discharged before receiving the birth admission screening or who were born outside a hospital or birthing center. State EHDI coordinators should be aware of some of the following situations under which infants may be lost to the UNHS system:

- Home births and other out-of-hospital births: states should develop a mechanism to systematically offer newborn hearing screening for all out-of-hospital births.
- Across-state-border births: states should develop written collaborative agreements among neighboring states for sharing hearing-screening results and follow-up information.
- Hospital-missed screenings: when infants are discharged before the hearing screening is performed, a mechanism should be in place for the hospital to contact the family and arrange for an outpatient hearing screening.
- Transfers to in-state or out-of-state hospitals: discharge and transfer forms should contain the information of whether a hearing screening was performed and the results of any screening. The recipient hospital should complete a hearing screening if one was not previously performed or if there is a change in medical status or a prolonged hospitalization.
- Readmissions: for readmissions in the first month of life when there are conditions associated with potential hearing loss (eg, hyperbilirubinemia that requires exchange transfusion or culture-positive sepsis), an ABR screening should be performed before discharge.

Additional mechanisms for states to share hearing-screening results and other medical information include (l) incorporating the hearing-screening results in a statewide child health information system and (2) providing combined metabolic screening and hearing-screening results to the primary care physician.

Confirmation of Hearing Loss in Infants Referred From UNHS

Infants who meet the defined criteria for referral should receive follow-up audiological and medical evaluations with fitting of amplification devices, as appropriate, at no later than 3 months of age. Once hearing loss is confirmed, coordination of services should be expedited by the infant's medical home and Part C coordinating agencies for early intervention services, as authorized by the Individuals With Disabilities Education Act, following the EHDI algorithm developed by the AAP (Appendix 1).

Audiological Evaluation

Comprehensive audiological evaluation of newborn and young infants who fail newborn hearing screening should be performed by audiologists experienced in pediatric hearing assessment. The initial audiological test battery to confirm a hearing loss in infants must include physiologic measures and, when developmentally appropriate, behavioral methods. Confirmation of an infant's hearing status requires a test battery of audiological test procedures to assess the integrity of the auditory system in each ear, to estimate hearing sensitivity across the speech frequency range, to determine the type of hearing loss, to establish a baseline for further monitoring, and to provide information needed to initiate amplification-device fitting. A comprehensive assessment should be performed on both ears even if only 1 ear failed the screening test.

Evaluation: Birth to 6 Months of Age

For infants from birth to a developmental age of approximately 6 months, the test battery should include a child and family history, an evaluation of risk factors for congenital hearing loss, and a parental report of the infant's responses to sound. The audiological assessment should include:

- Child and family history.
- A frequency-specific assessment of the ABR using air-conducted tone bursts and bone-conducted tone bursts when indicated. When permanent hearing loss is detected, frequency-specific ABR testing is needed to determine the degree and configuration of hearing loss in each ear for fitting of amplification devices.
- Click-evoked ABR testing using both condensation and rarefaction single-polarity stimulus, if there are risk indicators for neural hearing loss (auditory neuropathy/auditory dyssynchrony) such as hyperbilirubinemia or anoxia, to determine if a cochlear microphonic is present.[28] Furthermore, because some infants with neural hearing loss have no risk indicators, any infant who demonstrates "no response" on ABR elicited by tone-burst stimuli must be evaluated by a click-evoked ABR.[55]
- Distortion product or transient evoked OAEs.
- Tympanometry using a 1000-Hz probe tone.
- Clinician observation of the infant's auditory behavior as a cross-check in conjunction with electrophysiologic measures. Behavioral observation alone is not adequate for determining whether hearing loss is present in this age group, and it is not adequate for the fitting of amplification devices.

Evaluation: 6 to 36 Months of Age

For subsequent testing of infants and toddlers at developmental ages of 6 to 36 months, the confirmatory audiological test battery includes:

- Child and family history.
- Parental report of auditory and visual behaviors and communication milestones.
- Behavioral audiometry (either visual reinforcement or conditioned-play audiometry, depending on the child's developmental level), including pure-tone audiometry across the frequency range for each ear and speech-detection and -recognition measures.
- OAE testing.
- Acoustic immittance measures (tympanometry and acoustic reflex thresholds).
- ABR testing if responses to behavioral audiometry are not reliable or if ABR testing has not been performed in the past.

Other Audiological Test Procedures

At this time, there is insufficient evidence for use of the auditory steady-state response as the sole measure of auditory status in newborn and infant populations.[58] Auditory steady-state response is a new evoked-potential test that can accurately measure auditory sensitivity beyond the limits of other test methods. It can determine frequency-specific thresholds from 250 Hz to 8 kHz. Clinical research is being performed to investigate its potential use in the standard pediatric diagnostic test battery. Similarly, there are insufficient data for routine use of acoustic middle-ear muscle reflexes in the initial diagnostic assessment of infants younger than 4 months.[59] Both tests could be used to supplement the battery or could be included at older ages. Emerging technologies, such as broad-band reflectance, may be used to supplement conventional measures of middle-ear status (tympanometry and acoustic reflexes) as the technology becomes more widely available.[59]

Medical Evaluation

Every infant with confirmed hearing loss and/or middle-ear dysfunction should be referred for otologic and other medical evaluation. The purpose of these evaluations is to determine the etiology of hearing loss, to identify related physical conditions, and to provide recommendations for medical/surgical treatment as well as referral for other services. Essential components of the medical evaluation include clinical history, family history of childhood-onset permanent hearing loss, identification of syndromes associated with early- or late-onset permanent hearing loss, a physical examination, and indicated radiologic and laboratory studies (including genetic testing). Portions of the medical evaluation, such as urine culture for CMV, a leading cause of hearing loss, might even begin in the birth hospital, particularly for infants who spend time in the NICU.[60–62]

Pediatrician/Primary Care Physician

The infant's pediatrician or other primary health care professional is responsible for monitoring the general health, development, and well-being of the infant. In addition, the primary care physician must assume responsibility to ensure that the audiological assessment is conducted on infants who do not pass screening and must initiate referrals for medical specialty evaluations necessary to determine the etiology of the hearing loss. Middle-ear status should be monitored, because the presence of middle-ear effusion can further compromise hearing. The primary care physician must partner with other specialists, including the otolaryngologist, to facilitate coordinated care for the infant and family. Because 30% to 40% of children with confirmed hearing loss will demonstrate developmental delays or other disabilities, the primary care physician should closely monitor developmental milestones and initiate referrals related to suspected disabilities.[63] The medical home algorithm for management of infants with either suspected or proven permanent hearing loss is provided in Appendix 1.[15]

The pediatrician or primary care physician should review every infant's medical and family history for the presence of risk indicators that require monitoring for delayed-onset or progressive hearing loss and should ensure that an audiological evaluation is completed for children at risk of hearing loss at least once by 24 to 30 months of age, regardless of their newborn screening results.[25] Infants with specific risk factors, such as those who received ECMO therapy and those with CMV infection, are at increased risk of delayed-onset or progressive hearing loss[64–67] and should be monitored closely. In addition, the primary care physician is responsible for ongoing surveillance of parent concerns about language and hearing, auditory skills, and developmental milestones of all infants and children regardless of risk status, as outlined in the pediatric periodicity schedule published by the AAP.[16]

Children with cochlear implants may be at increased risk of acquiring bacterial meningitis compared with children in the general US population.[68] The CDC recommends that all children with, and all potential recipients of, cochlear implants follow specific recommendations for pneumococcal immunization that apply to cochlear implant users and that they receive age-appropriate *Haemophilus influenzae* type b vaccines. Recommendations for the timing and type of pneumococcal vaccine vary with age and immunization history and should be discussed with a health care professional.[69]

Otolaryngologist

Otolaryngologists are physicians and surgeons who diagnose, treat, and manage a wide range of diseases of the head and neck and specialize in treating hearing and vestibular disorders. They perform a full medical diagnostic evaluation of the head and neck, ears, and related structures, including a comprehensive history and physical examination, leading to a medical diagnosis and appropriate medical and surgical management. Often, a hearing or balance disorder is an indicator of, or related to, a medically treatable condition or an underlying systemic disease. Otolaryngologists work closely with other dedicated professionals, including physicians, audiologists, speech-language pathologists, educators, and others, in caring for patients with hearing, balance, voice, speech, developmental, and related disorders.

The otolaryngologist's evaluation includes a comprehensive history to identify the presence of risk factors for early-onset childhood permanent hearing loss, such as family history of hearing loss, having been admitted to the NICU for more than 5 days, and having received ECMO (see Appendix 2).[70,71]

A complete head and neck examination for craniofacial anomalies should document defects of the auricles, patency of the external ear canals, and status of the eardrum and middle-ear structures. Atypical findings on eye examination, including irises of 2 different colors or abnormal positioning of the eyes, may signal a syndrome that includes hearing loss. Congenital permanent conductive hearing loss may be associated with craniofacial anomalies that are seen in disorders such as Crouzon disease, Klippel-Feil syndrome, and Goldenhar syndrome.[72] The assessment of infants with these congenital anomalies should be coordinated with a clinical geneticist.

In large population studies, at least 50% of congenital hearing loss has been designated as hereditary, and nearly 600 syndromes and 125 genes associated with hearing loss have already been identified.[72,73] The evaluation, therefore, should include a review of family history of specific genetic disorders or syndromes, including genetic testing for gene mutations such as *GJB2* (connexin-26), and syndromes commonly associated with early-onset childhood sensorineural hearing loss[72,74–76] (Appendix 2). As the widespread use of newly developed conjugate vaccines decreases the prevalence of infectious etiologies such as measles, mumps, rubella, *H influenzae* type b, and childhood meningitis, the percentage of each successive cohort of early-onset hearing loss attributable to genetic etiologies can be expected to increase, prompting recommendations for early genetic evaluations. Approximately 30% to 40% of children with hearing loss have associated disabilities, which can be of importance in patient management. The decision to obtain genetic testing depends on informed family choice in conjunction with standard confidentiality guidelines.[77]

In the absence of a genetic or established medical cause, a computed tomography scan of the temporal bones may be performed to identify cochlear abnormalities, such as Mondini deformity with an enlarged vestibular aqueduct, which have been associated with progressive hearing loss. Temporal bone imaging studies may also be used to assess potential candidacy for surgical intervention, including reconstruction, bone-anchored hearing aid, and cochlear implantation. Recent data have shown that some children with electrophysiologic evidence suggesting auditory neuropathy/dyssynchrony may have an absent or abnormal cochlear nerve that may be detected with MRI.[78]

Historically, an extensive battery of laboratory and radiographic studies was routinely recommended for newborn infants and children with newly diagnosed sensorineural hearing loss. However, emerging technologies for the diagnosis of genetic and infectious disorders have simplified the search for a definitive diagnosis, which obviates the need for costly diagnostic evaluations in some instances.[70,71,79]

If, after an initial evaluation, the etiology remains uncertain, an expanded multidisciplinary evaluation protocol including electrocardiography, urinalysis, testing for CMV, and further radiographic studies is indicated. The etiology of neonatal hearing loss, however, may remain uncertain in as many as 30% to 40% of children. Once hearing loss is confirmed, medical clearance for hearing aids and initiation of early intervention should not be delayed while this diagnostic evaluation is in process. Careful longitudinal monitoring to detect and promptly treat coexisting middle-ear effusions is an essential component of ongoing otologic management of these children.

Other Medical Specialists

The medical geneticist is responsible for the interpretation of family history data, the clinical evaluation and diagnosis of inherited disorders, the performance and assessment of genetic tests, and the provision of genetic counseling. Geneticists or genetic counselors are qualified to interpret the significance and limitations of new tests and to convey the current status of knowledge during genetic counseling. All families of children with confirmed hearing loss should be offered, and may benefit from, a genetics evaluation and counseling. This evaluation can provide families with information on etiology of hearing loss, prognosis for progression, associated disorders (eg, renal, vision, cardiac), and likelihood of recurrence in future offspring. This information may influence parents' decision-making regarding intervention options for their child.

Every infant with a confirmed hearing loss should have an evaluation by an ophthalmologist to document

visual acuity and rule out concomitant or late-onset vision disorders such as Usher syndrome.[1,80] Indicated referrals to other medical subspecialists, including developmental pediatricians, neurologists, cardiologists, and nephrologists, should be facilitated and coordinated by the primary health care professional.

Early Intervention

Before newborn hearing screening was instituted universally, children with severe-to-profound hearing loss, on average, completed the 12th grade with a 3rd- to 4th-grade reading level and language levels of a 9- to 10-year-old hearing child.[81] In contrast, infants and children with mild-to-profound hearing loss who are identified in the first 6 months of life and provided with immediate and appropriate intervention have significantly better outcomes than later-identified infants and children in vocabulary development,[82,83] receptive and expressive language,[12,84] syntax,[85] speech production,[13,86–88] and social-emotional development.[89] Children enrolled in early intervention within the first year of life have also been shown to have language development within the normal range of development at 5 years of age.[31,90]

Therefore, according to federal guidelines, once any degree of hearing loss is diagnosed in a child, a referral should be initiated to an early intervention program within 2 days of confirmation of hearing loss (CFR 303.321d). The initiation of early intervention services should begin as soon as possible after diagnosis of hearing loss but at no later than 6 months of age. Even when the hearing status is not determined to be the primary disability, the family and child should have access to intervention with a provider who is knowledgeable about hearing loss.[91]

UNHS programs have been instituted throughout the United States for the purpose of preventing the significant and negative effects of hearing loss on the cognitive, language, speech, auditory, social-emotional, and academic development of infants and children. To achieve this goal, hearing loss must be identified as quickly as possible after birth, and appropriate early intervention must be available to all families and infants with permanent hearing loss. Some programs have demonstrated that most children with hearing loss and no additional disabilities can achieve and maintain language development within the typical range of children who have normal hearing.[12,13,85,90] Because these studies were descriptive and not causal studies, the efficacy of specific components of intervention cannot be separated from the total provision of comprehensive services. Thus, the family-centered philosophy, the intensity of services, the experience and training of the provider, the method of communication, the curricula, the counseling procedures, the parent support and advocacy, and the deaf and hard-of-hearing support and advocacy are all variables with unknown effects on the overall outcomes of any individual child. The key component of providing quality services is the expertise of the provider specific to hearing loss. These services may be provided in the home, a center, or a combination of the 2 locations.

The term "intervention services" is used to describe any type of habilitative, rehabilitative, or educational program provided to children with hearing loss. In some cases of mild hearing losses, amplification technology may be the only service provided. Some parents choose only developmental assessment or occasional consultation, such as parents with infants who have unilateral hearing losses. Children with high-frequency losses and normal hearing in the low frequencies may only be seen by a speech-language pathologist, and those with significant bilateral sensorineural hearing losses might be seen by an educator of the deaf and receive additional services.

Principles of Early Intervention

To ensure informed decision-making, parents of infants with newly diagnosed hearing loss should be offered opportunities to interact with other families who have infants or children with hearing loss as well as adults and children who are deaf or hard of hearing. In addition, parents should also be offered access to professional, educational, and consumer organizations and provided with general information on child development, language development, and hearing loss. A number of principles and guidelines have been developed that offer a framework for quality early intervention service delivery systems for children who are deaf or hard of hearing and their families.[92] Foundational characteristics of developing and implementing early intervention programs include a family-centered approach, culturally responsive practices, collaborative professional-family relationships and strong family involvement, developmentally appropriate practice, interdisciplinary assessment, and community-based provision of services.

Designated Point of Entry

States should develop a single point of entry into intervention specific for hearing impairment to ensure that, regardless of geographic location, all families who have infants or children with hearing loss receive information about a full range of options regarding amplification and technology, communication and intervention, and accessing appropriate counseling services. This state system, if separate from the state's Part C system, should integrate and partner with the state's Part C program. Parental consent must be obtained according to state and federal requirements to share the IFSP information with providers and transmit data to the state EHDI coordinator.

Regular Developmental Assessment

To ensure accountability, individual, community, and state health and educational programs should assume the responsibility for coordinated, ongoing measurement and improvement of EHDI process outcomes. Early intervention programs must assess the language, cognitive skills, auditory skills, speech, vocabulary, and social-emotional development of all children with hearing loss at 6-month intervals during the first 3 years of life by using assessment tools that have been standardized on children with normal hearing and norm-referenced assessment tools that are appropriate to measure progress in verbal and visual language.

The primary purpose of regular developmental monitoring is to provide valuable information to parents about the rate of their child's development as well as programmatic feedback concerning curriculum decisions. Families also become knowledgeable about expectations and milestones of typical development of hearing children. Studies have shown that valid and reliable documentation of developmental progress is possible through parent questionnaires, analysis of videotaped conversational interactions, and clinically administered assessments.* Documentation of developmental progress should be provided on a regular basis to parents and, with parental release of information, to the medical home and audiologist. Although criterion-referenced checklists may provide valuable information for establishing intervention strategies and goals, these assessment tools alone are not sufficient for parents and intervention professionals to determine if a child's developmental progress is comparable with his or her hearing peers.

Opportunities for Interaction With Other Parents of Children With Hearing Loss

Intervention professionals should seek to involve parents at every level of the EHDI process and develop true and meaningful partnerships with parents. To reflect the value of the contributions that selected parents make to development and program components, these parents should be paid as contributing staff members. Parent representatives should be included in all advisory board activities. In many states, parents have been integral and often have taken leadership roles in the development of policy, resource material, communication mechanisms, mentoring and advocacy opportunities, dissemination of information, and interaction with the deaf community and other individuals who are deaf or hard of hearing. Parents, often in partnership with people who are deaf and hard of hearing, have also participated in the training of professionals. They should be participants in the regular assessment of program services to ensure ongoing improvement and quality assurance.

Opportunities for Interaction With Individuals Who Are Deaf or Hard of Hearing

Intervention programs should include opportunities for involvement of individuals who are deaf or hard of hearing in all aspects of EHDI programs. Because intervention programs serve children with mild-to-profound, unilateral or bilateral, permanent conductive, and sensory or neural hearing disorders, role models who are deaf or hard of hearing can be significant assets to an intervention program. These individuals can serve on state EHDI advisory boards and be trained as mentors for families and children with hearing loss who choose to seek their support. Almost all families choose at some time during their early childhood programs to seek out both adults and child peers with hearing loss. Programs should ensure that these opportunities are available and can be delivered to families through a variety of communications means, such as Web sites, e-mail, newsletters, videos, retreats, picnics and other social events, and educational forums for parents.

Provision of Communication Options

Research studies thus far of early-identified infants with hearing loss have not found significant differences in the developmental outcomes by method of communication when measured at 3 years of age.† Therefore, a range of options should be offered to families in a nonbiased manner. In addition, there have been reports of children with successful outcomes for each of the different methods of communication. The choice is a dynamic process on a continuum, differs according to the individual needs of each family, and can be adjusted as necessary on the basis of a child's rate of progress in developing communication skills. Programs need to provide families with access to skilled and experienced early intervention professionals to facilitate communication and language development in the communication option chosen by the family.

Skills of the Early Intervention Professional

All studies with successful outcomes reported for early-identified children who are deaf or hard of hearing have intervention provided by specialists who are trained in parent-infant intervention services.[12,90,97] Early intervention programs should develop mechanisms to ensure that early intervention professionals have special skills necessary for providing families with the highest quality of service specific to children with hearing loss. Professionals with a background in deaf education, audiology, and speech-language pathology will typically have the skills needed for providing intervention services. Professionals should be highly qualified in their respective fields and should be skilled communicators who are knowledgeable and sensitive to the importance of en-

*Refs 10–13, 51, 85, 87–90, and 93–96.

†Refs 10–13, 85, 87, 88, 90, 93, and 96.

hancing families' strengths and supporting their priorities. When early intervention professionals have knowledge of the principles of adult learning, it increases their success with parents and other professionals.

Quality of Intervention Services

Children with confirmed hearing loss and their families have the right to prompt access to quality intervention services. For newborn infants with confirmed hearing loss, enrollment into intervention services should begin as soon after hearing-loss confirmation as possible and no later than 6 months of age. Successful early intervention programs (1) are family centered, (2) provide families with unbiased information on all options regarding approaches to communication, (3) monitor development at 6-month intervals with norm-referenced instruments, (4) include individuals who are deaf or hard of hearing, (5) provide services in a natural environment in the home or in the center, (6) offer high-quality service regardless of where the family lives, (7) obtain informed consent, (8) are sensitive to cultural and language differences and provide accommodations as needed, and (9) conduct annual surveys of parent satisfaction.

Intervention for Special Populations of Infants and Young Children

Developmental monitoring should also occur at regular 6-month intervals for special populations of children with hearing loss, including those with minimal and mild bilateral hearing loss,[98] unilateral hearing loss,[99,100] and neural hearing loss,[22] because these children are at risk of having speech and language delay. Research findings indicate that approximately one third of children with permanent unilateral loss experience significant language and academic delays.[99–101]

Audiological Habilitation

Most infants and children with bilateral hearing loss and many with unilateral hearing loss benefit from some form of personal amplification device.[32] If the family chooses personal amplification for its infant, hearing-aid selection and fitting should occur within 1 month of initial confirmation of hearing loss even when additional audiological assessment is ongoing. Audiological habilitation services should be provided by an audiologist who is experienced with these procedures. Delay between confirmation of the hearing loss and fitting of an amplification device should be minimized.[51,102]

Hearing-aid fitting proceeds optimally when the results of physiologic audiological assessment including diagnostic ABR, OAE, and tympanometry and medical examination are in accord. For infants who are below a developmental age of 6 months, hearing-aid selection will be based on physiologic measures alone. Behavioral threshold assessment with visual reinforcement audiometry should be obtained as soon as possible to cross-check and augment physiologic findings (see www.audiology.org).

The goal of amplification-device fitting is to provide the infant with maximum access to all of the acoustic features of speech within an intensity range that is safe and comfortable. That is, amplified speech should be comfortably above the infant's sensory threshold but below the level of discomfort across the speech frequency range for both ears. To accomplish this in infants, amplification-device selection, fitting, and verification should be based on a prescriptive procedure that incorporates individual real-ear measures that account for each infant's ear-canal acoustics and hearing loss.[32] Validation of the benefits of amplification, particularly for speech perception, should be examined in the clinical setting as well as in the child's typical listening environments. Complementary or alternative technology, such as frequency modulation (FM) systems or cochlear implants, may be recommended as the primary and/or secondary listening device depending on the degree of the infant's hearing loss, the goals of auditory habilitation, the infant's acoustic environments, and the family's informed choices.[3] Monitoring of amplification, as well as the long-term validation of the appropriateness of the individual habilitation program, requires ongoing audiological assessment along with electroacoustic, real-ear, and functional checks of the hearing instruments. As the hearing loss becomes more specifically defined through audiological assessments and as the child's ear-canal acoustics change with growth, refinement of the individual prescriptive hearing-aid gain and output targets is necessary. Monitoring also includes periodic validation of communication, social-emotional, and cognitive development and, later, academic performance to ensure that progress is commensurate with the child's abilities. It is possible that infants and young children with measurable residual "hearing" (auditory responses) and well-fit amplification devices may fail to develop auditory skills necessary for successful spoken communication. Ongoing validation of the amplification device is accomplished through interdisciplinary evaluation and collaboration with the early intervention team and family.

Cochlear implantation should be given careful consideration for any child who seems to receive limited benefit from a trial with appropriately fitted hearing aids. According to US Food and Drug Administration guidelines, infants with profound bilateral hearing loss are candidates for cochlear implantation at 12 months of age and children with bilateral severe hearing loss are eligible at 24 months of age. The presence of developmental conditions (eg, developmental delay, autism) in addition to hearing loss should not, as a rule, preclude the consideration of cochlear implantation for an infant or child who is deaf. Benefits from hearing aids and cochlear implants in children with neural hearing loss

have also been documented. The benefit of acoustic amplification for children with neural hearing loss is variable.[28,103] Thus, a trial fitting is indicated for infants with neural hearing loss until the usefulness of the fitting can be determined. Neural hearing loss is a heterogeneous condition; the decision to continue or discontinue use of hearing aids should be made on the basis of the benefit derived from amplification. Use of cochlear implants in neural hearing loss is growing, and positive outcomes have been reported for many children.[28]

Infants and young children with unilateral hearing loss should also be assessed for appropriateness of hearing-aid fitting. Depending on the degree of residual hearing in unilateral loss, a hearing aid may or may not be indicated. Use of "contralateral routing of signals" amplification for unilateral hearing loss in children is not recommended.[104] Research is currently underway to determine how to best manage unilateral hearing loss in infants and young children.

The effect of otitis media with effusion (OME) is greater for infants with sensorineural hearing loss than for those with normal cochlear function.[73] Sensory or permanent conductive hearing loss is compounded by additional transient conductive hearing loss associated with OME. OME further reduces access to auditory cues necessary for the development of spoken English. OME also negatively affects the prescriptive targets of the hearing-aid fitting, decreasing auditory awareness and requiring adjustment of the amplification characteristics. Prompt referral to either the primary care physician or an otolaryngologist for treatment of persistent OME is indicated in infants with sensorineural hearing loss.[105] Definitive resolution of OME should never delay the fitting of an amplification device.[73,106]

Medical and Surgical Intervention

Medical intervention is the process by which a physician provides medical diagnosis and direction for medical and/or surgical treatment options for hearing loss and/or related medical disorder(s) associated with hearing loss. Treatment varies from the removal of cerumen and the treatment of OME to long-term plans for reconstructive surgery and assessment of candidacy for cochlear implants. If necessary, surgical treatment of malformation of the outer and middle ears, including bone-anchored hearing aids, should be considered in the intervention plan for infants with permanent conductive or mixed hearing loss when they reach an appropriate age.

Communication Assessment and Intervention

Language is acquired with greater ease during certain sensitive periods of infant and toddler development.[107–109] The process of language acquisition includes learning the precursors of language, such as the rules that pertain to selective attention and turn taking.[20,110,111] Cognitive, social, and emotional development are influenced by the acquisition of language. Development in these areas is synergistic. A complete language evaluation should be performed at regular intervals for infants and toddlers with hearing loss. The evaluation should include an assessment of oral, manual, and/or visual mechanisms as well as cognitive abilities.

A primary focus of language intervention is to support families in fostering the communication abilities of their infants and toddlers who are deaf or hard of hearing.[20] Spoken- and/or sign-language development should be commensurate with the child's age and cognitive abilities and should include acquisition of phonologic (for spoken language), visual/spatial/motor (for signed language), morphologic, semantic, syntactic, and pragmatic skills, depending on the family's preferred mode of communication.

Early intervention professionals should follow family-centered principles to assist in developing communicative competence of infants and toddlers who are deaf or hard of hearing.[112–114] Families should be provided with information specific to language development and access to peer and language models as well as family-involved activities that facilitate language development of children with normal hearing and children who are hard of hearing or deaf.[115,116] Depending on family choices, families should be offered access to children and adults with hearing loss who are appropriate and competent language models. Information on spoken language and signed language, such as American Sign Language[117] and cued speech, should be provided.

Continued Surveillance, Screening, and Referral of Infants and Toddlers

Appendix 2 presents 11 risk indicators that are associated with either congenital or delayed-onset hearing loss. A single list of risk indicators is presented in the current JCIH statement, because there is significant overlap among those indicators associated with congenital/neonatal hearing loss and those associated with delayed-onset/acquired or progressive hearing loss. Heightened surveillance of all infants with risk indicators, therefore, is recommended. There is a significant change in the definition of risk-indicator 3, which has been modified from NICU stay more than 48 hours to NICU stay more than 5 days. Consistent with 2000 JCIH position statement,[3] the 2007 position statement recommends use of risk indicators for hearing loss for 3 purposes. Historically, the first use of risk indicators is for the identification of infants who should receive audiological evaluation but who live in geographic locations (eg, developing nations, remote areas) where universal hearing screening is not yet available.‡ This use has become less common as a result of the expansion of

‡Refs 3, 19, 21, 24, 25, 64, and 118–124.

UNHS. The second purpose of risk-indicator identification is to help identify infants who pass the neonatal screening but are at risk of developing delayed-onset hearing loss and, therefore, should receive ongoing medical, speech and language, and audiological surveillance. Third, the risk indicators are used to identify infants who may have passed neonatal screening but have mild forms of permanent hearing loss.[25]

Because some important indicators, such as family history of hearing loss, may not be determined during the course of UNHS,[14,72] the presence of all risk indicators for acquired hearing loss should be determined in the medical home during early well-infant visits. Risk indicators that are marked with a section symbol in Appendix 2 are of greater concern for delayed-onset hearing loss. Early and more frequent assessment may be indicated for children with CMV infection,[118,125,126] syndromes associated with progressive hearing loss,[72] neurodegenerative disorders,[72] trauma,[127–129] or culture-positive postnatal infections associated with sensorineural hearing loss[130,131]; for children who have received ECMO[64] or chemotherapy[132]; and when there is caregiver concern or a family history of hearing loss.[16]

For all infants with and without risk indicators for hearing loss, developmental milestones, hearing skills, and parent concerns about hearing, speech, and language skills should be monitored during routine medical care consistent with the AAP periodicity schedule.

The JCIH has determined that the previously recommended approach to follow-up of infants with risk indicators for hearing loss only addressed children with identifiable risk indicators and failed to consider the possibility of delayed-onset hearing loss in children without identifiable risk indicators. In addition, concerns were raised about feasibility and cost associated with the 2000 JCIH recommendation for audiological monitoring of all infants with risk indicators at 6-month intervals. Because approximately 400 000 infants are cared for annually in NICUs in the United States, and the 2000 JCIH recommendation included audiology assessments at 6-month intervals from 6 months to 36 months of age for all infants admitted to an NICU for more than 48 hours, an unreasonable burden was placed on both providers of audiology services and families. In addition, there was no provision for identification of delayed-onset hearing loss in infants without an identifiable risk indicator. Data from 2005 for 12 388 infants discharged from NICUs in the National Perinatal Information Network indicated that 52% of infants were discharged within the first 5 days of life, and these infants were significantly less likely to have an identified risk indicator for hearing loss other than NICU stay. Therefore, the 2007 JCIH recommends an alternative, more inclusive strategy of surveillance of all children within the medical home based on the pediatric periodicity schedule. This protocol will permit the detection of children with either missed neonatal or delayed-onset hearing loss irrespective of the presence or absence of a high-risk indicator.

The JCIH recognizes that an optimal surveillance and screening program within the medical home would include the following:

- At each visit, consistent with the AAP periodicity schedule, infants should be monitored for auditory skills, middle-ear status, and developmental milestones (surveillance). Concerns elicited during surveillance should be followed by administration of a validated global screening tool.[133] A validated global screening tool is administered to all infants at 9, 18, and 24 to 30 months or, if there is physician or parental concern about hearing or language, sooner.[133]
- If an infant does not pass the speech-language portion of the global screening in the medical home or if there is physician or caregiver concern about hearing or spoken-language development, the child should be referred immediately for further evaluation by an audiologist and a speech-language pathologist for a speech and language evaluation with validated tools.[133]
- Once hearing loss is diagnosed in an infant, siblings who are at increased risk of having hearing loss should be referred for audiological evaluation.[14,75,134,135]
- All infants with a risk indicator for hearing loss (Appendix 2), regardless of surveillance findings, should be referred for an audiological assessment at least once by 24 to 30 months of age. Children with risk indicators that are highly associated with delayed-onset hearing loss, such as having received ECMO or having CMV infection, should have more frequent audiological assessments.
- All infants for whom the family has significant concerns regarding hearing or communication should be promptly referred for an audiological and speech-language assessment.
- A careful assessment of middle-ear status (using pneumatic otoscopy and/or tympanometry) should be completed at all well-child visits, and children with persistent middle-ear effusion that last for 3 months or longer should be referred for otologic evaluation.[136]

Protecting the Rights of Infants and Families

Each agency or institution involved in the EHDI process shares responsibility for protecting infant and family rights in all aspects of UNHS, including access to information including potential benefits and risks in the family's native language, input into decision-making, and confidentiality.[77] Families should receive information about childhood hearing loss in easily understood language. Families have the right to accept or decline hearing screening or any follow-up care for their newborn

infant within the statutory regulations, just as they have for any other screening or evaluation procedures or intervention.

EHDI data merit the same level of confidentiality and security afforded all other health care and education information in practice and law. The infant's family has the right to confidentiality of the screening and follow-up assessments and the acceptance or rejection of suggested intervention(s). In compliance with federal and state laws, mechanisms should be established that ensure parental release and approval of all communications regarding the infant's test results, including those to the infant's medical home and early intervention–coordinating agency and programs. The Health Insurance Portability and Accountability Act (Pub L No. 104-191 [1996]) regulations permit the sharing of health information among health care professionals.

Information Infrastructure

In its 2000 position statement,[3] the JCIH recommended development of uniform state registries and national information databases that incorporate standardized methodology, reporting, and system evaluation. EHDI information systems are to provide for the ongoing and systematic collection, analysis, and interpretation of data in the process of measuring and reporting associated program services (eg, screening, evaluation, diagnosis, and/or intervention). These systems are used to guide activities, planning, implementation, and evaluation of programs and to formulate research hypotheses.

EHDI information systems are generally authorized by legislators and implemented by public health officials. These systems vary from a simple system that collects data from a single source to electronic systems that receive data from many sources in multiple formats. The number and variety of systems will likely increase with advances in electronic data interchange and integration of data, which will also heighten the importance of patient privacy, data confidentiality, and system security. The appropriate agencies and/or officials should be consulted for any projects regarding public health surveillance.[69]

Federal and state agencies are collaborating in the standardization of data definitions to ensure the value of data sets and to prevent misleading or unreliable information. Information management is used to improve services to infants and their families; to assess the quantity and timeliness of screening, evaluation, and enrollment into intervention; and to facilitate collection of demographic data on neonatal and infant hearing loss.

The JCIH endorses the concept of a limited national database to permit documentation of the demographics of neonatal hearing loss, including prevalence and etiology across the United States. The information obtained from the information-management system should assist both the primary health care professional and the state health agency in measuring quality indicators associated with program services (eg, screening, diagnosis, and intervention). The information system should provide measurement tools to determine the degree to which each process is stable and sustainable and conforms to program benchmarks. Timely and accurate monitoring of relevant quality measures is essential.

Since 1999, the CDC and the Directors of Speech and Hearing Programs in State Health and Welfare Agencies (DSHPSHWA) have collected annual aggregate EHDI program data needed to address the national EHDI goals. In 1999, a total of 22 states provided data for the DSHPSHWA survey. Participation had increased to 48 states, 1 territory, and the District of Columbia in 2003. However, many programs have been unable to respond to all the questions on the survey because of lack of a statewide comprehensive data-management and reporting system.

The Government Performance and Results Act (GPRA) of 1993 (Pub L No. 103-62) requires that federal programs establish measurable goals approved by the US Office of Management and Budget (OMB) that can be reported as part of the budgetary process, thus linking future funding decisions with performance. The HRSA has modified its reporting requirements for all grant programs. The GPRA measures that must be reported to the OMB by the MCHB annually for the EHDI program are:

- the number of infants screened for hearing loss before discharge from the hospital;
- the number of infants with confirmed hearing loss at no later than 3 months of age;
- the number of infants enrolled in a program of early intervention at no later than 6 months of age;
- the number of infants with confirmed or suspected hearing loss referred to an ongoing source of comprehensive health care (ie, medical home); and
- the number of children with nonsyndromic hearing loss who have developmentally appropriate language and communication skills at school entry.

One GPRA measure that must be reported to the OMB by the CDC annually for the EHDI program is the percentage of newborn infants with a positive screening result for hearing loss who are subsequently lost to follow-up.

EHDI programs have made tremendous gains in their ability to collect, analyze, and interpret data in the process of measuring and reporting associated program services. However, only a limited number of EHDI programs are currently able to accurately report the number of infants screened, evaluated, and enrolled in intervention, the age of time-related objectives (eg, screening by 1 month of age), and the severity or laterality of hearing loss. This is complicated by the lack of data standards and

by privacy issues within the regulations of the Family Educational Rights and Privacy Act of 1974 (Pub L No. 93-380).

Given the current lack of standardized and readily accessible sources of data, the CDC EHDI program, in collaboration with the DSHPSHWA, developed a revised survey to obtain annual EHDI data from states and territories in a consistent manner to assess progress toward meeting the national EHDI goals and the *Healthy People 2010* objectives. In October 2006, the OMB, which is responsible for reviewing all government surveys, approved the new EHDI hearing screening and follow-up survey. To facilitate this effort, the CDC EHDI Data Committee is establishing the minimum data elements and definitions needed for information systems to be used to assess progress toward the national EHDI goals.

The JCIH encourages the CDC and HRSA to continue their efforts to identify barriers and explore possible solutions with EHDI programs to ensure that children in each state who seek hearing-related services in states other than where they reside receive all recommended screening and follow-up services. EHDI systems should also be designed to promote the sharing of data regarding early hearing loss through integration and/or linkage with other child health information systems. The CDC currently provides funds to integrate the EHDI system with other state/territorial screening, tracking, and surveillance programs that identify children with special health care needs. Grantees of the MCHB are encouraged to link hearing-screening data with such child health data sets as electronic birth certificates, vital statistics, birth defects registries, metabolic or newborn dried "blood-spot" screenings, immunization registries, and others.

To promote the best use of public health resources, EHDI information systems should be evaluated periodically, and such evaluations should include recommendations for improving quality, efficiency, and usefulness. The appropriate evaluation of public health surveillance systems becomes paramount as these systems adapt to revise case definitions, address new health-related events, adopt new information technology, ensure data confidentiality, and assess system security.[69]

Currently, federal sources of systems support include Title V block grants to states for maternal and child health care services, Title XIX (Medicaid) federal and state funds for eligible children, and competitive US Department of Education personnel preparation and research grants. The NIDCD provides grants for research related to early identification and intervention for children who are deaf or hard of hearing.[137]

Universities should assume responsibility for special-track, interdisciplinary, professional education programs for early intervention for infants and children with hearing loss. Universities should also provide training in family systems, the grieving process, cultural diversity, auditory skill development, and deaf culture. There is a critical need for in-service and preservice training of professionals related to EHDI programs, which is particularly acute for audiologists and early interventionists with expertise in hearing loss. This training will require increased and sustained funding for personnel preparation.

Benchmarks and Quality Indicators

The JCIH supports the concept of regular measurements of performance and recommends routine monitoring of these measures for interprogram comparison and continuous quality improvement. Performance benchmarks represent a consensus of expert opinion in the field of newborn hearing screening and intervention. The benchmarks are the minimal requirements that should be attained by high-quality EHDI programs. Frequent measures of quality permit prompt recognition and correction of any unstable component of the EHDI process.[138]

Quality Indicators for Screening

- Percentage of all newborn infants who complete screening by 1 month of age; the recommended benchmark is more than 95% (age correction for preterm infants is acceptable).
- Percentage of all newborn infants who fail initial screening and fail any subsequent rescreening before comprehensive audiological evaluation; the recommended benchmark is less than 4%.

Quality Indicators for Confirmation of Hearing Loss

- Of infants who fail initial screening and any subsequent rescreening, the percentage who complete a comprehensive audiological evaluation by 3 months of age; the recommended benchmark is 90%.
- For families who elect amplification, the percentage of infants with confirmed bilateral hearing loss who receive amplification devices within 1 month of confirmation of hearing loss; the recommended benchmark is 95%.

Quality Indicators for Early Intervention

- For infants with confirmed hearing loss who qualify for Part C services, the percentage for whom parents have signed an IFSP by no later than 6 months of age; the recommended benchmark is 90%.
- For children with acquired or late-identified hearing loss, the percentage for whom parents have signed an IFSP within 45 days of the diagnosis; the recommended benchmark is 95%.
- The percentage of infants with confirmed hearing loss who receive the first developmental assessment with

standardized assessment protocols (not criterion reference checklists) for language, speech, and nonverbal cognitive development by no later than 12 months of age; the recommended benchmark is 90%.

CURRENT CHALLENGES, OPPORTUNITIES, AND FUTURE DIRECTIONS

Despite the tremendous progress made since 2000, there are challenges to the success of the EHDI system.

Challenges

All of the following listed challenges are considered important for the future development of successful EHDI systems:

- Too many children are lost between the failed screening and the rescreening and between the failed rescreening and the diagnostic evaluation.
- There is a shortage of professionals with skills and expertise in both pediatrics and hearing loss, including audiologists, deaf educators, speech-language pathologists, early intervention professionals, and physicians.
- There is often a lack of timely referral for diagnosis of, and intervention for, suspected hearing loss in children.
- Consistent and stable state and federal funding is needed for program sustainability.
- When compared with services provided for adults, pediatric services in all specialties are poorly reimbursed.
- Access to uniform Part C services is inadequate among states and within states.
- There is a lack of integrated state data-management and -tracking systems.
- Demographics and cultural diversity are changing rapidly.
- Funding for hearing aids, loaner programs, cochlear implants, and FM systems is needed.
- There is a lack of specialized services for children with multiple disabilities and hearing loss.
- Children may not qualify for services (state Part C guidelines) before demonstrating language delays (prevention model versus deficit model).
- Children may not qualify for assistive technology (prevention model versus deficit model).
- There is a lack of in-service education for key professionals.
- There are regulatory barriers to sharing information among providers and among states.
- No national standards exist for the calibration of OAE or ABR instrumentation, and there is a lack of uniform performance standards.

Opportunities for System Development and Research

- Establish programs to ensure the development of communication for infants and children with all degrees and types of hearing loss, allowing them access to all educational, social, and vocational opportunities throughout their life span.
- Develop improved, rapid, reliable screening technology designed to differentiate specific types of hearing loss.
- Develop and validate screening technologies for identifying minimal hearing loss.
- Develop state data-management systems with the capacity for the accurate determination of the prevalence for delayed-onset or progressive hearing loss.
- Develop state data-tracking systems to follow infants with suspected and confirmed hearing loss through individual state EHDI programs.
- Track the certification credentials of the service providers for children with confirmed hearing loss who are receiving Part C early intervention services and early childhood special education.
- Track genetic, environmental, and pharmacologic factors that contribute to hearing loss, thus allowing for tailored prevention and intervention strategies.
- Continue to refine electrophysiologic diagnostic techniques, algorithms, and equipment to enable frequency-specific threshold assessment for use with very young infants.
- Continue to refine techniques to improve the selection and fitting of appropriate amplification devices in infants and young children.
- Conduct translational research pertaining to young children with hearing loss, in particular, genetic, diagnostic, and outcomes studies.
- Initiate prospective population-based studies to determine the prevalence and natural history of auditory neural conduction disorders.
- Conduct efficacy studies to determine appropriate early intervention strategies for infants and children with all degrees and types of hearing loss.
- Conduct additional studies on the efficacy of intervention for infants and children who receive cochlear implants at younger than 2 years.
- Conduct additional studies on the efficacy of hearing-aid use in infants and children younger than 2 years.

- Conduct additional studies of the auditory development of children who have appropriate amplification devices in early life.
- Expand programs within health, social service, and education agencies associated with early intervention and Head Start programs to accommodate the needs of the increasing numbers of early-identified children.
- Adapt education systems to capitalize on the abilities of children with hearing loss who have benefited from early identification and intervention.
- Develop genetic and medical procedures that will determine more rapidly the etiology of hearing loss.
- Ensure transition from Part C (early intervention) to Part B (education) services in ways that encourage family participation and ensure minimal disruption of child and family services.
- Study the effects of parents' participation in all aspects of early intervention.
- Test the utility of a limited national data set and develop nationally accepted indicators of EHDI system performance.
- Encourage the identification and development of centers of expertise in which specialized care is provided in collaboration with local service providers.
- Obtain the perspectives of individuals who are deaf or hard of hearing in developing policies regarding medical and genetic testing and counseling for families who carry genes associated with hearing loss.[139]

CONCLUSIONS

Since the 2000 JCIH statement, tremendous and rapid progress has been made in the development of EHDI systems as a major public health initiative. The percentage of infants screened annually in the United States has increased from 38% to 95%. The collaboration at all levels of professional organizations, federal and state government, hospitals, medical homes, and families has contributed to this remarkable success. New research initiatives to develop more sophisticated screening and diagnostic technology, improved digital hearing-aid and FM technologies, speech-processing strategies in cochlear implants, and early intervention strategies continue. Major technological breakthroughs have been made in facilitating the definitive diagnosis of both genetic and nongenetic etiologies of hearing loss. In addition, outcomes studies to assess the long-term outcomes of special populations, including infants and children with mild and unilateral hearing loss, neural hearing loss, and severe or profound hearing loss managed with cochlear implants, have been providing information on the individual and societal impact and the factors that contribute to an optimized outcome. It is apparent, however, that there are still serious challenges to be overcome and system barriers to be conquered to achieve optimal EHDI systems in all states in the next 5 years. Follow-up rates remain poor in many states, and funding for amplification in children is inadequate. Funding to support outcome studies is necessary to guide intervention and to determine factors other than hearing loss that affect child development. The ultimate goal, to optimize communication, social, academic, and vocational outcomes for each child with permanent hearing loss, must remain paramount.

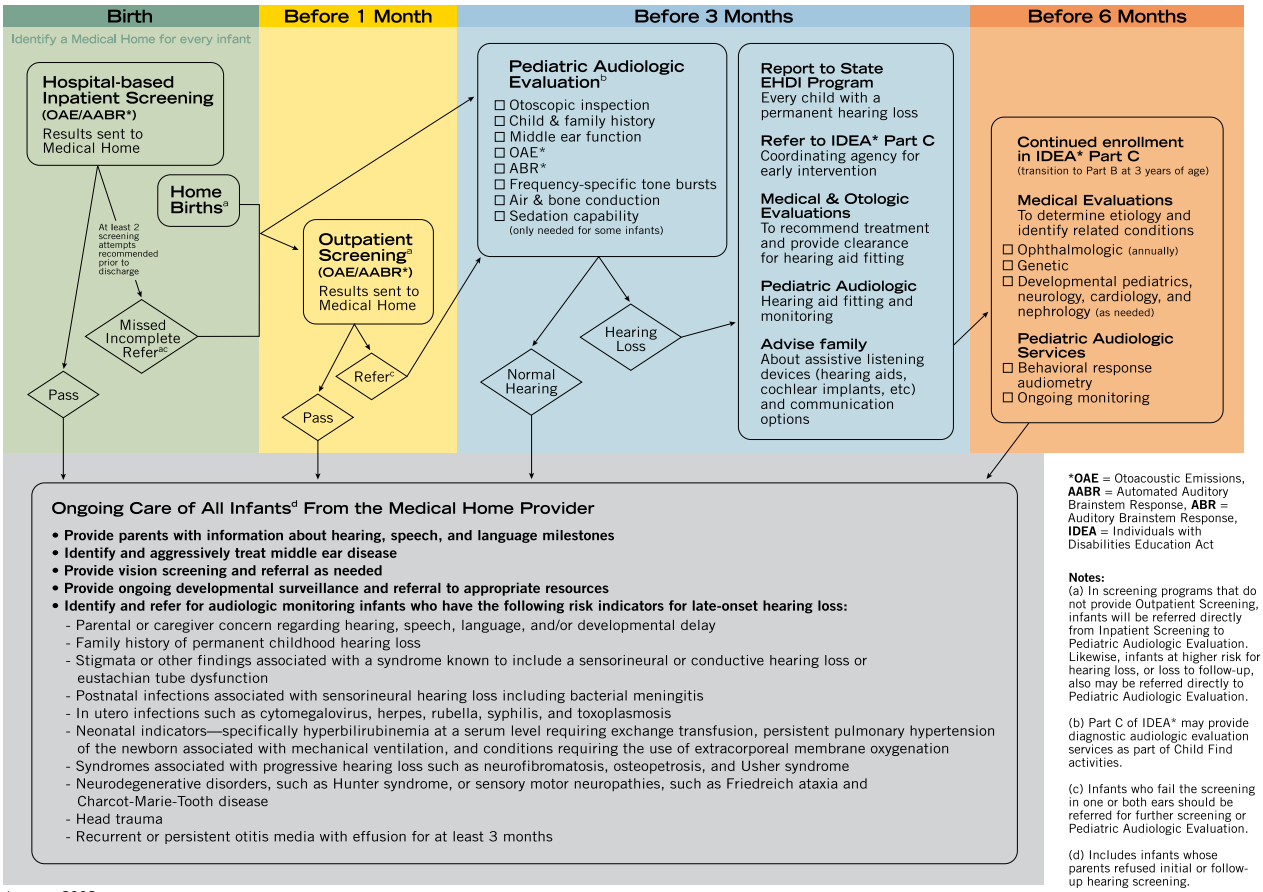
Universal Newborn Hearing Screening, Diagnosis, and Intervention

Guidelines for Pediatric Medical Home Providers



January 2003

APPENDIX 2: RISK INDICATORS ASSOCIATED WITH PERMANENT CONGENITAL, DELAYED-ONSET, OR PROGRESSIVE HEARING LOSS IN CHILDHOOD

Risk indicators that are marked with a "§" are of greater concern for delayed-onset hearing loss.

1. Caregiver concern§ regarding hearing, speech, language, or developmental delay.[62]
2. Family history§ of permanent childhood hearing loss.[24,140]
3. Neonatal intensive care of more than 5 days or any of the following regardless of length of stay: ECMO,§ assisted ventilation, exposure to ototoxic medications (gentimycin and tobramycin) or loop diuretics (furosemide/Lasix), and hyperbilirubinemia that requires exchange transfusion.[64,131]
4. In utero infections, such as CMV,§ herpes, rubella, syphilis, and toxoplasmosis.[64–67,125,126]
5. Craniofacial anomalies, including those that involve the pinna, ear canal, ear tags, ear pits, and temporal bone anomalies.[24]
6. Physical findings, such as white forelock, that are associated with a syndrome known to include a sensorineural or permanent conductive hearing loss.[24]
7. Syndromes associated with hearing loss or progressive or late-onset hearing loss,§ such as neurofibromatosis, osteopetrosis, and Usher syndrome[131]; other frequently identified syndromes include Waardenburg, Alport, Pendred, and Jervell and Lange-Nielson.[72]
8. Neurodegenerative disorders,§ such as Hunter syndrome, or sensory motor neuropathies, such as Friedreich ataxia and Charcot-Marie-Tooth syndrome.[131]
9. Culture-positive postnatal infections associated with sensorineural hearing loss,§ including confirmed bacterial and viral (especially herpes viruses and varicella) meningitis.[130,131,141]
10. Head trauma, especially basal skull/temporal bone fracture§ that requires hospitalization.[127–129]
11. Chemotherapy.§[132]
