16. Wheeled cot (conforming to national standard at the time of manufacture)
17. Folding stretcher
18. Stair chair or carry chair
19. Patient care charts/forms
20. Lubricating jelly (water soluble)

H. Infection Control*

1. Eye protection (full peripheral glasses or goggles, face shield)
2. Face protection (for example, surgical masks per applicable local or state guidance)
3. Gloves, nonsterile (must meet 1999 National Fire Protection Association requirements, which can be found at www.nfpa.org)
4. Coveralls or gowns
5. Shoe covers
6. Waterless hand cleanser, commercial antimicrobial (towelette, spray, liquid)
7. Disinfectant solution for cleaning equipment
8. Standard sharps containers, fixed and portable
9. Disposable trash bags for disposing of biohazardous waste
10. Respiratory protection (for example, N95 or N100 mask—per applicable local or state guidance)

*Latex-free equipment should be available.

I. Injury-Prevention Equipment

1. All individuals in an ambulance need to be restrained (there is currently no national standard for transport of uninjured children)
2. Protective helmet
3. Fire extinguisher
4. Hazardous material reference guide
5. Traffic-signaling devices (reflective material triangles or other reflective, nonigniting devices)
6. Reflective safety wear for each crew member (must meet or exceed American National Standards Institute/International Safety Equipment Association performance class II or III if working within the right of way of any federal-aid highway; visit www.reflectivevest.com/federalhighwayruling.html for more information)

REQUIRED EQUIPMENT: ALS AMBULANCES

For emergency medical technician-paramedic services, include all of the required equipment listed for the basic-level provider, plus the following additional equipment and supplies. For emergency medical technician–intermediate services (and other nonparamedic advanced levels), include all of the equipment for the basic-level

provider and selected equipment and supplies from the following list, on the basis of local need and consideration of prehospital characteristics and budget.

A. Airway and Ventilation Equipment

1. Laryngoscope handle with extra batteries and bulbs
2. Laryngoscope blades, sizes 0–4, straight (Miller); sizes 2–4, curved, (MacIntosh)
3. Endotracheal tubes, sizes 2.5–5.5 mm uncuffed and 6–8 mm cuffed (2 each), other sizes optional
4. Meconium aspirator adaptor
5. 10-mL non-Luerlock syringes
6. Stylettes for endotracheal tubes, adult and pediatric
7. Magill (Rovenstein) forceps, adult and pediatric
8. Lubricating jelly (water soluble)
9. End-tidal CO_2–detection capability
   - Colorimetric (adult and pediatric) or quantitative capnometry

B. Vascular Access

1. Crystalloid solutions, such as Ringer's lactate or normal saline solution (1000-mL bags × 4); fluid must be in bags, not bottles; type of fluid may vary depending on state and local requirements
2. Antiseptic solution (alcohol wipes and povidone-iodine wipes preferred)
3. Intravenous-fluid pole or roof hook
4. Intravenous catheters, 14–24 gauge
5. Intraosseous needles or devices appropriate for children and adults
6. Venous tourniquet, rubber bands
7. Syringes of various sizes, including tuberculin
8. Needles, various sizes (1 at least 1½ in for intramuscular injections)
9. Intravenous administration sets (microdrip and macrodrip)
10. Intravenous arm boards, adult and pediatric

C. Cardiac

1. Portable, battery-operated monitor/defibrillator
   - With tape write-out/recorder, defibrillator pads, quick-look paddles or electrode, or hands-free patches, ECG leads, adult and pediatric chest attachment electrodes, adult and pediatric paddles
2. Transcutaneous cardiac pacemaker, including pediatric pads and cables
   - Either stand-alone unit or integrated into monitor/defibrillator

D. Other Advanced Equipment

1. Nebulizer
2. Glucometer or blood glucose measuring device
   - With reagent strips
3. Large-bore needle (should be at least 3.25 in long for needle chest decompression in large adults)

E. Medications (Preloaded Syringes When Available)

Medications used on advanced-level ambulances should be compatible with current guidelines as published by the American Heart Association's Committee on Emergency Cardiovascular Care, as reflected in the Advanced Cardiac Life Support and Pediatric Advanced Life Support courses, or other such organizations and publications (ACEP, ACS, NAEMSP, and so on). Medications may vary depending on state requirements. Drug dosing in children should use processes that minimize the need for calculations, preferably a length-based system. In general, medications may include:

- Cardiovascular medication such as 1:10 000 epinephrine, atropine, antidysrhythmic agents (eg, adenosine and amiodarone), calcium-channel blockers, β blockers, nitroglycerin tablets, aspirin, vasopressor for infusion
- Cardiopulmonary/respiratory medications such as albuterol (or other inhaled β agonist) and ipratropium bromide, 1:1000 epinephrine, furosemide
- 50% dextrose solution (and sterile diluent or 25% dextrose solution for pediatrics)
- Analgesics, narcotic and nonnarcotic
- Antiepileptic medications such as diazepam or midazolam
- Sodium bicarbonate, magnesium sulfate, glucagon, naloxone hydrochloride, calcium chloride
- Bacteriostatic water and sodium chloride for injection
- Additional medications as per local medical director

OPTIONAL BASIC EQUIPMENT

This section is intended to assist EMS providers in choosing equipment that can be used to ensure delivery of quality prehospital care. Use should be based on local resources. The equipment in this section is not mandated or required.

A. Optional Equipment

1. Glucometer (per state protocol)
2. Elastic bandages
   - Nonsterile (various sizes)
3. Cellular phone
4. Infant oxygen mask
5. Infant self-inflating resuscitation bag
6. Airways

- Nasopharyngeal (12F, 14F)
- Oropharyngeal (size 00)

7. Alternative airway devices (eg, a rescue airway device such as the esophageal-tracheal double-lumen airway [ETDLA], laryngeal tube, or laryngeal mask airway [LMA]) as approved by local medical direction
8. Alternative airway devices for children (few alternative airway devices that have been approved by the Food and Drug Administration have been studied in children; those that have been studied, such as the LMA, have not been adequately evaluated in the prehospital setting)
9. Neonatal blood pressure cuff
10. Infant blood pressure cuff
11. Pediatric stethoscope
12. Infant cervical immobilization device
13. Pediatric backboard and extremity splints
14. Topical hemostatic agent
15. Appropriate chemical, biological, radiologic, nuclear, explosive personal protective equipment (CBRNE PPE), including respiratory and body protection
16. Applicable chemical antidote autoinjectors (at a minimum for crew members' protection; additional for victim treatment based on local or regional protocol; appropriate for adults and children)

B. Optional Advanced Equipment

1. Respirator
   - Volume-cycled, on/off operation, 100% oxygen, 40–50 psi pressure (child/infant capabilities)
2. Blood-sample tubes, adult and pediatric
3. Automatic blood pressure device
4. Nasogastric tubes, pediatric feeding tube sizes 5F and 8F, sump tube sizes 8F–16F
5. Pediatric laryngoscope handle
6. Size 1 curved (MacIntosh) laryngoscope blade
7. 3.5- to 5.5-mm cuffed endotracheal tubes
8. Needle cricothyrotomy capability and/or cricothyrotomy capability (surgical cricothyrotomy can be performed in older children in whom the cricothyroid membrane is easily palpable, usually by the age of 12 years)

OPTIONAL MEDICATIONS

A. Optional BLS Medications

1. Albuterol
2. EpiPens
3. Oral glucose
4. Nitroglycerin (sublingual tablet or paste)

B. Optional ALS Medications

1. Anxiolytic agents
2. Intubation adjuncts including neuromuscular blockers

INTERFACILITY TRANSPORT

Additional equipment may be needed by ALS and BLS prehospital care providers who transport patients between facilities. Transfers may be done to a lower or higher level of care, depending on the specific need. Specialty transport teams, including pediatric and neonatal teams, may include other personnel such as respiratory therapists, nurses, and physicians. Training and equipment needs may be different depending on the skills needed during transport of these patients. There are excellent resources available that provide detailed lists of equipment needed for interfacility transfer such as the American Academy of Pediatrics Guidelines for Air and Ground Transport of Neonatal and Pediatric Patients.

APPENDIX: EXTRICATION EQUIPMENT

Adequate extrication equipment must be readily available to the EMS responders but is more often found on heavy rescue vehicles than on the primary responding ambulance. In general, the devices or tools used for extrication fall into several broad categories: disassembly, spreading, cutting, pulling, protective, and patient related. The following is necessary equipment that should be available either on the primary response vehicle or on a heavy rescue vehicle:

Disassembly tools

- Wrenches (adjustable)
- Screwdrivers (flat and Phillips head)
- Pliers
- Bolt cutter
- Tin snips
- Hammer
- Spring-loaded center punch
- Axes (pry, fire)
- Bars (wrecking, crow)
- Ram (4 ton)

Spreading tools

- Hydraulic jack/spreader/cutter combination

Cutting tools

- Saws (hacksaw, fire, windshield, pruning, reciprocating)
- Air-cutting gun kit

Pulling tools/devices

- Ropes/chains
- Come-along
- Hydraulic truck jack
- Air bags

Protective devices

- Reflectors/flares
- Hard hats
- Safety goggles
- Fireproof blanket

- Leather gloves
- Jackets/coats/boots

Patient-related devices

- Stokes basket

Miscellaneous

- Shovel
- Lubricating oil
- Wood/wedges
- Generator
- Floodlights

Local extrication needs may necessitate additional equipment for water, aerial, or mountain rescue.

POLICY STATEMENT

Organizational Principles to Guide and Define the Child Health Care System and/or Improve the Health of All Children

Committee on Native American Child Health and Committee on Community Health Services

Ethical Considerations in Research With Socially Identifiable Populations

ABSTRACT. Community-based research raises ethical issues not normally encountered in research conducted in academic settings. In particular, conventional risk-benefits assessments frequently fail to recognize harms that can occur in socially identifiable populations as a result of research participation. Furthermore, many such communities require more stringent measures of beneficence that must be applied directly to the participating communities. In this statement, the American Academy of Pediatrics sets forth recommendations for minimizing harms that may result from community-based research by emphasizing community involvement in the research process.

ABBREVIATIONS. IRB, institutional review board; NARCH, Native American Research Centers for Health; IHS, Indian Health Service.

The term "community-based research" is used to describe the conduct of research in community settings (in contrast to research conducted primarily in hospitals, clinics, or institutions specifically dedicated to medical research). Within the specialty of pediatrics, the Muscatine Study examining the natural history of childhood obesity in a small Iowa town is a well-known example.[1] Generally, such projects are embraced by communities because of the perception in European cultures that scientific enterprise is likely to yield information that is potentially beneficial. However, there are communities in North America in which cultural perceptions and historical experience create a different, somewhat hostile view of Western science and research. Such communities commonly comprise persons of ethnic minorities who may be economically disadvantaged, culturally isolated, or politically underrepresented. They may include people with strong ethnic/tribal affinity living in relative geographic isolation (eg, American Indian/Alaska Native individuals living on reservations) or immigrants of common national origin living within a specific urban neighborhood. Although institutional review boards (IRBs) have developed well-recognized procedures to minimize risk to individuals who participate in research studies, collective risks to members of specific geographic, racial, religious, or ethnic communities may be overlooked. The purpose of this statement is to outline the special research-related concerns of such communities and to suggest means by which investigators working with socially identifiable communities can minimize risks and maximize benefits involved with research. The considerations discussed apply to the broad spectrum of research pursuits that may take place in such communities.

SPECIAL RISKS TO SOCIALLY IDENTIFIABLE POPULATIONS

Risks to socially identifiable populations or communities generally can be subdivided into 2 areas: external risks and intracommunity risks. Although most researchers and IRB members have some familiarity with the former, the latter are seldom understood or regarded outside the community of interest.[2]

External Risks

Harms inflicted by outsiders are the best-known collective risk to people with a shared social or cultural identity. Racism, with all its negative components, is an obvious example of this sort of external risk. However, investigators seldom appreciate that the research enterprise may have unintended harms on the ethnic, religious, and social well-being of isolated or socially identifiable communities. These unintended harms may affect economic, social, legal, and political life within such communities.

Economic Risks

The lay press and professional journals have given considerable attention to the potential for employment and insurance discrimination on the basis of genetic information uncovered in the course of genetic research studies. Theoretically, individual research participants and their communities may be placed at risk by such activities. Although few cases of genetic discrimination have been documented, it continues to be a major concern.[3] The same can be said for other kinds of community-based research. For example, documentation of a high prevalence of human immunodeficiency virus infection or domestic violence within a community could have important adverse economic effects on that community, ranging from increased insurance rates for commu-

nity members to decisions by businesses to move into or remain in that community.[4]

Social Risks

Studies that focus on community problems (eg, drug abuse, human immunodeficiency virus infection, teen pregnancy, youth violence) run the risk of stigmatizing such communities or inadvertently reinforcing common misconceptions about such communities within the dominant culture. Community members also may be harmed by the way they see themselves or one another in light of data that emphasize negative aspects of community life and neglect positive aspects of the community or culture. In each case, these harms may disproportionately affect children, whose cultural identity and self-esteem may be closely linked. Genetic studies inadvertently may limit community members in their opportunities for social interactions including marriage, adoption efforts, and child-custody claims.

Legal and Political Risks

In the United States, American Indian and Alaska Native persons share special social and political status on the basis of their descent from the people who inhabited the land before European contact. Issues of tremendous social, political, and economic complexity may be raised by research (including but not limited to genetic studies) that challenges claims of descent or status as original inhabitants of a specific region (eg, the "Kennewick Man" discovered in Washington state[5]). Thus, research findings or interpretations that might be innocuous to some communities may threaten the existence of others.

Intracommunity Risks

As noted previously, intracommunity risks may not be considered when IRBs review research involving human subjects, in part because intracommunity harms are highly localized and often not evident to those outside the community. Nonetheless, outside involvement in local communities—even seemingly beneficial interventions—can be highly disruptive to existing social relationships. Although the involvement of local community members on university IRBs, encouraged by federal regulation, may reduce the occurrence of such harms, it is unusual for communities geographically removed from university centers to have representation on university IRBs. Perhaps the most important consideration from the point of view of socially identifiable communities is the risk to cultural and moral authority that may be engendered by community members' participation in research.

Although informed consent by individuals participating in research is the standard by which many Europeans and Americans judge the ethical propriety of research activities, many societies require collective consensus and assent. Such considerations were, for example, at the heart of the establishment of the Iroquois Confederacy more than 500 years ago.[6] Collective assent is especially important when research activities or findings may affect the whole community. IRB standards and procedures that govern the protection of human subjects in scientific research are based on the rights of individuals. Research cannot be conducted without the informed consent of individuals (or in the case of children, the consent of their parents). However, in many instances of community research, there are other ethical considerations of collective consensus and assent that should be carefully considered and, where appropriate, documented. For example, the University of Washington's IRB requires documentation that appropriate letters of tribal support be presented for research projects involving American Indian/Alaska Native communities. Area offices of the Indian Health Service (IHS), which also sponsor IRBs for research conducted in their areas, maintain the same requirement.

None of these considerations should be construed to indicate that community consent may properly override the autonomy of an individual who does not wish to participate in research.

Involving community members and groups on the research team from planning, through analysis, and to dissemination of the results will help the research team recognize potential risks to the community and identify how best to avoid or minimize them.[7]

SPECIAL POTENTIAL BENEFITS TO SOCIALLY IDENTIFIABLE POPULATIONS

In addition to having to consider unique aspects of informed consent in socially recognizable communities, many indigenous populations desire a rethinking of the concept of beneficence, that is, of doing no harm while maximizing potential benefits.[8] In conventional views of research, an acceptable understanding of beneficence includes the notion that, although the research may not directly benefit study participants, it has significant potential to benefit society as a whole or to benefit some portion of the society (eg, people with a specific disease). Many indigenous populations have expressed dissatisfaction with this interpretation of beneficence and have required, instead, that research proposals contain concrete, well-defined plans for how the research findings will be used to directly benefit the community.[9] In many instances, such requirements include involvement by researchers in the community even after the data-gathering phase of the research is complete. Thus, for example, a study examining the impact of violence in a neighborhood's public schools might be considered unacceptable if the investigators proposing the study could not articulate clearly how study results might be used to ameliorate the problem.

The early and continuing involvement of community members and groups on the research team will help the team recognize potential benefits to the community and identify how best to maximize them.[7] The medical and public health literature contains numerous examples of successful research partnerships established between academic organizations and socially identifiable communities. The Kahnawake Schools Diabetes Prevention Project in a Mohawk community in Canada is an excellent example of the mutual benefits researchers and commu-

nities derive from ethically sound community-based research.[7] Successful research projects have been undertaken with community participation from the onset of the project, including writing the research proposal and grant application.[10] The establishment of community members as principal investigators in research projects was given further strength and credibility by the recently combined IHS/National Institutes of Health program for establishing Native American Research Centers for Health (NARCH). The NARCH initiative, which partners American Indian and Alaska Native tribes with academic centers and other research institutions, identifies tribes as the investigators and research institutions as partners, a direct reversal of what has been common practice until now. The National Institutes of Health-funded Excellence in Partnerships for Community Outreach, Research on Health Disparities and Training (Project EXPORT) encourages the same approach with other minority communities. The NARCH and Project EXPORT initiatives have the potential to promote the benefits of national, multisite research partnerships between academia and communities and to further the impact of community-based, socially responsible research.

In summary, the ethical conduct of research in socially identifiable communities requires application of standards not commonly used in biomedical or social sciences research. These special considerations are based on the cultural views of many such communities, their historical experience with European-dominated cultures, and in many cases, the unique political statuses of these communities. Important elements of the responsible conduct of research in and with such communities include engaging indigenous or other socially identifiable communities as partners in the research enterprise, developing common goals for researchers and community members, recognizing potential risks and identifying how best to avoid or minimize them, recognizing potential benefits and identifying how to maximize and achieve them, and using knowledge gained from the research to assist communities in need. Investigators who are meticulous in observing these standards almost invariably find that their research goals are met while they are enriched by a deeper knowledge of the unique histories and cultures of their community partners.

CONSIDERATIONS

In addition to the aforementioned points, the following concepts should be considered by researchers seeking to engage socially identifiable communities in research activities.

1. Members of the research team and, where appropriate, research sponsors should strive to assist community organizations in the designing and implementing of interventions based on their research findings. If, for example, the project has examined the prevalence of hypertension among obese adolescents in an inner-city community, researchers should be encouraged to follow their study with concrete assistance to the community in addressing this problem.
2. Efforts should be made to include persons of ethnic minorities as researchers on these teams. Given the small proportion of researchers of ethnic minorities, it is critical that mentorship opportunities be created for these individuals.
3. Researchers should offer their expertise to individuals in the community who may want to develop their own research to address questions raised by the original study.
4. Individual researchers are supported by academic institutions that also have responsibilities to communities. Institutions are strongly urged to create and maintain educational, training, and funding opportunities that facilitate the mentoring relationships necessary to enable communities to cultivate researchers, particularly those of ethnic minorities.

RECOMMENDATIONS

Several steps can be taken during the planning phase of a community-based research project to minimize the aforementioned risks.[11,12] It should be noted that these recommendations may not be applicable to every community. Communities sharing identical views as the dominant culture (eg, a project conducted in a neighborhood in suburban Boston) may not require the same cautious and painstaking approach. Thus, "community" here will refer to socially identifiable groups (not necessarily living in the same geographic region) for which there is a reasonable possibility that group ethos concerning research and/or community responsibility may differ from the dominant culture.

1. Members of the community should be consulted in the planning of the research and the definition of research objectives. Potential benefits to the community should be articulated clearly and unambiguously.[13]
2. Research participants should be considered partners, not research subjects. Responsible members of the community (eg, tribal health care leaders, planners) should have ongoing oversight of the project and be given responsibility for ensuring adherence to the original goals of the project and procedures designed to protect the community. (Research that expects to use any resources of the IHS [eg, IHS personnel, review charts, blood work] must first comply with the IHS requirement that the tribal government explicitly approve the research.)
3. Community members should be the first to be informed of study results. They should be active participants in the analysis and interpretation of data. To provide community members the opportunity to articulate their interpretation of study findings, community members also should be consulted about proper methods for publishing and disseminating the data gathered in their community.
4. If there is potential that the results could be damaging to a specific community, research investiga-

tors should keep the community anonymous when publishing and presenting the results.

5. Human research protection programs and IRBs should utilize appropriate options provided within the federal regulations (45 CFR 46) to guarantee that proper representation of community interests is part of the ethical review process. This often will require the recruitment of experts from outside of the IRB to help in the review of community-based studies. Appropriate IRB review of community-based research should also be promoted and enforced within human research protection accreditation standards.

AMERICAN ACADEMY OF PEDIATRICS

Committee on Bioethics

Ethical Issues With Genetic Testing in Pediatrics

ABSTRACT. Advances in genetic research promise great strides in the diagnosis and treatment of many childhood diseases. However, emerging genetic technology often enables testing and screening before the development of definitive treatment or preventive measures. In these circumstances, careful consideration must be given to testing and screening of children to ensure that use of this technology promotes the best interest of the child. This statement reviews considerations for the use of genetic technology for newborn screening, carrier testing, and testing for susceptibility to late-onset conditions. Recommendations are made promoting informed participation by parents for newborn screening and limited use of carrier testing and testing for late-onset conditions in the pediatric population. Additional research and education in this developing area of medicine are encouraged.

INTRODUCTION

The Human Genome Project formally began in 1990 with an original goal of mapping and sequencing the complete set of human genes by the year 2005. Remarkably, the sequencing of the human genome essentially was complete in early 2000. The ultimate purpose of the research is to develop more effective strategies for disease prevention and treatment. However, the first practical applications of this knowledge will be expanded possibilities for genetic testing for individual evaluation and population screening. Although pediatricians are familiar with genetic testing for specific indications and rare conditions, new generations of genetic technology will detect persons at increased risk for common conditions, such as cancer, hypertension, and Alzheimer disease.[1] Although genetic research offers great promise for improvements in child health, the use of new genetic tests in children must be considered carefully. In the absence of clearly beneficial treatments or effective preventive strategies, genetic testing of children and adolescents may not be justified. This statement reviews the potential uses of genetic testing in children and offers guidance for pediatricians on the appropriate applications of this technology. This statement draws on analyses of ethical issues in genetic testing by a number of influential bodies, including the National Academy of Sciences,[2] the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research,[3] the Institute of Medicine (IOM),[4] and the Working Group on Genetic Testing for the National Human Genome Research Institute.[5]

Medical testing is familiar to physicians in the routine practice of medicine. A legitimate question may be raised whether genetic testing is sufficiently different from other forms of testing to justify additional scrutiny. Several aspects of genetic testing should be considered in this regard.[6] First, genetic information is familial. Thus, the test results of one person have direct health implications for others who are genetically related. Second, the risks of genetic testing may not be obvious because the primary risks are psychological, social, and financial. The psychosocial risks include guilt, anxiety, impaired self-esteem, social stigma, and insurance and employment discrimination. Third, genetic information often has limited predictive power. Our genes interact with our environments in complex ways, often making predictions impossible about whether disease will develop or the severity of its manifestations. Finally, many genetic conditions remain difficult to treat or prevent, meaning the value of genetic information may be limited for altering the clinical care of the person. Genetic testing is not unique in any of these respects, but the cumulative complexity of these issues requires that genetic testing receive careful consideration. Given these concerns, detailed counseling, informed consent, and confidentiality should be key aspects of the genetic testing process, particularly when the benefits are uncertain. Because young children are unable to discern the value of genetic information for their own lives, particular care must be exercised by parents and pediatricians when making decisions about genetic testing for children.

The American Academy of Pediatrics (AAP) believes pediatricians can best help children and parents by working to promote child and parent understanding of relevant information, ensure privacy and confidentiality for test results to the extent permissible by law, and provide or refer children for counseling and testing only when it is in the best interest of the child or when the legitimate interests of the parents or family can be promoted without anticipated harm to the child. This statement addresses 3 potentially problematic applications of genetic testing and screening: newborn screening, carrier testing and screening, and predictive testing for late-onset disorders.

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

PEDIATRICS (ISSN 0031 4005).

NEWBORN SCREENING

The purpose of newborn screening for genetic disorders is to limit the morbidity and mortality attributable to selected inherited diseases. Because newborn screening programs are organized through state governments, substantial variability in testing exists between states.[7] As new genetic tests become available, extensive consideration will be given to the introduction of these tests into newborn screening programs. Consistent with earlier guidelines on the issue, the IOM report[4] recommends that 3 principles govern the introduction of new tests and the maintenance of established tests: 1) identification of the genetic condition must provide a clear benefit to the child; 2) a system must be in place to confirm the diagnosis; and 3) treatment and follow-up must be available for affected newborns.

The challenges of introducing new tests have been brought into focus by discussions about the appropriateness of newborn screening for cystic fibrosis (CF). In 1983, the Task Force on Neonatal Screening of the AAP advised against the introduction of state programs until the validity of screening tests and the relative benefits and risks of newborn screening for CF had been evaluated.[8] A key question has been whether detection of CF in the neonatal period improves the long-term pulmonary or nutritional status of affected children. The effects of false-positive results on parental anxiety also are a serious concern.[9–13] In addition, a small percentage of parents may have a persistent misunderstanding of their child's risk for developing CF after a false-positive newborn screen, and false-positive results may influence parental reproductive decisions.[14] Thus, the justification for newborn screening for CF has been a subject for debate, although several states, including Wyoming and Colorado, have initiated programs. A long-term study in Wisconsin demonstrated nutritional benefits to early detection of CF, and reports on the effects of screening for pulmonary function are anticipated.[15] Similarly, 19 states have introduced newborn screening for congenital adrenal hyperplasia, and a number of studies are under way to evaluate the sensitivity and specificity of different approaches used by these programs[16,17] and their impact on the health of affected children.

The AAP recommends that new newborn screening tests be introduced in a carefully designed manner that facilitates evaluation of the risks and benefits of screening, including the efficacy of follow-up and treatment protocols. The Wisconsin program for evaluating CF screening was a model in this regard. Furthermore, the AAP concurs with the IOM recommendation that established programs be reviewed periodically to consider the addition, elimination, or modification of current screening modalities.[4]

A persistent ethical issue in newborn screening is whether screening should be voluntary or mandatory. Whether programs are voluntary or mandatory has significant implications for informed responses to test results and for the integration of new tests into established programs. A *voluntary* approach in this context entails an informed decision by parents about newborn screening. Wyoming and Maryland are the only 2 states that require informed consent for newborn screening, although 13 other states require that parents be informed about newborn screening before testing.[18] A *mandatory* approach in this context requires an explicit refusal of screening by parents who object to this intervention. All states except South Dakota permit parental refusal of newborn screening for religious or personal reasons.[18]

The principal ethical justification offered for mandatory screening is the claim that society's obligation to promote child welfare through early detection and treatment of selected conditions supersedes parental prerogatives to refuse this simple medical intervention.[19] An opposing argument maintains that parents traditionally have broad discretion for making health care decisions for their children. Although parents do not have the prerogative to forgo effective treatments for life-threatening conditions, they generally have the prerogative to pursue a variety of options in less threatening circumstances, including options that some medical professionals would consider unwise. Furthermore, it is argued that the great majority of parents will continue to be supportive of newborn screening when they are informed adequately of the risks and benefits.[20] With continued broad public support, approaches involving informed consent (that is, parental permission[21]) may fulfill the important goals of the programs and enhance program quality while respecting traditional parental prerogatives to be informed participants in health care decisions for their children. In a study of newborn screening in Maryland involving informed consent, the majority of women preferred that permission be asked before screening, and the informed refusal rate was only 5 per 1000 infants.[22] In the Maryland study, the consent process typically took 5 minutes or less of staff time. Additional research to develop and evaluate models of parental education and consent will be valuable.

Two potential advantages of obtaining informed consent for newborn screening include more prompt and efficient responses to positive results and an ability to incorporate experimental tests into established screening programs. Under current programs, the information provided to parents about newborn screening is often minimal. A significant source of problems in newborn screening programs is slow or uninformed responses to test results by parents and physicians.[23] If an informed consent process promotes more thorough understanding of the implications of the tests, slow or inappropriate responses to positive results may decrease. Second, advances in genetic research will offer many additional tests for consideration by newborn screening programs.[24] The relative risks and benefits of new tests will be uncertain until adequate clinical research has been conducted. In these circumstances, experimental tests should be offered on a voluntary basis with informed consent. Experimental tests could be integrated more easily in screening programs that routinely sought informed consent for newborn screening tests.

The IOM report suggests that it is appropriate for states to mandate the *offering* of "established tests

(eg, phenylketonuria, hypothyroidism) where early diagnosis leads to improved treatable outcomes."[4] The AAP Committee on Genetics concurred that state governments should mandate the *offering* of tests (although some members of the Committee expressed the opinion that testing should be mandated).[16] Consistent with the recent report of the Newborn Screening Task Force,[25] the AAP recommends that states evaluate an informed consent process for newborn screening tests to foster parental education and promote informed responses to test results. Given the established efficacy of newborn screening programs, it will be essential to demonstrate that expanded education and consent function to enhance the quality of these programs. Carefully conducted pilot programs to document benefits and costs of newborn screening and the frequency and consequences of informed refusal of newborn screening tests will be important. In addition, research to develop an efficient and effective informed consent process for newborn screening is necessary. Attention should be given to the education of women and couples about newborn screening before the immediate postpartum period. Publication and peer review of this research will be appropriate before substantial changes in state health policy on this issue to ensure that efficacy of screening programs is not impaired. Informed consent in this context need not involve a signed consent form for tests of established value, but must include basic information on the purpose of screening and the importance of prompt responses to abnormal results.

CARRIER SCREENING

Medical technology permits the identification of persons who are carriers for mutations in genes responsible for a variety of conditions, including Tay-Sachs disease, muscular dystrophy, sickle cell anemia, CF, and thalassemia major. Carrier testing and counseling of prospective parents can permit informed reproductive choices. A significant concern raised by carrier screening programs is the possibility for individual and community misunderstanding of the carrier state. Confusion about the difference between being an asymptomatic carrier for a genetic condition and being affected with the condition may lead to stigma and discrimination, as well as to adverse psychological reactions in those being screened.[26–28] An historical example is provided by the carrier screening programs for sickle cell disease in the 1970s in the United States that were not preceded by adequate broad-based education. The subsequent misunderstanding of the benign nature of being a sickle cell carrier by employers, insurance companies, government agencies, and the community being screened led to many cases of discrimination and stigmatization.[3]

To date, carrier testing or screening has not been applied extensively to children or adolescents in the United States. Theoretically, carrier testing or screening before the initiation of sexual activity would increase the reproductive choices of those found to be carriers in comparison with carrier testing during pregnancy. However, children and adolescents may be more psychologically vulnerable than adults to knowledge of carrier status, and it remains uncertain whether testing at younger ages would result in changes in future reproductive behavior. Of note, however, a report of 2 decades of carrier screening in high school students in Montreal, Quebec, suggests that many persons can effectively use the genetic information in later reproductive decisions.[29] Additional research is necessary to thoroughly evaluate these issues in the US health care system and in a variety of different cultures and ethnic communities.[30] The AAP does not support the broad use of carrier testing or screening in children or adolescents. Carrier testing for the pregnant adolescent or for the adolescent who is planning a pregnancy and who has been fully informed of the benefits and risks of carrier testing may be appropriate.

In some circumstances, carriers will be identified through newborn screening programs. For example, newborn screening for sickle cell disease will identify infants who are carriers (in addition to those who are homozygous for the disease). Reporting the infant's carrier status to parents has the theoretical advantages of informing parents that they may be at risk for bearing an affected child (if both parents are carriers) and of enabling the family to be aware of the child's future reproductive risk. However, identification of infants as carriers may lead to misinterpretation by parents and others, resulting in changes in the parent-child relationship and social discrimination. Furthermore, parents should have the opportunity to obtain or refuse their own testing for carrier status (newborn screening should not be used as a surrogate for parental testing). Finally, it remains to be determined whether newborn screening results can be used effectively years later when the person is making reproductive decisions. The AAP concurs with the IOM recommendations that newborns not be screened for the purpose of determining carrier status.[4] Carrier status results that are obtained incidentally should be conveyed to parents who have undergone previous counseling and have given consent. Newborn screening tests should be conducted with adequate parental education, including information about implications for genetically related persons.

PREDICTIVE TESTING FOR LATE-ONSET DISORDERS

Genetic technology provides the means to diagnose disorders that develop beyond infancy, including some that become manifest only in adulthood. Examples of late-onset diseases with a high degree of predictability based on genetic tests include myotonic dystrophy, hemochromatosis, polycystic kidney disease, Huntington disease, and some cancers. Furthermore, it soon may be possible to identify genetic factors that increase the probability that common disorders, such as coronary artery disease, diabetes, stroke, hypertension, Alzheimer disease, forms of colon and breast cancer, several psychiatric conditions, and some rheumatoid diseases, will develop.

For some of these conditions, knowledge of risk status may help persons reduce morbidity or risk of

mortality. In addition, members of at-risk families may benefit psychologically from learning that they are not mutation carriers or from a reduction in uncertainty if they are found to be mutation carriers. However, a reduction in morbidity or mortality as a result of genetic testing has not been demonstrated for many conditions for which predispositional testing is available.[31,32] Whether current recommendations for prevention or early detection will be effective in this high-risk population remains unclear. Furthermore, the knowledge of increased risk status may trigger adverse psychological responses and, potentially, discrimination by insurers, employers, or others. For these reasons, the rapid introduction of BRCA1/BRCA2 (which confer increased risk for breast and ovarian cancer) and HNPCC (or hereditary nonpolyposis colon cancer, which confers increased risk for colon cancer) mutation testing into clinical medicine for adults has been discouraged.[33,34] The complexities of genetic testing and the uncertain risks and benefits of the results support the use of detailed genetic counseling for predictive testing for late-onset disorders. Many adults choose not to be tested for late-onset conditions, indicating that we cannot presume that children would want or will benefit from such testing.[35,36] Further, testing in childhood inappropriately eliminates the possibility of future autonomous choice by the person and risks stigma and discrimination. Unless there is anticipated benefit to the child, pediatricians should decline requests from parents or guardians to obtain predispositional genetic testing until the child has the capacity to make the choice.[37,38]

GENETIC SERVICES

The Human Genome Project will foster the development and rapid introduction of genetic tests into clinical practice. The number of genetic counselors and geneticists is insufficient for these professionals to take primary responsibility for managing this technology.[39] As a result, primary care physicians will need to expand their knowledge of genetics and the benefits and risks of genetic testing.[40]

RECOMMENDATIONS

1. Established newborn screening tests should be reviewed and evaluated periodically to permit modification of the program or elimination of ineffective components. The introduction of new newborn screening tests should be conducted through carefully monitored research protocols.
2. Genetic tests, like most diagnostic or therapeutic endeavors for children, require a process of informed parental consent and the older child's assent. Newborn screening programs are encouraged to evaluate protocols in which informed consent from parents is obtained. The frequency of informed refusals should be monitored. Research to improve the efficiency and effectiveness of informed consent for newborn screening is warranted.
3. The AAP does not support the broad use of carrier testing or screening in children or adolescents. Additional research needs to be conducted on carrier screening in children and adolescents. The risks and benefits of carrier screening in the pediatric population should be evaluated in carefully monitored clinical trials before it is offered on a broad scale. Carrier screening for pregnant adolescents or for some adolescents considering pregnancy may be appropriate.
4. Genetic testing for adult-onset conditions generally should be deferred until adulthood or until an adolescent interested in testing has developed mature decision-making capacities. The AAP believes that genetic testing of children and adolescents to predict late-onset disorders is inappropriate when the genetic information has not been shown to reduce morbidity and mortality through interventions initiated in childhood.
5. Because genetic screening and testing may not be well understood, pediatricians need to provide parents the necessary information and counseling about the limits of genetic knowledge and treatment capabilities, the potential harm that may be done by gaining certain genetic information, including the possibilities for psychological harm, stigmatization, and discrimination, and medical conditions and disability and potential treatments and services for children with genetic conditions. Pediatricians can be assisted in managing many of the complex issues involved in genetic testing by collaboration with geneticists, genetic counselors, and prenatal care providers.
6. The AAP supports the expansion of educational opportunities in human genetics for medical students, residents, and practicing physicians and the expansion of training programs for genetic professionals.[4]

Ethics and the Care of Critically Ill Infants and Children (RE9624)

AMERICAN ACADEMY OF PEDIATRICS

Committee on Bioethics

ABSTRACT. The ability to provide life support to ill children who, not long ago, would have died despite medicine's best efforts challenges pediatricians and families to address profound moral questions. Our society has been divided about extending the life of some patients, especially newborns and older infants with severe disabilities. The American Academy of Pediatrics (AAP) supports individualized decision making about life-sustaining medical treatment for all children, regardless of age. These decisions should be jointly made by physicians and parents, unless good reasons require invoking established child protective services to contravene parental authority. At this time, resource allocation (rationing) decisions about which children should receive intensive care resources should be made clear and explicit in public policy, rather than be made at the bedside.

Since the advent of means for supporting newborns with respiratory distress, neonatal and pediatric intensive care has helped tens of thousands of children survive life-threatening illness and the rigors of major surgical intervention. For more than a decade, however, many responsible for the health care of children have debated the appropriateness of applying life-sustaining medical technology (LSMT) to all critically ill children. (The term LSMT here applies to methods of supporting life typically applied in intensive care units, such as the use of ventilators and mechanical or pharmacologic support of circulation. The term critically ill here refers to disorders requiring such LSMT. Both terms defy precise definition.) As a recent AAP policy statement[1] on forgoing LSMT notes, the value of such therapy may be uncertain, especially when first considered. Good medical practice may favor initiation of LSMT until clarification of the clinical situation and relevant ethical values can occur. Much discussion has focused on highly visible "selective nontreatment of handicapped infants"[2] and the responses of the federal government, now known colloquially as the "Baby Doe" rules.[3,4] In the last few years, clinicians and the public also have become increasingly concerned about the high costs, in terms of money, time, and psychosocial consequences, of neonatal and pediatric intensive care.

NEWBORNS AND INFANTS

Much controversy has surrounded the treatment of newborns and older infants with readily identifiable medical problems, including genetic disorders, malformations and deformations, and, to some extent, extreme prematurity and/or low birth weight. Scientific understanding and improved technology have permitted reductions in mortality for infants affected by an enlarging list of conditions. A better appreciation of what can be done to help many infants with disabilities and social considerations of fairness have led to the application of life-saving medical interventions to critically ill newborns and infants who, not long ago, physicians might not have treated vigorously. Concern that some infants, eg, those with Down syndrome and gastrointestinal obstruction, received insufficient treatment led to the federal legislation (the 1984 Child Abuse Amendments) and regulations that sought to ensure appropriate medical therapy for all disabled infants.

Looking back, the measures to prevent undue discrimination against disabled infants seem to have produced at least two unintended consequences. First, it seems that many persons in the health care and child advocacy professions, along with the general public, misunderstand the various federal and other legal requirements regarding treatment decisions for infants with critical illnesses.[5-7] Thus, misconceptions about the Baby Doe rules may have become de facto benchmarks for treatment decisions about critically ill newborns and older infants. Second, attention concentrated on saving the lives of infants, some with permanent, severe disabilities or neurodegenerative disorders, has hampered sufficient attention to the possible overuse of LSMT.

With regard to the first point, the actual language of the 1984 Child Abuse Amendments may permit more physician discretion than some realize. Although the law mandates provision of LSMT to most seriously ill infants, it does provide for exceptions in the case of permanent unconsciousness, "futile" treatment, and "virtually futile" therapy that imposes excessive burdens on the infant. Physicians, with parental agreement, may even forgo giving hydration and nutrition when they think these measures are not "appropriate." (Quoted words and phrases come directly from the law.[3])

With regard to the second point, possible overuse of LSMT, several book-length studies,[8-11] one personal account from parents,[12] and recent essays by pioneering neonatologists[13,14] have suggested that modern newborn care may, at times, constitute overtreatment. Articles for the general public have communicated the same message.[15-17] As previously noted, after the Child Abuse Amendments of 1984, two reports of a survey of neonatologists[5,6] indicated that many who specialize in the care of sick newborns believe they are legally constrained to provide LSMT to infants, even when their medical judgments and the views of the parents concur that withholding treatment is preferable.

Although many would like to have simply interpreted and easily applied substantive standards for clinical decisions about critically ill infants, medical and moral complexity make such rules imprudent. Scientific uncertainty regarding outcome continues in the neonatal intensive care unit. Some very tiny infants with documented brain insults, such as those that may occur with periventricular hemorrhage, defy expectations and survive with no apparent clinical deficits. Available evidence, however, continues to indicate that the decreased mortality brought about by neonatal intensive care has been accompanied by increased morbidity, ie, serious mental and physical limitations among survivors that impose burdens on affected children and their families.[18,19] These factors also play legitimate roles in decision making.[20,21]

A few well-publicized cases in the early 1980s led some to conclude that physicians and parents commonly denied beneficial treatment to imperiled newborns. However, no reliable evidence that decisions endangering children have been widespread exists. Most cases of lethal nontreatment seem to have involved infants with trisomy 21 and myelomeningocele.[22-24] However, by the early 1980s professional and public views about infants with Down syndrome and spina bifida had generally shifted to favor treatment.[25] This view is supported by results from a survey of pediatricians done in Massachusetts in the mid-1980s.[24]

The AAP supports parental involvement in decisions about imperiled infants from the earliest possible moment. Obstetricians and pediatricians need to inform and counsel parents about available options when prenatal diagnostic procedures identify disorders in fetuses. Women may legitimately decide about the treatment they and their fetuses receive.[26,27] Once parturition occurs, parents continue to have a vital role in decision making under the presumption that they accept responsibility for nurturing the infant and providing reasonable care.[28]

The AAP believes that parents and physicians should make reasoned decisions together about critically ill infants using the principles of informed parental permission recently articulated by the AAP.[29] Such decisions should consider the benefits and burdens of treatment alternatives. Physicians should remember that many parents want a strong role in these decisions[30] and that parents may bring values to the process that differ sharply from those of the physician. In rare instances, as required by law and sound ethical standards, it may be necessary to invoke established child protective mechanisms if parents wish to forgo LSMT, physicians disagree, and the parties cannot resolve their differences with help from subspecialists, ethics consultants, or ethics committees.

CHILDREN BEYOND INFANCY

As with infants, two basic questions arise in the care of children beyond the first year: Which values and whose authority ought to govern in medical treatment decisions about the critically ill? Published court cases indicate that parents have been permitted to exercise broad discretion when acting on their children's behalf,[31-36] even when court-appointed guardians ad litem or other counsel opposed the parental choice.[37-39] Laws in some states permit parents to execute advance directives on behalf of minors (*Choice and Dying. State laws regarding end-of-life decision making for minors.* New York, NY: Choice and Dying; September 1995:1-2).[40] In addition to according due respect to the beliefs, feelings, and needs of the family as expressed by parents, as children get older and acquire cognitive skill, experience, and emotional maturity, their individual views deserve careful consideration. Sensitive clinicians and parents acknowledged this in the professional literature as long as 20 years ago.[41]

In the realm of pediatric critical care, the North American literature provides sparse evidence of systematic approaches to limiting LSMT.[42,43] The pediatric intensive care unit, however, unlike the neonatal intensive care unit, has not been the focus of bureaucratic or political debate and action. Pediatric intensivists and their colleagues and consultants in ethics have tended to make decisions about discontinuing LSMT similar to the way clinicians, loved ones, ethicists, and the courts make such decisions for incompetent adult patients.[44,45]

RESOURCE ALLOCATION AND DECISIONS TO LIMIT LSMT

Recently, concerns about the high cost of critical care have led to attempts to manage critical care resources through the use of quantitative indicators of prognosis.[46-51] Some physicians, administrators, and planners would like to use increasingly accurate statistical predictors of outcome to exclude patients from receiving intensive care services. Indeed, population-based mathematical tools may prove helpful in evaluating the effectiveness of various interventions, in comparing outcomes of similar treatments used at different sites, and in informing parents of the probability of the outcome of treatment. Such studies, however, have an important inherent limitation--their results apply to groups of patients, not individuals. In the absence of perfect outcome prediction (100% survival or death, based on experience with large numbers of patients), statistical indicators cannot tell clinicians which particular patient will die or live (and with what residual problems). Moreover, even overwhelming odds of success or failure of treatment cannot take into account the complex values that individuals, including patients, family members, physicians, and other health care providers, bring to a treatment decision. Therefore, the AAP opposes the use of these formulas as the principal determinants of whether individual patients receive intensive care.

The controversy over the usefulness of critical care resources has been most poignantly highlighted by public debates about futile medical treatment.[52-56] In these discussions, physicians and other care givers have demonstrated concern that medical resources are being used inappropriately and that continued treatment violates deeply held beliefs about what properly constitutes professional activities. Others feel that professional objections to so-called futile treatment masks prejudices about those who are disabled, who come from disadvantaged social groups, or who are dying.

The AAP thinks that judgments about which diagnostic categories of patients should receive or be denied intensive care based on considerations of resource use are social policy deliberations and should be made after considerable public discussion, not ad hoc at the bedside.

CONCLUSIONS

Our society has reached a consensus that some critically ill infants previously denied treatment should receive advanced medical and surgical care. A large majority of physicians and other persons agree that most infants with Down syndrome with gastrointestinal obstruction and most infants with myelomeningocele should have surgery and other treatment they need.

There is less agreement, however, about how much treatment to provide other critically ill infants and children. Medical and public controversy still rages about the appropriate limits, if any, to place on the treatment of extremely low birth weight and premature infants, about infants with hypoplastic left heart syndrome,[57] about children with chromosomal abnormalities with known very limited life spans, about infants with complex congenital abnormalities, and about children in the final stages of terminal cancer or other fatal chronic disorders. Many think that laws, regulations, and government policies have unduly constrained parents and physicians from exercising reasonable judgments about whether to forgo LSMT.

A judicial and legislative consensus has developed that the values of patients, rather than those of physicians or policy makers, should determine the extent of the application of LSMT.[58] As noted, some states have empowered proxy decision makers to execute advance directives regarding LSMT on behalf of minors. Legislation and regulation about disabled infants conflict with the legal trends governing all other patients. In the absence of compelling evidence that infants require special legal protection, the AAP thinks that parents of newborns should have the same decision-making authority they have with older children.

Limited resources may require equitable limits on medical treatment. Such restrictions require careful consideration of their social, cultural, and economic consequences and deserve to be made at a public policy level, not at the bedside.

RECOMMENDATIONS

1. Decisions about critical care for newborns, infants, and children should be made similarly and with informed parental permission.
2. Physicians should recommend the provision or forgoing of critical care services based on the projected benefits and burdens of treatment, recognizing that parents may perceive and value these benefits and burdens differently from medical professionals.
3. Decisions to forgo critical care services on the grounds of resource limitations, generally speaking, are not clinical decisions, and physicians should avoid such "bedside rationing."

However, because many in the American public think that our health care system spends excessively on critical care services, society should engage in a thoroughgoing debate about the economic, cultural, religious, social, and moral consequences of imposing limits on which patients should receive intensive care.

Practice parameter: Evaluating a first nonfebrile seizure in children

Report of the Quality Standards Subcommittee of the American Academy of Neurology, the Child Neurology Society, and the American Epilepsy Society

D. Hirtz, MD; S. Ashwal, MD; A. Berg, PhD; D. Bettis, MD; C. Camfield, MD; P. Camfield, MD; P. Crumrine, MD; R. Elterman, MD; S. Schneider, MD; and S. Shinnar, MD, PhD

Article abstract—*Objective:* The Quality Standards Subcommittee of the American Academy of Neurology develops practice parameters as strategies for patient management based on analysis of evidence. For this practice parameter, the authors reviewed available evidence on evaluation of the first nonfebrile seizure in children in order to make practice recommendations based on this available evidence. *Methods:* Multiple searches revealed relevant literature and each article was reviewed, abstracted, and classified. Recommendations were based on a three-tiered scheme of classification of the evidence. *Results:* Routine EEG as part of the diagnostic evaluation was recommended; other studies such as laboratory evaluations and neuroimaging studies were recommended as based on specific clinical circumstances. *Conclusions:* Further studies are needed using large, well-characterized samples and standardized data collection instruments. Collection of data regarding appropriate timing of evaluations would be important.

NEUROLOGY 2000;55:616–623

The Quality Standards Subcommittee (QSS) of the American Academy of Neurology (AAN) seeks to develop scientifically sound, clinically relevant practice parameters for physicians for diagnostic procedures, treatment modalities, and clinical disorders. Practice parameters are strategies for patient management that might include diagnosis, symptom, treatment, or procedure evaluation. They consist of one or more specific recommendations based on the analysis of evidence.

Every year, an estimated 25,000 to 40,000 US children experience their first nonfebrile seizure, a dramatic and frightening event.[1-4] This practice parameter reviews available evidence concerning the value of diagnostic testing after a first nonfebrile seizure in a child, and provides recommendations based on this evidence. It addresses the evaluation of children age 1 month to 21 years who have experienced a first nonfebrile seizure that cannot be explained by an immediate, obvious provoking cause such as head trauma or intracranial infection. Reports concerning serum laboratory studies, CSF examination, EEG, CT, and MRI are reviewed. This parameter concerns diagnostic evaluation; a subsequent parameter will focus on treatment of the first nonfebrile seizure.

The seizure types covered by this parameter include partial (simple or complex partial, or partial with secondary generalization), generalized tonic-clonic, or tonic seizures. We are specifically not including children diagnosed with epilepsy, defined as two or more seizures without acute provocation. For this reason, myoclonic and atonic seizures are excluded because they typically are not recognized until there have been multiple occurrences. We defined the first seizure using the International League Against Epilepsy (ILAE) criteria to include multiple seizures within 24 hours with recovery of conscious-

ness between seizures.[5] Children with significant head trauma immediately preceding the seizure or those with previously diagnosed CNS infection or tumor or other known acute precipitating causes are excluded. We excluded neonatal seizures (≤28 days), first seizures lasting 30 minutes or more (status epilepticus), and febrile seizures, because these disorders are diagnostically and therapeutically different. The American Academy of Pediatrics has recently published recommendations for evaluation of children with a first simple febrile seizure.[6]

Description of process. An initial MEDLINE literature search was performed for relevant articles published from 1980 to August 1996, using the following key words: epilepsy, seizures, convulsions, magnetic resonance imaging, computed tomography, electroencephalography, blood chemical analysis, neurological examination, and diagnostic errors. Standard search procedures were used, and subheadings were applied as appropriate. In addition, the database provided by *Current Contents* was searched for the most recent 6-month period. These searches produced 279 titles of journal articles in English, and 79 in non-English languages. An updated MEDLINE search was performed in June 1997 and again in November 1998.

Titles and abstracts were reviewed for content regarding first nonfebrile seizures in children and adults. Articles from the searches were identified for review and additional articles from the references in these primary articles were included. Articles were excluded if they contained only data on adults with established epilepsy, but references were reviewed pertaining to adults with first seizures only, to both children and adults with first seizures, and to children with both new and established seizures. Two of the articles published in non-English languages met our criteria and were included. Of the articles reviewed from searches, bibliographies, and committee member suggestions, 66 met the above criteria and were included as references. The age ranges included in the studies were variable, and most pediatric studies included up to age 16 to 19 years. In most reports, results were not broken down according to subsets of age groups.

A new three-tiered scheme of classification of evidence was developed specifically to be used for evaluation of diagnostic studies (Appendix 1). This classification scheme was approved by the QSS of the AAN and differs from one that has been used for the assessment of treatment efficacy studies, which largely pertains to randomized trials.

Each of the selected articles was reviewed, abstracted, and classified by at least two reviewers. Abstracted data included patient numbers, ages and gender, timing of subject selection (prospective, retrospective, or referral), case-finding methods, exclusion criteria, seizure characteristics, neurologic abnormalities prior to or after the seizure, evaluations and results, and recommendations of the authors. Methods of data analysis were also noted.

Goals of immediate evaluation. After stabilization of the child, a physician must determine if a seizure has occurred, and if so, if it is the child's first episode. It is critical to obtain as detailed a history as possible at the time of presentation. The determination that a seizure has occurred is typically based on a detailed history provided by a reliable observer (Appendix 2). A careful history and neurologic examination may allow a diagnosis without need for further evaluation. Children can present with seizure-like symptoms that may not in fact represent actual seizures, but rather breath-holding spells, syncope, gastro–esophageal reflux, pseudoseizures (psychogenic), and other nonepileptic events. No single clinical symptom can reliably discriminate between a seizure and a nonepileptic event.[7,8] Studies have investigated whether serum prolactin levels[9,10] or creatine kinase levels[11] may help distinguish seizures from nonepileptic events, but neither of these tests is sufficiently reliable to use routinely.

The next goal of assessment is to determine the cause of the seizure. In many children, the history and physical examination alone will provide adequate information regarding probable cause of the seizure[12] or the need for other tests including neuroimaging.[13] The etiology of the seizure may necessitate prompt treatment or provide important prognostic information. Provoked seizures are the result of an acute condition such as hypoglycemia, toxic ingestion, intracranial infection, trauma, or other precipitating factors. Unprovoked seizures occur in the absence of such factors; their etiology may be cryptogenic (no known cause), remote symptomatic (pre-existing brain abnormality or insult), or idiopathic (genetic).

Laboratory studies. *Evidence.* In one Class I study of 30 children ages 0 to 18 years, and 133 adults with seizures, of whom 24 (15%) had new onset seizures, the standard diagnostic laboratory workup, which included complete blood count (CBC), serum electrolytes, blood urea nitrogen (BUN), creatinine, glucose, calcium, and magnesium, revealed one case of hyperglycemia that was unsuspected clinically[14] (95% CI 0, 4.9%). This patient's age was not noted, nor were those with new onset seizures identified by age. Another prospective study of 136 new onset seizure patients found no clinically significant laboratory abnormalities in the 16 children in the study who were ages 12 to 19 years[15] (95% CI 0, 19%).

In two Class II studies including 507 children with both febrile and nonfebrile seizures, results of laboratory studies did not contribute to diagnosis or management.[12,16] In another Class II study including 65 children with new onset seizures not accompanied by fever, one had a positive cocaine screen, and seven had electrolyte abnormalities (additional data supplied by the author of reference 17). Of these, four children were hyponatremic and three were hy-

pocalcemic. Of the four children with hyponatremia, three had a history of illness, lethargy, or diarrhea, and one had no specific symptoms. Of the three with hypocalcemia, one (age 4 months) had clinical signs of rickets, one (age 1 month) had multiple seizures, and one (age 5 years) had a prolonged focal seizure. An exception to the small number of abnormal laboratory findings in the absence of specific suggestive features is in the under 6 month age group. Hyponatremia (<125 mM/L) was found to be associated with seizures in 70% of 47 infants younger than 6 months in a Class II study.[18]

In a sample of 56 children with a first seizure, 40 of whom were febrile, there was one positive urine toxicology screen of the 11 performed. None of 53 hematology tests (95% CI 0, 6%) and two of 96 (2%) chemistry tests were found to be clinically significant (both hyponatremia) (95% CI 0, 11%).[19] In three studies that included a total of 400 adults,[19-21] only 27 (<7%) were found to have abnormalities of calcium, sodium, glucose, BUN, or arterial blood gas (ABG) determinations. Of these abnormalities, only three were unsuspected on a clinical basis.

Conclusions. The fact that a first nonfebrile seizure occurred in the absence of any suggestive history or symptoms in a child who is older than age 6 months and has returned to baseline has not been shown to be sufficient reason to perform routine laboratory testing in the child with a first nonfebrile seizure. However, the number of children reported is too small to be confident that in rare circumstances, routine laboratory screening such as blood glucose determination[12,15,16] might not provide important information, even without specific clinical indications. There were only two reports of positive toxicology screens, but no studies that systematically evaluated the yield from doing routine toxicology screening in children with first seizures. If no cause for the seizure has been identified, it is important to ask questions regarding possible toxic ingestions or exposures.[20]

Recommendations.

- Laboratory tests should be ordered based on individual clinical circumstances that include suggestive historic or clinical findings such as vomiting, diarrhea, dehydration, or failure to return to baseline alertness.[12,14,15,20] **(Option)**
- Toxicology screening should be considered across the entire pediatric age range if there is any question of drug exposure or substance abuse. **(Option)**

Lumbar puncture. *Evidence.* Lumbar puncture (LP) is frequently performed in children in the presence of fever and seizures to rule out CNS infection.[6,21,22] In the only report found giving the frequency of positive spinal fluid examinations in children with nonfebrile seizures, of 57 spinal fluid samples in children ages 2 to 24 months following nonfebrile seizures, 12.3% had >5 leukocytes/mm^3 in the CSF.[23] These children did not have CNS infection. CSF glucose increased with seizure duration and the range of CSF glucose was 32 to 130 mg/dL; the range of CSF protein was 9 to 115 mg/dL.[23] A 1993 AAN practice parameter regarding the value of LP did not mention nonfebrile seizure as an indication for LP in either children or adults.[21]

Conclusions. There is no evidence regarding the yield of routine LP following a first nonfebrile seizure. The one study available (Class II) is limited in size and age range. Recommendations based on age and clinical symptoms are available from Class III publications. In the very young child (<6 months), in the child of any age with persistent (cause unknown) alteration of mental status or failure to return to baseline, or in any child with meningeal signs, LP should be performed.[6,21,22] If increased intracranial pressure is suspected, the LP should be preceded by an imaging study of the head.[20]

Recommendations.

- In the child with a first nonfebrile seizure, LP is of limited value and should be used primarily when there is concern about possible meningitis or encephalitis. **(Option)**

EEG. *Evidence.* Of 10 Class I studies reviewed[24-34] (references 26 and 27 were from the same study) and one meta analysis,[35] five studies addressed the prognostic value of EEG in a population of children with a first seizure.[25-27,30,32,33] In four of these studies, epileptiform discharges or focal slowing on the EEG were predictive of recurrence.[25,27,32,33] In children with a cryptogenic (cause unknown) first seizure, 54% of 103 children with an abnormal EEG had a recurrence compared with 25% of 165 children with a normal EEG ($p < 0.001$).[27] EEG abnormalities were reported to be the best predictors of recurrence in children who were neurologically normal; however, abnormal neurologic examination[25,26] and etiology[26,36] were also strong predictors of recurrence. Several of these studies indicated that the information provided by the EEG is useful for diagnosis of the event, identification of a specific syndrome, and prediction of long-term outcome.[26,27,32,33]

Of the four Class I studies of first seizures in adults only, or in both children and adults, an abnormal EEG was predictive for recurrence risk in three studies.[28,29,34] Inclusion of both an awake and a sleep tracing, as well as hyperventilation and photic stimulation,[27,31,32,37-39] are recommended by the American EEG Society,[38] as they increase the yield of abnormalities seen on EEG tracings.

A Class I study published in 1998 in children and adults concluded that an EEG obtained within 24 hours of a seizure was more likely to contain epileptiform abnormalities than one done later (51% versus 34%).[34] The value of an EEG performed in the emergency department shortly after a seizure was addressed in two Class II studies of adult first sei-

zure patients.[40,41] In these studies, interpretation was difficult in the presence of diffuse postictal slowing,[42] and an EEG done at that time was not helpful in determining which patients should be admitted to the hospital.[40]

A recent analysis of selected findings from several of the Class I studies referred to above[25-27,30,31] concluded that an EEG should not be routinely performed after a first seizure because it does not yield sufficient information to alter treatment decisions.[43] To reach this conclusion, the authors did not consider evidence that the EEG result does in fact alter treatment decisions. They assumed a treatment threshold to be at an 80% risk of recurrence, and used a univariate analysis. However, where the EEG is used as one of several variables, it can identify children with very high and very low recurrence risks.[25,26,32,35] The EEG is not used solely to determine recurrence, but also helps differentiate a seizure from other events, is essential to the diagnosis of a syndrome, and provides information on long-term prognosis; it influences the decision to perform subsequent neuroimaging studies[44] and may influence counseling about management of the child.

Conclusions. The majority of evidence from Class I and Class II studies confirms that an EEG helps in determination of seizure type, epilepsy syndrome, and risk for recurrence, and therefore may affect further management decisions. Experts commonly recommend that an EEG be performed after all first nonfebrile seizures.[39,45-47] It is not clear what the optimal timing should be for obtaining an EEG. Although an EEG done within 24 hours of the seizure is most likely to show abnormalities,[34] physicians should be aware that some abnormalities such as postictal slowing that can be seen on EEG done within 24 to 48 hours of a seizure may be transient and must be interpreted with caution.

There is no evidence that the EEG must be done before discharge from the emergency department; the study may be arranged on an outpatient basis. Epileptiform EEG abnormalities may be useful in confirming that the event was a seizure; however, an EEG abnormality by itself is not sufficient to make a diagnosis that an epileptic seizure occurred, nor can its absence rule out a seizure.[46,47] The EEG is necessary to determine the epilepsy syndrome and the diagnosis of an epilepsy syndrome may be helpful in determining the need for imaging studies.[34] The EEG is also useful in predicting the prognosis for recurrences.[20,39,45-47]

It is not clear what the optimal timing should be for obtaining an EEG. Although an EEG done within 24 hours of the seizure is most likely to show abnormalities, physicians should be aware that some abnormalities such as postictal slowing that can be seen on EEG done within 24 to 48 hours of a seizure may be transient and must be interpreted with caution.

Recommendations.

- The EEG is recommended as part of the neurodiagnostic evaluation of the child with an apparent first unprovoked seizure. **(Standard)**

Neuroimaging studies. *Evidence—CT scans.* There were five Class I studies regarding imaging by CT scan after a first seizure; the data pertained to children[32] and adults[24,42,48] with first seizures, and to adults and children over age 6 with both new onset and established seizures.[14] In the single Class I study of first seizures in children, the abnormalities (mostly atrophy) found in 12 children were "without therapeutic consequences" (95% CI 0, 3%).[32] In one of the adult studies, 1.3% of the patients who had CT scans were diagnosed with tumors,[24] and in another, of 62 patients there were three tumors seen on CT, all in patients with abnormal neurologic examinations.[42] Of 119 adults who had CT scans after a first generalized seizure, 20 had abnormalities that warranted therapeutic intervention.[48] In the Class I study in which 19 CT scans were done in selective cases (first seizures if greater than age 6 years, head trauma, or focal seizure), there was one significant abnormality (age of the patient was not given), a subdural hematoma, not predicted by history and physical examination.[14]

Of the 14 Class II studies, nine involved children only (n = 2559),[17,19,49-56] four were of adults only (n = 666),[24,42,57,58] and one involved children and adults (n = 109).[59] Only a small percentage of children in these studies (0 to 7%) had lesions on CT that altered or influenced management. These were most commonly brain tumors, communicating or obstructive hydrocephalus, one subarachnoid and one porencephalic cyst, and three children with cysticercosis. The yield of abnormality on CT when the neurologic examination and EEG were normal was 5 to 10%.[50,54] In a Class II study in which seven children (14% of children with nonfebrile seizures) had CT scans that influenced management, five had focal or complex partial seizures. Abnormalities on neuroimaging were associated with a higher recurrence risk.[54] In one study of febrile and nonfebrile children, CT scans were always normal in the absence of defined risk factors such as known neurologic diagnosis, age <5 months, or focal deficit.[57] Focal lesions on CT scans tended to be more commonly found in adults (18 to 34%)[40,48,57,58] than in children (0 to 12%),[17,32,49,52,54-56] particularly when ordered for specific clinical indications. At least three studies provided evidence that MRI scanning was preferable to CT[51,54,60] in children following nonfebrile seizures.

Evidence—MRI. There was one Class I report regarding MRI in children presenting with a first seizure[54] and another Class I report of newly diagnosed epilepsy in children.[60] Of 411 children who presented with a first seizure, 218 had neuroimaging studies. Four had lesions seen on MRI or CT (two brain tumors, two neurocysticercosis) that potentially altered

* Influencing treatment or management decisions.
† The author provided data regarding analyses of the children who presented with a first nonfebrile seizure.

management.[54] When these four were excluded, 407 children remained in this Class I study. Of these, 58 children had an MRI scan, and 19 (33%) scans were abnormal, but none of the children required intervention on the basis of the neuroimaging findings. In the Class I study of 613 children with newly diagnosed epilepsy, 273 had partial, generalized tonic clonic, or generalized tonic seizures and came to medical attention at the time of their first unprovoked seizure[60] (additional data supplied by the author of reference 60). Of these, 86% had neuroimaging, and none had abnormalities influencing immediate treatment or management decisions. One Class I study of 300 adults and children with first seizures reported 43 MRI scans done in 59 children, one showing hippocampal sclerosis and two showing single gray matter heterotopic nodules (additional data supplied by the author of reference 34).[34] All patients with generalized epilepsy had normal MRI scans.[34] In two Class II reports of retrospective evaluations of MRI in children with seizures, one of which was limited to children with first seizures only, abnormalities on MRI scan such as localized atrophy, mesial temporal sclerosis, and brain malformation were common but did not mandate a change in management.[51,61] There were also six Class III reports.[39,46,62-65]

It was consistently reported in the literature cited above that the MRI was more sensitive than the CT scan.[39,51,54,60,62,63,65] MRI findings included atrophy, infarction, evidence of trauma, cerebral dysgenesis, and cortical dysplasia. Authors of review articles also emphasized a preference for MRI to exclude progressive lesions such as tumors and vascular malformations, or focal cortical dysplasia.[39,62,63,65,66] Neuroimaging was recommended if there is a postictal focal deficit not promptly resolving.[46,66] A recently published practice parameter on neuroimaging in the emergency patient presenting with seizures reviewed literature primarily from adults but included children. This parameter recommended "emergent" neuroimaging if there was suspicion of a serious structural lesion, and that "urgent" neuroimaging should be considered if there was no clear cause of the seizure. This parameter states that if an emergent imaging study is needed, it would be to detect hemorrhage, brain swelling, or mass effect, conditions that are typically adequately imaged on CT.[66] These recommendations were not restricted to any age bracket.

Conclusions. Although abnormalities on neuroimaging are seen in up to one third of children with a first seizure, most of these abnormalities do not influence treatment or management decisions such as the need for hospitalization or further studies (table). Of available reported imaging results, from Class I and Class II studies of children, an average of about 2% revealed clinically significant findings that contributed to further clinical management, the majority of which were performed because the seizure was focal or there were specific clinical findings beyond the fact that a seizure had occurred (see the table).

Thus, there is insufficient evidence to support a recommendation at the level of standard or guideline for the use of routine neuroimaging, i.e., imaging performed for which having had a seizure is the sole indication, after a first nonfebrile seizure in children. However, neuroimaging may be indicated under some circumstances either as an emergent or nonurgent procedure.

The purpose of performing an *emergent* neuroimaging study in the context of a child's first seizure is to detect a serious condition that may require immediate intervention. The possible effects of emergency medication used to treat the seizure must be taken into consideration.

The purpose of performing a *nonurgent* neuroimaging study, which can be deferred to the next several days or later, is to detect abnormalities that may affect prognosis and therefore have an impact

on long-term treatment and management.[20,22] Factors to be considered include the age of the child, the need for sedation to perform the study, the EEG results, a history of head trauma, and other clinical circumstances such as a family history of epilepsy.

Recommendations.

- If a neuroimaging study is obtained, MRI is the preferred modality.[50,51,54,60,62,63,65] **(Guideline)**

Emergent neuroimaging should be performed in a child of any age who exhibits a postictal focal deficit (Todd's paresis) not quickly resolving, or who has not returned to baseline within several hours after the seizure.[46,66] **(Option)**

- Nonurgent imaging studies with MRI should be seriously considered in any child with a significant cognitive or motor impairment of unknown etiology, unexplained abnormalities on neurologic examination, a seizure of partial (focal) onset with or without secondary generalization, an EEG that does not represent a benign partial epilepsy of childhood or primary generalized epilepsy, or in children under 1 year of age.[20,34] **(Option)**

Summary. In the child with a first nonfebrile seizure, diagnostic evaluations influence therapeutic decisions, how families are counseled, and the need for hospital admission and/or specific follow-up plans. This practice parameter has reviewed the published literature concerning the usefulness of studies following a first nonfebrile seizure in children, and has classified the strength of the available evidence. There is sufficient Class I evidence, which involves a well executed prospective study, to provide a recommendation with the highest degree of clinical certainty—i.e., a **Standard**—that an EEG be obtained in all children in whom a nonfebrile seizure has been diagnosed, to predict the risk of recurrence and to classify the seizure type and epilepsy syndrome. The decision to perform other studies, including LP, laboratory tests, and neuroimaging, for the purpose of determining the cause of the seizure and detecting potentially treatable abnormalities, will depend on the age of the patient and the specific clinical circumstances. Children of different ages may require different management strategies.[20,22]

Future research. For most of the questions addressed by this parameter, evidence was insufficient for making a strong recommendation for a standard or guideline, particularly for laboratory studies. In order to generate definitive evidence regarding the value of routine (or selective) laboratory testing and the use of routine neuroimaging studies, sufficiently large samples allowing for adequate statistical power to provide precise estimates (i.e., with narrow confidence intervals) are needed. Neuroimaging studies are needed to understand the significance of neuronal migration defects in the context of a first seizure, and are important because of the improved technical ability of current MRI. In addition, prospective collection of data using standardized treatment protocols and standardized data collection instruments is essential. Results of studies will only be helpful if the patient sample and factors that resulted in inclusion into or exclusion from the sample are well described and documented. Ideally, large consecutive series of well-characterized patients are needed for the results to be accurate and generalizable. Finally, future studies should present separate data from children and adults, and it would be optimal for results in children to be presented by age groupings.

Appropriate timing as well as the choice of evaluative studies have not been adequately studied. Children may present as actively having a seizure when brought to the emergency department, as postictal, or as alert with a history of a possible seizure episode having occurred hours, days, or weeks previously. Data regarding the appropriate timing of laboratory testing, neuroimaging, or EEG studies require adequate prospective studies of these specific questions, with clearly defined entry criteria and a common protocol for type and timing of evaluations.

Research studies with adequate sample sizes and appropriate protocols that provide answers to these questions may serve to reduce the expense and discomfort of unnecessary testing in children with first seizures, and, more importantly, by identifying appropriate candidates, may improve the care and management that these children receive.

Disclaimer. This statement is provided as an educational service of the American Academy of Neurology. It is based on an assessment of current scientific and clinical information. It is not intended to include all possible proper methods of care for a particular neurologic problem or all legitimate criteria for choosing to use a specific procedure. Neither is it intended to exclude any reasonable alternative methodologies. The AAN recognizes that specific patient care decisions are the prerogative of the patient and the physician caring for the patient, based on all of the circumstances involved.

Acknowledgment

The authors thank the members of the Quality Standards Subcommittee of the AAN, and Wendy Edlund, the AAN Clinical Policy Administrator, for their time, expertise, and efforts in developing this document.

Appendix 1

Classification of evidence

Class I. Must have all of a–d:

a. Prospective study of a well defined cohort which includes a description of the nature of the population, the inclusion/exclusion criteria, demographic characteristics such as age and sex, and seizure type.

b. The sample size must be adequate with enough statistical power to justify a conclusion or for identification of subgroups for whom testing does or does not yield significant information.

c. The interpretation of evaluations performed must be done blinded to outcome.

d. There must be a satisfactory description of the technology used for evaluations (e.g., EEG, MRI).

Class II. Must have a or b:

a. A retrospective study of a well-defined cohort which otherwise meets criteria for Class 1a, 1b, and 1d.

b. A prospective or retrospective study which lacks any of the following: adequate sample size, adequate methodology, a description of inclusion/exclusion criteria, and information such as age, sex, and characteristics of the seizure.

Class III. Must have a or b:

a. A small cohort or case report.

b. Relevant expert opinion, consensus, or survey.

A cost-benefit analysis or a meta-analysis may be Class I, II, or III, depending on the strength of the data upon which the analysis is based.

Appendix 2

Outline for seizure assessment

Features of a seizure:

Associated factors
Age
Family history
Developmental status
Behavior
Health at seizure onset
Precipitating events other than illness—trauma, toxins

Health at seizure onset—febrile, ill, exposed to illness, complaints of not feeling well, sleep deprived

Symptoms during seizure (ictal)
Aura: Subjective sensations
Behavior: Mood or behavioral changes before the seizure
Preictal symptoms: Described by patient or witnessed
Vocal: Cry or gasp, slurring of words, garbled speech

Motor: Head or eye turning, eye deviation, posturing, jerking (rhythmic), stiffening, automatisms (purposeless repetitive movements such as picking at clothing, lip smacking); generalized or focal movements

Respiration: Change in breathing pattern, cessation of breathing, cyanosis

Autonomic: Pupillary dilatation, drooling, change in respiratory or heart rate, incontinence, pallor, vomiting

Loss of consciousness or inability to understand or speak

Symptoms following seizure (postictal)
Amnesia for events
Confusion
Lethargy
Sleepiness
Headaches and muscle aches
Transient focal weakness (Todd's paresis)
Nausea or vomiting

Appendix 3

Strength of recommendations

Standards. Generally accepted principles for patient management that reflect a high degree of clinical certainty (i.e., based on Class I evidence or, when circumstances preclude randomized clinical trials, overwhelming evidence from Class II evidence that directly addresses the issue, decision analysis that directly addresses the issue, or strong consensus of Class III evidence).

Guidelines. Recommendations for patient management that may identify a particular strategy or range of management strategies and that reflect moderate clinical certainty (i.e., based on Class II evidence that directly addresses the issue, decision analysis that directly addresses the issue, or strong consensus of Class III evidence).

Practice options. Other strategies for patient management for which the clinical utility is uncertain (i.e., based on inconclusive or conflicting evidence or opinion).

Practice parameters. Results, in the form of one or more specific recommendations, from a scientifically based analysis of a specific clinical problem.

Evaluating Infants and Young Children With Multiple Fractures

Carole Jenny, MD, MBA, FAAP, for the Committee on Child Abuse and Neglect

ABSTRACT

Infants and toddlers with multiple unexplained fractures are often victims of inflicted injury. However, several medical conditions can also cause multiple fractures in children in this age group. In this report, the differential diagnosis of multiple fractures is presented, and diagnostic testing available to the clinician is discussed. The hypothetical entity "temporary brittle-bone disease" is examined also. Although frequently offered in court cases as a cause of multiple infant fractures, there is no evidence that this condition actually exists.

INTRODUCTION

When infants and toddlers present with multiple unexplained fractures, the differential diagnosis can be difficult. Although child abuse is the most frequent cause of multiple fractures in children in these age groups, bone diseases associated with increased bone fragility can be subtle or difficult to diagnose. These children are usually preverbal and cannot give a cogent history of their experiences. If abuse has occurred, caregivers of young children may not be forthcoming with a truthful history. On the other hand, family members of a child having an undiagnosed bone disorder may not be able to explain any mechanism of injury and may be completely bewildered by the injuries. Many parents of children with genetic or metabolic bone disease report that they were initially accused of abusing their children.[1]

DIFFERENTIAL DIAGNOSIS OF MULTIPLE FRACTURES IN INFANTS

Child Abuse

Any type of fracture can be caused by child abuse, although some fractures, such as metaphyseal fractures and posterior rib fractures, are more frequently found in abused children.[2] A careful review of the clinical history and a careful examination for other signs of abuse or neglect are important when child abuse is suspected.

Osteogenesis Imperfecta

Osteogenesis imperfecta is a heterogeneous family of diseases, usually caused by mutations of the genes *COL1A1* and *COL1A2*.[3] These genes encode the chains of type I collagen, which forms the structural framework of bone. Although it is a genetic disease, the presentation of the disease within the same family can be quite variable. Phenotypic expression of the disease depends on the nature of the mutation, its relative abundance resulting from mosaicism, and its expression in target tissues.[4] Some types of osteogenesis imperfecta involve slow production of

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

collagen, and the symptoms resolve or lessen after bone growth stops.[5] In addition, spontaneous mutations are common, so there may be no family history of bone disease. Table 1 lists the various signs and symptoms that can be present in a case of osteogenesis imperfecta.

The diagnosis of osteogenesis imperfecta usually can be made by obtaining a careful medical and family history, performing a physical examination, and interpreting the results of appropriate biochemical and radiographic analyses. Many patients with osteogenesis imperfecta will have obvious diagnostic signs such as osteopenia, bone deformities, and wormian bones of the skull on radiographs. In addition, the classic metaphyseal lesions (planar microfractures through the primary spongiosum) that are often seen in abused children are not likely to be seen in children with osteogenesis imperfecta in the absence of obvious demineralization.[6] In some cases, the diagnostic signs of osteogenesis imperfecta can be quite subtle, and blue sclera (a sign found in many but not all cases of osteogenesis imperfecta) can also be seen in normal children with thin sclera.[7]

Osteogenesis imperfecta can be diagnosed by culturing of fibroblasts obtained from a skin biopsy. The cell culture is analyzed to determine if normal amounts and types of procollagen molecules are synthesized by the cells.[8] Eighty-seven percent of patients who are suspected to have osteogenesis imperfecta on the basis of clinical presentation will have abnormal collagen production that is identified by using this method.[9]

The authors of a recent study examined results of fibroblast cultures from skin biopsies that were obtained in cases of suspected child abuse.[10] In 138 children with fractures, osteogenesis imperfecta was identified in 9 cases. In an additional 6 cases, osteogenesis imperfecta could not be ruled out. Three of the 9 children with osteogenesis imperfecta were not suspected to have the disease before the collagen test was obtained. Rare cases of spontaneous subdural hematomas have been reported in children with osteogenesis imperfecta, presumably because of abnormally fragile blood vessels resulting from defective collagen.[11] In children, retinal hemorrhages have been documented in the posterior portion of the retina in nonabused children with osteogenesis imperfecta after accidental head trauma.[12] These hemorrhages have been described as small, intraretinal, and localized to the posterior pole of the retina. In contrast, retinal hemorrhages seen in abusive head trauma are often extensive, multilayered, and found from the posterior pole of the retina extending out to the ora serrata.[13]

A patient's DNA can also be sequenced to locate mutations of the *COLA1A* and *COLA2A* genes. This method can detect abnormal alleles in up to 96% of cases of serious osteogenesis imperfecta, but a genetic abnormality will be detected in only 60% of mild cases. In addition, approximately 5% of subjects without clinical osteogenesis imperfecta will have a sequence variation identified.[14]

In cases of osteogenesis imperfecta that are identified clinically, some patients who have abnormalities identified on analysis of their collagen will have a normal result on DNA sequencing, and some patients with abnormalities found on DNA testing will not have abnormal collagen test results. Both tests are expensive (approximately $2000 for collagen analysis and $3000 for DNA analysis). Although the collagen test requires a skin biopsy, the DNA sequencing can be performed on venous blood. Obtaining collagen test results takes 6 weeks to 3 months, and the DNA test results take up to 6 months to obtain. When testing for osteogenesis imperfecta, the better test to order is not always obvious, and each case should be considered individually. Consultation with a pediatric geneticist may be helpful in deciding which children to test and which test to order.

In cases where abuse is obvious (eg, when other abusive injuries are present or when abuse is witnessed), testing for osteogenesis imperfecta is not usually necessary.

TABLE 1 Signs and Symptoms of Osteogenesis Imperfecta

Fragile bones, with few, some, or many of the following findings:
Poor linear growth
Hypoplastic, translucent, carious, late-erupting, or discolored teeth
Blue sclera
Easy bruisability
Limb deformities
Scoliosis and/or kyphosis
Hyperextensible joints
Wormian bones
Hearing impairment as a result of otosclerosis
Inguinal and/or umbilical hernias
Triangular-shaped face
Macrocephaly
Demineralized bones

Preterm Birth

Preterm infants have decreased bone mineralization at birth, but after the first year of life, bone density normalizes.[15] Osteopenia of prematurity has been well described as a complication in low birth weight infants, particularly when prolonged parenteral nutrition is required.[16] Osteopenia of prematurity is multifactorial. Contributing factors can include inadequate calcium and phosphorus stores, inadequate mineral intake to support rapid growth, effects of medications used to treat complications of preterm birth, and limited patient mobility.[17–21] Osteopenia commonly presents between 6 and 12 weeks of postnatal age. The issue of multiple fractures in preterm infants is complicated by the fact that these infants have been reported to be at an increased risk of abuse.[22]

Rickets

Vitamin D deficiency is an uncommon condition that can be seen in infants who are solely breastfed and not receiving vitamin supplements or in dark-skinned children who are not exposed to adequate sunlight because of lifestyle or geographic location. The American Academy of Pediatrics recently recommended that all breastfed infants receive daily vitamin D supplementation.[23] Rickets can be diagnosed by typical changes on radiographs, including cupping and fraying of the costochondral junctions and epiphyses, demineralization, widened epiphyses, and cortical thinning. Serum concentrations of vitamin D metabolites are low, and alkaline phosphatase concentration is usually elevated. Other metabolic diseases can also cause rickets.

Osteomyelitis

Osteomyelitis in infants can present as multiple lesions at the metaphyses of the long bones, initially resembling the classical metaphyseal lesions found in abused children.[24] Over time, the sites of infection change in appearance to lytic lesions of the bone. Other signs of infection will be present, such as fever, increased erythrocyte sedimentation rate, elevated C-reactive protein concentration, and elevated white blood cell count.

Copper Deficiency

Preterm infants are born with lower stores of copper than term infants.[25] With their rapid rate of growth, copper deficiency can occur, usually in the second 6 months of postnatal life. Copper deficiency can cause pathologic fractures. Children with copper deficiency also have severe sideroblastic anemia and often have neutropenia. Obvious radiographic bone changes will occur before fractures occur, including symmetrical cupping and fraying of the metaphyses, osteopenia, subperiosteal new bone formation, and delayed bone age. Copper deficiency is not likely to occur in term infants of normal birth weight in the absence of a severely restricted diet or in the absence of an underlying genetic or metabolic disease.

Fractures Secondary to Demineralization From Paralysis

Any child with paralysis of the limbs can be at risk of fractures secondary to disuse demineralization, even with normal handling.[26] Often, these fractures are reported to occur during physical therapy and range-of-motion exercises. It can be difficult to distinguish between fractures caused by abnormally rough handling and fractures that occurred accidentally in these fragile children. When multiple fractures are recurring in disabled children, rarely a trial change in caregivers may be indicated to determine if the fractures can be prevented. This is an extreme intervention and should be reserved for very unusual circumstances.

Other Rare Conditions That Mimic Child-Abuse Fractures

Other conditions that can be confused with child abuse include Menkes syndrome (kinky hair syndrome), scurvy, osteopetrosis, hypophosphatasia, congenital syphilitic periostitis, leukemia, vitamin A toxicity, and metabolic and kidney diseases that cause calcium wasting and demineralization. Prolonged administration of prostaglandins, glucocorticoids, or methotrexate also can lead to bony changes that resemble child abuse. These conditions have very distinctive clinical presentations and radiographic findings.[27] Careful history, physical examination, and consultation with a pediatric radiologist may avoid mistaking these conditions for child abuse.

HYPOTHESIZED CONDITIONS PRESENTED IN MULTIPLE-FRACTURE CASES

A few articles in the literature have hypothesized the existence of a condition referred to as "temporary brittle-bone disease." One proponent of this theory claims that an infant's bones can be especially vulnerable to fractures for a short period of time because of some unknown metabolic abnormality, perhaps involving copper metabolism.[28] Another proposed explanation is that the bones are fragile because of decreased fetal movement in utero.[29] Neither of these theories are supported by any clinical or laboratory studies. The very nature of bone maturation and development make it unlikely that bones would quickly change from fragile to normal. Temporary brittle-bone disease is neither clinically validated nor generally accepted by expert professionals and should not be invoked to explain multiple fractures in an infant.[22]

DIAGNOSING CHILD ABUSE WHEN A CHILD PRESENTS WITH MULTIPLE FRACTURES

Child abuse is many times more common in the population than osteogenesis imperfecta.[30] Although osteogenesis imperfecta and other conditions should be considered, clinicians should not hesitate to report suspected child abuse and institute protective measures even before the diagnostic workup is complete. When multiple or suspicious fractures are detected, a complete skeletal survey should be performed on any child younger than 2 years.[31] Computed tomography or MRI of the head as well as a careful retinal examination by an ophthalmologist should be considered. A complete blood cell count and serum calcium, phosphorus, and alkaline phosphatase concentrations should be obtained, although the alkaline phosphatase concentration may be elevated as a result of the fractures. A serum 25-hydroxy-vitamin D concentration can be obtained if rickets is suspected because of radiographic findings or history. Serum copper and ceruloplasmin concentrations should be obtained if radiographic findings suggest copper deficiency.

In any case of suspected child abuse, liver-function studies should be performed and amylase and lipase

concentrations should be obtained to evaluate for possible occult abdominal injury.[32] A urinalysis should be performed to screen for occult blood. A careful physical examination should be performed to document bruising or other skin injury. If fractures stop occurring when the child moves to a protected environment, the diagnosis of bone disease is most likely ruled out, especially if the child has begun walking and falling without refracturing.

Bone densitometry might prove to be helpful in the future, but at this time, no age-adjusted reference values have been determined by studying a large population of infants and children. The threshold level of decreased mineralization that leads to increased fracturability is unknown. Differences in bone size and shape in the pediatric age group make densitometry results difficult to interpret.[33]

If a child has an underlying bone disorder or disability, child abuse can still coexist with the disease. Children with disabilities have been shown to have an increased risk of child abuse.[34]

Distinguishing child abuse from other conditions that cause multiple or suspicious fractures requires the clinician to have an open mind. Thoughtful and objective evaluation of the clinical evidence is required. It is critical to remember that child abuse occurs in all racial and socioeconomic groups. Physicians should not hesitate to comply with state laws that require reporting of suspected abuse.

CLINICAL REPORT

Evaluation and Management of the Infant Exposed to HIV-1 in the United States

Guidance for the Clinician in Rendering Pediatric Care

Peter L. Havens, MD, Lynne M. Mofenson, MD, and the Committee on Pediatric AIDS

ABSTRACT

The pediatrician plays a key role in the prevention of mother-to-child transmission of HIV-1 infection. For infants born to women with HIV-1 infection identified during pregnancy, the pediatrician ensures that antiretroviral prophylaxis is provided to the infant to decrease the risk of acquiring HIV-1 infection and promotes avoidance of postnatal HIV-1 transmission by advising HIV-1–infected women not to breastfeed. The pediatrician should perform HIV-1 antibody testing for infants born to women whose HIV-1 infection status was not determined during pregnancy or labor. For HIV-1–exposed infants, the pediatrician monitors the infant for early determination of HIV-1 infection status and for possible short- and long-term toxicity from antiretroviral exposures. Provision of chemoprophylaxis for *Pneumocystis jiroveci* pneumonia and support of families living with HIV-1 by providing counseling to parents or caregivers are also important components of care. *Pediatrics* 2009;123:175–187

Key Words
human immunodeficiency virus, HIV-1, perinatal transmission, antiretroviral prophylaxis, diagnosis, infant

Abbreviations
MTCT—mother-to-child transmission
ARV—antiretroviral
AAP—American Academy of Pediatrics
PCP—*Pneumocystis jiroveci* pneumonia
CDC—Centers for Disease Control and Prevention
ZDV—zidovudine
TB—tuberculosis
NAAT—nucleic acid amplification test
PCR—polymerase chain reaction
BCG—bacille Calmette-Guérin
TST—tuberculin skin test

INTRODUCTION

Each year in the United States, approximately 6000 pregnant women infected with HIV-1 give birth. Implementation of effective, cost-saving[1–3] preventive strategies during pregnancy has reduced the risk of mother-to-child transmission (MTCT) of HIV-1 to approximately 1% to 2%.[4] Preventive strategies include universal HIV-1 antibody testing of all pregnant women and, for women who are infected with HIV-1, (1) administration of antiretroviral (ARV) prophylaxis during pregnancy and labor and to the infant for 6 weeks after birth; (2) elective cesarean delivery before the onset of labor and before rupture of membranes for women with an HIV-1 viral load of >1000 copies per mL before delivery; and (3) complete avoidance of breastfeeding.[5,6] These strategies have been outlined in a separate American Academy of Pediatrics (AAP) policy statement titled "HIV Testing and Prophylaxis to Prevent Mother-to-Child Transmission in the United States."[7] The current clinical report offers companion guidance on the evaluation and management of the HIV-1–exposed infant after birth.

The pediatrician plays a key role in prevention of MTCT of HIV-1 by (1) identifying HIV-1–exposed infants even if the mother's HIV-1 infection was not recognized before delivery; (2) prescribing ARV prophylaxis for infants born to HIV-1–infected women to reduce the risk of MTCT of HIV-1; and (3) further reducing the risk of HIV-1 transmission by advising women with HIV-1 infection not to breastfeed. In addition to standard pediatric care, the pediatrician is also responsible for (1) monitoring of the infant for early determination of HIV-1 infection status, (2) evaluation for possible short- and long-term toxicities of in utero and neonatal ARV exposure, (3) providing chemoprophylaxis for *Pneumocystis jiroveci* pneumonia (PCP) as required, (4) administering vaccines as appropriate, and (5) supporting families living with HIV-1 infection, including providing counseling to parents or caregivers. Care of the infant or child with perinatal infection with HIV-1 should be undertaken in consultation with a pediatric HIV specialist.

Continuing technologic and medical advances in the prevention, diagnosis, and treatment of pediatric HIV-1 infection require an ongoing assessment and review of recommendations relating to management of infants known to be exposed to HIV-1 infection. This report updates previous AAP guidelines.[8]

IDENTIFICATION OF THE INFANT EXPOSED TO HIV-1

Identification of Maternal HIV Infection

Although there has been a dramatic decline in the number of new HIV-1 infections in infants in the United States since 1994, when ARV prophylaxis was first documented to prevent MTCT,[9] transmission continues to occur.[4] Many of these infant infections could have been prevented if HIV-1 infection had been identified in their mothers through adequate preconception and prenatal care and if appropriate prophylactic interventions had been performed. The Centers for Disease Control and Prevention (CDC), the AAP, and the American College of Obstetricians and Gynecologists recommend documented, routine HIV-1 antibody testing for all pregnant women in the United States after notifying the patient that testing will be performed, unless the patient declines HIV-1 testing ("opt-out" consent or "right of refusal"[5,7,10]). All HIV-1 antibody testing should be performed in a manner consistent with state and local laws. (A compendium of state HIV testing laws can be found at www.nccc.ucsf.edu/StateLaws/Index.html.)

Identification of HIV-1 infection early in pregnancy affords the greatest ability to treat the pregnant woman for her HIV-1 infection for her own health and to prevent MTCT of HIV-1. Rapid HIV-1 antibody testing allows timely identification of HIV-1 infection in women even late in pregnancy, during labor, or in the immediate postpartum period as well as rapid identification of the exposed infant whose mother's HIV-1 status is unknown. The results can be available quickly enough to allow successful ARV interventions, which can reduce MTCT of HIV-1, when administered to the mother late in pregnancy or during labor or even to the infant when administered within the first few hours of life. Rapid HIV-1 antibody testing should be immediately available at all facilities with maternity services and/or a neonatal care unit.

HIV-1 Testing of the Infant if the Mother's HIV-1 Infection Status Is Unknown

For newborn infants whose mother's HIV-1 serostatus is unknown, the newborn infant's health care provider should perform rapid HIV-1 antibody testing on the mother or the infant with appropriate consent as required by state and local law. Test results should be reported to health care providers quickly enough to allow effective ARV prophylaxis to be administered to the infant as soon after birth as possible but certainly within 12 hours of life.[5,7,11,12] ARV prophylaxis for mother and newborn infant to prevent MTCT of HIV-1 should be administered promptly solely on the basis of a positive rapid antibody test result, without waiting for results of confirmatory HIV-1 testing. Initiation of breastfeeding should be postponed while awaiting results of confirmatory testing. If confirmatory test results are negative, then prophylaxis should be stopped and breastfeeding may be initiated.

INTERVENTIONS FOR PREVENTION OF PERINATAL HIV-1 TRANSMISSION

Maternal ARV Prophylaxis to Prevent Perinatal HIV-1 Transmission

Prenatal ARV Prophylaxis

In the United States, most pregnant women with HIV-1 infection receive care during the prenatal period, which allows (1) institution of effective ARV prophylaxis for the prevention of MTCT and ARV treatment if required for maternal health, (2) decisions to be made regarding optimal mode of delivery, and (3) counseling to the mother not to breastfeed. Current US Public Health Service guidelines for prevention of MTCT recommend use of combination ARV regimens including at least 3 ARV drugs during pregnancy and labor for all pregnant women with HIV-1 infection. ARV agents are discontinued for the mother after birth unless such therapy is required for her own health, in which case ARV therapy is continued by following guidelines for nonpregnant HIV-1–infected adults. For women who are not being treated with ARV drugs and who have very low viral load (<1000 copies per mL), some experts would consider use of zidovudine (ZDV) alone during pregnancy for prophylaxis of MTCT, stopping the drug after birth.[6,13]

Interventions During Labor and at Delivery

Intravenous ZDV should be administered to all pregnant women with HIV-1 infection during labor even if they receive combination ARV therapy during pregnancy and viral load is undetectable, unless there is a contraindication to maternal receipt of ZDV. Intravenous ZDV is started after the onset of labor or rupture of membranes, or approximately 3 hours before an elective cesarean delivery. There is no maximum time for use of intravenous ZDV for women with prolonged labor. Intravenous ZDV is administered at 2 mg/kg over the first hour and then continued at 1 mg/kg per hour until delivery is complete and the cord is clamped.

Elective cesarean delivery at 38 weeks' gestation is recommended for all HIV-1–infected pregnant women with HIV-1 RNA levels of >1000 copies per mL near the time of delivery (or who have unknown viral load), irrespective of maternal prenatal ARV prophylaxis.[6]

For women who have HIV-1 infection first identified at the time of labor, prompt initiation of maternal intrapartum prophylaxis with intravenous ZDV, followed by infant prophylaxis with ZDV for 6 weeks, is recommended, because such treatment is associated with an approximately 60% lower risk of MTCT of HIV-1 compared with no prophylaxis.[6,11,12,14] In this setting, some experts may administer other ARV agents, in addition to ZDV, to both the woman during labor and the newborn infant. A detailed discussion of prophylaxis when the mother has not received antepartum ARV prophylaxis is provided in the US Public Health Service guidelines for prevention of MTCT.[6]

TABLE 1 **Newborn Infant ZDV Dose for Prophylaxis of MTCT of HIV-1**[15,16]

Gestational Age at Birth	Oral Dose, mg/kg per Dose	Intravenous Dose, mg/kg per Dose	Dosing Frequency	Duration, wk
≥35 wk	2	1.5	Every 6 h[a]	6
>30 wk but <35 wk	2	1.5	Every 12 h, advancing to every 8 h at 2 wk of age	6
<30 wk	2	1.5	Every 12 h, advancing to every 8 h at 4 wk of age	6

[a] Although there are no definitive data in infants to show pharmacokinetic equivalence or equal therapeutic efficacy of administration of double the standard oral ZDV dose twice daily, for term infants administration of ZDV 4 mg/kg per dose twice daily instead of 2 mg/kg per dose every 6 hours may increase adherence to the regimen and could be considered when there are concerns about adherence to drug administration to the infant.[26,77,78]

Infant ARV Prophylaxis

All HIV-1–exposed infants should receive postpartum ARV drugs to reduce the risk of perinatal HIV-1 transmission. The 6-week neonatal ZDV chemoprophylaxis regimen is recommended for all HIV-1–exposed infants,[6] and a quantity of drug sufficient to finish the full course of prophylaxis should be supplied to the family before hospital discharge. Insurance providers should provide payment for this medication, and issues of availability of payment should not prevent appropriate administration of ARV agents.

In certain situations, some experts combine the 6-week infant ZDV prophylaxis regimen (Table 1)[15,16] with additional ARV drugs. Such circumstances may include those under which infants are born to mothers (1) who received prenatal ARV drugs but had suboptimal viral suppression at delivery, (2) who have received only intrapartum ARV drugs, (3) who have received no antepartum or intrapartum ARV drugs, and (4) with known drug-resistant virus. Combining the 6-week infant ZDV with other ARV drugs may provide additional efficacy for prevention of MTCT of HIV-1, but this remains unproven in clinical trials. In addition, appropriate formulations are not available for all ARV drugs, dosing regimens for neonates are incompletely defined for many drugs, and there are minimal data about the safety of combination ARV drugs in the neonate. Combination infant ARV prophylaxis, therefore, involves balancing possible benefits of enhanced prevention of MTCT of HIV-1 against risks of toxicity to the infant.

The most information about use of ARV combinations in neonates is available for ZDV in combination with single-dose nevirapine[17–22] and the dual combination of ZDV and lamivudine,[23–27] which has been combined with daily nevirapine (although there are no published data on this last approach). Careful infant monitoring is needed if combination drugs are provided, because there may be enhanced hematologic toxicity from the combination of ZDV and lamivudine compared with ZDV alone. Long-lasting resistance is possible if the infant is already infected when prophylaxis is given, especially if nevirapine is used.[28] The US Public Health Service guidelines for prevention of MTCT of HIV-1 include an extensive discussion of considerations for infant ARV prophylaxis regimens for different clinical scenarios and should be reviewed for specific recommendations.[6] If drugs in addition to ZDV are considered, neonatal dosing recommendations can be found in the *Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection*.[16] Decisions should be made in consultation with a pediatrician experienced in the care of infants and children with HIV-1 infection.

The administration of ZDV (possibly with other ARV agents) to the infant should be initiated as soon as possible after birth but certainly within 12 hours after delivery.[5,7,11,12] If the infant's HIV exposure is recognized between 12 and 48 hours after delivery, ZDV prophylaxis should be initiated in that time period. Initiation of postexposure prophylaxis after 2 days of age is not likely to be efficacious in preventing transmission. Data from animal studies indicate that the longer the delay in institution of prophylaxis, the less likely that infection will be prevented. In most animal studies, ARV prophylaxis initiated 24 to 36 hours after exposure usually is not effective for preventing infection.[29–31] HIV-1 infection is established in most perinatally infected infants by 1 to 2 weeks of age.[32]

The full 6-week course of infant ARV prophylaxis and careful instructions for its administration should be provided to the family before discharge from the hospital. A prescription and recommendations to purchase ZDV for the infant are not adequate to ensure appropriate prophylaxis. In some states, infants may not be registered for insurance for a few weeks after birth, so even if the family has insurance, coverage may not immediately be available to pay for health care costs of the infant. Some families have health insurance that covers inpatient costs but not prescription medications. Outpatient pharmacies may not stock the infant dosage form of ZDV. At hospital discharge, the family should be supplied with the medication itself, not just a prescription. Special hospital programs to support this may need to be established.

Avoidance of HIV-1 Infection From Human Milk

Postnatal transmission of HIV-1 through ingestion of human milk from a mother with HIV-1 infection is well documented, with rates as high as 9% to 15% with prolonged breastfeeding.[33] In the United States, where the risk of infant mortality from infectious diseases and malnutrition is low and effective alternative sources of feeding are readily available, women with HIV-1 infection, including those receiving ARV therapy, should be counseled not to breastfeed their infants or donate their milk. Although maternal ARV therapy has been shown to reduce the concentration of cell-free HIV-1 in human milk, such therapy does not affect the amount of cell-associated virus in human milk, and there can be discor-

dance between plasma and human milk viral load.[34] It is not yet known whether maternal ARV treatment during lactation will reduce the risk of HIV-1 transmission to the infant via human milk. Ongoing studies are evaluating this question.[35] In addition, there is differential penetration of ARV drugs into human milk. Some ARVs have concentrations in human milk that are much higher than concentrations in maternal plasma, and others have human milk concentrations that are much lower than in plasma or are not detectable.[6,36] This raises concerns about infant drug toxicity and the potential for selection of drug-resistant virus within human milk. Thus, in the United States, where safe alternatives to breastfeeding are available, all HIV-1–infected women should avoid breastfeeding.

Counseling the mother about the avoidance of breastfeeding should occur in a culturally sensitive manner. For some women, the prohibition to breastfeed may be one of the most emotionally painful components of their efforts to protect their newborn infant from HIV-1 infection. Other mothers, particularly those who have migrated from parts of the world in which breastfeeding is nearly universal, may feel that formula feeding their infant publicizes their HIV-1 infection to family members or friends. Pediatricians should recognize the possibility that advice to not breastfeed may not always be followed and stress the importance of compliance with this intervention to prevent MTCT of HIV-1. Support for open communication regarding feeding practices is necessary to ensure appropriate follow-up and testing of all infants. Women should be educated regarding appropriate formula feeding with a discussion of the affordability of formula, including enrollment in the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) when appropriate. Assistance from social service agencies may be necessary to help with education and support compliance.

CARE OF THE HIV-1–EXPOSED INFANT

Evaluation for Maternal Coinfections

At the time of the initial assessment of the infant, maternal health information should be reviewed to determine if the infant has been exposed to maternal coinfections, including tuberculosis (TB), syphilis, toxoplasmosis, hepatitis B or C, cytomegalovirus, or herpes simplex virus. Although there is little information as to the relative transmission or infection rates of such pathogens in infants of mothers with HIV-1 infection, there is concern that reactivation of latent infections in immunocompromised pregnant women may cause increased risk of transmission to, and disease in, exposed newborn infants. Diagnostic testing and treatment of such coinfections in infants born to women with HIV-1 infection are based both on maternal findings and evaluation of the infant.[37] In the absence of suggestive history or routine evaluation, specific laboratory testing for these pathogens is not recommended.

Testing to Determine the Infant's HIV-1 Infection Status

The early identification of HIV-1 infection in exposed infants is important to allow early initiation of ARV and adjunctive therapies and care as needed. Appropriate HIV-1 diagnostic testing for infants and children younger than 18 months differs from that for older children, adolescents, and adults. Passively transferred maternal HIV-1 antibodies may be detectable in an exposed but uninfected infant's bloodstream until 18 months of age. Therefore, routine serologic testing of HIV-1–exposed infants and children is generally only informative before the age of 18 months if the test result is negative.

Assays that directly detect HIV-1 DNA or RNA (generically referred to as HIV-1 nucleic acid amplification tests [NAATs]) represent the gold standard for diagnostic testing of infants and young children under the age of 18 months. With such testing, the diagnosis or the presumptive exclusion of HIV-1 infection can be established within the first several weeks of life among nonbreastfed infants. Although neonatal ARV use may decrease the concentration of HIV-1 RNA in infant plasma in the first 6 weeks of life,[38] HIV-1 DNA test results remain positive even in individuals receiving combination ARV therapy who have undetectable plasma HIV-1 RNA. The sensitivity of both DNA and RNA testing is high,[39,40] so either can be used for the diagnosis of HIV-1 infection in infancy.[41] False-positive results with low-level viral copy numbers have been described by using HIV-1 RNA assays,[38,42,43] reinforcing the importance of repeating any positive assay result to confirm the diagnosis of HIV-1 infection in infancy.[16] False-negative results are also possible, and even infants with multiple negative HIV-1 NAAT results should be retested (perhaps by using a different test) if clinical findings suggest the presence of HIV-1 infection.

The Detection of Non–Subtype B HIV-1 and of HIV-2 by NAATs

For infants born to women known or suspected to have acquired infection with non-B subtypes of HIV-1, use of HIV-1 RNA assays may be preferable to the use of HIV-1 DNA assays for diagnostic testing. Women who acquire HIV-1 infection in North America are most commonly infected with HIV-1 subtype B.[44] Women who acquire HIV-1 outside of North America are often infected with other HIV-1 subtypes. Subtypes C and D predominate in southern and eastern Africa, subtype C on the Indian subcontinent, and subtype E in much of Southeast Asia.[45] Currently available HIV-1 DNA polymerase chain reaction (PCR) assays may be less sensitive in the detection of non-B subtype HIV-1, and false-negative HIV-1 DNA PCR assay results have been reported in infants infected with non-B subtype HIV-1.[46,47] Some of the currently available HIV-1 RNA assays have improved sensitivity for detection of non-B subtype HIV-1 infection, although even these assays may not detect all non-B subtypes, such as the uncommon group O HIV-1 strain. When testing infants suspected of infection with non-B subtype HIV-1, consultation with a pediatrician experienced in the care of infants and children with HIV infection is recommended.

HIV-2 is a retrovirus similar to HIV-1 and is found

TABLE 2 **Evaluation and Treatment of the Infant Exposed to HIV-1 (Birth to 18 Months of Age), in Addition to Routine Pediatric Care and Immunizations**

Action[a]	Infant Age						
	Birth	14 d	4 wk	6 wk	8 wk	4 mo	12–18 mo
History and physical examination[b]	X		X				
Assess risk of other infections	X						
ARV prophylaxis[c]	→	→	→	→|			
Recommend against breastfeeding	X→						
Hemoglobin or complete blood cell count	X		X[d]		X[d]		
HIV-1 DNA PCR or RNA assay[e]	[f]	X[g]	X		[h]	X	
Initiate PCP prophylaxis[i]				X			
Enzyme immunoassay for antibody to HIV-1[j]							X

[a] See text for detailed discussion of each action. If during this period the infant is diagnosed as HIV-1 infected, laboratory monitoring and immunizations should follow guidelines for treatment of pediatric HIV infection.[16,37]

[b] Review maternal health information for possible exposure to coinfections (see text). Frequency of examinations is determined, in part, by frequency of visits for immunizations in infancy.

[c] ARV prophylaxis is initiated as soon as possible after birth but certainly within 12 hours. ZDV prophylaxis is continued for 6 weeks, at which time it is stopped.

[d] Checked at 4 weeks by some experts and rechecked at 8 weeks if the week 4 hemoglobin level was significantly low.

[e] All HIV-1–exposed infants should undergo virologic testing for HIV-1 with HIV-1 DNA PCR or RNA assays at 14 to 21 days of age and, if results are negative, repeated at 1 to 2 and 4 to 6 months of age to identify or exclude HIV-1 infection as early as possible. Any positive test result at any age is promptly repeated to confirm the diagnosis of HIV-1 infection.

[f] HIV-1 DNA PCR or RNA assay testing in the first few days of life allows identification of in utero infection and might be considered if maternal ARV agents were not administered during pregnancy or in other high-risk situations. A negative test result at this age requires repeat testing to exclude HIV-1 infection.

[g] If HIV-1 RNA or DNA testing of the newborn infant was not performed shortly after birth, or if such test results were negative, diagnostic testing with HIV-1 NAAT is delayed until 14 to 21 days of age, because the diagnostic sensitivity of virologic assays increases rapidly by the age of 2 weeks. A negative test result at this age requires repeat testing to exclude HIV-1 infection. Presumptive uninfected indicates negative NAAT result at ≥14 days and ≥4 weeks (1 month) of age; definitive uninfected, negative NAAT result at ≥1 and ≥4 months of age (see text for complete details).

[h] No NAAT is needed at 8 weeks of age if previous test results at 2 and 4 weeks of age were negative. A single negative NAAT result at 8 weeks identifies a presumptively uninfected infant.

[i] Infants diagnosed with HIV-1 infection should be given PCP prophylaxis until 1 year of age, at which time infants are reassessed on the basis of age-specific $CD4^+$ T-lymphocyte count/percentage thresholds. Infants with indeterminate HIV-1 infection status should receive prophylaxis starting at 4 to 6 weeks of age until they are deemed to be presumptively or definitively uninfected with HIV-1. Prophylaxis is not recommended for infants who meet criteria for presumptive or definitive lack of HIV-1 infection; therefore, an NAAT at 2 and 4 weeks of age allows avoidance of PCP prophylaxis if both are negative.

[j] Many experts confirm the absence of HIV-1 infection with a negative HIV-1 antibody assay result at 12 to 18 months of age.

most commonly in western Africa. It is less virulent, with a slower rate of progression of clinical disease and lower rates of transmission from mother to child.[48] If infant infection with HIV-2 is suspected, specific HIV-2 virologic testing must be requested, because virologic tests for HIV-1 will not identify HIV-2. Consultation with the CDC via the state department of health may be helpful in arranging this testing.

Timing of Diagnostic Testing in Infants With Known Perinatal Exposure to HIV-1

It is recommended that diagnostic testing with HIV-1 DNA or RNA assays be performed at 14 to 21 days of age and, if results are negative, repeated at 1 to 2 months of age and again at 4 to 6 months of age.[41] Viral diagnostic testing in the first few days of life is recommended by some experts to allow for the early identification of infants with infection acquired in utero. For children with negative virologic tests, many experts confirm the absence of HIV-1 infection with HIV-1 antibody assay testing at 12 to 18 months of age (Table 2).

An HIV-1 NAAT might be considered at birth or in the first few days of life for infants at high risk of infection, including those whose mothers received no ARV drugs during pregnancy or when maternal prophylaxis was started late in pregnancy or during labor or if the mother had primary HIV-1 infection during pregnancy. In the absence of maternal ARV therapy, as many as 30% to 40% of infants with HIV-1 infection can be identified by 48 hours of age.[32,49] Infants with a positive virologic test result at or before 48 hours of age are considered to have in utero infection with HIV-1, whereas infants who have a negative virologic test during the first week of life and a subsequent positive test are considered to have intrapartum infection.[50] Cord blood specimens should not be used for HIV-1 RNA or DNA testing, because they are associated with an unacceptably high rate of false-positive test results.

If HIV-1 RNA or DNA testing of the newborn infant was not performed shortly after birth, or if such test results were negative, diagnostic testing with HIV-1 NAAT is delayed until 14 to 21 days of age, because the diagnostic sensitivity of virologic assays increases rapidly by 2 weeks of age. This change in assay sensitivity in the first 2 weeks of life reflects the biology of MTCT, because when HIV-1 is acquired at the time of delivery, NAAT positivity may be delayed until at or after 14 days.[50] Therefore, negative results of HIV-1 DNA PCR or RNA tests performed before 14 days of age are less helpful in excluding HIV-1 infection acquired at the time of birth than are results of tests performed at or after 14 days of age.[51]

Management if an HIV-1 Virologic Test Result Is Positive

If any of the HIV-1 virologic test results are positive, an immediate repeat HIV-1 NAAT is recommended to confirm the diagnosis of HIV-1 infection. A diagnosis of HIV-1 infection can be made on the basis of 2 separate blood samples, each of which is positive for HIV-1 DNA or RNA. If infection is confirmed, a pediatric HIV specialist should be consulted for advice regarding ARV therapy and care. HIV-1 disease can progress very rapidly in HIV-1–infected infants, and neither CD4 T-lymphocyte count nor HIV-1 RNA copy number are reliable predictors of the risk of progression in infected infants.[52] For this reason, current US pediatric HIV-1 treatment guidelines state that combination ARV treatment is recommended for all HIV-1–infected infants younger than 12 months regardless of clinical symptoms and immunologic or virologic measurements.[16]

Interpretation of Negative HIV-1 Test Results

On the basis of analysis of HIV-1 DNA PCR and HIV-1 RNA assay results from multiple studies, the CDC has revised the case definition for exclusion of HIV-1 infection in infants for surveillance purposes.[51] The definitions supplied here are based on the CDC surveillance definitions and are appropriate for the management of children born to women with HIV-1 infection. These definitions of exclusion of HIV-1 infection are only for use in infants who do not meet the criteria for HIV-1 infection noted previously.

In nonbreastfeeding infants younger than 18 months of age with no positive HIV-1 virologic test results, presumptive exclusion of HIV-1 infection is based on:

- 2 negative HIV-1 RNA or DNA virologic test results, from separate specimens, both of which were obtained at ≥2 weeks of age and 1 of which was obtained at ≥4 weeks of age; or
- 1 negative HIV-1 RNA or DNA virologic test result from a specimen obtained at ≥8 weeks of age; or
- 1 negative HIV-1 antibody test result obtained at ≥6 months of age; and
- no other laboratory or clinical evidence of HIV-1 infection (ie, no subsequent positive results from virologic tests if tests were performed and no AIDS-defining condition for which there is no other underlying condition of immunosuppression).

Infants or children with these test results are presumptively not infected with HIV-1, but further testing is required to definitively exclude and then confirm the absence of HIV-1 infection. In the unusual case of an infant with a positive HIV NAAT result followed by a negative test result, an expert in care of children with HIV infection should be consulted for further testing recommendations.

In nonbreastfeeding infants with no positive HIV-1 virologic test results, definitive exclusion of HIV-1 infection is based on:

- at least 2 negative HIV-1 RNA or DNA virologic test results, from separate specimens, both of which were obtained at ≥1 month of age and 1 of which was obtained at ≥4 months of age, or
- at least 2 negative HIV-1 antibody test results from separate specimens obtained at ≥6 months of age; and
- no other laboratory or clinical evidence of HIV-1 infection (ie, no subsequent positive results from virologic tests if tests were performed and no AIDS-defining condition for which there is no other underlying condition of immunosuppression).

Infants or children with these test results are definitively not infected with HIV-1, but follow-up testing allows confirmation of that assessment.

Many experts confirm the absence of HIV-1 infection with a negative HIV-1 antibody assay result at 12 to 18 months of age (see next section). For both presumptive and definitive exclusion of infection, the child should have no other laboratory (eg, no positive virologic test results) or clinical (eg, no AIDS-defining conditions) evidence of HIV-1 infection.

For breastfeeding infants, a similar testing algorithm can be followed, with timing of testing based on the date of complete cessation of breastfeeding instead of the date of birth.

Role of HIV-1 Antibody Testing in HIV-Exposed Infants

In HIV-1–exposed infants who are not infected with HIV-1, maternal HIV-1 antibodies transferred in utero may persist until 18 months of age (seroreversion). Many initially seropositive infants serorevert to HIV-1 antibody negativity by 12 months of age.[53] Many experts confirm the absence of HIV-1 infection with a negative HIV-1 antibody assay at 12 to 18 months of age. If an HIV-1–exposed infant who is not known to be infected is tested at 12 months of age and is still antibody-positive, then testing should be repeated at 18 months of age. Performing the first antibody test at 18 months of age to confirm seroreversion may avoid the cost and pain of performing 2 tests. Loss of HIV-1 antibody in an infant with previously negative HIV-1 virologic test results definitively confirms that the infant is not infected with HIV-1. Positive HIV-1 antibodies at 18 months of age or older indicate HIV-1 infection. A positive antibody test at or beyond 18 months of age in an infant with infection previously excluded as outlined above suggests that the infant was infected after infancy, such as through breastfeeding, premastication of solid food by an HIV-1–infected caregiver,[54] or sexual abuse.

Prevention of PCP

PCP is the most common serious opportunistic infection in HIV-1–infected infants and children. The highest incidence of PCP in HIV-1–infected infants is during the first year of life, with cases peaking at 3 to 6 months of age.[55,56] Chemoprophylaxis is highly effective in the prevention of PCP. HIV-1–exposed infants should be considered for prophylaxis beginning at 4 to 6 weeks of age.[37]

Infants diagnosed with HIV-1 infection should be given prophylaxis until 1 year of age, at which time

TABLE 3 **Regimens for PCP Prophylaxis in Infants[37]**

Drug	Dose	Route	Schedule
Trimethoprim-sulfamethoxazole	Trimethoprim 150 mg/m^2 per d, with sulfamethoxazole 750 mg/m^2 per d	PO	Twice daily for 3 d/wk on consecutive days (eg, Monday, Tuesday, and Wednesday) or on alternate days (eg, Monday, Wednesday, and Friday); alternatives: once daily for 3 d/wk or twice daily 7 d/wk
Dapsone	2 mg/kg	PO	Once daily
	4 mg/kg	PO	Once weekly
Pentamidine	4 mg/kg	IV	Every 2–4 wk
Atovaquone			
Infants 1–3 mo old	30 mg/kg	PO	Once daily
Infants 4–24 mo old	45 mg/kg	PO	Once daily

For further discussion, see "Guidelines for the Prevention and Treatment of Opportunistic Infections Among HIV-Exposed and Infected Children."[37] PO indicates per os (by mouth); IV, intravenous.

reassessment is made on the basis of age-specific CD4$^+$ T-lymphocyte count/percentage thresholds. Trimethoprim/sulfamethoxazole is the drug of choice for prophylaxis because of its high efficacy, relative safety, low cost, and broad antimicrobial spectrum (Table 3; for further discussion see "Guidelines for the Prevention and Treatment of Opportunistic Infections Among HIV-Exposed and Infected Children"[37]).

Infants with indeterminate HIV-1 infection status should receive prophylaxis starting at 4 to 6 weeks of age until they are deemed to be presumptively or definitively uninfected (see previous section). Prophylaxis is not recommended for infants who meet criteria for presumptive or definitive lack of HIV-1 infection. Thus, for infants with negative HIV-1 NAAT results at 2 and 4 weeks of age (who are presumptively not infected with HIV-1), PCP prophylaxis can be avoided altogether. If PCP prophylaxis is started at 4 to 6 weeks of age in an HIV-1–exposed infant with indeterminate HIV-1 infection status, prophylaxis can be stopped if the child subsequently meets criteria for presumptive or definitive lack of HIV infection (Table 4).

Prevention of TB

Although the bacille Calmette-Guérin (BCG) vaccine is routinely recommended for administration at birth to infants born in countries with a high prevalence of TB, it is not routinely administered in the United States, where TB exposure is uncommon. BCG immunization is not recommended for infants born to women with HIV-1 infection in the United States. BCG vaccine should not be administered to infants and children with known HIV-1 infection because of its potential to cause disseminated disease.[37] Counseling should be provided to families originally from countries with endemic TB, because many will visit such destinations and seek BCG vaccine during those trips.

The populations at risk for infection with HIV-1 and TB overlap, and numerous studies have documented the increased risk of TB in HIV-1–infected adults. Infants and children with TB infection and disease are almost always infected by an adult in their daily environment. Therefore, information should be obtained regarding the TB infection status of the mother and other household contacts of all infants born to HIV-1–infected mothers.

TABLE 4 **Sample Clinical Scenario for Evaluation and Treatment of the Infant Exposed to HIV-1 in the United States**

Timing (Infant Age)	Action	Comment
Birth	History and physical examination; assess risk of other infections; start ARV prophylaxis; check hemoglobin level	HIV-1 NAAT[a] is not needed at birth in this setting, because risk of in utero transmission is low; for infant whose mother had high virus load during pregnancy, consider HIV-1 NAAT at this time
14 d	HIV-1 NAAT	If result is negative, repeat at 4 wk[b,c]
4 wk	HIV-1 NAAT	If result is negative, HIV-1 infection is presumptively excluded (given previous negative result at ≥2 wk of age)
6 wk	Stop ARV prophylaxis	PCP prophylaxis is not needed if HIV-1 NAAT result is negative at 14 d and 4 wk of age[d]
8 wk	No HIV-1 NAAT needed if previous test results were negative at 14 d and 4 wk of age	A single negative result of HIV-1 NAAT performed at 8 wk of age allows presumptive exclusion of HIV-1 infection[e]
4 mo	HIV-1 NAAT	If negative, HIV-1 infection is definitively excluded in the infant with previous presumptive exclusion
12–18 mo	Enzyme immunoassay for antibody to HIV	To confirm the absence of HIV infection[f]

Scenario: infant born to an HIV-infected mother taking highly active ARV therapy since second trimester, virus load undetectable the week before delivery, and mother received 3 hours of ZDV intravenously before delivery.

[a] Either an HIV-1 DNA PCR or RNA assay.

[b] If any positive HIV-1 NAAT result, test is promptly repeated to confirm the diagnosis of HIV-1 infection (see "Management if an HIV-1 Virologic Test Result Is Positive").

[c] Some experts recommend checking hemoglobin level or complete blood cell count at 2 weeks and/or 4 weeks of age. These more frequent measurements might be warranted for preterm infants or if the baseline hemoglobin level is low.

[d] If no testing was performed before this or only a single test was performed between 14 days and 6 weeks of age, start PCP prophylaxis at this point until HIV infection is presumptively excluded.

[e] If PCP prophylaxis was started because of indeterminate HIV-1 infection status from incomplete previous testing, it can be stopped when this 8-week test result is negative.

[f] Many experts confirm the absence of HIV-1 infection with a negative HIV-1 antibody assay result at 12 to 18 months of age.

HIV-1–exposed and –infected infants living in households with people who have had positive tuberculin skin test (TST) results should be evaluated for TB with a TST (5 tuberculin units of purified protein derivative) at 3 months of age and be retested at least once per year.[37] Infants with a positive TST result or who have exposure to a person who has active TB (regardless of the child's TST result) should be treated for latent TB infection (after excluding active TB in the infant), according to published guidelines.[37,57] If the mother or a household member has active TB that is of a contagious form (smear-positive), the infant should be separated from that person, if possible, until the person receives TB treatment and is no longer contagious (becomes smear-negative). Should the mother have documented hematogenous dissemination of TB, the infant should be evaluated for congenital TB following published guidelines.[57] Consultation with a pediatric infectious disease expert should be sought.

Immunizations

Immunization schedules for children 0 to 6 and 7 to 18 years of age are published annually (www.cdc.gov/vaccines/recs/schedules/default.htm). A schedule for HIV-1–infected children is also published.[37] All routine infant immunizations should be given to HIV-1–exposed infants. If HIV-1 infection is confirmed, then guidelines for the HIV-1–infected child should be followed.[37] All inactivated vaccines can be administered safely to HIV-1–infected children regardless of whether the vaccine is a killed whole organism or a recombinant, subunit, toxoid, polysaccharide, or polysaccharide protein-conjugate vaccine, and the usual doses and schedules are recommended. Persons with severe cell-mediated immunodeficiency should not receive live-attenuated vaccines. However, children with HIV-1 infection are at increased risk of complications of varicella, herpes zoster, and measles compared with immunocompetent children. On the basis of limited safety, immunogenicity, and efficacy data among HIV-1–infected children, varicella and measles-mumps-rubella vaccines can be considered for HIV-1 infected children who are not severely immunosuppressed (those with $CD4^+$ T-lymphocyte percentages of $\geq$15%).[37] Note that the combined measles-mumps-rubella-varicella (MMRV) vaccine is not recommended for use in children with HIV-1. HIV-1–exposed and HIV-1–infected infants should receive 1 of the live-attenuated rotavirus vaccines at 2, 4, and 6 months of age (RotaTeq) or at 2 and 4 months of age (Rotarix). The first dose should be administered between 6 and 13 weeks of age, and the last should be administered at no later than 32 weeks of age.[37]

Monitoring for Toxicity From in Utero and Neonatal ARV Drug Exposure

Monitoring for and Management of Short-term Toxicity During Infant ARV Prophylaxis

A baseline hemoglobin or complete blood cell and differential count should be performed on the newborn infant, because infants whose mothers have received ARV agents during pregnancy are at risk of small but measurable differences in several hematologic variables, including hemoglobin level and neutrophil and lymphocyte counts.[58] The risk of anemia and neutropenia is greater in infants whose mothers were treated with combination ARV therapy during pregnancy,[59,60] but anemia is also more common in infants whose mothers were treated only with ZDV compared with infants whose mothers received no ARV treatment during pregnancy.[9] Nevertheless, the benefits of maternal ARV therapy in prevention of MTCT of HIV-1 clearly outweigh the risks of this hematologic toxicity in the newborn infant.[61,62]

Anemia is the primary clinically important complication of the 6-week ZDV regimen in the neonate, but it is unusual for the anemia to be clinically significant. Anemia associated with ZDV prophylaxis resolves when ZDV is stopped. Severe anemia that persists after prophylaxis is stopped should be further evaluated for alternative etiologies. Hematologic toxicity is more significant in infants who were exposed to antepartum ZDV in combination with other ARV drugs and in infants who received both ZDV and lamivudine as infant prophylaxis for 6 weeks.[24,63] Although anemia is mild and asymptomatic in most term infants treated with ZDV, it may be more severe in preterm infants or those with additional medical problems.

Decisions about the timing of hematologic monitoring of infants treated with prophylactic ARV agents after birth depend on a number of factors, including baseline hematologic values, gestational age at birth, clinical condition of the child, receipt of concomitant medications, and maternal antepartum therapy. Some experts recheck hematologic values in a healthy infant who is receiving 6 weeks of ZDV prophylaxis only if the child is symptomatic, and others recheck hemoglobin and/or neutrophil counts after 4 weeks of ZDV treatment, particularly if the infant was born preterm or if trimethoprim/sulfamethoxazole prophylaxis is anticipated.

If hematologic abnormalities are identified, decisions on whether to continue infant ARV prophylaxis need to be individualized. Considerations include the extent of the laboratory abnormality, associated clinical symptoms, duration of infant prophylaxis already received, the magnitude of the risk of HIV-1 infection in the infant (as assessed by maternal receipt of ARV prophylaxis, maternal viral load near delivery, and mode of delivery), and availability of alternative interventions (eg, erythropoietin, red blood cell transfusion). Consultation with a pediatric HIV-1 specialist is advised if early discontinuation of prophylaxis is considered.

Routine measurement of serum lactate concentration in asymptomatic neonates to assess for potential mitochondrial toxicity is not recommended, because the clinical relevance of increased lactate concentrations is unknown, transient elevations return to normal, and predictive value for later appearance of symptomatic toxicity seems poor.[64–67] However, should an infant develop severe clinical symptoms of unknown etiology, particularly neurologic symptoms, serum lactate concentration should be determined. If the serum lactate con-

centration is significantly abnormal in an infant with compatible clinical symptoms, an expert in pediatric HIV-1 infection should be consulted regarding potential early discontinuation of prophylaxis. In most circumstances, prophylaxis should be continued unless there is a compelling reason to stop.

Long-term Toxicity

Data remain insufficient to address the effect that exposure to ZDV or other ARV agents in utero might have on long-term risk of neoplasia or organ-system toxicities. There are conflicting data regarding whether mitochondrial dysfunction is associated with perinatal ARV exposure. Mitochondrial dysfunction should be considered in children with perinatal ARV exposure who present with severe clinical findings of unknown etiology, particularly neurologic findings.[67–74]

Information regarding in utero and/or neonatal ARV exposure should be part of the ongoing permanent medical chart of the child, particularly for uninfected children. Children with in utero ARV exposure who develop significant organ-system abnormalities of unknown etiology, particularly of the nervous system or heart, should be evaluated for potential mitochondrial dysfunction.[71,73] Follow-up of children with ARV exposure should continue into adulthood because of the theoretical concerns regarding potential for carcinogenicity and teratogenicity of the nucleoside analog ARV drugs. Long-term follow-up should include yearly physical examinations of all children exposed to ARV drugs.

Testing Family Members

On identification of an HIV-1 exposed infant, HIV-1 screening should be recommended and offered to all immediate family members with unknown HIV-1 infection status, including the infant's father (or mother's sexual partners) and all siblings. The age of the siblings should not be a deterrent to testing, because it is possible for perinatally infected children to remain asymptomatic into adolescence.[75,76]

Counseling and Support

When counseling the mother of an HIV-1–exposed infant, the pediatrician should take into account that the diagnosis of HIV-1 infection may be recent for the mother, whose infection may first have been identified during or after pregnancy. The diagnosis has profound implications for the mother and the family. If the mother is not already receiving care for her HIV-1 infection, she should be referred for appropriate care for herself. Some families may require additional support because of HIV-1–associated illness or death in other family members.

Other factors that may lead to an increased need for social and psychological support services include poverty, substance abuse, depression, social isolation, lack of health care, unemployment, difficulty in finding housing, domestic violence, and fear of loss of existing supports and services, such as loss of support from a partner or loss of employment, insurance, or health care coverage. Pregnant adolescents with HIV-1 infection are a particularly vulnerable group.

For women and their families who have emigrated from other countries, there are frequently additional factors related to culture and concerns about immigration status. Many will have experienced or know of stigmatization and discrimination against people with HIV-1 infection and may have known individuals who died because they did not have access to appropriate ARV therapy. They may not have had experiences with the type of medical care available to them in the United States, which may lead to distrust or misunderstanding, complicating care and follow-up of the infant.

When counseling new parents or caregivers of an HIV-1–exposed infant, the pediatrician should provide an outline of plans for medical care for the infant. Important topics to cover include medications to prevent MTCT of HIV-1 and opportunistic infections, such as PCP, as well as the schedule of follow-up visits for assessment and laboratory assays (both for diagnosis of HIV-1 infection and to check for any adverse effects of ARV drug exposure). Mothers should be advised not to breastfeed regardless of whether they are receiving ARV drugs for treatment of their HIV-1 disease. Parents and caregivers should be advised of the importance of prompt assessment if the infant becomes ill. For the infant in foster care, caregivers should have sufficient information about the infant's health, including HIV-1 exposure status, to ensure appropriate care.

Education should be provided regarding the lack of transmission risk in family activities such as eating, bathing, or sleeping together. The pediatrician has the opportunity to review prevention of HIV-1 transmission through safer sex practices, including encouraging condom use for all acts of sexual intercourse. Similarly, review of, or referral for, risk-reduction practices regarding injection drug use should be incorporated into visits when appropriate. Education and planning regarding future reproductive plans for the family, likely in collaboration with the family's adult HIV and gynecologic and obstetric providers, can minimize the risk of HIV-1 acquisition for sexual partners and MTCT in future pregnancies.

The necessity of maintaining confidentiality should be emphasized. There may be family members who are not aware of the mother's diagnosis, so caution should be exercised in the labor and delivery unit and when discussing the management of the infant in the postpartum unit. HIV-1 exposure and infection are not reasons for exclusion from infant child care or school. Pediatricians should discuss the need for planning for future care if the mother were to become ill with her HIV-1 infection.

HIV-1 Exposure and Infection Status Reporting

By the start of 2008, name-based HIV-1 reporting to state health departments is required in all states and territories for surveillance purposes. Many require reporting pregnancy in HIV-1–infected women and also require reporting the HIV-1 infection status of their infants. Collecting the maternal ARV treatment history, maternal demographics, labor and delivery record, and

newborn records at the time of birth facilitates this required reporting. If reporting is delegated to another party, the pediatrician should facilitate the necessary information getting to the reporting provider.

SUMMARY

1. Whenever possible, maternal HIV-1 infection should be identified before or during pregnancy, which allows earlier initiation of care for the mother and for more effective interventions to prevent MTCT. The AAP recommends documented, routine HIV-1 antibody testing for all pregnant women in the United States, after notifying the patient that testing will be performed, unless the patient declines HIV-1 testing ("opt-out" consent, or "right of refusal"). All HIV-1 antibody testing should be performed in a manner consistent with state and local laws. In states where laws and regulations require written informed maternal consent for testing, practitioners should work to modify the laws or regulations to permit opt-out consent.
2. If the mother's HIV-1 serostatus is unknown at the time of labor or birth, the newborn infant's health care provider should perform rapid HIV-1 antibody testing on the mother or the newborn infant with appropriate consent consistent with state and local laws. The results should be reported to health care providers quickly enough to allow effective ARV prophylaxis to be administered to the infant as soon as possible after birth but certainly by 12 hours after birth.
3. ARV prophylaxis for the mother and newborn infant should be administered promptly on the basis of a positive rapid antibody test result without waiting for results of confirmatory HIV-1 testing, and breastfeeding should not be initiated. If the rapid test result is positive, confirmatory testing should be performed, and if confirmatory test results are negative (indicating that the infant was not truly exposed to HIV-1), then ARV prophylaxis should be stopped and breastfeeding can be initiated.
4. In the United States, HIV-1–infected mothers should not breastfeed their infants and should be educated about safe alternatives.
5. Maternal health information should be reviewed to determine if the infant may have been exposed to maternal coinfections such as TB, syphilis, toxoplasmosis, hepatitis B or C, cytomegalovirus, or herpes simplex virus. Diagnostic testing and treatment of coinfections in the infant are based on maternal findings and evaluation of the infant.[37]
6. Pediatricians should provide counseling to parents and caregivers of HIV-1–exposed infants about HIV-1 infection, including anticipatory guidance on the course of illness, infection-control measures, care of the infant, diagnostic tests, and potential drug toxicities.
7. All HIV-1–exposed infants should undergo virologic testing with HIV-1 DNA or RNA assays at 14 to 21 days of age, and if results are negative, tests should be repeated at 1 to 2 and 4 to 6 months of age to identify or exclude HIV-1 infection as early as possible. For children with negative virologic test results, many experts confirm the absence of HIV-1 infection with HIV-1 antibody assay testing at 12 to 18 months of age. If any test result is positive, the test should be repeated immediately for confirmation.
8. Initial testing in the first few days of life allows identification of in utero infection and might be considered if maternal ARVs were not administered during pregnancy or in other high-risk situations. If HIV-1 RNA or DNA testing of the newborn infant was not performed shortly after birth, or if such test results were negative, diagnostic testing with HIV-1 NAAT is delayed until 14 to 21 days of age, because the diagnostic sensitivity of virologic assays increases rapidly by 2 weeks of age.
9. For nonbreastfeeding infants and children younger than 18 months with no positive HIV-1 virologic test results, presumptive exclusion of HIV-1 infection is based on 2 negative HIV-1 RNA or DNA virologic test results from separate specimens, both of which were obtained at ≥2 weeks of age and 1 of which was obtained at ≥4 weeks of age; 1 negative HIV-1 RNA or DNA virologic test result obtained at ≥8 weeks of age; or 1 negative HIV-1 antibody test result obtained at ≥6 months of age. If these test results are negative, further testing is required to definitively exclude HIV-1 infection.
10. For nonbreastfeeding infants and children younger than 18 months of age with no positive HIV-1 virologic test results, definitive exclusion of HIV-1 infection is based on 2 negative HIV-1 RNA or DNA virologic test results from separate specimens, both of which were obtained at ≥1 month of age and 1 of which was obtained at ≥4 months of age, or 2 negative HIV-1 antibody test results from separate specimens, both of which were obtained at ≥6 months of age. Further testing is suggested to confirm the absence of HIV-1 infection.
11. Many experts confirm the absence of HIV-1 infection with a negative HIV-1 antibody assay result at 12 to 18 months of age. These laboratory tests can only be used to exclude HIV-1 infection if there is no other laboratory or clinical evidence of HIV-1 infection (ie, no subsequent positive results from virologic tests if tests were performed and no AIDS-defining condition for which there is no other underlying condition of immunosuppression).
12. For breastfeeding infants, a similar testing algorithm can be followed, with timing of testing based on the date of complete cessation of breastfeeding instead of the date of birth.

13. Infants born of HIV-1–infected mothers should be considered for PCP prophylaxis beginning at 4 to 6 weeks of age. Infants with indeterminate HIV-1 infection status should receive prophylaxis until they are determined presumptively or definitively not to be infected with HIV-1. Prophylaxis is not recommended for infants who meet criteria for presumptively or definitively not infected with HIV-1 (see "Interpretation of Negative HIV-1 Test Results").
14. All infants exposed to ARV agents in utero or as infants should be monitored for short- and long-term drug toxicity.
15. Immunizations and TB screening should be provided for HIV-1–exposed infants in accordance with published guidelines.[37]
16. HIV-1 testing should be offered and recommended to family members of HIV-1–exposed infants.
17. The practitioner providing care for the HIV-1–exposed or HIV-1–infected infant should consult with a pediatric HIV-1 specialist. If the HIV-1–infected mother is an adolescent, consultation with a practitioner familiar with the care of adolescents is advised.

Guidance for the Clinician in Rendering Pediatric Care

Clinical Report—The Evaluation of Sexual Behaviors in Children

abstract

Most children will engage in sexual behaviors at some time during childhood. These behaviors may be normal but can be confusing and concerning to parents or disruptive or intrusive to others. Knowledge of age-appropriate sexual behaviors that vary with situational and environmental factors can assist the clinician in differentiating normal sexual behaviors from sexual behavior problems. Most situations that involve sexual behaviors in young children do not require child protective services intervention; for behaviors that are age-appropriate and transient, the pediatrician may provide guidance in supervision and monitoring of the behavior. If the behavior is intrusive, hurtful, and/or age-inappropriate, a more comprehensive assessment is warranted. Some children with sexual behavior problems may reside or have resided in homes characterized by inconsistent parenting, violence, abuse, or neglect and may require more immediate intervention and referrals. *Pediatrics* 2009;124:992–998

INTRODUCTION

Sexual behaviors in children range from normal and developmentally appropriate to abusive and violent. Concerned parents often present to the pediatrician's office with questions about whether their child's sexual behavior is normal, whether the behavior indicates that the child has been sexually abused, and how to manage such behavior. Although earlier studies[1,2] have suggested a strong correlation between sexual abuse and sexual behavior problems in children, more recent studies[3,4] have broadened this perspective, recognizing a number of additional stressors, family characteristics, and environmental factors that are associated with intrusive and frequent sexual behaviors. Clinicians must first distinguish age-appropriate and normal sexual behaviors from behaviors that are developmentally inappropriate and/or abusive (sexual behavior problems). Children with sexual behavior problems require further assessment and more specialized treatment approaches.

Sexual behaviors are common in children. More than 50% of children will engage in some type of sexual behavior before their 13th birthday.[5,6] In 1 retrospective study of 339 child welfare and mental health professionals in which participants were asked about their own experiences before 13 years of age, 73% recalled engaging in sexual behaviors with other children, 34% recalled showing their genitals to another child, 16% recalled simulating intercourse with another child, and 5% recalled inserting an object in the vagina or rectum of another

child.[7] Another study[8] of female undergraduates reported that 26% recalled exposing themselves, 17% recalled unclothed genital touching, and 4% recalled oral-genital contact during childhood. Frequencies of childhood sexual behaviors retrospectively reported by adults may differ from frequencies contemporaneously reported by parents; recollection differences through time, personal acceptance of sexual behaviors as normal, and the extent to which the behavior is covert may explain some of the discrepant results. Mothers who are more educated and who acknowledge that sexual behaviors in children can be normal tend to report more sexual behaviors in their children when compared with mothers with fewer years of education and less acceptance of these behaviors.[9] It is not clear whether the mother's acceptance of certain sexual behaviors as normal affects her observation of such behavior or her response to such behavior; a mother who is less accepting of sexual behaviors may be less likely to report such behavior or may modify her child's overt sexual behavior with disapproval or negative feedback.

Whether a child is brought to the pediatrician's office with a complaint of sexual behaviors depends in part on the parents' knowledge and attitude about the behavior. Several additional factors modify the extent and nature of the child's sexual behavior: age of the child, developmental stage of the child, family environment, and parental behavior and response to the child. Some children may display sexual behaviors that are common and age-appropriate but that can become problematic and require intervention if the frequency is such that the behavior is disruptive to others.

DIFFERENTIATING NORMAL SEXUAL BEHAVIORS FROM SEXUAL BEHAVIOR PROBLEMS

Differentiating between normal and problem sexual behaviors is a critical role for the pediatrician (Table 1) and may, at times, require more decisive therapeutic evaluation and intervention by a mental health professional. However, normal sexual behavior and sexual behavior problems are not always clearly dichotomous, and distinguishing victim from perpetrator is not always unambiguous, especially when both are children. All children involved, however, do require assistance and guidance from health care professionals as well as parents and schools.

Different terms have been used to characterize sexual or "sexualized" behavior in children. Behavior such as sexualized play may be within a range of normal development among social peers, especially at various critical stages of growth and development, and may only require adult guidance and redirection. On the other hand, sexual behavior problems are behaviors that are developmentally inappropriate, intrusive, or abusive; an alternative, less precise term is "sexual acting out." "Sexually reactive youth" is a more descriptive and less inflammatory term than "youth sex offenders" in describing children and adolescents with sexual behavior problems as a result of inappropriate sexual experiences that include sexual abuse, exposure to sexualized material, and/or witnessing sexual activity by others.

Types of Sexual Behaviors

In a prospective study of children aged 2 to 5 years without a history of abuse (determined by parental screening), common sexual behaviors reported by caregivers include touching their genitals at home and in public, masturbating, showing their genitals to others, standing too close, and trying to look at nude people.[9] These behaviors do

TABLE 1 Examples of Sexual Behaviors in Children 2 to 6 Years of Age

Normal, Common Behaviors	Less Common Normal Behaviors[a]	Uncommon Behaviors in Normal Children[b]	Rarely Normal[c]
● Touching/masturbating genitals in public/private	● Rubbing body against others	● Asking peer/adult to engage in specific sexual act(s)	● Any sexual behaviors that involve children who are 4 or more years apart
● Viewing/touching peer or new sibling genitals	● Trying to insert tongue in mouth while kissing	● Inserting objects into genitals	● A variety of sexual behaviors displayed on a daily basis
● Showing genitals to peers	● Touching peer/adult genitals	● Explicitly imitating intercourse	● Sexual behavior that results in emotional distress or physical pain
● Standing/sitting too close	● Crude mimicking of movements associated with sexual acts	● Touching animal genitals	● Sexual behaviors associated with other physically aggressive behavior
● Trying to view peer/adult nudity	● Sexual behaviors that are occasionally, but persistently, disruptive to others	● Sexual behaviors that are frequently disruptive to others	● Sexual behaviors that involve coercion
● Behaviors are transient, few, and distractable	● Behaviors are transient and moderately responsive to distraction	● Behaviors are persistent and resistant to parental distraction	● Behaviors are persistent and child becomes angry if distracted

[a] Assessment of situational factors (family nudity, child care, new sibling, etc) contributing to behavior is recommended.
[b] Assessment of situational factors and family characteristics (violence, abuse, neglect) is recommended.
[c] Assessment of all family and environmental factors and report to child protective services is recommended.

not vary significantly when boys are compared with girls across all age groups, but they do diminish in both boys and girls after 5 years of age.[9] Children also engage in sexual behaviors that include other individuals, such as putting their tongue in another's mouth while kissing, rubbing their body against others, and touching children's and adults' genitals, but these behaviors are less common, occurring in fewer than 8% of children 2 to 5 years old.[9] Fewer than 1.5% exhibit any of the following: putting the mouth on genitals, asking to engage in specific sex acts, imitating intercourse, inserting objects into the vagina or anus, and touching animal genitals.[9] Such behaviors do not necessarily imply the child has been sexually abused but do merit further assessment. Among normative study samples of children, all 38 sexual behaviors that were studied were observed in at least some of the children,[10,11] which suggests that there is no single sexual behavior that is a pathognomonic sign of sexual behavior problems or abuse. Normal sexual behaviors usually diminish or become less apparent with redirection and admonishment from the parent, and although such behaviors may result in feelings of embarrassment in the child, feelings of anger, fear, and anxiety are uncommon.[7]

Sexual behaviors that involve children who are developmentally dissimilar or use of coercion and control by 1 child are abusive.[12] Distinct developmental differences occur when children are at least 4 years apart in age or cognitive abilities. Children who are fewer than 4 years apart in age may still engage in abusive sexual contact when 1 child uses physical force or threat of harm against the other child. Abusive behaviors generally occur without other witnesses, and threats to "keep the secret" are common. Abusive sexual behaviors require immediate and effective intervention.

Children with sexual behavior problems are more likely than children with normal sexual behaviors to have additional internalizing symptoms of depression, anxiety, withdrawal, and externalizing symptoms of aggression, delinquency, and hyperactivity.[9] This association suggests that some sexual behaviors occur within a continuum of behavioral problems with multifactorial causes.

Another group of children may engage in a greater variety and frequency of sexual behaviors that may be disruptive to others but not necessarily abusive. These behaviors are often noted after a shift in caregiving environments; examples include children placed in foster homes and children who attend child care. Among children who are not suspected victims of abuse, more time spent in child care correlates positively with the number and frequency of observed sexual behaviors.[9] Child care provides more opportunities for children to interact and explore each other in both sexual and nonsexual ways.

Age

The variety and frequency of sexual behaviors increases in young children up to 5 years of age and then decreases gradually thereafter.[9] In 1 normative study of 1114 children aged 2 to 12 years, a greater variety and frequency of sexual behaviors were reported by parents of boys and girls aged 2 to 5 years when compared with parents of children aged 6 to 9 and 10 to 12 years.[3] These data do not necessarily suggest that sexual behaviors are more common among young children but may reflect differences in observation patterns by parents and display tendencies by young children. Younger children are less aware of breaches in personal space and how their behavior may be construed as sexual or inappropriate. Reactions from others of embarrassment and shame may be misinterpreted as positive responses, prompting the child to persist in the sexual behavior.

FACTORS THAT AFFECT FREQUENCY AND TYPES OF SEXUAL BEHAVIORS

In addition to the child's developmental level and child care environments, other factors influence the frequency and types of sexual behaviors manifested by children. Family sexuality and attitudes toward nudity; exposure to sexual acts or materials; extent of supervision; stressors, including violence, parental absence because of incarceration, death, or illness; and abuse can affect sexual behaviors in children.[3,7]

Situational Factors

Depending on the child's developmental level, changes in environment and situations may result in an increase in sexual behaviors. Preschool-aged children are naturally inquisitive and undergo periods of enhanced awareness of their environments. Recognition of physiologic gender differences occurs during this time and contributes to inquisitive viewing and touching of other children's genitals. This curiosity-seeking behavior tends to occur within the context of other similar, nonsexual explorations. The birth of a new sibling, suddenly viewing another child or adult in the bathroom, or seeing their mother breastfeed can trigger or amplify children's sexual behaviors. These behaviors tend to be transient and distractible and diminish once the child understands that such behaviors are inappropriate, particularly for public viewing.

Environments in Which Sexuality Is More Open

Children who reside in homes in which there is family nudity, cobathing, or

less privacy when dressing, going to the bathroom, or bathing or in which sexual activities are occurring openly are more likely to openly engage in sexual behaviors.[3] Similarly, children from homes with readily accessible pornographic materials or poor supervision of children's access to such materials may use age-inappropriate sexual language and be more prone to engage others in sexual play.

Family Dysfunction and Stress

Sexual behavior problems in children are significantly related to living in homes in which there is disruption because of poor health, criminal activity, or violence. The greater the number of life stresses—including parental battering, death, incarceration, or illness requiring hospitalization; deaths of other family members; and child illness requiring hospitalization—the greater the number and frequency of sexual behaviors observed in children.[3] Because child abuse and neglect are more common in homes characterized by violence and criminal activity, children with sexual behavior problems who reside in such homes should be carefully assessed for abuse and neglect. Among children with a history of sexual abuse, 52% indicated that they had lived with an adult batterer during their childhood, and 58% of the child sexual offenders who were in-home males also battered their adult female partner.[13] As many as 68% of children with sexual behavior problems have witnessed intimate partner violence among their caregivers.[4] Adult violence in the home is strongly linked to abuse, neglect, and sexual behavior problems in children.

Children With Developmental Disabilities

Children with developmental disabilities may have deficits in several domains that can affect their sexual knowledge and activity. Such children may encounter challenges with social skills, personal boundaries, impulse control, and understanding what is hurtful or uncomfortable to others, factors that contribute to an increased risk of sexual behavior problems as well as sexual victimization.[14] In evaluating sexual behaviors in disabled children, the clinician should focus on developmental level rather than age when assessing whether behavior is appropriate; an adolescent with the cognitive abilities of a 3-year-old may exhibit self-stimulatory behavior that is consistent with his or her developmental level and inability to determine what behavior is appropriate in public.[15]

Abuse and Neglect

Sexual abuse and physical abuse of children are both associated with sexual behavior problems. One meta-analysis of 13 studies involving sexually abused children revealed that 28% had sexual behavior problems,[16] with the highest prevalence occurring in the youngest age groups. Conversely, in 1 study of 201 children 6 to 12 years of age with inappropriate, intrusive, or aggressive sexual behaviors, 48% were sexually abused, 32% had a physical abuse history, 35% had a history of emotional abuse, and 16% had a history of neglect[17]; from another study, a 38% sexual abuse validation rate among children with sexual behavior problems was reported.[4] Manifestation of sexual behavior problems may not immediately follow sexually abusive experiences; in a study of 127 children aged 6 to 12 years with repetitive, diverse, disruptive, or abusive sexual behavior, the latency time between sexual abuse and manifestation of sexual behavior problems was 2.2 to 2.7 years for 6- to 9-year-olds and 3 to 4 years for 10- to 12-year-olds.[18] This period of latency may explain why some children placed out of abusive homes develop sexual behavior problems a number of months later. Although sexually abused children display more sexual behaviors with greater frequencies than do nonabused children,[3,19] there is no 1 specific sexual behavior that is indicative of sexual abuse. On average, sexually abused children display sexual behaviors of a variety and frequency that is 2 to 3 times that of children who are not abused or who have psychiatric diagnoses but have not been abused.[3] In sexually abused children, sexual behavior problems correlate positively with severity of abuse, number of perpetrators, family member perpetrators, and use of force.[3,10]

Given the strong correlation between violent and abusive family environments and sexual behaviors in children, it is not surprising that children who live in such homes may present clinically with sexual behavior problems after they are placed with alternative caregivers or in foster care. Sexual behaviors in these children may precede placement but may not have presented clinically or may manifest for the first time while in placement as a result of stress, situational changes, or greater accessibility to other children who may participate in such behaviors.

Neglect has also been associated with sexual behaviors in children. Lack of appropriate supervision and accessibility to sexually explicit materials may contribute to sexual behaviors seen in children from such homes. In addition, indiscriminate affection-seeking and interpersonal boundary problems have been reported in children who are victims of neglect[20]; such behaviors are often manifestations of attachment disorders seen in abused or neglected children.

Comorbid Diagnoses

In a clinical sample of 127 children aged 6 to 12 years with sexual behavior

problems, 96% had additional psychiatric diagnoses.[18] The most common diagnosis was conduct disorder (76%), followed by attention-deficit/hyperactivity disorder (40%) and oppositional defiant disorder (27%); most of the children in this sample had more than 1 psychiatric diagnosis.[18] The family environment of children diagnosed with conduct disorders is similar to the family environment of abused children: parents are more likely to administer harsh punishment, dislike their child, be unaware of where their child is, and be emotionally unavailable or unsupportive.[21] Families of children with severe sexual behavior problems seem to have the same parent-child conflicts as families of children who develop conduct disorders and engage in delinquent behaviors.[22]

CLINICAL ASSESSMENT AND TREATMENT

When children present to a clinical setting for an assessment, normal sexual behaviors should be differentiated from behaviors that are frequent, intrusive, or abusive. The Child Sexual Behavior Inventory (available at www.parinc.com/products/product.aspx?Productid=CSBI), developed to evaluate sexual behaviors in children aged 2 to 12 years who have been or may have been sexually abused, may assist clinicians in differentiating normative and atypical sexual behaviors. Because assessments are primarily based on parent history, the clinician should realize that some behaviors that are reported as problematic by the parent may be normal for the child. If sexual behaviors are normal and age-appropriate, parental reassurance and guidance regarding appropriate responses to the behavior may be all that is needed. If sexual behaviors are escalating, frequent, or intrusive, a more comprehensive assessment and treatment may be needed. If child abuse is suspected, or if the parent is ineffective in limiting the child's access to sexual material in the home, then a referral to child protective services is warranted. In addition, repetitive sexual behaviors between children that have not resolved despite pediatrician and parental guidance and redirection require more urgent intervention and may necessitate a report to child protective services for further investigation. When possible, it is important for pediatricians to maintain a dispassionate clinical response regarding the child perpetrator who may have been a victim of sexual abuse.

When conducting an assessment, clinicians may find that factors contributing to the child's sexual behaviors are multifactorial. A complete, careful assessment of sexual behavior problems will address all possible causes, including sexual abuse. An assessment of sexual behaviors in children may include the following:

1. Developmental considerations: Normal behaviors are seen more frequently in children younger than 6 years and between children of similar age and development. Sexual behavior between children of different development and/or age requires further assessment and possibly reporting to child protective services.
2. Types/frequency of sexual behaviors: Self-stimulation, personal space intrusiveness, interest in language or images of a sexual nature, exhibitionism, and mutual curiosity in peers' genitals are common normal sexual behaviors. Normal behavior tends to be transient and responsive to parental redirection or admonishment. Sexual behavior problems include behaviors that are coercive, persistently intrusive, injurious, and frequent; such behavior usually requires assessment of familial and situational factors and treatment beyond parent redirection.
3. Parent response to the behavior: Children relish attention and may enjoy the parent's discomfort that results from the sexual behaviors they display. Such children may repeat their behavior to elicit the (desired) parent response. If parents divert the child's behavior without emotional response, normal sexual behaviors tend to diminish. Sexual behavior problems may be persistently frequent or may escalate despite an appropriate parental effort to distract the child.
4. Situational factors (siblings, shift in care, nudity, parent education, acceptance of sexual behaviors): New siblings or new caregiving situations with additional children may trigger sexual behaviors; alternatively, new caregivers may become more observant of such behaviors. Children residing in homes in which nudity and/or sexuality are more open and acceptable may demonstrate more sexual behaviors.
5. Access to sexually explicit material or acts: Inappropriate or accidental exposure to sexual acts or materials can result in sexual behaviors. Such behaviors may become problematic if children are exposed to such material persistently or if the material is disturbing. In the latter situation, a careful assessment for abuse and supervisional neglect is appropriate.

In the absence of sex education at home and at school, various forms of media have been a primary source of information for many adolescents.[23] This information is often inaccurate, age-inappropriate, and misleading. In addition, early exposure to sexual content in the media has been linked to earlier onset of sexual intercourse among adolescents.[24,25]

6. Dysfunctional home environment: Life stresses, especially interparental violence, are strongly associ-

ated with sexual behavior problems in children.

7. Abuse/neglect: Children from homes characterized by physical abuse, sexual abuse, or neglect are more likely to have sexual behavior problems than children who are not from such homes. Any child with frequent, persistently intrusive, or abusive sexual behaviors should be assessed for possible abuse and neglect.

PARENTAL GUIDANCE

Reassurance and guidance about normal sexual behaviors can allay questions and concerns that many parents may have. A 3-year-old who begins to masturbate before falling asleep may simply have discovered a self-soothing technique, may have seen the genitals of a new sibling, or may be responding to the stress of returning to his or her mother's house after a weekend visit with his or her father. Appropriate parental responses are key to managing such behaviors.

The assessment of a child with sexual behavior problems may reveal a home environment characterized by abuse, neglect, or interpersonal violence. Sexual behavior problems in children who remain in such homes will be difficult to treat and manage. If the safety of the child is at risk, child protective services may place the child in alternative care, and sexual behaviors may escalate. Many children with sexual behavior problems will require referral to therapists for further assessment and treatment.

CONCLUSIONS

Many sexual behaviors in children are developmentally normal and transient and occur within a developmental trajectory that includes curiosity-seeking behaviors, testing of interpersonal boundaries, and situational factors that elicit such behaviors. Sexual behaviors that are persistently intrusive, coercive, developmentally abnormal, or abusive are associated with numerous situational and familial factors, including sexual abuse, physical abuse, and neglect. Sexual abuse is a common, but not exclusive, experience among children with sexual behavior problems. Once sexual behavior problems are identified, a careful assessment of family behaviors and home environment may clarify underlying causes and contributing factors. The clinical approach to children with sexual behaviors may entail a range of responses including tolerance and understanding, parental redirection, further assessment by a mental health professional, and referral to child protective services when abuse or neglect is suspected.

CLINICAL REPORT

Evaluation of Suspected Child Physical Abuse

Guidance for the Clinician in Rendering Pediatric Care

Nancy D. Kellogg, MD, and the Committee on Child Abuse and Neglect

ABSTRACT

This report provides guidance in the clinical approach to the evaluation of suspected physical abuse in children. The medical assessment is outlined with respect to obtaining a history, physical examination, and appropriate ancillary testing. The role of the physician may encompass reporting suspected abuse; assessing the consistency of the explanation, the child's developmental capabilities, and the characteristics of the injury or injuries; and coordination with other professionals to provide immediate and long-term treatment and follow-up for victims. Accurate and timely diagnosis of children who are suspected victims of abuse can ensure appropriate evaluation, investigation, and outcomes for these children and their families.

PREVALENCE

In 2004, 152 250 children and adolescents were confirmed victims of physical abuse in the United States.[1] Of the 4 types of child maltreatment (neglect, physical abuse, sexual abuse, and emotional abuse), physical abuse is second to neglect, constituting approximately 18% of the total.[1]

Despite these statistics, the estimated number of victims is much higher; in 1 retrospective cohort study of 8613 adults, 26.4% reported they were pushed, grabbed, or slapped; had something thrown at them; or were hit so hard they got marks or bruises at some time during their childhood.[2] It has been estimated that 1.3% to 15% of childhood injuries that result in emergency department visits are caused by abuse.[3] Physical abuse remains an underreported (and often undetected) problem for several reasons including individual and community variations in what is considered "abuse," inadequate knowledge and training among professionals in the recognition of abusive injuries, unwillingness to report suspected abuse, and professional bias. For example, in 1 study,[4] 31% of children and infants with abusive head trauma were initially misdiagnosed. Misdiagnosed victims were more likely to be younger, white, have less severe symptoms, and live with both parents when compared with abused children who were not initially misdiagnosed. Such studies suggest a need for practitioners to be vigilant to the possibility of abuse when evaluating children who have atypical accidental injuries or obscure symptoms that are suggestive of traumatic etiologies but who do not have a history of trauma.

Child abuse has significant long-term medical and mental health morbidity.[5] Children with abusive head or abdominal injuries are more likely to die or become more severely incapacitated than are children with head or abdominal injuries caused by accidents.[6–8] Victims of physical abuse in childhood are more likely to

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

develop a variety of behavioral and functional problems including conduct disorders, physically aggressive behaviors, poor academic performance, and decreased cognitive functioning.[9,10] Additional problems include anxiety and depression, as well as social and relationship deficits.

CHARACTERISTICS OF VICTIMS AND RISK FACTORS

Child physical abuse affects children of all ages, genders, ethnicities, and socioeconomic groups. Male and female children experience similar rates of physical abuse. In 1 survey study of more than 2000 children and adolescents,[11] 15% of adolescents received injuries from a physical assault and were more likely than children in younger age groups to receive injuries from abuse. Although the risk of physical abuse increases with age, fatal abuse and serious abusive injuries are more common among children and infants younger than 2 years.[1] Children in homes with annual incomes of less than $15 000 per year have 3 times the number of fatalities, 7 times the number of serious inflicted injuries, and 5 times the number of moderate inflicted injuries when compared with children living in homes with annual incomes of greater than $15 000 per year.[12] Risk factors for infant maltreatment include maternal smoking, the presence of more than 2 siblings, low infant birth weight, and an unmarried mother.[13] One study found that children living in households with unrelated adults were approximately 50 times more likely to die of inflicted injuries than were children residing with 2 biological parents.[14] The US Department of Health and Human Services has indicated that the rate of physical abuse is 2.1 times higher among children with disabilities than children without disabilities.[15] The presence of risk factors should not be used as indicators of child abuse but rather to provide guidance in prevention strategies as well as management and treatment plans.

ROLE OF THE PEDIATRICIAN

The role of the pediatrician encompasses prevention of abuse and detection and medical management of victims of abuse. Accurate identification of children who are suspected victims of abuse can facilitate appropriate evaluation, referral, investigation, and outcomes for these children and their families.[16] Children usually sustain abuse at the hands of a caregiver who misinterprets and responds inappropriately to the child's behavior. For example, caregivers who had smothered, shook, or slapped their infant within the first 6 months of life were more likely to be worried about crying and to believe that their infants cried excessively.[17] There is a close correlation between the age-specific incidence curve of infants hospitalized with abusive head trauma and the age-specific normal crying behavior of infants up to 36 weeks of age.[18]

In an anonymous telephone survey of 1435 mothers, 2.6% of children younger than 2 years were shaken by their mothers as a means of discipline.[19] Caregivers may respond inappropriately to their child's behavior when they are unduly stressed. Poverty, significant life events, and caregiver role conflicts are stressors that are often associated with abuse.[14] Pediatricians can effectively educate parents regarding the range of normal behaviors in infants and children, provide anticipatory guidance, and be a resource when the behavior becomes unmanageable for parents. In addition, pediatricians can screen for adult-partner violence; in 1 study, child abuse was 4.9 times more likely in families with identified spouse abuse than in families without identified spouse abuse.[20] Other conditions that place children at risk of being abused, such as maternal depression or drug abuse, may also be identified.

Careful medical assessment, detection of suspicious injuries, and reporting of abuse may prevent further abusive trauma in infants and adults.[4] In 1 study of abuse victims younger than 24 months, 75% had evidence of previous trauma or history of a previous injury.[21] Child abuse may recur 35% of the time without appropriate detection and intervention.[22]

As with other types of child maltreatment, there have been recent advances in medical knowledge regarding physical abuse. Most recent developments have addressed more accurate differentiation between inflicted and accidental injuries as well as detecting conditions that may mimic abusive injuries. Although consideration of nonabusive causes of injuries may merit additional evaluation and testing, the physician is mandated by law to report suspicions of abuse and should not delay reporting pending confirmatory testing or information. In all states, the law also provides some type of immunity for good-faith reporting. Once a suspected victim is identified and further assessment and management is required, using a pediatric child abuse consultant, if available, early in this process may obviate the need for invasive or expensive testing and can help direct the pediatrician toward appropriate evaluation. The detection and diagnosis of child physical abuse depends on the clinician's ability to recognize suspicious injuries, conduct a careful and complete physical examination with judicious use of auxiliary tests, and consider whether the caregivers' explanation is supported by the characteristics of the injury or injuries and the child's developmental capabilities. The physician should also ensure that the child's immediate medical and safety needs are met. Child abuse injuries, particularly traumatic brain injuries, may result in significant long-term disabilities including learning deficits, attention-deficit/hyperactivity disorder, behavioral problems, seizures, spasticity, blindness, paralysis, and mental retardation.[23,24] Continuity of care for such children is essential, especially if they are transferred to other caregivers or foster homes.

Many hospitals and communities have developed

child abuse–assessment teams of pediatricians and other professionals who specialize in the assessment of suspected victims of child abuse.[25] Such teams usually have access to additional information from law enforcement and child protective services, such as scene investigation, that may facilitate more thorough injury assessment and diagnosis. Involving such teams early in the process can ensure accurate and comprehensive assessments and information sharing among the medical and nonmedical disciplines involved and can provide for intermediate and long-term management of the child and family. Pediatricians with expertise in evaluating suspected abuse should provide training and assistance to emergency physicians and other first responders to enhance detection and appropriate referral of these patients.

Many regions do not have specialized child abuse teams but do have physicians with expertise in child abuse. Pediatricians should know which hospitals in their region have the most available expertise in the emergency evaluation of suspected child abuse. In turn, pediatricians with expertise in child abuse often act as consultants for emergency departments and child protective services. Close collaboration is necessary, particularly for establishing how the child should be transported between facilities, who should notify child protective services, who should notify the caregiver(s) of suspected abuse and when, and whether law enforcement should be notified. For those who do not require emergent transportation by ambulance, child protective services may facilitate transportation of a suspected child victim from one facility to another, assist in notifying the caregivers and law enforcement of suspected abuse, and provide an emergent safety plan on hospital discharge or clinic dismissal.

DEFINITIONS

The recognition and reporting of physical abuse is hindered by the lack of uniform or clear definitions. Many state statutes use words such as "risk of harm," "substantial harm," "substantial risk," or "reasonable discipline" without further clarification of these terms. Many states still permit the use of corporal punishment with an instrument in schools; on the other hand, the American Academy of Pediatrics has proposed that "striking a child with an object" is a type of physical punishment that "should never be used"[26] and has recommended that corporal punishment be abolished in schools.[27] The variability and disparities in definitions may hinder consistent reporting practices.

CLINICAL PRESENTATIONS AND SETTINGS

Most physical abuse injuries are likely to not be detected or reported. Minor injuries may not require medical attention and may be obscure or hidden. Infants and children are reported as suspected victims of physical abuse when 1 or more of the following occurs: an individual (including a professional) sees and reports a suspicious injury; an individual witnesses an abusive event; a caregiver observes symptoms and brings the child in for medical care but is unaware that the child has sustained an injury; an individual asks a child if he or she has been hurt in an abusive way; the abuser thinks the inflicted injury is severe enough to require medical attention; or the child victim discloses abuse. The American Academy of Pediatrics has indicated that "hospitalization of children requiring evaluation and treatment for abuse or neglect should be viewed by third-party payors as medically necessary."[28]

The clinical approach to an infant or child with possible abusive injuries is not significantly different from standard pediatric care. As with all patients, a severely injured child must be stabilized before further evaluation is undertaken. This initial evaluation may encompass a trauma response team and pediatric specialists in surgery, emergency medicine, and critical care. Careful documentation may not be possible initially and must always be secondary to resuscitation and stabilization of the patient. Once the child is stabilized, a careful and well-documented history, as always, is the most critical element of the medical evaluation. Using quotes whenever possible, the pediatrician should document descriptions of the mechanisms of injury or injuries, onset and progression of symptoms, and the child's developmental capabilities. The physical examination should include detailed documentation, either by body diagrams and/or photographs, of any concerning cutaneous findings and should include a thorough search for other signs that may suggest a nontraumatic cause. If the child is verbal, it may be helpful to gather parental and patient histories separately. If abuse is a concern after this preliminary evaluation, consultation with a child abuse pediatrician, pediatric specialist, or pediatrician experienced in this area, if available, may be helpful in determining the best way to proceed with assessment.

Physical discipline is commonly inflicted on areas of the body that are concealed by clothing (eg, back/buttocks). When inflicted injuries are visible or incidentally discovered, child victims and their abusers typically explain the injuries as accidental; if clinicians or professionals are not critical or skeptical of this information, the injuries may be incorrectly attributed to accidental causes. Other victims present with severe inflicted injuries that require medical care. The initial history is typically vague and/or benign and may become inconsistent as the investigation progresses.

MEDICAL HISTORY

The interview of parents or caregivers of infants or children who present with serious injuries may be conducted in an outpatient or inpatient setting. If the child presents to a clinic with a serious injury that requires further medical care in a specialty (eg, orthopedics) or

hospital setting, the clinician may opt to gather the minimum information to establish a need for reporting to child protective services. Any statements made by the caregiver regarding the injury should be documented accurately and completely. Once the clinician has assessed all the injuries, including approximate ages of injuries (when possible), a careful, complete, and detailed history should be obtained from the caregivers.

Explanations that are concerning for intentional trauma include:

1. no explanation or vague explanation for a significant injury;
2. an important detail of the explanation changes dramatically;
3. an explanation that is inconsistent with the pattern, age, or severity of the injury or injuries;
4. an explanation that is inconsistent with the child's physical and/or developmental capabilities; and
5. different witnesses provide markedly different explanations for the injury or injuries.

Information regarding the child's behavior before, during, and after the injury occurred, including feeding times and levels of responsiveness, should be gathered. Victims of significant trauma usually have observable changes in behavior. Access to caregivers and caregiver activities before, during, and after the injury occurred are also important to document. Frequently, infants and children present to medical settings with a history of a fall. Recent studies have indicated that short falls may result in bruising; however, more significant types of head trauma, including skull fractures, are exceedingly uncommon but possible.[29,30]

Information should be gathered in a nonaccusatory but detailed manner. Other information that may be useful in the medical assessment of suspected physical abuse includes:

1. past medical history (trauma, hospitalizations, congenital conditions, chronic illnesses);
2. family history (especially of bleeding, bone disorders, and metabolic or genetic disorders);
3. pregnancy history (wanted/unwanted, planned/unplanned, prenatal care, postnatal complications, postpartum depression, delivery in nonhospital settings);
4. familial patterns of discipline;
5. child temperament (easy to care for or fussy child);
6. history of past abuse to child, siblings, or parents;
7. developmental history of child (language, gross motor, fine motor, psychosocial milestones);
8. substance abuse by any caregivers or people living in the home;
9. social and financial stressors and resources; and
10. violent interactions among other family members.

PHYSICAL EXAMINATION

Most injuries of childhood are not the result of abuse or neglect. Minor injuries in children are exceedingly common. Physicians must also consider that unusual events, including accidents, do happen to children[31] and may produce injuries that are not characteristically seen from accidental causes. An injury pattern is rarely pathognomonic for abuse or accident without careful consideration of the explanation provided. In addition, both inflicted and accidental injuries may be seen simultaneously in a child.

General Assessment

The child's alertness and demeanor may reflect neurologic status and degree of discomfort and pain. A thorough and complete neurologic examination must be performed. For example, if alertness appears compromised, eye-opening, verbal, and motor responses should be assessed systematically. Spontaneous and symmetrical movement of all extremities should be noted, as well as any of the child's responses that indicate pain when extremities are examined and moved. Because abusive caregivers are rarely informative regarding the injuries that have been inflicted, special care should be taken during the examination of the child's extremities and neck, which may be fractured and require immobilization until diagnostic radiographs can be performed. Evidence of spinal cord injury, such as abnormal reflexes, muscle tone, or responsiveness to tactile stimuli, should be carefully pursued.

When the child is stable, height, weight, and frontooccipital circumference should be carefully measured and then plotted on a growth chart. Previous measurements obtained from past medical visits should also be obtained to gauge whether growth velocity has been appropriate. Plotting parameters is essential, because clinicians may miss significant growth failure in infants and children if the clinician relies only on their clinical impressions. Physical abuse and failure to thrive are sometimes concurrent[32,33]; in addition, some children are starved intentionally.[34]

Evidence of neglect may be seen during the general examination of the infant or child; extensive dental caries, severe diaper dermatitis, or neglected wound care may be noted in addition to injuries that raise suspicion of abuse. Bald areas on the scalp may sometimes be seen with severe nutritional deficits or with traumatic alopecia. These findings should be differentiated from nonabusive or benign causes such as tinea capitis, alopecia areata, and occipital bald spots caused by supine positioning of young infants.

If the child can be interviewed, his or her demeanor

should be noted during questioning. Some children display strong nonverbal cues of anxiety and reluctance when answering questions regarding potential abuse, because they are protective of their abuser or they fear retribution for "telling." Others may appear openly fearful of their abuser. Such responses may be important to consider when a safety plan for the child is made.

Skin Injuries

Location, size, and shape of any bruises, lacerations, burns, bites, or other skin injuries should be documented in a medical chart as well as with high-quality 35-mm or digital photographs. Inspection for injuries should be thorough and involve all aspects of the neck and head; mouth; extremities, including feet and hands; genitals; anus; buttocks; torso; and back. Obscure sites for inflicted injuries include the ears, especially the posterior aspects, the neck and angle of the jaw, scalp, and the frenula of the lip and tongue. In contrast to accidental injuries, inflicted injuries tend to occur on surfaces away from bony prominences, such as the neck, head, buttocks, trunk, hands, and upper arms.[35,36] In 1 patient series, approximately 60% of abused children had injuries on the head, face, or neck.[37] Hematomas of the scalp may be detected through palpation or may be visualized on radiographs. Some deeper bruises may not be readily visible for several hours; areas that are painful to palpate may require further examination in 1 to 2 days, when bruises may become apparent. Measurement of skin injuries may assist in determining the mechanism of injury and/or object used to inflict the injury. For example, a child that is kicked may have a discernable shoe imprint, or a knuckle imprint may be apparent if the child was punched.

Bite marks can yield important forensic information; referral to professionals that can gather such information and maintain a chain of custody is advisable.[38] Bite marks, recent or healed, should be carefully measured and photodocumented when possible; an intercanine distance of more than 2 cm suggests a human adult-sized bite.[39] In some facilities, forensic odontologists are available and may use special examination and photographic techniques to analyze bite marks. Fresh bites should be swabbed with sterile, premoistened cotton-tipped applicators for forensic analysis of potential genetic markers found in saliva.

The age of a bruise cannot be determined accurately.[40] Soft tissue swelling is seen more commonly with recent trauma but can persist for several days. The age and developmental capabilities of the infant or child also determine the frequency of bruising. For example, 1 study of infants and toddlers presenting for health maintenance examinations found that 17.8% of infants starting to "cruise" and 51.9% of ambulatory toddlers had bruises; bruises were observed only 2.2% of the time in infants who were not yet cruising.[36] In addition to accidents, bruising may occur secondary to coagulopathies and vasculitides such as idiopathic thrombocytopenic purpura, vitamin K deficiency, Henoch-Schönlein purpura, hemophilia, or von Willebrand disease.

Burn injuries may be chemical, thermal (including exposure to scalding liquids or hot objects), or electrical. The child's clothing worn during the burn should be collected and may provide information regarding the cause of the burn. Burns inflicted with hot objects can be difficult to differentiate from accidental mechanisms, because both burns may be patterned. The history, number of burns, and continuity of the burn pattern over curved body surfaces may indicate a greater probability of inflicted trauma. Accidental scalds most commonly involve hot liquids pulled or splashed onto the child's upper extremities, torso, and or neck and head.[41] Inflicted scalds or forced-immersion burns may be well demarcated in pattern, with few or no splash marks. When evaluating an apparent burn injury, other noninflicted causes to consider include chemical burns of the buttocks with senna-containing laxatives,[42] bullous impetigo, and accidents.

Cranial Injuries

Head trauma is the leading cause of child abuse fatalities.[43] When compared with child victims of severe accidents, children with abusive head trauma are more likely to have subdural and subarachnoid hematomas, multiple subdural hematomas of differing ages, more extensive retinal hemorrhages, and associated cutaneous, skeletal, and visceral injuries.[6] The inflicted injuries tend to occur in younger patients. Abusive head trauma tends to result in higher mortality and longer hospital stays than does accidental head trauma.[6,7] Infants with intracranial injuries frequently have no or nonspecific symptoms,[44,45] so the absence of neurologic symptoms should not exclude the need for imaging. Careful consideration of symptoms, signs, history, and judicious use of other ancillary tests should guide the clinician in determining the need for imaging.

Skull fractures can occur from accidents or inflicted injury. Studies have indicated that simple linear skull fractures can result from short falls of less than 3 ft and that such fractures are usually associated with scalp bruising or swelling.[46] However, it is unknown how many infants and children sustain skull fractures from simple falls, are asymptomatic, and, therefore, never present for a medical evaluation; hence, the incidence of skull fractures among infants who sustain such falls is likely unknown. Abuse should be suspected when there is a history of minor head trauma such as a short fall in children with multiple, complex, diastatic, or occipital skull fractures.[47] Whenever an infant or child presents with a skull fracture, care should be taken to ensure that there are no other injuries.

Conditions that may be confused with abusive head

trauma include glutaric aciduria type 1 (macrocranium, subdural hematoma, sparse intraretinal and preretinal hemorrhages, frontotemporal atrophy) and hemorrhagic disease of the newborn (including risk factors such as home birth, no vitamin K prophylaxis, or breastfeeding).

A fundoscopic examination for retinal hemorrhages should be considered for any infant or young child who is a suspected victim of physical abuse. Under optimal conditions, an ophthalmologist with pediatric experience should conduct an examination of dilated pupils by using indirect ophthalmoscopy. The ophthalmologist should provide documentation of the retinal hemorrhages by photography or detailed annotated drawings. Location, depth, and extent of retinal hemorrhages may distinguish between abusive and nonabusive causes of head trauma.[48] Retinal hemorrhages occur in approximately 85% of infants and children who are subjected to abusive, repetitive, acceleration-deceleration (shaking) forces with or without impact.[48] Although newborn infants may have retinal hemorrhages in the superficial nerve fiber layers, most resolve by 2 weeks of age, and most intraretinal hemorrhages resolve by 4 to 6 weeks of age.[49]

Thoracoabdominal Injuries

Inflicted injuries that involve the heart are rare and severe. Rib fractures in infants are usually caused by forceful squeezing of the chest[50]; posterior or lateral rib fractures or multiple rib fractures are especially predictive of abusive trauma.[51] Cardiopulmonary resuscitation, whether performed by experienced or inexperienced individuals, is an unlikely cause of rib fractures[52] or retinal hemorrhages. Acute rib fractures may be associated with shallow breathing attributable to pain and splinting; in severe cases, a fractured rib may puncture the lung. Alterations in respiratory patterns may also signal central nervous system damage or response to pain. Other rare injuries associated with abusive blows or compressive forces to the chest include hemopericardium, cardiac contusions occurring as a result of abusive blows to the chest, and shearing of the thoracic duct resulting in chylothorax.[53,54]

Auscultation, performed before palpation, may reveal decreased or no bowel sounds if the child has sustained intraabdominal injury. If the intestines, liver, or spleen have been ruptured, guarding or abdominal muscle rigidity may be noted on palpation. Abdominal bruising is often not seen, even with severe blows to the abdomen.[55] In 1 study,[56] solid organ injuries were most common in children with accidental and inflicted abdominal trauma, but abused children were more likely to have a hollow viscus injury or both hollow viscus and solid organ injuries than were children with accidental abdominal injuries. In comparison with children who sustain accidental trauma to the abdomen, victims of inflicted intraabdominal injury tend to be younger, are more likely to have delayed presentations to a clinical setting, have a higher mortality rate, and are more likely to have an injury to hollow viscera.[8] Liver and pancreatic enzyme tests are helpful in screening children for abdominal trauma, especially when the child presents with acute symptoms or shortly after the incident has occurred. A urinalysis may also lead to the discovery of unexpected trauma to the urinary tract and kidneys. Radiographic studies, including computed tomography, are helpful in determining the types and severity of intraabdominal trauma and are warranted in most cases when the physical examination is unreliable because of patient age, presence of other injuries that may obfuscate the abdominal examination, or the presence of head injury.

Skeletal Injuries

Careful palpation of the legs, arms, feet, hands, ribs, and head may reveal acute or healing (callus formation) fractures. If a fracture is suspected, surfaces should be carefully examined for "grab marks" that may indicate restraint or areas that were pulled or twisted to create the fracture; however, absence of such bruising does not exclude abusive mechanisms of injury. Soft tissue swelling, with or without bruising, may indicate more recent trauma. Many fractures, including rib and metaphyseal fractures, may not be clinically detectable, so a negative clinical examination should not preclude the need for a skeletal radiologic survey when inflicted trauma is suspected, particularly in children younger than 2 years.

Long-bone fractures that should be evaluated carefully for nonaccidental causes include metaphyseal fractures and spiral/oblique fractures, especially in nonambulatory infants; both types of fractures have been associated with accidental mechanisms of injury as well. Accidental causes of lower-extremity spiral or oblique fractures have been described among infants in "exersaucers"[57] and in the tibia of newly ambulatory toddlers.[58] Osteogenesis imperfecta is a rare congenital disorder that typically presents with bone fragility. Other associated findings are common and include deep-blue sclera, ligamentous laxity, osteopenia, wormian skull bones, dentinogenesis imperfecta, positive family history, and hearing loss. Less common types of this disease may present with fewer and less-severe clinical symptoms.[59] Patients with osteogenesis imperfecta are often suspected as victims of abuse before diagnosis, because the history of the injury insufficiently explains the severity of the fracture, and osteopenia may be lacking in occult cases of this disease.[60]

A complete neurologic assessment, including reflexes, cranial nerves, sensorium, gross motor, and fine motor abilities, should be conducted. Abnormalities may reflect current or past injuries to the central nervous system. Abused children may also have developmental disabili-

ties because of deprivation in the home environment or other causes.

DIAGNOSTIC TESTING AND CONSULTATIONS

When abuse is suspected as the cause of an injury, the clinician may conduct tests to screen for other injuries or underlying medical causes for the injury. The extent of diagnostic testing depends on several factors including the severity of the injury, the type of injury, the age of the child, and examination findings. In general, the more severe the injury and younger the child, the more extensive is the need for diagnostic testing for other injuries. Table 1 is a summary of tests, some of which may be used during a medical assessment for suspected abuse.

When 1 child is identified as a suspected victim of abuse, siblings and other child contacts of the suspected abuser should also be assessed for injuries. The extent of the assessment depends on the child's age, symptoms, and signs; infants and toddlers may require more extensive testing, because symptoms and signs may be less useful in determining the presence of occult inflicted injuries.

DOCUMENTATION AND DIAGNOSTIC CONSIDERATIONS

Complete documentation of visible injuries on body diagrams and with photographs is strongly urged and facilitates peer review as well as court testimony, when required. In some regions, investigators from law enforcement or child protective services are specially trained to take forensic photographs. Diagnostic impressions should address whether the explanation adequately correlates with the severity, age, pattern, and distribution of the injury or injuries and the likelihood of nonaccidental causes for the injury. If a child has sustained a serious injury because he or she was left unsu-

TABLE 1 Diagnostic Tests That May Be Used in the Medical Assessment of Suspected Physical Abuse and Differential Diagnoses

Type of Injury or Condition	Diagnostic Tests	Comments
Fractures	Skeletal survey: humeri, forearms, femurs, lower legs, hands, feet, skull, cervical spine, thorax (including oblique views[61]) and lumbar spine, pelvis[62]	1. Recommended for all children with fractures and children with any suspicious injuries under age 2 2. Repeat skeletal survey in 2 wk for high-risk cases[63] 3. Single whole-body films are unacceptable
Bruises	Tests for hematologic disorders: CBC count, platelets, prothrombin time, partial thromboplastin time, INR, bleeding time; additional testing (eg, factor levels) may be indicated after initial screening tests	1. Recommended when bleeding disorder is a concern because of clinical presentation or family history 2. A DIC screen should be performed for patients with intracranial injury, because intraparenchymal damage can alter coagulation[64] 3. PFa-100: platelet function activity is preferable to bleeding time for establishing platelet function but is not widely available
Liver injury	Liver enzyme tests: aspartate aminotransferase and alanine aminotransferase	1. May be helpful in diagnosing occult hepatic injury[65]
Pancreatic injury, pseudocyst	Pancreatic enzymes: amylase and lipase	
Urinary system/renal injury	Urinalysis	
Intracranial and extracranial injury	MRI: head/neck	1. Diffusion-weighted scan may surpass CT in characterizing extent of intercerebral edema[66] 2. May provide better dating of intracranial injuries than CT 3. More sensitive than CT for subtle intracranial injuries in patients with normal CT results and abnormal neurologic exams[67] 4. More sensitive than plain radiographs and CT for detecting cervical spine fractures/injury[68]
Intracranial and extracranial injury	CT scan: head[a]	1. When used in conjunction with radiographs, may enhance detection of skull fractures
Intracranial injury	Urine: organic acids	1. Screen for glutaric aciduria type 1
Intra-abdominal injuries	CT scan: abdomen	1. IV contrast should be used and is preferable to PO[62]
Cardiac injury	Cardiac enzymes: troponin and creatine kinase with muscle and brain subunits (CK-MB)	
Skeletal	Radionuclide bone scan	1. Better for acute rib fractures and subtle, nondisplaced long-bone fractures[62]
Osteogenesis imperfecta	Skin biopsy for fibroblast culture and/or venous blood for DNA analysis	
Bone-mineralization disorders: rickets	Calcium, alkaline phosphatase, phosphorus, vitamin D, and parathyroid hormone	

Tests should be ordered judiciously and in consultation with the appropriate genetics, hematology, radiology, and child abuse specialists. Careful consideration of the patient's history, age, and clinical findings should guide selection of the appropriate tests. CBC indicates complete blood cell; INR, international normalized ratio; DIC, disseminated intravascular coagulation; CT, computed tomography; IV, intravenous; PO, oral; CK-MB, creatine kinase MB band.

[a] CT scanning may provide clinically relevant information more expeditiously than MRI in some facilities.

pervised in a dangerous environment, the physician should report suspected neglect or inappropriate adult supervision, including injuries sustained while under the care of an intoxicated adult, to child protective services.[69] When the child is evaluated or tested for other nonabusive causes, documentation should reflect the results of this assessment as well. In general, concern for abuse is greatest for infants younger than 12 months regardless of the severity of the injury.

TREATMENT

Once medical assessment and stabilization are achieved and a referral has been made to investigative agencies, the physician should ensure that the child receives the necessary follow-up services. The child's primary care physician should be notified, and child protective services should ensure that the family complies with the plan of care. These services should not only include referral to appropriate medical providers but also address the psychological effects of abuse or neglect on the young child, the siblings, and the nonoffending caregiver. Because adult-partner violence commonly co-occurs with child abuse, several family members may require medical and mental health assistance. Medical passports, which are abbreviated medical chart forms usually kept by foster parents and presented at each medical visit, are recommended to optimize treatment regimens in children who are shifted among agencies and individuals during the course of the child abuse investigation.[70]

LEGAL ISSUES

All 50 states have statutes that mandate reporting of suspected child abuse and neglect; the physician is not required to prove abuse before reporting. Familiarity with state laws will ensure that physicians report to the appropriate agency within the required time frame; some states have provided the option of making such a report through the Internet. Information on specific state laws are provided by the Children's Bureau (Administration for Children and Families, US Department of Health and Human Services; see www.childwelfare.gov/systemwide/laws_policies/search/index.cfm). Many states have laws that permit physicians to evaluate children who are suspected victims of abuse, to conduct tests, and to take photographs without parental consent.

The physician may be required to write a sworn statement of his or her findings and to testify in civil or criminal trial proceedings. Civil hearings include testimony about the safety of the child and the need for appropriate placement with caregivers or state agencies. Judgments are based on a "preponderance of the evidence" with respect to the likelihood of abuse. Criminal hearings involve testimony about the guilt or innocence of an individual with respect to causing the injuries in a child. The burden of proof is greater than that of civil hearings; cases must be proven "beyond a reasonable doubt." Physicians are expected to testify to the facts on the basis of their knowledge and experience in pediatrics and, when appropriate, in child abuse. As such, they may be asked to render opinions regarding the normal developmental capabilities of children at certain ages as well as the mechanisms of injury, severity of the injury, and prognosis. Pediatricians should not testify to anything that is beyond their level of knowledge or expertise. Physicians act primarily as scientists and educators in legal settings rather than as child advocates.

CONCLUSIONS

Child physical abuse is a common problem of childhood. The physician must be able to recognize suspicious injuries, conduct a comprehensive and careful examination with appropriate auxiliary tests, critically assess the explanation provided for the injury or injuries, and establish the probability that the explanation does or does not correlate with the pattern, severity, and/or age of the injury or injuries. The physician is responsible for reporting suspected abuse, documenting his or her opinions clearly, and providing the necessary information and expertise to investigative and legal personnel and parents, when appropriate. In addition, pediatricians are uniquely qualified to work with parents and caregivers to prevent abuse by providing anticipatory guidance on normal child behavior and its management. Finally, physicians must advocate that children in foster care who have medical or mental health problems receive the appropriate services and medications and continuity of care through a medical home, and that a medical passport is maintained for these children.

Excessive Sleepiness in Adolescents and Young Adults: Causes, Consequences, and Treatment Strategies

ABSTRACT. Adolescents and young adults are often excessively sleepy. This excessive sleepiness can have a profound negative effect on school performance, cognitive function, and mood and has been associated with other serious consequences such as increased incidence of automobile crashes. In this article we review available scientific knowledge about normal sleep changes in adolescents (13–22 years of age), the factors associated with chronic insufficient sleep, the effect of insufficient sleep on a variety of systems and functions, and the primary sleep disorders or organic dysfunctions that, if untreated, can cause excessive daytime sleepiness in this population. *Pediatrics* **2005;115:1774–1786;** ***sleep, sleepiness, adolescents, pediatric sleep problems, daytime sleepiness, young adults, circadian rhythm, melatonin, motor vehicle accidents, depression, attention-deficit/hyperactivity disorder, school start times, school performance, obstructive sleep apnea, narcolepsy, idiopathic hypersomnia, delayed phase syndrome, insufficient sleep.***

ABBREVIATIONS. REM, rapid eye movement; MSLT, Multiple Sleep Latency Test; GPA, grade point average; ADHD, attention-deficit/hyperactivity disorder; PSG, polysomnography; SDB, sleep-disordered breathing; RLS, restless-legs syndrome; DSPS, delayed sleep-phase syndrome.

INTRODUCTION

During adolescence (13–22 years of age), many changes occur in sleep patterns, and there are many influences on sleep quality and quantity. Excessive daytime sleepiness in this population is a widespread problem and can have major negative effects on the individuals' performance, health, and safety. Pediatricians and other health care professionals have an important opportunity to evaluate their adolescent patients for evidence of excessive daytime sleepiness and underlying sleep deprivation and/or sleep disorders.

Development of Normal Sleep and Waking

A variety of sleep-pattern changes occur from childhood through adolescence. Laboratory evaluations, as well as field studies and surveys, have shown that across the second decade of life, there are numerous alterations in sleep physiology associated with consistent developmental patterns of sleep. Notable findings include decreased sleep duration with increasing age, a delay in bedtime and rise time (except on school mornings), and an increasingly large discrepancy between school-night and weekend sleep patterns. Children at 9 to 10 years of age who sleep approximately 10 hours on school nights usually will not sleep more than that (and sometimes will sleep less) on weekends. In contrast, adolescents typically will extend sleep on weekends, and this tendency increases as they age and as their school-night sleep decreases, causing them to accumulate a significant sleep debt. Sleep-research data indicate that adolescents still require 9 to 10 hours of sleep per night.[1,2]

A number of groups have examined sleep across adolescent development in laboratory-based studies. In these studies, laboratory constraints may affect outcomes, and this needs to be kept in mind when interpreting findings. For instance, although some studies have used participants' usual schedules to set bedtimes and rise times,[3–7] other studies have used a fixed period of time (10:00 PM to 8:00 AM) for sleep.[2,8,9] In addition, a number of studies have used a longitudinal approach,[2,6,8,9] whereas others have used a cross-sectional approach.[7,10,11] In laboratory studies in which the sleep schedule was varied, total sleep time has consistently been decreased in older adolescents, as expected, because of changed (school-night) sleep habits. Despite the varied methodologies used, consistent changes in sleep/wake architecture have been reported in adolescents. These changes include a decrease in slow-wave sleep time (decreased by nearly 40% from prepubertal to late pubertal adolescents with a 10-hour sleep opportunity[8]), an increase in the amount of stage 2 sleep, and a decrease in the latency to the first episode of rapid eye movement (REM) sleep.

Developmental changes in the amount of REM sleep obtained in a number of these studies typically parallel the findings for total sleep time. With increasing age, the time in bed for sleep and, hence, the total sleep time is decreased, with a concurrent de-

PEDIATRICS (ISSN 0031 4005).

crease in the amount of time spent in REM sleep. Conversely, the duration of REM sleep is maintained at a constant level in adolescent subjects when time in bed is fixed.[8,9] Differences in the time of child versus adolescent spontaneous morning awakenings have also been reported (ie, differences in Tanner stages 1 and 2 vs 3–5). In a longitudinal study with a fixed time in bed for sleep, younger children were more likely than adolescents to spontaneously awake before 8:00 AM.[2] Although a small number of studies have reported gender differences in sleep patterns of older children and adolescents,[12] these findings are not consistent.[13]

Sleep/Wake Regulatory Processes

The circadian and sleep homeostatic systems act to coordinate most physiologic and behavioral systems of the body and brain. These 2 systems, working together or in opposition, influence the activities of the endocrine, thermoregulatory, neurobehavioral, renal, cardiovascular, digestive, and sleep/wake systems. With regard to sleep/wake, the circadian system may be viewed as wake promoting, and the homeostatic sleep system reflects sleep need or sleep debt and provides a drive for sleep.

In humans, the central circadian pacemaker, or biological clock, is located in the suprachiasmatic nuclei of the anterior hypothalamus.[14,15] These tiny paired nuclei are responsible for the generation of the daily (circadian) rhythms of physiologic, neurobiologic, and behavioral systems.[16] The circadian pacemaker is synchronized to the 24-hour day through external time cues from the environment (zeitgebers). The strongest of these zeitgebers is exposure to the light/dark cycle. Phototransduction from the retina to the suprachiasmatic nuclei occurs primarily via the retinohypothalamic tract. Entrainment of the circadian system to Earth's 24-hour day provides temporal balance between endogenous activities and the external environment such that sleeping/waking behavior, hormonal activity, temperature fluctuations, and neurobehavioral functioning occur in proper synchrony with the environmental day.

The circadian system plays an integral role not only in regulating the timing of sleeping and waking periods but also in influencing waking neurobehavioral functioning capabilities, alertness or fatigue levels,[17] sleep/wake duration, and sleep structure (REM sleep).[18–20] Opposing the wake drive provided by the circadian system, the sleep homeostatic system affects sleep propensity, sleep duration, and sleep structure.[21]

During waking periods, and especially during periods of extended wakefulness, the homeostatic drive for sleep gradually increases, with a consequent increase in the likelihood that sleep onset will occur. The circadian variation in wake drive occurs concurrently, producing peaks and troughs in sleepiness and alertness levels across the 24-hour day. The magnitude of sleepiness or alertness experienced at a given time is a product of the opposing influences of these 2 systems.[22] As a result, across a normal waking day, clock-dependent (circadian) alertness is usually lowest in the early morning and increases into the late afternoon or evening, thus opposing the growing sleepiness from having been awake all day. Consequently, alertness may be greater in the evening even if wakefulness has been sustained or a sleep debt has accumulated.

In 1993, a theory emerged attributing certain changes in adolescent sleep to an alteration in the circadian timing system. Carskadon and colleagues[23] demonstrated that circadian phase preference was delayed in association with more mature self-reported pubertal ratings in sixth-grade girls. In a laboratory-based study,[23] it was reported that the offset time of melatonin secretion in the morning was significantly correlated with Tanner stage. These findings indicate that a change in the biological system regulating circadian timing may accompany adolescent development. Such a change may promote the later timing of sleep that occurs during adolescence.

Surveys addressing sleep habits of older children and adolescents have been performed in many countries and across many decades. These surveys demonstrate remarkable consistency with regard to developmental changes in sleep habits, although specifics of bedtimes, rise times, and sleep length tend to vary among ethnic groups. Several review articles have summarized these findings[24,25] and concluded that, irrespective of location, developmental trends are similar. Older children and young adolescents tend to sleep about the same length of time on school days as non–school days. With increasing adolescent age, however, bedtime gets later on school and non–school days, with the magnitude of the delay greater on non–school days. Additionally, rising time on non–school days also gets later as adolescence progresses. We should note that the tendency for a phase delay of sleeping pattern is not a novel finding; Terman and Hocking[26] in 1913, for example, noted a shift from "vesperal" to "matinal" sleeping during adolescence, attributing the change to increasing homework.

As a consequence of these changes, the total sleep time obtained by older adolescents is shorter than sleep time for children and younger adolescents, and the discrepancies between school-day and weekend sleep and wake times increase with age. Maternal questionnaires from the Zurich longitudinal studies[27] have provided impressive data regarding developmental changes in sleep patterns of adolescents. Although the findings are not as extreme as those reported for US teenagers, similar trends are apparent. In contrast, differences have been found in total sleep obtained by adolescents in the United States and those in Zurich, Switzerland. A recent sample of eighth-grade students in the United States demonstrates an average school-night bedtime of 10:44 PM, wake time of 6:35 AM, and total sleep period of 7.9 hours.[28] The Zurich data, on the other hand, show an average bedtime of 10:02 PM, wake time of 6:30 AM, and total sleep period of 8.5 hours. Thus, although overall trends are similar for data from developed nations, significant differences in total sleep time may point to important concerns for young people who obtain minimal sleep.

Daytime Sleepiness

The Multiple Sleep Latency Test (MSLT) is an objective test that measures speed of falling asleep to determine the tendency to fall asleep during the day. A faster sleep onset indicates a greater level of sleepiness, as does an increased number of sleep onsets during multiple tests. During an MSLT, subjects are asked to fall asleep while lying in bed in a dark and quiet room during 4 or 5 20-minute periods spaced at 2-hour intervals.[29] If sleep occurs during this time period, it is allowed for only 1.5 minutes (experimental test) or 15 minutes (clinical test); if no sleep occurs, lights are turned on after the 20-minute test and the subject has to get out of bed and stay awake until the next testing period. In a longitudinal study using the MSLT, Carskadon and colleagues[2] assessed developmental changes in daytime sleepiness and demonstrated a change in the pattern of daytime alertness occurring at midpuberty. The prepubertal and early pubertal adolescents did not fall asleep on most of the tests (average latency across all naps of approximately 19.5 minutes of a maximum of 20 minutes), whereas midpubertal and late pubertal adolescents were more likely to fall asleep during the midafternoon tests, and the average sleep latency across all the naps decreased to approximately 15 minutes. This increase in sleep propensity occurred even though the more mature adolescents were sleeping as much as the less mature adolescents. This finding indicates that either adolescents may need more sleep than children or the pattern of sleepiness is reorganized during adolescent development.[24]

External Determinants of Sleep Patterns

Parental Influence

With the transition from childhood to adolescence, parents seem to change the manner in which they exert influence on children's sleep patterns, particularly on school days.[30] In Carskadon's study,[30] children 10 and 11 years of age were significantly more likely than children 12 and 13 years of age to report that parents set their school-night bedtimes. In later studies of high school students in 9th through 12th grades, only 5% of these older adolescents had a school-night bedtime set by their parents, and more than 75% went to bed when homework, television viewing, or socializing was done for the day or whenever they felt sleepy.[31]

Thirteen-year-old children reported more frequently than younger children that they required either alarm clocks or their parents to wake them up on school mornings. This difficulty in waking in the morning continues into the older years. More than 85% of high school students in 1 study used an alarm or their parents to awaken them in the morning on school days.[32] Thus, the influence of parents shifts from setting bedtimes during childhood to assisting with rising time during adolescence.

School Start Times

Historically, schools in the United States have started early in the morning. In addition, many US school districts use a 3- or 4-tiered schedule in which high schools open first, followed by middle or junior high schools, and then elementary schools.[33] In a preliminary survey of 40 schedules posted on the Internet from high schools throughout the United States for the 1996–1997 academic year, 48% started at 7:30 AM or earlier, whereas only 12% started between 8:15 AM and 8:55 AM.[34] Most recently, in the 2001–2002 academic year, 35% of 50 high schools surveyed started earlier than 7:30 AM, nearly 50% started between 7:31 AM and 8:14 AM, and only 16% started between 8:15 AM and 8:55 AM.

Early high school start time is a significant, externally imposed constraint on teenagers' sleep/wake schedules; for most adolescents, waking up to go to school is neither spontaneous nor negotiable. Szymczak and colleagues[35] followed Polish students between 10 and 14 years of age for more than 1 year and found that all of them slept longer on weekends and during vacations by extending their sleep and waking up later. These investigators concluded that the school schedule was the predominant determinant of wake times for these students. Similarly, several surveys of high school students have found that students who start school at 7:30 AM or earlier obtain less total sleep on school nights because of earlier rise times.[31,36–38]

In a laboratory and field study, Carskadon and colleagues[39] evaluated the effect of a 65-minute advance in school start time on approximately 40 9th-graders in their transition to 10th grade. Specifically, junior high school started at 8:25 AM and high school started at 7:20 AM in a large urban school district. Sixty-two percent of the students in 9th grade and less than half the students in 10th grade got an average of as much as 7 hours of sleep on school nights. Students awoke earlier on school days in 10th grade than in 9th grade and had shorter sleep latencies on the MSLT in 10th than in 9th grade, particularly on the 8:30 AM assessment. In addition, 16% of participants experienced 2 REM episodes on the MSLT in 10th grade (48% of subjects experienced 1 REM episode). The occurrence of REM sleep episodes on the MSLT was associated with a delayed timing of melatonin secretory pattern in these adolescents. In a study of nearly 600 young adolescents (10–12 years of age), Epstein and colleagues[40] compared a 7:10 AM with an 8:00 AM school start time. In their survey, children with early start times reported significantly shorter mean sleep times (ie, approximately 25 minutes less) than did children who started school after 8:00 AM.

Employment and Extracurricular Activities

Another major influence on sleep patterns of high school students in the United States is the number of hours they spend working for pay. Students who work 20 or more hours per week report going to bed later at night, sleeping fewer hours per night, oversleeping more in the morning, and falling asleep more in class than those who do not work or who work fewer than 20 hours per week. In a survey of more than 3000 high school students (grades 9–12) from several Rhode Island school districts, nearly 60% of the students reported that they held part-time

jobs, and almost 30% indicated that they worked 20 hours or more per week.[31,34] The 11th- and 12th-grade students who worked more than 20 hours per week reported significantly different sleep/wake behaviors from those of their peers who worked less than 20 hours per week or not at all. The high-work group reported more symptoms of daytime sleepiness such as struggling to stay awake while driving, in classes, and while reading, studying, or doing homework. This group also reported greater use of caffeine, alcohol/drugs, and tobacco.

Clinical Consequences of Inadequate Sleep

Excessive Daytime Sleepiness

Alertness is defined as the inherent ability of the brain to sustain attentive wakefulness with little or no external stimulation. When someone is excessively sleepy, alertness and vigilance become unstable and unreliable. Cognitive capabilities slow down, and over time there is an increased risk of making errors[41] and an increased risk of accidents (for example, automobile crashes). When excessively sleepy, individuals may begin tasks well, but as time on tasks continues, performance will decrease. Sleepy individuals may increasingly neglect activities judged to be nonessential. High levels of sleepiness impair complex performance, leading to lapses in attention, slowing of motor and cognitive reactions, mental mistakes, working-memory errors, time-on-task decrements, and potentially uncontrolled sleep attacks.[42]

Despite the laboratory findings on the effects of sleep loss on neurocognitive functioning, it is commonly assumed that sleep loss has little or no effect on waking brain function, that the effects of sleep loss are primarily motivational, and that the amount of sleep required to maintain stable waking performance is less than that obtained.[43] In reality, the opposite is true. There have been several studies assessing the effect of sleep deprivation on tendency to fall asleep.[30,44,45] In these studies, successive days of restricting sleep duration led to a significant tendency to doze off in quiet settings. This might manifest as falling asleep in class, or there may be uncontrollable "microsleeps" leading to poor task performance. More recent studies have supported these earlier findings. For example, Fallone and colleagues[25] studied young people between 8 and 15 years of age and restricted them to 1 night of only 4 hours of sleep. Their daytime sleepiness was increased both subjectively and objectively. The effect of sleepiness on neurobehavioral functioning in these studies is less clear and may depend on whether the sleep loss is across a single night or multiple nights. There also seems to be an emotional overlay. Maayan and colleagues[46] studied 10 adolescents the day after a night of total sleep deprivation. They found that the adolescents exposed to emotion-producing pictures during the test demonstrated decreased performance on a working-memory task.

School Performance Problems

In a recent critical review, academic performance and sleep were analyzed extensively by Wolfson and Carskadon.[47] Studies clearly suggest that shortened total sleep and irregular sleep schedules are highly associated with poor school performance for adolescents. After a year-long study of 17 school districts in Minnesota, Minneapolis Public Schools changed their high school start time from 7:15 AM to 8:40 AM, beginning with the 1997–1998 school year. The Center for Applied Research and Educational Improvement at the University of Minnesota has examined the effect of the later start time.[48] The study examined student grades and attendance through district records and administered the School Sleep Habits Survey to 50 962 students in 7 high schools (grades 9–12). Analyses found that daily attendance rates were higher in the 1999–2000 academic year than they were in 1995–1996; the percentage of high school students who were continuously enrolled in the district or in the same school increased in 1999–2000, relative to the percentage in 1995–1996; and with the later start time, the dropout rate decreased. The School Sleep Habits Survey showed no change in average school-night bedtimes or weekend bedtimes and rise times. However, because of later rise times on weekdays, Minneapolis students reported that they obtained, on average, 60 more minutes of sleep on school nights than did their peers in high schools with start times 1 hour earlier. In addition, Epstein and colleagues[40] compared young adolescents who started school at 7:15 AM or earlier at least 2 times a week with those who started at 8:00 AM. Early risers complained more of daytime fatigue and sleepiness throughout the school day, greater tendency to doze off in class, and attention/concentration difficulties in school.

Wolfson and Carskadon[31] administered the School Sleep Habits Survey to 3120 high school students from 4 high schools representing 3 school districts in southern New England. Adolescents with self-reported higher grades reported significantly longer and more regular sleep/wake schedules. Specifically, they said that they got more total sleep and had earlier bedtimes on school nights than did students with lower grades. In fact, these differences distinguished students reporting mostly Bs or better from those reporting Cs and worse. Students' weekend sleep habits also differed according to self-reported grades. Specifically, A and B students reported earlier bedtimes and earlier rise times than did students with poorer grades. Students with worse grades reported greater weekend delays of sleep schedule than did those with better grades.

Meijer and colleagues[49] focused more on the relationship between sleep/wake patterns and young adolescents' perceptions of their school functioning than on academic grades or examination scores. They assessed young adolescents in 7th and 8th grades. Adolescents who reported having difficulty getting up were less motivated to do their best at school, whereas children with higher-quality sleep and reports of feeling more rested were more receptive to teacher influence, had a more positive image of themselves as students, and reported higher motivation to do their best in school.

A few studies have examined the relationship be-

tween sleep/wake patterns and academic performance in college students. Trockel and colleagues[50] interviewed or surveyed 185 randomly selected first-year college students regarding sleep/wake habits, exercise, eating, mood, perceived stress, social support, religious habits, and semester grade point averages (GPAs). Sleep habits, particularly rise times, accounted for the largest amount of variance in GPAs. In particular, later weekday and weekend wake times and increased number of work hours (paid/volunteer) were associated with lower GPAs. Eating habits, mood, stress, time management, and social support were not associated with these first-year college students' grades. Kelly and colleagues[51] also studied college students and found that short-sleepers reported significantly lower overall GPAs than did long-sleepers. Although there were no age or gender differences, long-sleepers (≥9 hours per night) reported significantly higher GPAs than did short-sleepers (≤6 hours per night; mean GPA: 3.24 vs 2.74, respectively). Average-sleepers (7–8 hours per night) were not significantly different from long- or short-sleepers.

Sleep and Attention-Deficit/Hyperactivity Disorder in Adolescents and Young Adults

As noted above, lack of sleep may cause problems with attention and concentration in the laboratory setting. The well-recognized clinical syndrome is attention-deficit/hyperactivity disorder (ADHD), which is estimated to affect 5% to 10% of the school-aged population. This disorder persists into adolescence and young adulthood in 10% to 60% of affected individuals.[52] The relationship between sleep problems and ADHD in children has been examined in multiple studies, using a number of approaches,[53–66] but similar data in adolescents and adults are largely unavailable. Reviews of clinical complications of ADHD in adolescents include some anecdotal references to sleep disturbances,[67–69] but studies of childhood ADHD and sleep are rare and have included small numbers of subjects between 12 and 18 years of age.[64]

Studies of children with ADHD have used either parental- or self-report surveys or all-night sleep testing (polysomnography [PSG]) to examine the relationship between sleep architecture/disturbances and ADHD. Methodologic limitations of these studies include small sample sizes and selection bias, variability in diagnostic criteria for ADHD, failure to document pubertal status, and variability in control groups. In addition, although parental assessment of their children's sleep behavior and disturbances is clearly more subjective, relatively objective methods such as PSG may not reflect "real-world" conditions accurately. Finally, many studies have failed to consider the effects of medication and the presence of comorbid psychiatric conditions. Despite these limitations, most of the "objective" studies have failed to find consistent differences in sleep architecture and patterns between children with ADHD and controls,[70–79] yet most parental-report studies have reported increased sleep problems in children with ADHD, including difficulty falling asleep, night wakings, and restless sleep. However, more recent studies have suggested that many of these sleep disturbances are attributable to either medication-related effects from psychostimulants or common psychiatric comorbid conditions rather than to ADHD per se.[80]

The etiology of sleep disturbances associated with ADHD in childhood is likely to be multifactorial and vary across patients. In addition to medication-related effects on sleep and the influence on sleep behavior of such common comorbid conditions as oppositional defiant disorder, depression, and anxiety disorders, primary sleep disorders may present itself with ADHD-like symptoms or may exacerbate underlying ADHD.[81–83] For example, there is mounting evidence not only that sleep-disordered breathing (SDB) is strongly associated with inattention, hyperactivity, impaired "executive" cognitive functioning, and disruptive behaviors in children but also that treatment of SDB results in significant improvement or even complete amelioration of ADHD-related symptoms.[84,85] Likewise, other primary sleep disorders such as restless-legs syndrome (RLS), periodic limb-movement disorder,[86–89] delayed sleep-phase syndrome (DSPS),[90] and narcolepsy[91] may present with ADHD symptomatology.

Primary abnormalities in central nervous system regulation of arousal, behavioral inhibition and self-regulation, and/or vigilance associated with ADHD also have been postulated to result in sleep disturbances. These disturbances suggest a more "intrinsic" sleep/wake dysregulation in at least some individuals with ADHD.[92,93] There is considerable empirical evidence to suggest that brain systems regulating sleep and attention/arousal are linked and that abnormalities in similar neurotransmitters such as the noradrenergic and dopaminergic systems may be found in ADHD and sleep disturbances.[94] Although intriguing, at the current time these hypotheses are still largely speculative. Nevertheless, it is clear from clinical observations and on theoretic grounds that an association between ADHD and sleep disturbances exists, that symptoms of ADHD and sleep disorders frequently overlap, and furthermore that the presence of a comorbid sleep disorder may significantly increase the level of impairment in an individual with ADHD.

Mood Disturbances

The relationship between sleepiness and depressed mood in adolescents must be considered in both directions. That is, there is extensive evidence that adolescents with clinical mood disorders (particularly major depressive disorder) report high rates of sleep disturbances and complaints.[95,96] There are also data indicating that adolescents with sleep problems report increased negative mood and/or difficulties with mood regulation.[97–99] Part of the relationship may be accounted for by the effects of stress and emotional arousal interfering with sleep in adolescents with emotional problems,[100] whereas there is also evidence that sleep disruption can cause irritability and negative mood in adolescents.[92]

Studies of sleep and major depressive disorder in

adolescents provide evidence for subjective sleep complaints (especially difficulty falling asleep) and are extremely common, affecting most adolescents interviewed during an episode of depression.[96] Objective electroencephalogram studies of clinical samples have revealed evidence of sleep disturbances in some depressed adolescents but at lower rates than sleep disturbances seen in adult depression.[101–105] However, subjects who showed objective evidence of sleep-onset abnormalities in adolescence were more likely to develop depressive episodes in the future.[106,107] More recently, studies focusing on the microarchitecture of sleep in depressed adolescents provide some evidence that more subtle disturbances in sleep also may be predictive of a worse clinical course among adolescents with mood problems.[108]

Given the evidence of negative effects in both directions, one of the major concerns regarding the co-occurrence of sleep and mood problems in adolescents is that it can contribute to a "negative spiral" in school and social functioning. For example, late-night and erratic schedules and early school start times can lead to sleep deprivation, which in turn can erode mood and motivation. Difficulties with mood, motivation, and school performance create greater stress and affective problems. The negative affective experiences further interfere with sleep and arousal regulation and circadian effects and lead to difficulty falling asleep, more erratic schedules, and additional deterioration across these systems. Research is needed to examine the effects of early intervention aimed at sleep while examining mood symptoms to address these important concerns.

Drowsy Driving

Motor vehicle crashes are a leading cause of death in adolescents and young adults, and sleepiness can be deadly for adolescents behind the wheel. Studies analyzing motor vehicle crash data by age group have found that young people between 16 and 29 years of age were the most likely to be involved in crashes caused by the driver falling asleep.[109–112] Pack and colleagues[109] reviewed the 5104 crash reports from North Carolina from 1990 to 1992 in which the driver was judged to have fallen asleep. In 771 of the crashes, the driver was also thought to be intoxicated. Of the remaining 4333 crashes, the majority occurred with younger individuals. Fifty-five percent occurred with a driver who was 25 years or younger. Unlike crashes with adults older than 65 years, which typically occur during midafternoon, crashes with this younger age range generally take place at night and involve young males driving alone and going off the road.

Lack of sleep has been implicated as a cause of falling asleep at the wheel.[113] Compared with sleeping 8 or more hours each night, sleeping 6 to 7 hours was associated with a 1.8 times higher risk for involvement in a sleep-related crash versus a non–sleep-related crash, and sleeping fewer than 5 hours per night invoked a 4.5 times higher risk. Forty percent of drivers had been awake for 15 or more hours before falling asleep at the wheel and crashing, and nearly 20% had been awake for 20 or more hours.

Additional Causes of Daytime Sleepiness

As described in the previous sections, there is an inherent tendency for adolescents and young adults to get insufficient sleep, and as a result, excessive daytime sleepiness may be frequently seen in this age group. Nevertheless, it is also essential to acknowledge the importance of untreated sleep disorders and other organic causes of excessive daytime sleepiness. It is very difficult to differentiate insufficient sleep from other causes of daytime sleepiness without taking a formal sleep history. The following sections will review clinical sleep disorders and propose a working algorithm to help clinicians sort through the differential diagnoses.

Insomnia and Circadian-Rhythm Disorders

Insomnia is a broad term used to describe a wide range of complaints relating to disorders of sleep. For many people, insomnia is a subjective complaint of dissatisfaction with sleep, including decreased sleep quality, decreased sleep quantity, trouble getting to sleep, and trouble maintaining sleep. In some cases, insomnia is a symptom of another underlying medical or psychological disorder, and in other cases there is no apparent physiologic cause (this type of insomnia generally is called "psychophysiological insomnia"). The waking effects of insomnia include daytime fatigue or sleepiness, neurocognitive deficits, and altered mood.

The major insomnia complaint in adolescents is difficulty initiating sleep. In this age group, a major cause of this insomnia is DSPS. DSPS is a circadian-based disorder in which an individual's internal circadian pacemaker is not in synchrony with external or environmental time. Affected adolescents typically experience difficulty in initiating and terminating sleep at a "normal" time[114] and prefer later sleep times (between 2:00 AM and 6:00 AM) and wake times (between 10:00 AM and 1:00 PM). The sleep structure of DSPS patients is otherwise normal. DSPS is characterized by a delay in the timing of activities demonstrating circadian rhythmicity, such as melatonin secretion,[115] changes in core body temperature, and the sleep/wake cycle.

The incidence of DSPS in the general population is unclear. Some reports suggest that only 0.7% of middle-aged adults have DSPS and 7% or more of adolescents suffer from this disorder.[116–118] In adolescents, there may be an overestimation of the incidence of DSPS because of developmental and/or environmental influences on the circadian system that produce a DSPS-like profile in this age group. As mentioned previously, Carskadon and colleagues[30,39] reported a phase delay in the timing of daytime sleepiness in midpubertal children by using the MSLT as an index of sleepiness. Adolescents typically do not go to sleep until late because of school, work, social, and family commitments but still must awaken early for school. When allowed to sleep without time constraints on weekends, adolescents choose to go to bed and rise later than on weekdays

and sleep for longer periods (in essence, "catching up" on sleep).[119]

The diagnosis of DSPS is based on clinical history. The classic patient with DSPS is more frequently tardy or absent from school because of an inability to get out of bed in the morning despite parental intervention. If the adolescent with DSPS does make it to class, he or she may fall asleep, frequently has poor grades, and frequently is labeled as having a behavioral problem. Although not a practical treatment option, these symptoms would abate if the adolescent were allowed to sleep late in the morning and arrive later at school.

Treatment regimens for DSPS need to be designed to resynchronize the circadian system. There is a high incidence of relapse, however, after discontinuation of treatment, especially if patients are unable to maintain a rigid sleep/wake schedule. Czeisler and colleagues[120] delayed the sleep times of adult patients by 3 hours each day over a period of 5 to 6 days until the desired sleep time was reached. An alternative approach is to have the patient get up and stare into a bright light box for 30 minutes first thing in the morning to "reset the clock." However, studies using light exposure to re–entrain subjects have reported mixed findings.[117,121]

Another proposed treatment for DSPS is the administration of melatonin. Melatonin is an endogenous hormone that plays a role in the control of the circadian system[122] and potentially in the initiation of sleep.[123,124] Exogenously administered melatonin has been reported to have both chronobiotic (phase-shifting)[125] and soporific (sleep-inducing) properties.[126] As a treatment for DSPS, melatonin exerts its effects primarily by shifting the timing of the circadian system and has been demonstrated to be successful in re-entraining sleep/wake rhythms in people with jet lag and people who perform shift work.[127]

The efficacy of melatonin treatment for DSPS has been examined in a number of studies. Phase advance of the sleep/wake cycle was reported after daily administration of melatonin for up to 6 weeks.[76,128–130] After termination of the treatment, however, the melatonin-induced phase advances were reversed and subjects returned to being phase delayed. Although melatonin administration may be an effective treatment for DSPS, it should be used with caution. As yet, there is no established dose of melatonin to be administered for effective results, and the timing of administration is also important to achieve phase shifts in the desired direction.[131] In addition, the safety of melatonin administration, particularly in adolescents and young adults, is not established. Melatonin levels are high during puberty,[132] and melatonin has been implicated in reproductive development and seasonal breeding in several species. Additionally, studies on the safety of long-term melatonin administration have not been performed. Therefore, at present, melatonin should be thought of as a research tool and not a clinical solution.

Sleep-Disordered Breathing

SDB, or obstructive sleep apnea, is a condition in which the pharynx intermittently and repetitively collapses during sleep. Arterial oxygen levels decrease and carbon dioxide levels increase until a subconscious arousal from sleep occurs. The pharyngeal dilator muscles then contract, the pharynx opens, air rushes in under pressure creating a loud snoring sound, ventilation resumes, and blood gas abnormalities are corrected. SDB in adolescents and young adults leads to the same daytime sequelae related to excessive daytime sleepiness as seen with insufficient sleep (sleep restriction).

The most common cause of sleep apnea in this age range is enlarged tonsils and adenoids. The epidemic of childhood weight problems, however, has resulted in obesity becoming a major cause of SDB in children as well as adults. Other contributing factors include retrognathia, nasal obstruction,[133] evening alcohol ingestion, family history of sleep apnea,[134] black race,[134] and history of wheezing and cough.[134]

The profile of an adolescent or young adult with sleep apnea is of someone who snores loudly and frequently, has been observed to have episodes of apnea during sleep, has awakened choking, and is excessively sleepy. Clues on physical examination that would help the physician suspect SDB include enlarged tonsils, retrognathia, mouth breathing, and upper-body obesity.

The true prevalence of SDB in this age range is unknown because of a lack of studies and lack of consensus about minimum criteria for diagnosis. Part of the problem is that some studies have included younger children as well as adolescents.[135] Although an obstructive-apnea index (the number of episodes of obstructive apnea per hour of sleep) greater than or equal to 1 per hour may be diagnostic of SDB in younger children,[136] the threshold may be higher in adolescents and young adults. Acebo and colleagues[137] reported that an obstructive apnea index of 1 per hour was normal in 13-year-old boys and girls and in 22-year-olds.[137] In fact, in this study of normal subjects, an apnea index up to 3.6 in young boys and 4.5 in young men was considered to be normal.

Hui and colleagues[138] evaluated 1910 freshman at the Chinese University of Hong Kong and found that 26% snored, 11% reported impaired performance ability, and 42% reported daytime sleepiness. A limited number of these college students underwent all-night sleep studies, leading to a calculation of 0.1% prevalence of SDB in this population. In contrast, Sanchez-Armengol and colleagues[139] studied 101 adolescents 12 to 16 years of age. Of this population, 29% snored, 14% were excessively sleepy, and 3% had SDB.

The diagnosis of sleep apnea requires overnight assessment by PSG, typically in a sleep laboratory. Once sleep apnea is diagnosed, treatment options include removal of the tonsils and adenoids if they are enlarged, weight reduction if overweight or obese, and/or nightly continuous positive airway

pressure therapy to prevent intermittent upper-airway collapse.[140]

Narcolepsy and Idiopathic Hypersomnia

Narcolepsy is a neurologic disorder associated with inappropriate control of REM sleep. Recent studies have suggested that the pathophysiology of narcolepsy involves depletion of the neuropeptide hypocretin known as orexin.[141] The true prevalence of narcolepsy is unknown, but 4 to 10 people per 10 000 in the United States may have the disorder.

Core symptoms of narcolepsy reflect the components of REM sleep, specifically loss of muscle tone and an extremely active cortex during sleep, leading to vivid dreams. Patients with narcolepsy may have sleep attacks in which they inappropriately doze off. Many will have cataplexy, which is a sudden loss of muscle tone typically precipitated by anger or laughter. In severe cases, the patient may lose all tone and collapse to the floor. Symptoms may even present as unexplained syncope. If left alone, the patient will fall asleep and be in REM sleep. The presence of cataplexy is diagnostic of narcolepsy.[142] People with narcolepsy may also experience sleep-onset paralysis as they are starting to fall asleep; they suddenly become paralyzed while they are still awake. Sleep paralysis may also occur on awakening, but this may happen in people without narcolepsy as well, either sporadically or on a familial basis. Patients with narcolepsy may also experience hypnagogic hallucinations (vivid, dreamlike visual images) before falling asleep. Only a minority of patients present with the complete tetrad of symptoms.[91,143]

Although the symptoms of narcolepsy typically begin during adolescence and young adulthood, adults with narcolepsy frequently report that the diagnosis was not established for several more years.[144] Frequently, adolescents with narcolepsy have behavioral and emotional disturbances. Dahl and colleagues[91] found that 12 of 16 adolescents with narcolepsy had emotional problems, and 4 patients were misdiagnosed as having a psychiatric disorder. Delayed and mistaken diagnoses may contribute to adult psychosocial dysfunction.[143,145]

A definitive diagnosis of narcolepsy can be made if cataplexy is present. Testing for narcolepsy includes overnight PSG to exclude other causes of daytime sleepiness, such as SDB. In addition, patients will undergo MSLT testing the following day. There is no specific test for cataplexy. Adolescents with narcolepsy will be pathologically sleepy with a mean sleep latency across all naps of less than 6 minutes, compared with a normal mean sleep latency of 15 minutes. Patients with narcolepsy, as well as patients with insufficient sleep, may demonstrate REM sleep in at least 2 of the naps, whereas normal subjects have no REM sleep.

Treatment includes stimulant drugs such as methylphenidate and dextroamphetamine to decrease daytime sleepiness, wake-promoting agents such as modafinil, and REM-suppressant agents such as tricyclic antidepressants and serotonin reuptake inhibitors to control cataplexy. Recently, sodium oxybate has become available to prevent cataplexy.[146] In addition, education, counseling, and working closely with both family and school personnel are essential. Regular sleep/wake schedules need to be established, and daytime restorative naps may be helpful.

"Idiopathic hypersomnia" is a term used to describe patients who are excessively sleepy for no apparent cause and who do not have cataplexy.[147] Despite adequate sleep time for age and despite a normal all-night PSG result, these patients have MSLT results in the sleepy range, yet do not demonstrate any episodes of REM sleep in individual naps or any of the associated symptoms of narcolepsy. It is possible that these patients may be found to have narcolepsy in the future. Patients with idiopathic hypersomnia are frequently treated with stimulant medications such as methylphenidate and dextroamphetamine, although the response to treatment is usually less effective than it is with narcolepsy.

Periodic Limb Movement During Sleep and RLS

Periodic limb movements during sleep are repetitive contractions of the anterior tibialis muscles occurring during sleep. Although more common in aging adults, leg movements may also be seen in adolescents and young adults. Periodic limb movements may be an incidental finding on all-night PSG, but they can also be a cause of subconscious sleep disruption, leading to daytime sleepiness, or a trigger for full awakenings and subsequent insomnia.

A related disorder is RLS, in which patients complain of an uncontrollable feeling in their lower legs at rest, either lying or sitting. The sufferer may become so uncomfortable that he or she has to move around or get up and walk to control the symptoms. Symptoms will typically disappear when the patient starts moving around. Restless-legs complaints are more common with increasing age but may be seen in younger patients as well, as with certain medical conditions such as renal failure and diabetes mellitus or under special circumstances such as pregnancy. Although most patients with restless-legs complaints will have periodic limb movements during sleep, the inverse correlation is very uncommon. RLS has been associated with insomnia and recently has been found to be associated with ADHD in children and adolescents.[87–89]

Treatment typically is directed at increasing central nervous system dopamine concentrations with agents such as carbidopa-levodopa, pergolide, or pramipexole. Gabapentin and benzodiazepines are also used to treat RLS.

Effect of Medications/Substances

Many common medications may have a marked effect on sleep and sleep patterns. A detailed summary is beyond the scope of this review. Examples include the use of extremely long-acting stimulants for ADHD. These agents may paradoxically increase sleepiness and augment problems with attention, concentration, and mood during the daytime. By causing overstimulation, these agents may actually have a negative effect on sleep and decrease actual sleep time. Similarly, medications used for depression may have a profound effect on sleep quality.

TABLE 1. "BEARS": A Sample Sleep History

B =	Bedtime problems (Do you have any problems falling asleep at bedtime?)
E =	Excessive daytime sleepiness (Do you feel sleepy a lot during the day? In school? While driving?)
A =	Awakenings during the night (Do you wake up a lot at night?)
R =	Regularity and duration of sleep (What time do you usually go to bed on school nights? Weekends? How much sleep do you usually get?)
S =	Sleep-disordered breathing (Parent: Does your teenager snore loudly or nightly? Patient: Has anyone ever told you that you snore loudly at night?)

Even over-the-counter cold and allergy medications may be overstimulating (eg, pseudoephedrine) or oversedating (eg, diphenhydramine). Adolescents or young adults abusing prescription or illegal drugs are at high risk of significant adverse sleep effects.

Alcohol is a potent short-term sedating substance.

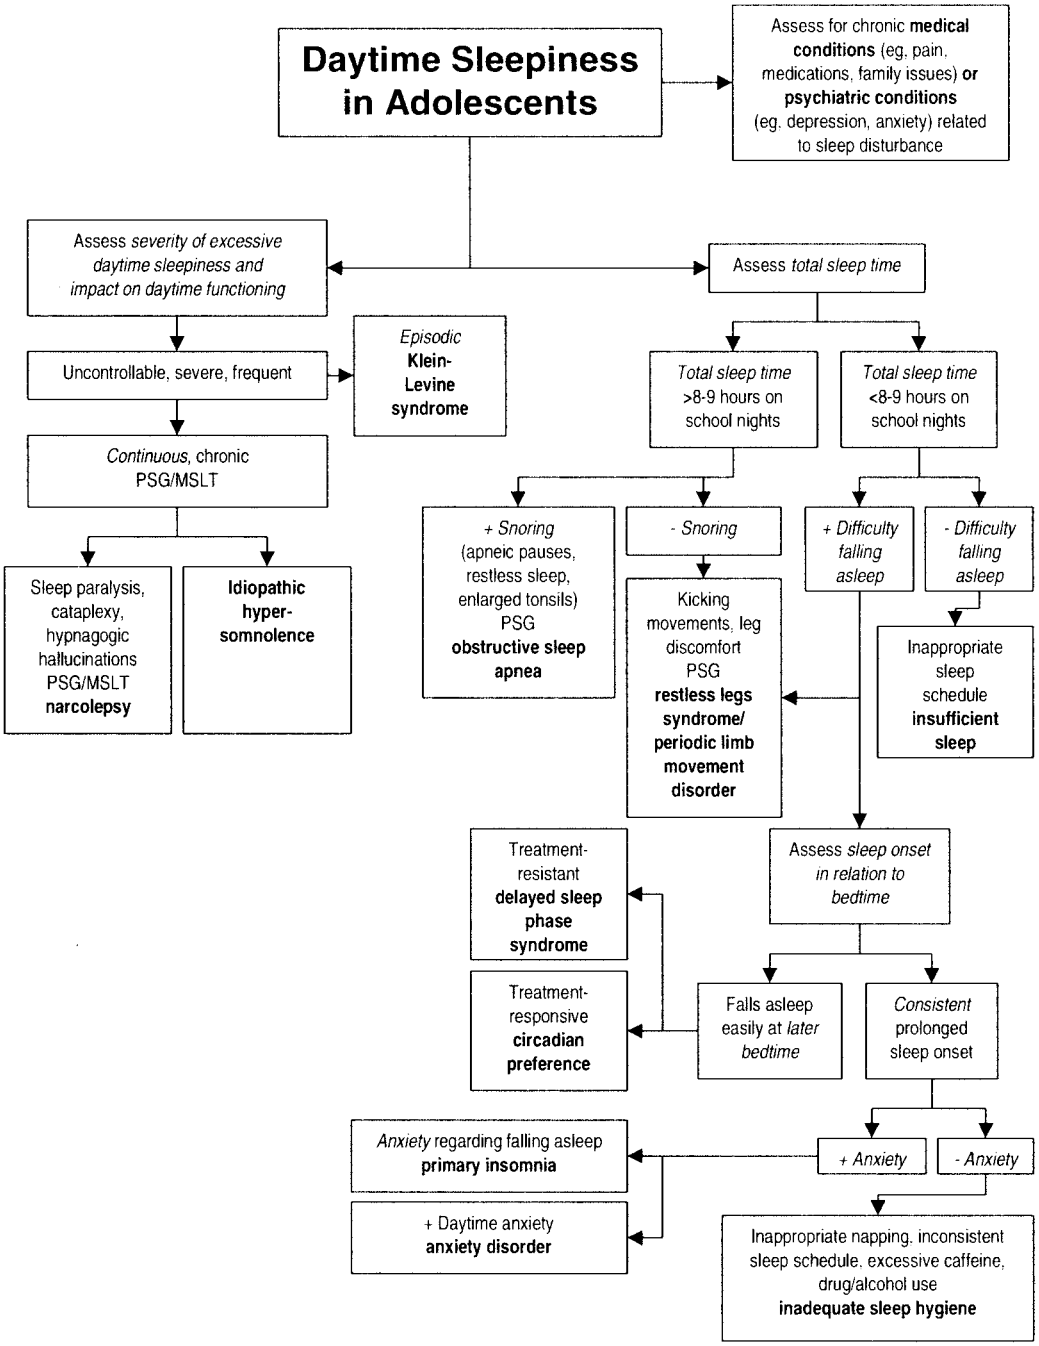

Fig 1. Sample clinical assessment flowchart. PSG indicates polysomnography; MSLT, Multiple Sleep Latency Test. (Reproduced with permission from Mindell JA, Owens JA. *A Clinical Guide to Pediatric Sleep: Diagnosis and Management of Sleep Problems*. Philadelphia, PA: Lippincott Williams & Wilkins; 2003:56.)

Although it may induce sleep, once the blood alcohol concentrations have dropped low enough, one may develop acute rebound insomnia. In addition, alcohol causes pharyngeal dilator muscle relaxation and hence precipitates snoring and even sleep apnea in susceptible individuals.[148,149]

Caffeine is ubiquitous in coffee, tea, chocolate, and soft drinks and may lead to insomnia or subconscious sleep disruption and subsequent daytime drowsiness, which in turn may lead to an increased need for caffeine the next day. Excessive use of caffeine, nicotine, or stimulants under conditions of sleepiness may provide apparent short-term gain but long-term negative consequences on sleep and circadian health.

IMPLICATIONS FOR CLINICAL PRACTICE

Excessive sleepiness is a significant problem in adolescents and young adults. In most cases, it results from insufficient sleep caused by insufficient time in bed and is associated with intrinsic changes in the sleep/wake cycle as well as extrinsic pressures to go to bed later and get up earlier. At a minimum, clinicians evaluating individuals in this age range need to ask questions routinely about sleep patterns and how much sleep an individual is receiving as well as whether there are any sleep-related symptoms. Specific tools such as the "BEARS" Pediatric Sleep History (Table 1) have been used in younger children and adolescents[150] and can serve as a template for the development of a routine review of systems for clinicians in asking sleep questions. This instrument is designed to provide a practical and user-friendly vehicle for incorporating pediatric sleep history into the standard histories and physical examinations in both outpatient and inpatient settings. The "BEARS" instrument is divided into 5 major sleep domains and provides a comprehensive screen for the major sleep disorders affecting children in the 2- to 18-year age range. Each sleep domain has a set of age-appropriate "trigger questions" for use in the clinical interview.

The key message for clinicians is that insufficient sleep (time in bed) occurs commonly but that this is not the only process that may be present. Consideration, therefore, needs to be given to possible depression, obstructive sleep apnea, insomnia, narcolepsy, and other sleep disorders as well as to medications or stimulants such as caffeine as the cause of impaired sleep quality and excessive daytime sleepiness.

There is not an established and validated algorithm that all clinicians use for diagnosing and treating sleep disorders in this age range. One sample assessment tool is shown in Fig 1. Treatment should be directed at any potentially reversible process. At a minimum, adolescents and young adults need to be counseled about normal age-appropriate sleep needs and the detrimental effects of sleep loss on performance and overall health.

POSITION PAPER

Executing Juvenile Offenders: A Fundamental Failure of Society

Position Paper of the Society for Adolescent Medicine

The Society for Adolescent Medicine (SAM) and the American Academy of Pediatrics (AAP) have the protection of the health and well-being of adolescents as a primary goal. With this joint policy statement, SAM and AAP express our strong opposition to the juvenile death penalty and call upon the United States Supreme Court, the federal government, and states to abolish the practice of executing juvenile offenders.

SAM and AAP have previously affirmed the importance of ensuring the health and well-being of young people who are involved in the juvenile and criminal justice systems [1,2]. It is well established that the vast majority of adolescents involved in these systems suffer from serious psychological and physical health problems and are more likely than the general adolescent population to have been victims of child abuse or neglect and to have experienced school failure or learning disabilities [1–3].

For more than a century, the juvenile justice system has been based on the principle that young people who commit crimes should have an opportunity for rehabilitation and treatment. The imposition of the death penalty for juvenile offenders represents the ultimate rejection of that principle. The execution of offenders who were under age 18 at the time of their crime is expressly prohibited by international law in several treaties, such as the United Nations' Convention on the Rights of the Child, the American Convention on Human Rights, the International Covenant on Civil and Political Rights, and the Geneva Convention Relative to the Protection of Civilian Persons in Time of War, and numerous resolutions and reports by other international bodies such as the European Union, the United Nations Economic and Social Council, and the United Nations Sub-Commission on Human Rights [4–6].

The Society for Adolescent Medicine and the American Academy of Pediatrics add our voices to the emerging national and international consensus opposing the death penalty for juvenile offenders. SAM and the AAP are committed to working with other professionals to address the comprehensive health care needs of young people in the context of their families, schools, and communities. We view the execution of juvenile offenders as the most fundamental failure of society to provide young people with the supports they need to grow up to lead healthy, responsible, and productive lives.

American Academy of Pediatrics
DEDICATED TO THE HEALTH OF ALL CHILDREN™

Policy Statement—Expert Witness Participation in Civil and Criminal Proceedings

abstract

The interests of the public and both the medical and legal professions are best served when scientifically sound and unbiased expert witness testimony is readily available in civil and criminal proceedings. As members of the medical community, patient advocates, and private citizens, pediatricians have ethical and professional obligations to assist in the administration of justice. The American Academy of Pediatrics believes that the adoption of the recommendations outlined in this statement will improve the quality of medical expert witness testimony in legal proceedings and, thereby, increase the probability of achieving outcomes that are fair, honest, and equitable. Strategies for enforcing guidance and promoting oversight of expert witnesses are proposed. *Pediatrics* 2009;124:428–438

BACKGROUND

The American Academy of Pediatrics (AAP) first articulated policy on appropriate medical expert witness testimony in 1989 and was among the first medical specialty societies to do so.[1] The statement was revised in 1994[2] to incorporate additional provisions on expert witness testimony guidelines from the Council of Medical Specialty Societies.[3] A 2002 revision outlined responsible practices that physicians should follow to safeguard their objectivity in preparing and presenting expert witness testimony. Key legal concepts were explained, and the role of the expert witness in the litigation process (pretrial and trial) was described.[4] This latest AAP iteration expands the requirements and qualifications for experts testifying in civil and criminal cases, the latter primarily relating to cases involving alleged child abuse and/or neglect. The importance of expert witness testimony in the process of determining civil liability, child safety, or criminal culpability and its unique significance in pediatric cases are also stressed. Recent efforts to improve the quality of medical expert witness testimony are described. The known strengths or weaknesses of these programs are noted. Enforcement of policy recommendations are sought for the first time.

WHAT IS EXPERT TESTIMONY?

The expert witness plays an essential role under the US system of jurisprudence. Courts rely on expert witness testimony in most civil and criminal cases to explain scientific matters that may or may not be understood by jurors and judges. Standards of admissibility of expert witness testimony vary depending on state and federal rules of proce-

dure and evidence. Although most state laws conform to both the Federal Rules of Procedure and Federal Rules of Evidence (FRE),[5] some do not. The same testimony from a given expert witness, therefore, might be admissible in some state courts but not in federal court, and vice versa. FRE 702 authorizes a judge to admit expert testimony into evidence if it assists the jury or the judge to "understand the evidence or to determine a fact in issue." FRE 703 permits a qualified expert to give testimony based on data of others, provided that the data are of the kind customarily used by the expert's peers. FRE 704 permits an expert to opine on the ultimate factual issue.

In a malpractice case, testimony of an expert witness differs from that of other witnesses. "Witnesses of fact" (those testifying because they have personal knowledge of the incident or are persons involved in the lawsuit) typically restrict their testimony to the facts of the case at issue. The expert witness is given more latitude. The expert witness is allowed to compare the applicable standards of care with the facts of the case and interpret whether the evidence indicates a deviation from the standards of care. Without the expert's explanation of the range of acceptable treatment modalities within the standard of care and interpretation of medical facts, juries may not have the technical expertise needed to distinguish malpractice (an adverse event caused by negligent or "bad" care) from maloccurrence (an unavoidable adverse event or "bad outcome").[6] An expert must be qualified. Although the rules vary among jurisdictions about whether the expert must be of the same specialty as the defendant, the expert, nevertheless, must demonstrate to the judge sufficient knowledge and expertise about the issue to qualify as an expert.

LEGAL AND ETHICAL STANDARDS OF TESTIMONY

The judge acts as the gatekeeper in deciding the qualifications of the expert as well as the relevance and reliability of the testimony. The 2 main standards used by judges in determining relevance and reliability are referred to as the Daubert and Frye standards.[7,8] The Daubert standard (expanded in later cases known as Joiner[9] and Kumho[10]) was established by the US Supreme Court in the 1993 case *Daubert v Merrell Dow Pharmaceuticals Inc*. This standard is used in federal courts and has been adopted by many states for use in state courts. Under the *Daubert* decision, a judge will act as the gatekeeper for expert testimony in determining whether the opinion is both relevant and reliable. The judge can, but is not required to, assess testimony according to 4 guidelines in determining whether it is reliable: (1) whether the expert's theory or technique can be (or has been) tested; (2) whether the theory or technique has been subjected to peer review or publication; (3) the known or potential error rate of the theory; and (4) whether there is general acceptance in the relevant scientific community. The latter "general-acceptance" standard is at the core of the Frye standard of expert testimony established more than 80 years ago.[8] The Frye standard is still used in some states. Other states use a hybrid of the Daubert and Frye standards. Under the Daubert standard, trial judges are to focus on the reasoning or scientific validity of the methodology, not the conclusion of the methodology. Once the judge permits expert testimony to be admitted into evidence, it is the role of the jury to determine the "weight" (or importance) of the testimony. The *Daubert* court noted that challenges to questionable testimony are to be contested via cross-examination and the presentation of contrary evidence.[7]

The effect of the *Daubert* decision in reducing "junk science" from being admitted into evidence continues to be debated.[11] Yet, it seems to have benefited, rather than harmed, the process.[12] The importance of standards for admissibility of expert testimony at the trial level is underscored by the fact that appellate courts can only consider an "abuse-of-discretion" standard in reviewing a trial judge's decision to admit or exclude expert testimony (ie, defers to the trial judge's rulings unless overtly erroneous).[9] Critics have voiced concern over judicial discretionary power in admitting experts simply because some judges may lack the requisite scientific or medical background to interpret potentially complex medical issues.[13]

Attorneys may request experts to state that their testimony is being given "within a reasonable degree of medical certainty." This rubric is not universally defined and has been interpreted differently by the courts.[14,15] Also, it is not a standard required in all jurisdictions.[16] Ideally, expert witnesses should be unbiased conveyers of information. The pivotal factor in the medical tort process is the integrity of the expert witness testimony. It should be reliable, objective, and accurate and provide a truthful analysis of the standard of care. Regrettably, not all medical experts testify within these boundaries.[17] The medical community has long been aware that not all experts testify within scientific standards and ethical guidelines.[17,18] However, more research is needed to determine how invasive improper expert testimony is in the legal process. In a study of expert witnesses in lawsuits against neurologists over a 10-year period, significant errors of fact or interpretation and incorrect statements were noted to be common.[19] One study of charac-

teristics of expert witnesses in neurologic birth injury cases noted that a small group of physicians provided a disproportionate percentage of expert testimony in cases and that there may be suboptimal expertise and possible bias in testimony.[20]

WHAT IS MEDICAL MALPRACTICE?

Medical malpractice law is based on concepts drawn from tort and contract law. It is commonly understood as liabilities arising from the delivery of medical care. Causes of action can be based on negligence, insufficient informed consent, intentional misconduct, breach of a contract (ie, guaranteeing a specific therapeutic result), defamation, divulgence of confidential information, or failure to prevent foreseeable injuries to third parties. Medical negligence is the predominant theory of liability in medical malpractice actions.

According to *Black's Law Dictionary*,[21] negligence is defined as "the failure to exercise the standard of care that a reasonably prudent person would have exercised in a similar situation." To establish negligence, the plaintiff must prove all of the following elements: (1) the existence of the physician's duty to the plaintiff, usually based on the existence of the physician-patient relationship; (2) the applicable standard of care and its violation (ie, breach of the duty); (3) damages (a compensable injury); and (4) a legally causal connection between the violation of the standard of care and the injury. In a medical malpractice case, experts may be asked to provide an opinion about 1 or all of these elements of a malpractice case. Experts should not testify about all of these elements if they are not within their area of expertise (eg, it may not be appropriate for a pediatrician to testify about whether a cesarean delivery should have been performed to prevent a brachial plexus injury).

Besides negligence, a medical malpractice lawsuit may also include an allegation of insufficient informed consent. Informed consent includes a discussion with a noncoerced patient or parent who has decision-making capacity. The discussion should include the benefits versus the risks of proposed and alternative tests or treatments and the option of no treatment. When insufficient informed consent is an aspect of the case, the expert should be familiar with the standards of informed consent in the particular state involved. There are 2 main standards of providing informed consent that have been implemented by either judicial decision or statute: the "reasonable-patient" standard versus the "reasonable-physician" standard (also known as "community" or "professional" standard).[22] In the former standard, the physician must disclose the treatments and risks that a reasonable patient/person would want disclosed (at trial, typically decided by the jury but may require expert testimony). In the latter standard, the physician must disclose the treatments and risks that a reasonable physician would disclose to the patient (at trial, typically requires expert testimony). In some circumstances in some jurisdictions, failure to obtain informed consent can result in a claim of "battery" (intentional, unauthorized touching of a person).[22,23]

HOW ARE STANDARDS OF CARE DETERMINED?

In the law of negligence, the standard of care is generally thought of as "that degree of care which a reasonably prudent person should exercise in same or similar circumstances."[21] If the defendant's conduct falls outside the standards, then he or she may be found liable for any damages that resulted from this conduct. In medical negligence disputes, the defendant's medical decision-making and practice are compared with the applicable standard of care. Generally, this is understood to be "that reasonable and ordinary care, skill, and diligence as physicians and surgeons in good standing in the same general line of practice, ordinarily have and exercise in like cases."[21] Many courts have held that the increased specialization of medicine and establishment of national board certification is more significant than geographic differences in establishing the standard of care. These courts contend that board-certified medical or surgical specialists should adhere to standards of their respective specialty boards (ie, a national standard). However, this recognition of specialty-based standards has critics, because it does not account for rural and other underserved communities or access to specialized health care facilities.[24] Thus, some jurisdictions continue to use a "locality" standard in which the physician is held to the standards of like physicians in the community.[24] Some states require out-of-state experts to demonstrate that they have familiarity with the "local" standard of care.

WAS THE STANDARD OF CARE BREACHED?

In medical liability cases, the role of the expert witness is often to establish standards of care applicable to the case at issue. The expert may also be asked to opine about any deviation from acceptable standards. When care has been deemed "substandard," the expert witness may be asked to opine whether that deviation from the standard of care could have been the proximate (ie, legal) cause of the patient's alleged injury. Because courts and juries depend on medical experts to make medical standards understandable, the testimony should be clear,

coherent, and consistent with the standards applicable at the time of the incident. Although experts may testify as to what they think the most appropriate standard of care was at the time of occurrence, they should know and consider alternative acceptable standards. These alternatives may be raised during direct testimony or under cross-examination. Expert witnesses should not consider new evidence, guidelines, or studies that were not available to the treating physicians at the time of the occurrence. Expert witnesses should not define the standard so narrowly that it only encompasses their opinion on the standard of care to the exclusion of other acceptable treatment options available at the time of the incident.

MEDICAL ERRORS VERSUS NEGLIGENCE

The Institute of Medicine's sentinel report on medical errors, *To Err Is Human*: *Building a Safer Health System*,[25] provides a helpful framework for understanding the many factors involved in medical interventions and how their permutations can affect patient outcome. Whenever a medical intervention is undertaken, several outcomes can occur—the patient's condition can improve, stay the same, or deteriorate. These same outcomes are possible even when the medical treatment is performed properly. A negative outcome alone is not sufficient to indicate professional negligence. It is essential that the trier of the case (either jury or judge) understand that negligence cannot be inferred solely from an unexpected result, a bad result, failure to cure, failure to recover, or any other circumstance that shows merely a lack of success.

BURDEN OF PROOF

In a medical malpractice case, the plaintiff bears the burden of proof and must convince a jury by a "preponderance of the evidence" that its theory of the case is more probably true than alternative theories. A "preponderance of the evidence" means more than 50% likely. Thus, jurors in a medical malpractice case must be persuaded that the evidence presented by the plaintiff is more plausible than any counterargument offered by the defendant.[26] The plaintiff and defense attorneys will present their respective experts, each side hoping their witnesses will appear more knowledgeable, objective, and credible than their counterparts. In a criminal case, the prosecutor bears the burden of proof, and the guilt must be proven by the much higher standard of "beyond a reasonable doubt."

PRETRIAL ROLE OF EXPERT TESTIMONY

In medical malpractice, expert witness testimony may be used to evaluate the merits of a malpractice claim before filing legal action. Some states have enacted laws that require that a competent medical professional in the same area of expertise as the defendant review the claim and be willing to testify that the standard of care was breached.[27] This may require a filing of an affidavit or certificate of merit that malpractice has occurred. Some states have deemed this system unconstitutional, claiming that legitimate plaintiffs may be denied access to the legal system solely on procedural, rather than substantive, grounds.[28]

Some states use review panels to prescreen medical malpractice cases. These panels typically consist of a physician, attorney, and lay representative. However, state laws that govern the timing and process for review panels can vary. Depending on the state, the review can take place before or after the claim has been filed. Review-panel findings can be binding or nonbinding. The opinion of the review panel may or may not be admissible should the matter proceed to litigation. The continuing future role of these panels has been questioned.[29]

Those who are seeking regulation of expert witness testimony have noted that the expert opinions provided during this early stage of the legal process are subject to even less scrutiny and accountability than testimony provided later. Critics believe that the lack of oversight of experts during the pretrial reviews allows too many nonmeritorious cases to proceed, thereby defeating the purpose of having pretrial reviews.[30]

EXPERT REPORTS AND DEPOSITION

The purpose of "discovery" is to identify all the facts related to the case. Discovery is applicable to both fact witnesses and expert witnesses. The deposition of key fact witnesses is a very important facet of the discovery process in malpractice cases. A deposition is a witness's recorded testimony, given under oath, while being questioned by attorneys for the parties in the case. Throughout the deposition process, attorneys gather information on what fact witnesses will say and assess the relative effectiveness of their testimony as well as their demeanor (eg, clarity, believability, arrogance, sincerity). Crucial decisions in determining the next phase of the case (eg, seeking a settlement, going to trial, moving for dismissal/summary judgment) are often based on the strength of the testimony. Experts can also be deposed. Rather than through depositions, written reports of the experts are typically shared between the 2 parties before trial. However, some states may not require disclosure of the identity of the expert or even disclosure of the report. Most medical malpractice lawsuits that are re-

solved in favor of the plaintiff are typically settled during or at the conclusion of the discovery phase.[31]

UNIQUE FACTORS IN PEDIATRIC CASES

In theory, expert witness testimony from the plaintiff and the defense should give the jury enough of a technical understanding of the medical care provided and its appropriateness to determine if the preponderance of the evidence proves the defendant liable for the plaintiff's injury. In cases that reach trial, some authorities note that jurors can generally be effective in assessing expert testimony.[32] However, other aspects of the proceedings may unduly influence triers of the case. This is particularly true in cases that involve children. Because people tend to have a natural sympathy for children, the focus of the trial has the potential to become the plaintiff rather than the evidence. A jury might be influenced by the needs of, for example, a family with a neurologically impaired infant or a ventilator-dependent teenager.

Patients who experience long-term consequences of injuries attributable to medical negligence should be appropriately and promptly compensated. However, using malpractice awards to compensate patients for adverse outcomes not caused by medical negligence is not the intent of the system. Whether society at large should provide more assistance to families faced with such tragic circumstances is a policy decision. Wanting to assist the families of children with disabilities or injuries regardless of whether the physician committed any medical error may seem altruistic to the jury, but in fact, it is an inappropriate outcome. To prevent unjust results, objective expert witness testimony is needed.

CRIMINAL CASES

Pediatricians often serve as experts in civil child protection cases (in which custody of children may be at issue) and in criminal cases of alleged child abuse and neglect. The new subspecialty of "child abuse pediatrics" approved by the AAP and the American Board of Pediatrics sets high standards for professional competence and conduct in this area. Pediatricians who are not board certified in child abuse pediatrics may still be called to testify in cases of abuse and neglect if they have special knowledge and experience that qualifies them to explain medical issues to the court, both as experts and as fact witnesses. Pediatricians who are inexperienced in evaluating children suspected of abuse or neglect should be cautious of providing an expert opinion because of the devastating outcome of a wrongful conviction based on inaccurate testimony. This is a high-risk area for expert testimony, and even experienced professionals have been engaged in controversy.[33] If a general pediatrician feels uncomfortable in testifying in these cases, consultation with subspecialists in child abuse pediatrics should be strongly considered.

IMPROVING THE QUALITY OF EXPERT TESTIMONY

Various branches of organized medicine and some state medical licensure boards have implemented programs to help curb unscientific expert witness testimony. Strategies for regulating expert witness testimony generally fall under the principles of education, prevention, peer review, and sanctioning.

Education

Continuing medical education about the expert witness process is needed at all levels of pediatric experience.[34] The 2006 AAP graduating resident survey revealed that only 25% of residents reported that their training program provided adequate education on the expert witness process.[35] Educational programs at both the national and state levels are critical for this effort. One strategy for effective programs is to use false or unscientific testimony from closed cases for teaching purposes in continuing medical education venues. This strategy is particularly effective when biased or false testimony played an important role in the outcome of the case. It illustrates the power of expert witness testimony in malpractice litigation and can be an excellent teaching technique to present acceptable and optimal treatment modalities that should have been introduced by the experts.

Prevention

Despite the critical importance of the expert witness, no uniform standards on credentialing of experts currently exist. One specialty society has initiated a process to certify experts.[36] Imposing eligibility restrictions on those who provide expert witness testimony might be a way to prevent irresponsible testimony. By 2006, approximately 22 states had measures requiring minimum qualifying standards for physician experts.[37] Some states have proposed or enacted legislation or regulations that tighten the qualifications for medical experts to more closely match those of the defendant physician (eg, geographic factors, specialty training, certification, percentage of time spent on direct patient care, etc).[38,39]

Other preventive measures decrease financial incentives for serving as an expert witness, which is especially applicable to witnesses who travel extensively to provide expert ser-

vices ("itinerant" witnesses). Examples include recommending caps on the percentage of annual revenue that a medical expert can derive from testimony fees or establishing fee schedules for expert witness testimony that are based on a set hourly rate (determined to be reasonable or comparable to other medical consulting services). The medical profession has deemed it unethical for expert witnesses to base their fees for testifying contingent on the outcome of the case.[40–42] Other suggestions for preventing itinerant experts include the sponsoring by medical specialty societies of expert scientific panels and court-appointed medical experts (permitted under FRE 706). A few medical societies have proposed that, for physicians to serve as experts in malpractice cases, they are required to join their medical society (even those from out-of-state). Thus, all experts testifying in that state would be potentially subject to disciplinary action of the local medical organization. Some states require an expert to hold a medical license in that state. Some states consider expert testimony as part of the "practice of medicine," with possible sanctioning by the licensing board for improper testimony.[43] The American Medical Association House of Delegates has discussed a series of resolutions aimed at curtailing improper testimony by physicians and in 1998 adopted the position that the provision of expert witness testimony should be considered the practice of medicine and should be subject to peer review.[44] Adopting this approach not only makes medical licensure a requirement for providing expert witness testimony but also puts physicians on notice about potential actions against their medical license for giving false, biased, or unscientific testimony. Because licensing boards already function as disciplinary bodies, they may be an appropriate setting for judging the appropriateness of physician conduct, which can include expert testimony.[45] However, not all courts have agreed that medical expert witness testimony is engaging in the practice of medicine.[46]

Peer Review

Specialty medical organizations have established programs in which a panel of peers will review and critique the content of expert witness testimony.[47–50] Sometimes, the testimony and the peer analysis, along with commentary, are published in scientific journals. Some specialty societies, such as the American Association of Neurologic Surgeons (www.aans.org/about/membership/professional_conduct10_06.pdf), maintain libraries of expert witness testimony that are accessible by legal counsel of their members. There are obstacles to an effective peer-review process, including costs, time, and possibility of lawsuits against peer reviewers.[51–53] Any oversight process must be fair and objective and ensure due process. Peer review has lead to sanctioning of experts.

Sanctioning

The most aggressive method of curbing irresponsible testimony is to discipline physicians whose expert opinions are deemed to be biased, inaccurate, incomplete, or unscientific. Disciplinary actions can even result in the physician being expelled from membership in professional organizations. Such actions have been upheld by the appellate courts.[54]

There have been lawsuits against expert witnesses for alleged improper testimony. Historically, the principle of witness immunity has shielded experts from legal reprisal that is based on the nature of their testimony.[55,56] To bring greater accountability to expert witness testimony in malpractice cases, some legal authorities have sought to have a distinction drawn between expert witnesses and witnesses of fact relating to immunity.[55] These critics postulate that because experts testify voluntarily and receive significant compensation for their services, general witness immunity should not apply to them. Various courts have responded differently to this concept.

Additional proposals that may affect or improve the expert witness system include mediation and arbitration[57,58]; specialized health courts[59]; an internal dispute-resolution process within the hospital[60]; standardizing and regulating expert medical case review, analysis, and testimony[61]; adopting a "data-based standard of care in allegations of medical negligence"[62]; use of third-party experts[63]; and encouraging academic institutions to be accountable for the testimony of their faculty members.[64] At least 1 federal judge has suggested that judges may be more willing to use third-party experts if the experts were more easily accessible and their fairness and impartiality could be ensured by professional oversight and discipline.[65]

Because of the increasing complexity and uncertainty surrounding the issue of expert testimony by physicians, the medical community must proceed cautiously. Although courts have upheld the right of specialty organizations to discipline a member for improper testimony, any disciplinary process is fraught with risks and must be fair and objective and ensure due process. An expert witness disciplinary program that is too aggressive may be seen as organized medicine's discouragement of physicians from testifying. Some courts have been punitive about efforts to quash potential experts from testifying.[66] The physician community

will need to remain firmly committed to reviewing and sanctioning false statements by medical experts for both the defense and the plaintiff or prosecutor. It has been suggested that fear of sanctions could dissuade physicians from fulfilling their civic and professional duty to participate as experts in legal processes. One concern is that a decrease in the number of physicians willing to provide expert witness testimony may be associated with greater reliance on "professional" witnesses. Beyond the considerable legal risks, disciplinary programs are labor intensive and may be expensive to implement and maintain. Because disciplinary programs can be beyond what a state or local organization can shoulder, specialty societies are often urged to provide this service for their members on a nationwide basis.[47,67] Continual attempts to improve the expert witness process should affect the delivery of future medical care by reducing the number of lawsuits and litigation costs and ensuring adequate physician supply in those specialties with high exposure to malpractice lawsuits.[68]

RECOMMENDATIONS

The AAP recognizes that physicians have the professional, ethical, and legal duty to assist in the legal process when medical issues are involved. Physicians who serve as expert witnesses have an obligation to present complete, accurate, and unbiased information to assist the triers of facts to understand the scientific issues so that they can arrive at a fair and equitable result. At this time, the best strategies for improving the quality of medical expert witness testimony must include strengthening the qualifications for serving as a medical expert, educating pediatricians about standards for experts, and providing more specific guidelines for physician conduct throughout the legal process. To that end, the following recommendations are offered.

Advocacy and Education

The AAP believes that the establishment of certain minimal qualifications for physicians who serve as expert witnesses will improve the quality of testimony and promote just and equitable verdicts. Therefore, the AAP supports the following efforts.

1. Implement the recommendations of this statement through legislative or regulatory reform of expert witness testimony (eg, establish minimal qualifications for expert witnesses).
2. Educate pediatricians (during residency training and through continuing medical education) and provide them with the skills and knowledge base needed for them to provide objective, scientific, and ethical expert witness testimony in legal proceedings.
3. Implement additional specialized education as well as oversight safeguards for experts participating in the criminal law process because of heightened concerns for convictions based on inaccurate expert testimony in criminal cases.
4. Aid in the establishment of expert panels to study, standardize, and disseminate elements of expert testimony that have been inadequately addressed (eg, define "within a reasonable degree of medical certainty," establish the role of evidence-based medicine in expert opinions, opine whether expert testimony should be considered "the practice of medicine").

Relevant Qualifications

Physicians should limit their participation as medical experts to cases in which they have genuine expertise. The following qualifications must be met (and verified) to demonstrate relevant education, certification, and experience.

1. Physician expert witnesses must hold a current, valid, and unrestricted medical license in the state in which they practice medicine.
2. Physician expert witnesses should be certified by the relevant board recognized by the American Board of Medical Specialties or a board recognized by the American Osteopathic Association or by a board with equivalent standards. Alternatively, the expert should be capable of demonstrating sufficient training or clinical experience in the clinical area at issue to be qualified and accepted as an expert by the relevant specialty board(s).
3. Physician expert witnesses must have been actively engaged in clinical practice in the medical specialty or area of medicine about which they testify, including knowledge of or experience in performing the skills and practices at issue to the lawsuit. Alternatively, the expert should be able to demonstrate updated competence in the profession within a reasonable time period contiguous to the alleged act. Evidence of updated competence could include medical student or resident teaching, relevant publications, or research.
4. Unless retired from clinical practice, most of the expert's professional time should not be devoted to expert witness work. If retired, the physician should render expert opinions on cases that occurred at the time he or she was in active practice.
5. Physician expert witnesses should not give false, misleading, or misrepresentative details about their qualifications.

Standards of Testimony

Physician expert witnesses should take all necessary steps to provide thorough, fair, objective, and impartial review of the medical facts. To meet that obligation, physicians who agree to testify as experts in medical malpractice cases should conduct themselves as follows.

1. Regardless of the source of the request for testimony (plaintiff or defendant), physician expert witnesses should lend their knowledge, experience, and best judgment to all relevant facts of the case.
2. Physician expert witnesses should take necessary steps to ensure that they have access to all documents used to establish the facts of the case and the circumstances surrounding the occurrence. If all medical records are unavailable for review, experts should consider recusing themselves from serving in an expert capacity.
3. Physician expert witnesses should not exclude relevant information for any reason and certainly not to create a perspective that favors the plaintiff or the defendant.
4. The physician expert should be comfortable with his or her testimony regardless of whether it is to be used by the plaintiff or defendant.

Standards of Care

The physician expert witness should be familiar with the medical standards of care at the time of the incident at issue. A physician who is unfamiliar with the medical standards would not meet the recommended qualifications of an expert.

1. Before testifying, the physician expert witness should thoroughly review and understand the current concepts and practices related to that standard as well as the concepts and practices related to that standard at the time of the incident that led to the lawsuit.
2. The testimony presented should reflect generally accepted standards within the specialty or area of practice about which the physician expert witness is testifying, including those held by a significant minority.
3. When a variety of acceptable treatment modalities exist, this should be stated candidly and clearly.
4. In states where the standard of practice is based on the "locality rule," the physician expert witness must be knowledgeable about local practice and procedure at the time of the incident at issue.
5. Expert witness testimony should not condemn performance that clearly falls within generally accepted practice standards or condone performance that clearly falls outside accepted practice standards.
6. An expert should respect the privacy and confidentiality of the process as required by law.

Assessing Breach of Care and Proximal Cause

Physician expert witnesses must exercise care in assessing the relationship between the breach in the standard of care and the patient's condition, because deviation from a practice standard may not be the cause of the patient outcome at issue. Thus, physician expert witnesses should base distinctions between medical malpractice and medical maloccurrence on science, not on unique theories of causation that would not be deemed reliable according to the Daubert, Frye, or other applicable standards.

Ensuring That Testimony Is Proper

Physician expert witnesses:

1. Must take all necessary precautions to ensure that the expert work is relevant, reliable, honest, unbiased and based on sound scientific principles.
2. Know that transcripts of depositions and courtroom testimony are public records and may be reviewed by others outside the courtroom.

Ethical Business Practices

The business practices (eg, marketing, contractual agreements, and payment for services) associated with the provision of expert witness testimony must be conducive to remaining nonpartisan and objective throughout the legal proceedings.

1. Contractual agreements between physician expert witnesses and attorneys should be structured in a way that promotes fairness, accuracy, completeness, and objectivity.
2. Compensation for expert witness work should be reasonable and commensurate with the time and effort involved and prevailing market value.
3. Compensation for expert witness work must not be contingent on the outcome of the case.

DEDICATED TO THE HEALTH OF ALL CHILDREN™

CLINICAL REPORT

Exposure to Nontraditional Pets at Home and to Animals in Public Settings: Risks to Children

Guidance for the Clinician in Rendering Pediatric Care

Larry K. Pickering, MD, Nina Marano, DVM, MPH, Joseph A. Bocchini, MD, Frederick J. Angulo, DVM, PhD, and the Committee on Infectious Diseases

ABSTRACT

Exposure to animals can provide many benefits during the growth and development of children. However, there are potential risks associated with animal exposures, including exposure to nontraditional pets in the home and animals in public settings. Educational materials, regulations, and guidelines have been developed to minimize these risks. Pediatricians, veterinarians, and other health care professionals can provide advice on selection of appropriate pets as well as prevention of disease transmission from nontraditional pets and when children contact animals in public settings. *Pediatrics* 2008;122:876–886

NASPHV—National Association of State and Public Health Veterinarians
CSTE—Council of State and Territorial Epidemiologists
CDC—Centers for Disease Control and Prevention

INTRODUCTION

The majority of households in the United States own 1 or more pets. In national surveys conducted by the American Pet Products Manufacturers Association, the percentage of US households that have 1 or more pets increased from 56% in 1998 to 63% (71.1 million homes) in 2007.[1] Dogs are owned by 44.8 million households, cats are owned by 38.4 million, freshwater fish are owned by 14.2 million, birds are owned by 6.4 million, small animals are owned by 6.0 million, horses are owned by 4.3 million, and saltwater fish are owned by 0.8 million. Total US pet industry expenditure in 2007 is estimated at $40.8 billion.[1] In recent years, the number of families that have chosen nontraditional pets has increased.[1]

Many pet owners and people in the process of choosing a pet often are unaware of the potential risks posed by certain animals, especially nontraditional pets. These risks are associated with changes in physical and behavioral characteristics as young animals reach maturity. Pediatricians, veterinarians, and other health care professionals are in a unique position to offer advice on proper pet selection, to provide information about safe pet ownership and responsibility, and to minimize risks to infants and children.

In addition to exposure to animals in their homes, children may come in contact with animals in a variety of public settings.[2] Although there are many benefits to experiences with animals outside the home, contact with animals in public settings also can be associated with significant risks to children, including infections and injuries. These potential risks are enhanced when there is an inadequate understanding of disease transmission, methods of preventing transmission, animal behavior, or appropriate facilities for animals.

This report deals with the potential exposure of infants, children, and adolescents to nontraditional pets in the home and to animals in public settings. The objectives of this report are to (1) summarize information regarding emerging and reemerging infectious diseases, injuries, and allergies associated with exposure to nontraditional pets in the home and to animals in a variety of public settings, (2) outline regulations and recommendations applicable to these exposures, and (3) define measures to minimize or prevent illness and injury in children from exposure to these animals and cite resources for additional information for health care professionals and families.

METHODS

To identify original research publications and review articles dealing with infections, injury, and allergies in children resulting from nontraditional pets, including exotic animals, in the home and from animals in public settings, a search of the National Library of Medicine's Medline database was performed by using PubMed, and the Cochrane Library was searched for articles published between 1975 and 2007. The terms "nontraditional pets," "exotic animals," "farm

TABLE 1 **Animals That Are Considered Nontraditional Pets and/or Animals That May Be Encountered in Public Settings**

Categories	Examples
Amphibians	Frogs, toads, newts, salamanders
Fish	Many types
Mammals: wildlife	Raccoons, skunks, foxes, coyotes, civet cats, tigers, lions, bears, nonhuman primates
Domesticated livestock	Cattle, pigs, goats, sheep
Equines	Horses, mules, donkeys, zebras
Weasels	Ferrets, minks, sables, skunks
Lagomorphs	Rabbits, hares, pikas
Rodents	Mice, rats, hamsters, gerbils, guinea pigs, chinchillas, gophers, lemmings, squirrels, chipmunks, prairie dogs, hedgehogs
Feral animals	Cats, dogs, horses, swine
Reptiles	Turtles, lizards, iguanas, snakes, alligators

animals," "pets," "wildlife hybrids," "indigenous wildlife," "reptiles," and "rodents" were selected as Medical Subject Headings (MeSH), and text words were combined in the search strategy. In addition, the "related links" option on PubMed was used. References in all relevant published articles, including reviews, letters, commentaries, and Web sites, also were reviewed to identify original research.

Studies were assessed as to whether they should be included in this review on the basis of their reporting or summarizing original data that examined infections or injuries in children resulting from nontraditional pets in the home or animals in public settings. Previously published recommendations to prevent infections and injuries were reviewed.

For the purpose of this report, nontraditional pets include exotic animals, defined either as imported, nonnative species or species that originally were nonnative but now are bred in the United States; indigenous wildlife; and wildlife hybrids (wildlife crossbred with domestic animals producing offspring known as hybrids). The definition of nontraditional pets includes reptiles and certain species of mammals.

NONTRADITIONAL PETS

Nontraditional pets are increasing in popularity among a pet-loving public as lifestyle choices of owners dictate the need for smaller or more unusual pets. Table 1 provides examples of animals that are considered nontraditional pets as well as animals to which children may be exposed in public settings.

Since 1992, the number of exotic animals available in the United States has increased 75%.[1] In 2005, 87 991 mammals (including 29 species of rodents), 1.3 million reptiles, and 203 million fish were imported legally into the United States. The US Fish and Wildlife Service estimates that in 2002, 365 000 birds were imported legally. Reptiles are now in 4.4 million homes.[1] In addition, there is a worldwide illegal trade of exotic animals, estimated at $6 to $10 billion dollars annually,[3–5] only exceeded by the trafficking of arms and drugs. This illegal trade subverts rules established by regulatory agencies to reduce introduction of disease and potentially dangerous animals through importation restriction, inspection, and/or quarantine.[5]

A number of public health concerns are related to human contact with nontraditional pets and, specifically, to exotic animals. Most imported nonnative species are caught in the wild rather than bred in captivity. Health screening often is not performed before shipment of these animals to the United States, and there is mixing of animal species in holding locations, including animals that might be ill or incubating illness or carriers of potential pathogens. In addition, the significant wildlife black market, through which a large number of exotic animals enter the United States, compounds the risks of introduction of zoonoses.[6]

Despite the popularity of nontraditional pets, after making the initial decision to acquire a nontraditional pet, owners may discover that they are unable to provide the animal with the environment or nutrition required for a healthy life and often subsequently abandon or release the animal into the wild, which poses risks for zoonotic disease and injury to people and other animals.

ZOONOSES ASSOCIATED WITH NONTRADITIONAL PETS

Zoonotic diseases or zoonoses are infections transmitted between other vertebrate animals and humans. Most emerging infectious diseases in humans are zoonotic in origin.[6–9] A list of 1415 human pathogens demonstrates that 61% are known to be zoonotic, and pathogens with multiple host species are twice as likely to be associated with an emerging infectious disease.[8] From 1980 to 2003, more than 35 new infectious diseases have emerged in humans, many of which are zoonoses.[9] The leading causes of their emergence are human behavior (travel and leisure activities, preferences for pet ownership) and modifications of natural habitats, including expansion of human populations and encroachment on wildlife habitats, changes in food-production processes, changes in agricultural practices, and global trade in wildlife.[5,6,9] Domestic animals and humans may acquire zoonotic pathogens from nontraditional pets. Wild animals also can serve as reservoirs for transmission of zoonotic agents to domesticated animals and to humans.[7] An outbreak of tularemia in US wild-caught prairie dogs held in a commercial facility in Texas led to human transmission.[10] Some of the infected animals were distributed to a pet shop in Texas and were exported as far away as the Czech Republic.

Exotic animals imported to the United States have been associated with introduction of infectious agents otherwise not present in the United States. Contact between animals from different areas of the world can lead to the appearance of disease in a new species and establishment of a pathogen in a new geographic area. An example occurred in 2003 when human monkeypox was introduced into the United States. Investigators determined that the source of monkeypox was importation of African Gambian rats, which, in turn, ultimately infected prairie dogs being sold as pets, which infected humans in close contact with the prairie dogs.[11] In this case, prompt recognition and public health efforts controlled this outbreak and may have been respon-

sible for preventing establishment of monkeypox in North America.

Zoonotic transmission of infections by household pets or animals with which children come in contact in their homes or public settings is a common event. Infections can be caused by bacteria, viruses, fungi, and parasites. Transmission may be direct or indirect through contact, aerosols, bites or scratches, contamination of the environment, food or water, or disease-carrying vectors. Animals may become ill or, more commonly, are asymptomatic carriers of specific organisms and may contaminate the environment to which children are exposed. Infants and children younger than 5 years are at the greatest risk, in part because they have less-than-optimal hygiene practices, attraction to or curiosity about animals, and developing immune systems[12] but also because these infections tend to be more severe in infants and young children. People of all ages with primary or secondary immunodeficiencies are at risk of more severe disease, as are pregnant women and elderly people.[13]

Reptiles

Among nontraditional pets, reptiles pose a particular risk because of high carriage rates of *Salmonella* species, the intermittent shedding of *Salmonella* organisms in their feces, and persistence of *Salmonella* organisms in the environment.[12,14–16] The US Food and Drug Administration (FDA) ban on commercial distribution of turtles with shells less than 4 inches long in 1975 resulted in an important and sustained reduction of human *Salmonella* infections as a result of prevention of transmission of *Salmonella* from these reptiles, although illegal distribution of small turtles with subsequent disease in humans continues to occur.[17,18] Amphibians also can serve as a source of salmonellosis in households.[12] Six percent of all sporadic *Salmonella* infections in the United States (11% among people younger than 21 years)—approximately 74 000 cases annually—are the result of direct or indirect contact with reptiles or amphibians.[12]

Rodents

Multistate outbreaks of salmonellosis attributable to contact with hamsters[19] and other rodents[20] purchased from retail pet stores have been described. Hamsters also have been associated with outbreaks of disease attributable to lymphocytic choriomeningitis virus.[21] Hedgehogs, originally from Europe, Asia, and Africa and now estimated to be in approximately 40 000 US households, have proven to be an important source of *Salmonella* serotype Tilene in the United States.[22] Other *Salmonella* serotypes as well as *Yersinia pseudotuberculosis*, *Mycobacterium marinum,* and rabies also have been shown to be zoonotic diseases carried by hedgehogs.

The natural reservoir of plague is wild rodents, with humans becoming infected through bites of infected rodent fleas and through handling infected animals, especially rodents, lagomorphs, and domestic cats.[23,24] In parts of the United States where plague is endemic, people with rodent-seeking animals can be exposed to *Yersinia pestis* through direct contact with plague-infected pets or their fleas.[24] People who live in areas where plague is endemic should follow a flea-control program designed by their veterinarians to keep their cats and dogs free from fleas.

Skin infections also can be acquired from nontraditional pets and include ringworm, monkeypox, orf, cutaneous anthrax, tularemia, erysipeloid, ectoparasites, and endoparasites.[25–30] Hedgehogs pose a significant risk, because their spines readily penetrate skin and can be the source of *M marinum* and *Y pseudotuberculosis* infections.[22]

Nonhuman Primates

Herpes B virus (cercopithecine herpesvirus 1) is a zoonotic agent that can be found in macaque monkeys that are kept as pets or displayed in public exhibits. The virus is endemic in macaque monkeys, which may remain asymptomatic or may develop mild oral lesions. Herpes B virus infections in humans have been reported after animal bites, scratches, or percutaneous inoculation with infected material or splashes to mucous membranes. Human infections most often result in fatal meningoencephalitis.[31]

Fish

Mycobacterial infections are among the major zoonoses that can be transmitted by aquarium fish,[32] but other organisms have been reported after exposure to aquarium water, usually sporadically or in immunocompromised people. These organisms include *Aeromonas* species, *Vibrio* species, *Edwardsiella* species, *Salmonella* species, *Streptococcus iniae,* and *Erysipelothrix rhusiopathiae*.[33]

Other Sources of Infection

Infection attributable to *Salmonella* species can be acquired from other sources. Outbreaks of *Salmonella* species infections in people who have been in contact with chicks and other baby poultry purchased at agricultural feed stores have been reported.[34] Parents who purchase these birds for their children generally are not aware that *Salmonella* infections can be transmitted from poultry to humans. In addition to direct exposure to animals, exposure to animal-derived pet food treats and pet food has resulted in human infections attributable to *Salmonella*.[35,36] Animals may become colonized with *Salmonella* after ingesting contaminated pet food treats or raw meats. These animals may remain asymptomatic and become unrecognized sources of contamination in the household. Handling of pet food treats by humans may result in infection.[36] In the United States, pet treats are regulated by the FDA. *Salmonella*-contaminated pet treats are considered adulterated under the Federal Food, Drug, and Cosmetic Act (21 USC §301–399). The American Pet Products Manufacturers Association published guidelines to educate its members about risks of contamination of pet treats.[37] In 2004, the FDA initiated annual nationwide testing of pet treats for *Salmonella* species.

TABLE 2 **Potential Exposures of Children to Animals in Public Settings**

Area	Animal Involved	Organism
Metropolitan zoo	Elephants, giraffes, rhinoceroses, buffaloes	*M tuberculosis*[56,57]
	Komodo dragons	*Salmonella* serotype *enteritidis*[15]
County or state agricultural fairs	Cattle, calves	*E coli* O157:H7[38,45,51,64]
	Cattle	*Campylobacter* species[50]
	Reptiles	*Salmonella* species[14]
	Goats	Rabies[62,64]
Farm tours or visits	Cattle, calves	*E coli* O157[38–40,43,44,46,47,52,62]
	Raw milk	*Campylobacter* species, *Salmonella* species[64]
	Calves	*Cryptosporidium* species, *E coli* O157:H7, *Salmonella* species, *Campylobacter* species[48]
	Sheep, goats, calves	*Cryptosporidium* species[38,53–55,64]
	Sheep	Orf[25]
Livestock exhibits	Cattle	*E coli* O157[45]
Pet stores	Hamsters, mice, rats	*Salmonella* species[20]
	Kittens	Rabies[61]
	Hamsters	Tularemia,[10] lymphocytic choriomeningitis[21]
	Prairie dogs	Monkeypox[11]
Petting zoos	Cattle, sheep, goats	*E coli* O157[38,42,49,64]
	Rabbits	*Giardia* species[64]
	Bear cubs	Rabies[63]
Rodeo events	Ponies	Rabies[60]
Fish tanks	Fish	*Mycobacterium* species,[32] *Salmonella* species[33]
Agricultural feed store	Baby poultry (chicks, ducklings, goslings, turkeys)	*Salmonella* species[34]

DISEASES ASSOCIATED WITH ANIMALS IN PUBLIC SETTINGS

Infants and children can come in contact with numerous different animal species (Table 1) in a number of public settings (Table 2), potentially resulting in millions of human-animal interactions annually. Public animal exhibits can be permanent, such as zoos and science museums; temporary, such as in shopping malls, schools, or community events; or recurring, such as agricultural fairs and petting zoos.[38] Petting zoos are common at agricultural fairs, animal parks, and other public events. Although numerous positive benefits of human-animal contacts exist, including opportunities for education and entertainment, infectious diseases, injuries, and other health problems associated with these venues are well documented. Infections with enteric bacteria and parasites pose the highest risk of human disease from animals in public settings. Although ruminant livestock (cattle, sheep, and goats) are the major source of infection, poultry, rodents, and other domestic and wild animals are also potential sources.[2]

From 1991 to 2005, more than 55 outbreaks of human disease, the most common of which were enteric, involved animals in public settings.[3] Serious infections with *Escherichia coli* O157:H7 have been associated with multiple animals in public settings.[39–52] The primary reservoir of *E coli* O157:H7 is ruminant livestock, which are colonized asymptomatically. In many studies, the primary route of transmission has been foodborne,[46] but person-to-person spread, direct animal contact, and contact with environmental items contaminated by animals are common.[41] In 2004 and 2005, there were 3 *E coli* O157:H7 outbreaks, accounting for 173 cases from 3 states associated with direct and indirect animal contact at petting zoos.[42] Outbreaks[14] and sporadic cases of salmonellosis and outbreaks of cryptosporidiosis[53–55] have been described after visits to farms at which visitors had either direct or indirect contact with animals. Additional illnesses include salmonellosis, campylobacteriosis, tuberculosis, rabies, orf virus infection, giardiasis, tularemia, ringworm, and infected bites or wounds.[10,15,25,48,50,56,57] Direct contact with animals (especially young animals), contamination of the environment or food or water sources, inadequate hand-washing facilities or lack of education about hand hygiene, and inappropriate layout and maintenance of facilities at animal exhibits have been implicated as sources of or reasons for infection in these public settings.[2] As an example, in a study of observations of practices at petting zoos in Canada, hand-hygiene facilities were provided but often not used, items that would come into contact with mouths of infants and children (pacifiers, infant bottles, sippy cups) were carried into the petting zoos, and education about hygiene was lacking.[58] The recommendation to wash hands immediately after leaving an animal exhibit is the single most important prevention step to reduce the risk of disease transmission, even if an animal is not touched.

RABIES

Rabies is a fatal viral zoonosis and a serious public health problem.[59,60] Although human rabies deaths caused by animal contact in public exhibits have not been reported, exposure to rabid mammals at pet stores,[61] county fairs,[62] petting zoos,[63,64] and rodeo events[64] have required extensive public health investigations and med-

ical follow-up. For example, raccoon-variant rabies in pet rabbits and a guinea pig have led to postexposure prophylaxis of adults and children.[65] Prevention of rabies in domestic cats, dogs, and ferrets can be achieved by regular rabies immunization and reimmunization.[59,60] Control of rabies among wildlife reservoirs is difficult, and use of licensed oral vaccines for mass immunization of free-ranging wildlife depends on the circumstances surrounding each animal rabies outbreak and is restricted to use in state and federal rabies-control programs.[59] No parenteral rabies vaccine is licensed for use in wild animals or hybrids. Because of the risk of rabies in wild animals (especially raccoons, skunks, coyotes, foxes, and bats), the American Veterinary Medical Association (AVMA), National Association of State and Public Health Veterinarians (NASPHV), and Council of State and Territorial Epidemiologists (CSTE) recommend enactment and enforcement of state laws that prohibit importation, distribution, and/or relocation of these animals. The AVMA has recommended that wild animals or hybrids not be kept as pets (www.avma.org/careforanimals/animatedjourneys/petselection/consider.asp).

INJURIES AND ALLERGIES

Infants and children younger than 5 years are at increased risk of injuries associated with animal interactions because of their size and behavior. Bites, scratches, kicks, falls, and crush injuries of hands or feet or from being pinned between an animal and a fixed object can occur at home or during exposure to animals in a public setting. Serious and fatal injuries can be caused by a large animal or an animal with aggressive behavior. Some nontraditional pets are chosen when they are young and small without consideration that they may grow into dangerous, aggressive adults. For example, iguanas sold shortly after birth measure less than 8 inches but grow to several feet in 2 to 3 years, and baby chicks become full-grown chickens and have a life span of up to 20 years.

An estimated 4 to 5 million animal bites occur in the United States annually. Although approximately 90% of bites are from dogs or cats, severe and fatal bites can occur from large or aggressive nontraditional pets. Animal bites or scratches often become infected. Infectious organisms, depending on the biting animal, include *Pasteurella multocida*, *Francisella tularensis*, *Capnocytophaga canimorsus*, *Streptobacillus moniliformis*, *Spirillum minor*, *Bartonella henselae*, leptospira, and herpes B virus. Tularemia occurred in a 3-year-old child who was bitten by an infected hamster that was purchased at a pet store.[30] Reptiles can produce injuries by bites, with claws, or with tails. Severe hand injury[29] and cellulitis[26] have been reported after green iguana bites. Unprovoked attacks by ferrets on children, particularly infants sleeping or lying down, can be severe, with mutilation of the ears or nose.[66,67] Attacks on sleeping infants are similar to those inflicted by rats.[68]

Although the frequency is not known, the potential for having an allergy to nontraditional pets is likely to be significant. The American Academy of Allergy Asthma & Immunology estimates that approximately 15% of the population experiences allergies to dogs and cats.[69] Allergy to animals usually is attributable to sensitization to their dander, scales, fur, feathers, body waste, or saliva. Flea bites also can lead to allergic manifestations. Hives have been described in people who have contact with hedgehogs.[70] Although scaly animals are not as likely to be as allergenic as furry animals, there are case reports of allergic rhinitis, asthma, and contact hypersensitivity reactions to iguanas. In 1 case, a person with respiratory allergic symptoms was found to be allergic to iguana scales.[28] In addition, an iguana bite–induced hypersensitivity reaction has been reported.[29]

REPORTABLE DISEASES ACQUIRED FROM NONTRADITIONAL PETS AND ANIMALS IN PUBLIC SETTINGS

Many national and state-notifiable diseases can be transmitted from animals. Public health officials at state health departments and personnel from the Centers for Disease Control and Prevention (CDC) collaborate in determining which infectious diseases should be notifiable nationally; states determine which diseases are reportable within their borders. A disease may be added to the national or state list as a new pathogen emerges, or a disease may be removed from the list as disease incidence decreases. Because disease reporting varies according to state, specific requirements should be obtained from the appropriate state health department. Provisional data are published weekly in the *Morbidity and Mortality Weekly Report*, and final data are published each year by the CDC in the annual "Summary of Notifiable Diseases," which can be found online (www.cdc.gov/ncphi/disss/nndss/phs/infdis.htm). These data are necessary for the study of epidemiologic trends and development of disease-prevention policies. Physicians and other health care professionals should report suspected cases of human illness to local and state health departments as soon as possible, especially when the patient has a history of visiting an animal exhibit during the incubation period.

IMPORTATION LAWS AND REGULATIONS REGARDING EXOTIC ANIMALS

Addressing importation and regulation of animals in the United States is complex. No single federal agency has the authority to limit importation, interstate distribution, movement, sale, or ownership of exotic animals in the United States. Federal agencies that do have regulatory authority over some aspects of the exotic-animal trade as it relates to their individual mission include the CDC, the Animal and Plant Health Inspection Service of the US Department of Agriculture, the FDA, and the US Fish and Wildlife Service. There also is a patchwork of state bans, permits, and tracking systems for exotic animals. Agencies responsible for enforcing regulations vary among states.

Among the federal agencies, the CDC is responsible for regulations regarding importation of dogs and cats; nonhuman primates, small turtles, terrapins, and tortoises; African rodents; civets; and birds from countries with H5NI influenza. In addition, CDC regulations in-

clude etiologic agents, hosts, and vectors, under which importation of bats is regulated. The US Fish and Wildlife Service requires permits to import fish, reptiles, spiders, wild birds, rabbits, bears, wild members of the cat family, and other wild or endangered animals. The FDA regulates interstate transactions involving turtles, molluscan shellfish, psittacine birds, prairie dogs, and African rodents. Many states also have laws that make it illegal to own or keep certain wild animals or a variety of exotic pets, including nonhuman primates.

The Animal Welfare Act (7 USC §2131-216) covers the sale and exhibition of wild/exotic animals and the wholesale distribution of pet animals. Wholesale breeders, dealers, exhibitors, and research laboratories are covered by this act. Birds, rats, and mice are exempted; dogs, cats, and other animals have limited coverage; and cold-blooded species such as reptiles are not regulated under this act. Small retail breeders and pet shops that sell only domestic pet animals are not regulated under this act; these animals usually are covered by local (state, county) anticruelty laws and, in some instances, by local animal regulations or public health laws. The US Department of Agriculture has issued a position statement on risks of ownership of large, wild, and exotic cats (www.aphis.usda.gov/animal_welfare/downloads/big_cat/position.pdf).

CDC efforts are underway to galvanize partner agencies into further actions to enhance protection of humans from zoonotic diseases. A meeting of stakeholder organizations was held at the CDC in 2006, a summary of which was published in the *Federal Register*.[71] The AVMA, CSTE, and NASPHV have each issued position statements calling for a coordinated federal approach to better control of infectious disease risks associated with the exotic-animal trade (these publications are available through the Web sites of the respective organizations). Uniform importation laws, better quarantine and surveillance methods for animals coming into the country, and prevention of illegal wildlife trade are necessary components of an overall plan to protect the public.

PREVENTION MEASURES AND THE ROLE OF PEDIATRICIANS AND VETERINARIANS

Pediatricians and veterinarians play an important role in guiding parents and their children about mitigation of risks associated with ownership of nontraditional pets or contact with animals in public settings. Parents and pet owners typically lack knowledge about the multiple modes of transmission of zoonotic infectious diseases from pets. Although pediatricians recognize the importance of anticipatory guidance about pet-related hazards, only 5% reported that they regularly educated patients or families about pet-associated salmonellosis or toxoplasmosis.[72]

Pediatricians and veterinarians together can remind parents, children, and pet owners about the importance of measures to avoid illness. Simple and effective advice includes frequent hand-washing and avoiding direct contact with animals and their environments. This is particularly important with animals from which transmission of enteric pathogens is a risk, including young ruminants, young poultry, reptiles, rodents, amphibians, and animals that are ill. Young children always should be supervised closely when in contact with animals in public settings. The NASPHV has developed an excellent compendium with standardized recommendations for use by public health officials, veterinarians, animal venue operators, animal exhibitors, and others who are concerned with disease control and minimizing risks associated with animals in public settings.[2]

To reduce the possibility of injury, health care professionals should remind pet owners about matching the size and temperament of a pet to the age and behavior of their infant or child, providing close supervision of younger children, and educating all children about appropriate human-animal interactions.

The decision to obtain a nontraditional pet by parents with children in the household is often not discussed with a physician or veterinarian. However, as trusted sources of health care information, pediatricians and veterinarians are in a unique position to offer information and advice to families considering the purchase of a nontraditional pet or to families who already have a nontraditional pet in the household. Informational brochures and posters available for display in physician and veterinarian offices could allow for parent education without significantly increasing time of a visit. Parents can be made aware of Web sites that provide guidelines for safe pet selection and appropriate handling of pets. Proper pet health maintenance, immunization, flea and tick control, deworming, and diet and activity can minimize the risk of infection or injury and ensure the health of the pet. Referral to a veterinarian also can be helpful when parents are contemplating purchase of a nontraditional animal. Veterinarians can provide information about appropriate pet selection, the size of an animal when it attains adulthood, the temperament and husbandry needs of an animal, and suitability as a pet.

A history of contact with pets in the home or animals in public settings should be part of every well-child evaluation and especially should be part of an evaluation of a suspected infectious disease. A history of nontraditional pets in the home or contact with animals in public settings can lead to specific testing and additional management recommendations and occasionally will result in early identification of an unusual infection from another part of the world.

AVAILABLE RECOMMENDATIONS AND GUIDELINES

Recommendations from several organizations dealing with nontraditional pets and animals in public settings have been developed and are summarized in Table 3. In addition, Table 4 provides Web-site addresses for health care professionals and parents at which information for prevention of human disease from nontraditional pets and animals in public settings can be found. Recommendations for prevention of enteric disease transmission from animal contact in public settings resulted from outbreaks of *E coli* O157:H7 at farms open to the public at which animal contact and inadequate hand hygiene occurred.[40] The NASPHV and CDC have established recommendations to prevent disease outbreaks associated with animals in public settings.[2] The CDC has issued

TABLE 3 Guidelines for Prevention of Human Diseases From Nontraditional Pets at Home and Exposure to Animals in Public Settings

- General
  - Wash hands immediately after contact with animals, animal products, or their environment
  - Supervise hand-washing for children younger than 5 y
  - Wash hands after handling animal-derived pet treats
  - Never bring wild animals home, and never adopt wild animals as pets
  - Teach children never to handle unfamiliar, wild, or domestic animals even if the animals appear friendly
  - Avoid rough play with animals to prevent scratches or bites
  - Children should not be allowed to kiss pets or put their hands or other objects into their mouths after handling animals
  - Do not permit nontraditional pets to roam or fly freely in the house or allow nontraditional or domestic pets to have contact with wild animals
  - Do not permit animals in areas where food or drink are prepared or consumed
  - Administer rabies vaccine to mammals as appropriate
  - Keep animals clean and free of intestinal parasites, fleas, ticks, mites, and lice
  - People at increased risk of infection or serious complications of salmonellosis (eg, children younger than 5 y, older adults, and immunocompromised hosts) should avoid contact with animal-derived pet treats
- Animals visiting schools and child-care facilities
  - Designate specific areas for animal contact
  - Display animals in enclosed cages or under appropriate restraint
  - Do not allow food in animal-contact areas
  - Always supervise children, especially those younger than 5 y, during interaction with animals
  - Obtain a certificate of veterinary inspection for visiting animals and/or proof of rabies immunization according to local or state requirements
  - Properly clean and disinfect all areas where animals have been present
  - Consult with parents or guardians to determine special considerations needed for children who are immunocompromised or who have allergies or asthma
  - Animals not recommended in schools, child-care settings, and hospitals include nonhuman primates, inherently dangerous animals (lions, tigers, cougars, bears, wolf-dog hybrids), mammals at high risk of transmitting rabies (bats, raccoons, skunks, foxes, and coyotes), aggressive animals or animals with unpredictable behavior, stray animals with unknown health history, reptiles, and amphibians
  - Ensure that people who provide animals for educational purposes are knowledgeable regarding animal handling and zoonotic disease issues
- Public settings
  - Venue operators must know about risks of disease and injury
    - Venue operators and staff must maintain a safe environment
  - Venue operators and staff must educate visitors about the risk of disease and injury and provide appropriate preventive measures
- Animal specific
  - Children younger than 5 y and immunocompromised people should avoid contact in public settings with reptiles, amphibians, rodents, ferrets, baby poultry (chicks, ducklings), and any items that have been in contact with these animals or their environments
  - Reptiles, amphibians, rodents, ferrets, and baby poultry (chicks, ducklings) should be kept out of households that contain children younger than 5 y, immunocompromised people, or people with sickle cell disease and should not be allowed in child-care centers
  - Reptiles, amphibians, rodents, and baby poultry should not be permitted to roam freely throughout a home or living area and should not be permitted in kitchens or other food-preparation areas
  - Disposable gloves should be used when cleaning fish aquariums, and aquarium water should not be disposed in sinks used for food preparation or for obtaining drinking water
  - Mammals at high risk of transmitting rabies (bats, raccoons, skunks, foxes, and coyotes) should not be touched by children

recommendations for preventing transmission of *Salmonella* organisms from reptiles to humans[18] and information regarding health risks from *Salmonella* species posed by contact with baby poultry.[34] Guidelines for prevention of zoonoses in immunosuppressed people also are available.[13,73]

The AVMA supports the view that exotic animals, wildlife, and wildlife–domestic animal hybrids do not make good pets. These animals are dangerous and are a hazard to human health, other animals, and the environment. The AVMA also recommends that ferret owners have knowledge about the species and stress that no one who is incapable of removing himself or herself from the bite of a ferret should be left unattended with a ferret. Measures to control and prevent psittacosis in humans and birds were published by a committee formed by the NASPHV and were endorsed by the AVMA,[74] the CSTE, and the Association of Avian Veterinarians.

Guidelines for animals that might have contact with children in a child-care setting have been published by the National Resource Center for Health and Safety in Child Care and Early Education.[75] These guidelines state that any pet or animal present at the facility, indoors or outdoors, should be in good health; show no evidence of carrying any disease; be fully immunized; and be maintained on a flea-, tick-, and worm-control program. A current (time-specified) certificate from a veterinarian should be on file in the facility and state that the specific pet meets these conditions. All contact between animals and children should be supervised by a caregiver who is close enough to remove the child immediately if the animal shows signs of distress or the child shows signs of treating the animal inappropriately. The caregiver should instruct children on safe procedures to follow when in close proximity to these animals (eg, not to provoke or startle animals or touch them when they are near their food). Potentially aggressive animals should not be in the same physical space with children. The facility should not keep or bring in turtles, iguanas, lizards, or other reptiles; ferrets; psittacine birds; or any wild or dangerous animals. Recommendations for hand-

washing by staff, volunteers, and children as well as maintenance of animals housed on the premises are provided in the guidelines.[75] In addition to exposures to animals within a center, child-care and school field trips can result in disease. A field trip to a petting zoo at which hand-hygiene facilities were not adequate resulted in 44 cases of *E coli* O157:H7 infection in British Columbia.[76] Guidelines for infection control in health care facilities are not part of this document but are available (www.cdc.gov/ncidod/dhqp/pdf/guidelines/Enviro_guide_03.pdf).

FUTURE

In 2006, the CDC hosted a meeting dealing with infectious disease risks associated with exotic-animal importation and trade. The CSTE, NASPHV, and AVMA—3 organizations involved in the issue of infectious disease risks associated with the exotic-animal trade—presented policy statements of their organizations or calls to action. There was a consensus that rules and regulations need to be strengthened and standardized to reduce risks associated with exotic pets and that federal and state efforts are needed to eliminate illegal wildlife trade. In addition, the Zoonoses Education Coalition organized by the CDC aims to increase partnerships between government and industry. An effort is underway by a number of regulatory and public health agencies and veterinary organizations to address issues raised by legal and illegal importation of exotic animals and to develop a comprehensive set of regulations to protect the public (J. McQuiston, DVM [veterinary epidemiologist, Viral and Rickettisial Zoonoses Branch, National Center for Zoonotic, Vector-Borne, and Enteric Diseases, CDC], verbal personal communication, August 2007).

SUMMARY

Most nontraditional pets pose a risk to the health of young children, and their acquisition and ownership should be discouraged in households with young children. Exposures to animals in public settings also pose specific risks. Parents need to be educated about the increased risks of exposure to nontraditional pets and animals in public settings for infants and for children younger than 5 years and for immunosuppressed people of all ages and should be made aware of the general recommendations for reduction of risks of infection, injury, and allergy. Resources are available for physicians, veterinarians, and parents, and recommendations, including specific guidelines for reducing the risk of *Salmonella* infection from reptiles, are offered by a number of organizations. In addition, physicians and veterinarians are encouraged to work together to educate one another and to communicate a common message to pet owners regarding the benefits and risks of pet ownership and of contact with animals outside the home. Joint training seminars and joint sponsorship of health-communication campaigns in pediatrician and veterinarian offices would greatly increase awareness in pet owners. The "One Medicine" initiative supported by the AVMA

to increase veterinary collaboration with counterparts in human medicine is an excellent step forward to benefit clinical medicine and public health and will build and reinforce partnerships between the 2 professions to reduce human illness and injury related to contact with animals.[77]

Clinical Report—The Eye Examination in the Evaluation of Child Abuse

abstract

FREE

Retinal hemorrhage is an important indicator of possible abusive head trauma, but it is also found in a number of other conditions. Distinguishing the type, number, and pattern of retinal hemorrhages may be helpful in establishing a differential diagnosis. Identification of ocular abnormalities requires a full retinal examination by an ophthalmologist using indirect ophthalmoscopy through a pupil that has been pharmacologically dilated. At autopsy, removal of the eyes and orbital tissues may also reveal abnormalities not discovered before death. In previously well young children who experience unexpected apparent life-threatening events with no obvious cause, children with head trauma that results in significant intracranial hemorrhage and brain injury, victims of abusive head trauma, and children with unexplained death, premortem clinical eye examination and postmortem examination of the eyes and orbits may be helpful in detecting abnormalities that can help establish the underlying etiology. *Pediatrics* 2010;126:376–380

eye examination, child abuse, abusive head trauma, retinal hemorrhage

ABBREVIATIONS

ALTE—apparent life-threatening event
AHT—abusive head trauma

BACKGROUND

When a previously well child experiences an apparent life-threatening event (ALTE) or unexpected death without obvious cause, pediatricians and other physicians must attempt to identify the etiology. In the case of an ALTE, one should consider diagnoses such as gastroesophageal reflux, seizures, other central nervous system disease, metabolic disease, breath-holding, and abusive head trauma (AHT). Retinal examinations have been used with limited success for screening ALTE victims for possible AHT.[1,2] Victims of AHT present to medical care with a wide range of symptoms, from mild irritability and vomiting to unexplained coma or seizures.[3] It has been estimated that approximately 4% to 6% of abused children present first to an ophthalmologist,[4] and the most common ocular manifestation of abuse is retinal hemorrhage. Some children present with a false history of trauma, and others present with only the symptoms that resulted from their abuse. Unsuspecting physicians misdiagnose the condition of up to one-third of symptomatic victims, depending on their age, severity of symptoms, and family composition.[5] When a child dies unexpectedly, considerations include previously undiagnosed or new systemic disease, sudden infant death syndrome, and covert abusive injury.

Retinal hemorrhages have been recognized as a key indicator of abusive head injury for more than 30 years, particularly in association with severe repetitive acceleration-deceleration forces with or without blunt head impact, in children younger than 5 years.[6,7] Because retinal

hemorrhage rarely results in visual compromise, there may be no external indicators of eye injury unless the vision is significantly impaired by damage to the optic nerve or occipital cortex or there is retinal detachment, significant vitreous hemorrhage, or other severe disruption of the intraocular contents. Both eyes need to have significant visual compromise for a child to become visually symptomatic. Therefore, one cannot rely on ocular signs or symptoms to determine which children might benefit from ophthalmologic consultation and postmortem eye removal. Likewise, retinal examinations should not be limited to patients who are victims of suspected AHT. Searching for retinal hemorrhages as diagnostic criteria for AHT only in infants with suspected abuse creates a selection bias.

Although health care professionals other than ophthalmologists may be skilled at detecting the absence or presence of retinal hemorrhage,[8] a full view of the retina and characterization of the number, types, and patterns of the hemorrhages requires consultation by an opthalmologist using indirect ophthalmoscopy, preferably with a dilated pupil. Even when there may be a concern about transiently obliterating pupillary reactivity in the face of a need to monitor neurologic status acutely, techniques such as dilation of 1 eye at a time, use of short-acting mydriatics, and use of a lens that affords some view through an undilated pupil can be employed to allow indirect ophthalmoscopy, preferably within the first 24 hours and ideally within 72 hours after the child's acute presentation. Even if the need for eye examination is realized after 72 hours, ophthalmologic consultation may still be useful to identify persistent abnormalities such as hemorrhages, retinoschisis, and papilledema.

The range of retinal hemorrhage findings in AHT and accidental trauma is broad, and the severity of the findings can be informative of etiology. For example, retinal hemorrhage—predominantly intraretinal, in small numbers, and confined to the posterior pole of the retina—can be seen after significant accidental head injury or in AHT.[6,9] More dramatic retinal hemorrhages—multilayered, too numerous to count, and extending to the edge of the retina (ora serrata)—can be seen after AHT, normal birth, fatal extreme accidental injury (such as motor vehicle accidents), and perhaps after fatal head crush injury.[6,10–13] Ocular fundus examination can also reveal findings of systemic illness that may shed light on the etiology of a child's symptoms, such as a cherry-red spot in metabolic disease, retinal vascular abnormalities in Menkes disease, papilledema, and retinal manifestations of leukemia or bacterial endocarditis. There are no known retinal ocular findings in sudden infant death syndrome, although routine ocular examination has not been common practice in these cases.[6,14]

Excluding retinal hemorrhages that are associated with vaginal delivery, AHT is the leading cause of retinal hemorrhages in infants. The association of retinal hemorrhage and AHT has been demonstrated repeatedly in clinical studies.[15–17] Although retinal hemorrhages in AHT can be unilateral or bilateral and vary in degree, the severity of retinal hemorrhage often parallels the severity of brain injury.[18,19] Because intraretinal hemorrhages may resolve quickly, a retinal examination is not a substitute for brain imaging when screening physically abused infants who have no neurologic symptoms for AHT.[20]

The ophthalmologist is in a unique position to detail the hemorrhagic retinopathy. The indirect ophthalmoscope provides a wide and stereoscopic field of view and enables the ophthalmologist to examine the anterior aspects of the retina to the ora serrata, which is not possible using a direct ophthalmoscope even if the pupils are dilated. Eye examination for this purpose should be performed by an ophthalmologist. Attention must be paid to special features, such as the presence of traumatic macular retinoschisis, because these features may have particular diagnostic significance for abuse.

Autopsy is a unique opportunity for examination not only of the eye and its contents but also of the orbital tissues, which may yield findings helpful in differential diagnosis. This is particularly true when a child dies before clinical ophthalmologic consultation can be obtained. Even when premortem ophthalmoscopy is performed, postmortem examination is necessary for viewing the orbital tissues. When possible, examination by a trained ocular pathologist or ophthalmologist with experience in interpreting ocular pathology is ideal. Postmortem eye and orbital tissue examination is another means of documenting retinal hemorrhage and retinoschisis but may also reveal hemosiderin deposition from previous events and orbital findings, such as hemorrhage into the fat, muscles, and cranial nerve sheaths as well as intradural hemorrhage, all of which may have diagnostic significance in identifying abused children.[21]

One obstacle to postmortem examination of the eyes and orbits has been a societal distaste or resistance that, in some cases, has led to fear among pathologists of legal repercussion. This may reflect a cultural or emotional objection specifically to eye removal. There might be a misconception that eye or orbital removal will alter the appearance of the body postmortem at a funeral viewing when this is not, in fact, the case. Techniques allow

for proper removal of the eye and orbits without disfigurement.[6] Although consent is not routinely obtained for coroner cases/forensic autopsies, there may be situations or jurisdictions in which specific consent for eye and orbital tissue removal may be sought. If a substitute decision-maker refuses this procedure, it may be necessary to seek legal intervention to allow the procedure to be performed.

STATEMENT OF THE PROBLEM

Although a retinal examination may suggest the etiology for ALTEs and previously unexplained early childhood deaths, premortem clinical ophthalmologic consultation and postmortem removal of the eyes and orbital tissues are not routine practice in some centers. Those who fail to conduct these procedures, particularly when there is no other explanation for the life-threatening event or death, risk losing an important opportunity to gain valuable information. Information gained in such an evaluation might lead to identifying an etiology and, in the case of a surviving child, prevent death by preventing further abuse or recognizing other disease.

In recent years, 3 important trends have emerged in the understanding of hemorrhagic retinopathy in young children. First, there has been a continued and dramatic increase in the evidence supporting the diagnostic specificity of severe hemorrhagic retinopathy as an indicator of AHT, in particular, severe repeated acceleration-deceleration with or without blunt head impact. Extensive literature worldwide, including clinical studies,[7] animal models,[22] and computer modeling,[23,24] well beyond the scope of this report, support this theory. It seems that vitreoretinal traction and orbital injury sustained during the unique repetitive acceleration-deceleration mechanism that distinguishes this form of abuse from single-impact trauma is the critical factor in causing retinal hemorrhage.[8] Factors such as hypoxia, anemia, and intracranial pressure may play important secondary roles in modulating the appearance of retinal hemorrhages but do not, in and of themselves, result in such a retinopathy.[6] Further research is needed to better define the role of these and other factors as our understanding of the pathophysiology and diagnostic specificity of retinal hemorrhage continues to evolve.

Second, there has been increasing recognition of the importance of detailing the appearance of the hemorrhagic retinopathy rather than simply using the term "retinal hemorrhage" generically. The differential diagnosis of a few intraretinal hemorrhages surrounding the optic nerve is vastly greater than that for "too-numerous-to-count" multilayered retinal hemorrhages that extend to the ora serrata.

Third, there continue to be novel reports of causes of retinal hemorrhage and other ocular findings in young children. These hypothesis-generating observations allow practitioners to broaden and at the same time narrow differential diagnosis. For example, mild posterior pole retinal hemorrhages have been described in osteogenesis imperfecta[25] as well as head trauma sufficient to cause epidural hemorrhage,[9] and more severe hemorrhage was observed in 2 cases of fatal head crush injury.[10,11] Only with more widespread use of ophthalmologic consultation and postmortem ocular and orbital examination can such entities be discovered and fit into the differential diagnostic process appropriately. Photodocumentation, when available, has also proven to be an important ophthalmic procedure for documenting retinal abnormalities for both clinical and educational purposes.

Full ophthalmic examination by an ophthalmologist and/or postmortem eye removal and pathologic examination can be a critical part of the diagnostic evaluation of previously well children who have experienced an unexplained ALTE or death and also for children who have disorders in which there are known associations with ophthalmic findings, particularly AHT.

GUIDANCE FOR PEDIATRICIANS

Ophthalmologic consultation should be part of the diagnostic evaluation of all previously well children younger than 5 years who experience an unexplained death or unexplained ALTE or have a systemic disorder known to have ocular manifestations.

- All infants and young children who present with significant intracranial hemorrhage should have an ophthalmologic consultation. Retinal examination is particularly important when there is a suspicion of AHT, but some retinal hemorrhages may occasionally also be found in infants and children with other causes of intracranial hemorrhage.
- Ophthalmologic examination should include, whenever possible, full indirect ophthalmoscopic examination through a dilated pupil. Descriptions of findings should be detailed and include the number, type, extent, and pattern of retinal hemorrhages, if present. Retinal abnormalities may be photographed after the clinical examination when a camera is available. When indicated, the examination should include slit-lamp inspection of the anterior segment to identify signs of trauma (eg, hyphema).
- Because findings such as retinal hemorrhage may be transient, it is desirable that the ophthalmologic consultation take place preferably

within 24 hours after the patient presents for medical care and ideally within 72 hours.

- A retinal examination is not an appropriate screening test for brain injury in neurologically asymptomatic potential victims of abuse. Such children should undergo brain imaging as the appropriate screen.
- When pharmacologic dilation is felt to be undesirable, as for children with severe unstable central nervous system injury, timely ophthalmologic consultation is still needed. An attempt should still be made to view the retina and optic nerve through the use of direct ophthalmoscopy, small pupil indirect ophthalmoscopic techniques, sequential pharmacologic dilation, and/or fast-acting mydriatics (eg, phenylephrine 2.5%).
- When a previously well child younger than 5 years dies without explanation, regardless of whether a premortem retinal examination was conducted, the eyes and orbital tissues should be removed en bloc at autopsy per published techniques.[26] When possible, an examination by an ocular pathologist or ophthalmologist with experience in interpreting ocular pathology is preferable.
- Postmortem eye removal may not be indicated in children who have clearly died from witnessed severe accidental head trauma or otherwise readily diagnosed systemic medical conditions.
- Ophthalmologic examination and/or postmortem eye and orbital tissue removal should be performed in all cases in which a child is alleged to have suffered significant morbidity secondary to a short fall or other minor trauma disproportionate to the clinical injury and consistent with child abuse.

Organizational Principles to Guide and Define the Child Health Care System and/or Improve the Health of All Children

Eye Examination in Infants, Children, and Young Adults by Pediatricians

ABSTRACT. Early detection and prompt treatment of ocular disorders in children is important to avoid lifelong visual impairment. Examination of the eyes should be performed beginning in the newborn period and at all well-child visits. Newborns should be examined for ocular structural abnormalities, such as cataract, corneal opacity, and ptosis, which are known to result in visual problems. Vision assessment beginning at birth has been endorsed by the American Academy of Pediatrics, the American Association for Pediatric Ophthalmology and Strabismus, and the American Academy of Ophthalmology. All children who are found to have an ocular abnormality or who fail vision assessment should be referred to a pediatric ophthalmologist or an eye care specialist appropriately trained to treat pediatric patients.

INTRODUCTION

Eye examination and vision assessment are vital for the detection of conditions that result in blindness, signify serious systemic disease, lead to problems with school performance, or at worst, threaten the child's life. Through careful evaluation of the ocular system, retinal abnormalities, cataracts, glaucoma, retinoblastoma, strabismus, and neurologic disorders can be identified, and prompt treatment of these conditions can save a child's vision or even life. Examination of the eyes should be performed beginning in the newborn period and at all well-child visits. Visual acuity measurement should be performed at the earliest possible age that is practical (usually at approximately 3 years of age). Early detection and prompt treatment of ocular disorders in children is important to avoid lifelong permanent visual impairment.

TIMING OF EXAMINATION AND SCREENING

Children should have an assessment for eye problems in the newborn period and then at all subsequent routine health supervision visits. These should be age-appropriate evaluations as described in subsequent sections. Infants and children at high risk of eye problems should be referred for specialized eye examination by an ophthalmologist experienced in treating children. This includes children who are very premature; those with family histories of congenital cataracts, retinoblastoma, and metabolic or genetic diseases; those who have significant developmental delay or neurologic difficulties; and those with systemic disease associated with eye abnormalities. Because children do not complain of visual difficulties, visual acuity measurement (vision screening) is an important part of complete pediatric eye care and should begin at 3 years of age. To achieve the most accurate testing possible, the most sophisticated test that the child is capable of performing should be used (Table 1).[1,2] The frequency of examinations recommended is in accordance with the American Academy of Pediatrics "Recommendations for Preventive Pediatric Health Care."[2] Any child unable to be tested after 2 attempts or in whom an abnormality is suspected or detected should be referred for an initial eye evaluation by an ophthalmologist experienced in the care of children.

PROCEDURES FOR EYE EVALUATION

Eye evaluation in the physician's office should include the following:

Birth to 3 Years of Age

1. Ocular history
2. Vision assessment
3. External inspection of the eyes and lids
4. Ocular motility assessment
5. Pupil examination
6. Red reflex examination

3 Years and Older

1 through 6, plus:

7. Age-appropriate visual acuity measurement
8. Attempt at ophthalmoscopy

TABLE 1. Eye Examination Guidelines*

Function	Recommended Tests	Referral Criteria	Comments
Ages 3–5 Years			
Distance visual acuity	Snellen letters Snellen numbers Tumbling E HOTV Picture tests –Allen figures –LEA symbols	1. Fewer than 4 of 6 correct on 20-ft line with either eye tested at 10 ft monocularly (ie, less than 10/20 or 20/40) or 2. Two-line difference between eyes, even within the passing range (ie, 10/12.5 and 10/20 or 20/25 and 20/40)	1. Tests are listed in decreasing order of cognitive difficulty; the highest test that the child is capable of performing should be used; in general, the tumbling E or the HOTV test should be used for children 3–5 years of age and Snellen letters or numbers for children 6 years and older. 2. Testing distance of 10 ft is recommended for all visual acuity tests. 3. A line of figures is preferred over single figures. 4. The nontested eye should be covered by an occluder held by the examiner or by an adhesive occluder patch applied to eye; the examiner must ensure that it is not possible to peek with the nontested eye.
Ocular alignment	Cross cover test at 10 ft (3 m)	Any eye movement	Child must be fixing on a target while cross cover test is performed.
	Random dot E stereo test at 40 cm	Fewer than 4 of 6 correct	
	Simultaneous red reflex test (Bruckner test)	Any asymmetry of pupil color, size, brightness	Direct ophthalmoscope used to view both red reflexes simultaneously in a darkened room from 2 to 3 feet away; detects asymmetric refractive errors as well.
Ocular media clarity (cataracts, tumors, etc)	Red reflex	White pupil, dark spots, absent reflex	Direct ophthalmoscope, darkened room. View eyes separately at 12 to 18 inches; white reflex indicates possible retinoblastoma.
6 years and older			
Distance visual acuity	Snellen letters Snellen numbers Tumbling E HOTV Picture tests -Allen figures -LEA symbols	1. Fewer than 4 of 6 correct on 15-ft line with either eye tested at 10 ft monocularly (ie, less than 10/15 or 20/30) or 2. Two-line difference between eyes, even within the passing range (ie, 10/10 and 10/15 or 20/20 and 20/30)	1. Tests are listed in decreasing order of cognitive difficulty; the highest test that the child is capable of performing should be used; in general, the tumbling E or the HOTV test should be used for children 3–5 years of age and Snellen letters or numbers for children 6 years and older. 2. Testing distance of 10 ft is recommended for all visual acuity tests. 3. A line of figures is preferred over single figures. 4. The nontested eye should be covered by an occluder held by the examiner or by an adhesive occluder patch applied to eye; the examiner must ensure that it is not possible to peek with the nontested eye.
Ocular alignment	Cross cover test at 10 ft (3 m)	Any eye movement	Child must be fixing on a target while cross cover test is performed.
	Random dot E stereo test at 40 cm	Fewer than 4 of 6 correct	
	Simultaneous red reflex test (Bruckner test)	Any asymmetry of pupil color, size, brightness	Direct ophthalmoscope used to view both red reflexes simultaneously in a darkened room from 2–3 feet away; detects asymmetric refractive errors as well.
Ocular media clarity (cataracts, tumors, etc)	Red reflex	White pupil, dark spots, absent reflex	Direct ophthalmoscope, darkened room. View eyes separately at 12 to 18 inches; white reflex indicates possible retinoblastoma.

* Assessing visual acuity (vision screening) represents one of the most sensitive techniques for the detection of eye abnormalities in children. The American Academy of Pediatrics Section on Ophthalmology, in cooperation with the American Association for Pediatric Ophthalmology and Strabismus and the American Academy of Ophthalmology, has developed these guidelines to be used by physicians, nurses, educational institutions, public health departments, and other professionals who perform vision evaluation services.

Ocular History

Parents' observations are valuable. Questions that can be asked include:

- Does your child seem to see well?
- Does your child hold objects close to his or her face when trying to focus?
- Do your child's eyes appear straight or do they seem to cross or drift or seem lazy?
- Do your child's eyes appear unusual?
- Do your child's eyelids droop or does 1 eyelid tend to close?
- Have your child's eye(s) ever been injured?

Relevant family histories regarding eye disorders or preschool or early childhood use of glasses in parents or siblings should be explored.

Vision Assessment

Age 0 to 3 Years

Vision assessment in children younger than 3 years or any nonverbal child is accomplished by evaluating the child's ability to fix and follow objects.[3,4] A standard assessment strategy is to determine whether each eye can fixate on an object, maintain fixation, and then follow the object into various gaze positions. Failure to perform these maneuvers indicates significant visual impairment. The assessment should be performed binocularly and then monocularly. If poor fix and following is noted binocularly after 3 months of age, a significant bilateral eye or brain abnormality is suspected, and referral for more formal vision assessment is advisable.[5] It is important to ensure that the child is awake and alert, because disinterest or poor cooperation can mimic a poor vision response.

Visual Acuity Measurement or Vision Screening (Older Than 3 Years)

Various tests are available to the pediatrician for measuring visual acuity in older children. Different picture tests, such as LH symbols (LEA symbols) and Allen cards, can be used for children 2 to 4 years of age. Tests for children older than 4 years include wall charts containing Snellen letters, Snellen numbers, the tumbling E test, and the HOTV test (a letter-matching test involving these 4 letters).[6] A study of 102 pediatric practices revealed that 53% use vision testing machines.[3] Because testing with these machines can be difficult for younger children (3–4 years of age), pediatricians should have picture cards and wall charts available.

Photoscreening

Using this technique, a photograph is produced by a calibrated camera under prescribed lighting conditions, which shows a red reflex in both pupils. A trained observer can identify ocular abnormalities by recognizing characteristic changes in the photographed pupillary reflex.[7] When performed properly, the technique is fast, efficient, reproducible, and highly reliable. Photoscreening is not a substitute for accurate visual acuity measurement but can provide significant information about the presence of sight-threatening conditions, such as strabismus, refractive errors, media opacities (cataract), and retinal abnormalities (retinoblastoma). Photoscreening techniques are still evolving. (For further information, see also the American Academy of Pediatrics policy statement, "Use of Photoscreening for Children's Vision Screening."[8])

External Examination (Lids/Orbit/Cornea/Iris)

External examination of the eye consists of a penlight evaluation of the lids, conjunctiva, sclera, cornea, and iris. Persistent discharge or tearing may be attributable to ocular infection, allergy, or glaucoma, but the most common cause is lacrimal duct obstruction. It often manifests during the first 3 months as persistent purulent discharge out of 1 or both eyes. Topical or oral antibiotics should be given, and lacrimal sac massage should be attempted. Because these same findings are often seen in congenital glaucoma, failure to promptly resolve after treatment or the presence of cloudy or asymmetrically enlarged corneas should prompt ophthalmologic referral for additional evaluation.

Unilateral ptosis can cause amblyopia by inducing astigmatism, even if the pupil is not occluded. Patients with this condition require ophthalmic evaluation. Bilateral ptosis may be associated with significant neurologic disease, such as myasthenia. Additional investigation by a child neurologist and pediatric ophthalmologist is warranted.

Ocular Motility

The assessment of ocular alignment in the preschool and early school-aged child is of considerable importance. The development of strabismus in children may occur at any age and can represent serious orbital, intraocular, or intracranial disease. The corneal reflex test, cross cover test, and random dot E stereo test are useful in differentiating true strabismus from pseudostrabismus (see Appendix 1). The most common cause of pseudostrabismus is prominent epicanthal lid folds that cover the medial portion of the sclera on both eyes, giving the impression of crossed eyes (esotropia). Detection of an eye muscle imbalance or inability to differentiate strabismus from pseudostrabismus necessitates a referral.

Pupils

The pupils should be equal, round, and reactive to light in both eyes. Slow or poorly reactive pupils may indicate significant retinal or optic nerve dysfunction. Asymmetry of pupil size, with 1 pupil larger than the other, can be attributable to a sympathetic disorder (Horner syndrome) or a parasympathetic abnormality (third nerve palsy, Adie syndrome). Small differences can occur normally and should be noted in the chart for reference in case of subsequent head injury. Larger pupil asymmetries (>1 mm) can be attributable to serious neurologic disorders and need additional investigation.

Red Reflex Test (Monocular and Binocular, Bruckner Test)

The red reflex test can be used to detect opacities in the visual axis, such as a cataract or corneal abnor-

mality, and abnormalities of the back of the eye, such as retinoblastoma or retinal detachment. When both eyes are viewed simultaneously, potentially amblyogenic conditions, such as asymmetric refractive errors and strabismus, also can be identified. The test should be performed in a darkened room (to maximize pupil dilation). The direct ophthalmoscope is focused on each pupil individually approximately 12 to 18 inches away from the eye, and then both eyes are viewed simultaneously at approximately 3 feet away. The red reflex seen in each eye individually should be bright reddish-yellow (or light gray in darkly pigmented, brown-eyed patients) and identical in both eyes. Dark spots in the red reflex, a blunted dull red reflex, lack of a red reflex, or presence of a white reflex are all indications for referral. After assessing each eye separately, the eyes are viewed together with the child focusing on the ophthalmoscope light (Bruckner test, see Appendix 1). As before, any asymmetry in color, brightness, or size is an indication for referral, because asymmetry may indicate an amblyogenic condition.

Visual Acuity Measurement (Vision Screening)

Visual acuity testing is recommended for all children starting at 3 years of age.[6] In the event that the child is unable to cooperate for vision testing, a second attempt should be made 4 to 6 months later. For children 4 years and older, the second attempt should be made in 1 month. Children who cannot be tested after repeated attempts should be referred to an ophthalmologist experienced in the care of children for an eye evaluation. Appendix 1 provides a detailed explanation of the techniques available for visual acuity measurement in children.

Ophthalmoscopy

Ophthalmoscopy may be possible in very cooperative 3- to 4-year-olds who are willing to fixate on a toy while the ophthalmoscope is used to evaluate the optic nerve and retinal vasculature in the posterior pole of the eye.

RECOMMENDATIONS

1. All pediatricians and other providers of health care to children should be familiar with the joint eye examination guidelines of the American Association for Pediatric Ophthalmology and Strabismus, the American Academy of Ophthalmology, and the American Academy of Pediatrics.
2. Every effort should be made to ensure that eye examinations are performed using appropriate testing conditions, instruments, and techniques.
3. Newborns should be evaluated for ocular structural abnormalities, such as cataract, corneal opacities, and ptosis, which are known to result in vision problems, and all children should have their eyes examined on a regular basis.[1]
4. The results of vision assessments, visual acuity measurements, and eye evaluations, along with instructions for follow-up care, should be clearly communicated to parents.[2]
5. All children who are found to have an ocular abnormality or who fail vision screening should be referred to a pediatric ophthalmologist or an eye care specialist appropriately trained to treat pediatric patients.

APPENDIX 1. TESTING PROCEDURES FOR ASSESSING VISUAL ACUITY

The child should be comfortable and in good health at the time of the examination. It is often convenient to have younger children sit on a parent's lap. If possible, some preparation before the actual testing situation is helpful, and parents can assist by demonstrating the anticipated testing procedures for their child. Children who have eyeglasses generally should have their vision tested while wearing the eyeglasses. Eyeglasses prescribed for use only

while reading should not be worn when distance acuity is being tested.

Consideration must be given to obtaining good occlusion of the untested eye; cardboard and paddle occluders have been found inadequate for covering the eye because they allow "peeking." Commercially available occluder patches provide complete occlusion necessary for appropriate testing.[1] Vision testing should be performed at 10 feet (except Allen cards) and in a well-lit area. When ordering wall charts, be sure to indicate that a 10-foot testing distance will be used.

Visual Acuity Tests

Snellen Acuity Chart

When performing visual acuity testing, test the child's right eye first by covering the left. A child who has corrective eyeglasses should be screened wearing the eyeglasses. Tell the child to keep both eyes open during testing. If the child fails the practice line, move up the chart to the next larger line. If the child fails this line, continue up the chart until a line is found that the child can pass. Then move down the chart again until the child fails to read a line. After the child has correctly identified 2 symbols on the 10/25 line, move to the critical line (10/20 or 20/40 equivalent). To pass a line, a child must identify at least 4 of the 6 symbols on the line correctly. Repeat the above procedure covering the right eye.

Tumbling E

For children who may be unable to perform vision testing by letters and numbers, the tumbling E or HOTV test may be used. Literature is available from the American Academy of Ophthalmology (*Home Eye Test*, American Academy of Ophthalmology, PO Box 7424, San Francisco, CA 94109, 415/561-8500 or http://www.aao.org) and Prevent Blindness America (*Preschoolers Home Eye Test*, Prevent Blindness America, 500 East Remington Rd, Schaumburg, IL 60173, 847/843-2020 or http://www.preventblindness.com) for home use by parents to prepare children for the tumbling E test. This literature contains the practice Es, a tumbling E wall chart, and specific instructions for parents.

HOTV Test (Matching Test)

An excellent test for children who are unable to perform vision testing by verbally identifying letters and numbers is the HOTV matching test. This test consists of a wall chart composed only of Hs, Os, Ts, and Vs. The child is provided an 8½ × 11-inch board containing a large H, O, T, and V. The examiner points to a letter on the wall chart, and the child points to (matches) the correct letter on the testing board. This can be especially useful in the 3- to 5-year-old who is unfamiliar with the alphabet.

Allen Cards

The Allen card test consists of 4 flash cards containing 7 schematic figures: a truck, house, birthday cake, bear, telephone, horse, and tree. When viewed at 20 feet, these figures represent 20/30 vision. It is important that a child identify verbally or by matching all 7 pictures before actual visual testing. Testing should only be performed with the figures that the child readily identified. Perform initial testing with the child having both eyes open, viewing the cards at 2 to 3 feet away. Present 1 or 2 figures to ensure that the child understands the testing procedure. Then begin walking backward 2 to 3 feet at a time, presenting different pictures to the child. Continue to move backward as long as the child directly calls out the figures presented. When the child begins to miss the figures, move forward several feet to confirm that the child is able to identify the figures at the shorter distance. To calculate an acuity score, the furthest distance at which the child is able to identify the pictures accurately is the numerator and 30 is the denominator. Therefore, if a child were able to identify pictures accurately at 15 feet, the visual acuity would be recorded as 15/30. This is equivalent to 30/60, 20/40, or 10/20. To perform this test in the same way as for HOTV testing, a "matching panel" of all of the Allen figures may be prepared on a copy machine.

LH Symbols (LEA Symbols)

The LH symbol test is slightly different from the Allen card test in that it is made up of flash cards held together by a spiral binding. The flash cards contain large examples of a house, apple, circle, and square; these should be presented to the child before formal vision testing to see if they can be correctly identified. Unlike the Allen cards, the LH symbol test contains flash cards with more than 1 figure per card and with smaller figure sizes so that testing may be performed at 10 feet. Recorded on each card is the symbol size and visual acuity value for a 10-foot testing distance. The visual acuity is determined by the smallest symbols that the child is able to identify accurately at 10 feet. For example, if the child is able to identify the 10/15 symbol at 10 feet, the child's visual acuity is 10/15 or 20/30.

If it is not possible to perform testing at 10 feet, move closer to the child until he or she correctly identifies the largest symbol. At this point, proceed down in size to the smallest symbols the child is consistently able to correctly identify. The vision is recorded as the smallest symbol identified (bottom number) at the testing distance (top number). For example, correctly identifying the 10/15 symbols at 5 feet is recorded as 5/15 or 20/60. Likewise, identifying the 10/30 symbols at 2 feet is 2/30 or 20/300 (both the bottom and top numbers can be multiplied or divided by the same number to give an equivalent vision.) A "matching panel" is provided with the LH test and may be helpful in testing very young children. At least 3 of 4 figures should be identified for each size or distance.

Testing Procedures for Assessing Ocular Alignment

Corneal Light Reflex Test

A penlight may be used to evaluate light reflection from the cornea. The light is held approximately 2 feet in front of the face to have the child fixate on the light. The corneal light reflex (small white dot) should be present symmetrically and appear to be in the center of both pupils. A reflex that is off center in 1 eye may be an indication of an eye muscle imbalance. A slight nasal displacement of the reflex is normal, but a temporal displacement is almost never seen unless the child has a strabismus (esotropia).

Simultaneous Red Reflex Test (Bruckner Test)

This test can detect amblyogenic conditions, such as unequal refractive errors (unilateral high myopia, hyperopia, or astigmatism), as well as strabismus and cataracts. When both eyes are viewed simultaneously through the direct ophthalmoscope in a darkened room from a distance of approximately 2 to 3 feet with the child fixating on the ophthalmoscope light, the red reflexes seen from each eye should be equal in size, brightness, and color. If 1 reflex is different from the other (lighter, brighter, or bigger), there is a high likelihood that an amblyogenic condition exists. Any child with asymmetry should be referred for additional evaluation. Examples of normal and abnormal Bruckner test appearances are available from the AAP. "See Red" cards are available for purchase at http://www.aap.org/sections/ophthal.htm.

Cross Cover Test

To perform the cross cover test, have the child look straight ahead at an object 10 feet (3 meters) away. This could be an eye chart for older children or a colorful noise-making toy for younger children. As the child looks at a distant object, cover 1 eye with an occluder and look for movement of the uncovered eye. As an example, if the occluder is covering the left eye, movement is looked for in the uncovered right eye. This movement will occur immediately after the cover is placed in front of the left eye. If the right eye moves outward, the eye was deviated inward or esotropic. If the right eye moves inward, it was deviated outward or exotropic. After testing the right eye, test the left eye for movement in a similar manner. If there is no apparent misalignment of either eye, move the cover back and forth between the 2 eyes, waiting about 1 to 2 seconds between movements. If after moving the occluder, the uncovered eye moves in or out to take up fixation, a strabismus is present. Any movement in or out when shifting the cover indicates a strabismus is present, and a referral should be made to an ophthalmologist.

Random Dot E Stereo Test

The random dot E stereo test measures stereopsis. This is different from the light reflex test or the cover test, which detects physical misalignment of the eyes. Stereopsis can be absent in patients with straight eyes. An ophthalmologic evaluation is necessary to detect the causes of poor stereo vision with straight eyes. To perform the

random dot E stereo test, the cards should be held 16 inches from the child's eyes. Explain the test to the child. Show the child the gray side of the card that says "model" on it. Hold the model E in the direction at which the child can read it correctly. Have the child touch the model E to understand better that the picture will stand out. A child should be able to indicate which direction the legs are pointing. Place the stereo glasses on the child. If the child is wearing eyeglasses, place the stereo glasses over the child's glasses. Make sure the glasses stay on the child and the child is looking straight ahead. The child should be shown both the stereo blank card and the raised and recessed E card simultaneously. Hold each card so you can read the back. The blank card should be held so you can read it. The E card should be held so you can read the word "raised." Both cards must be held straight. Do not tilt the cards toward the floor or the ceiling—this will cause darkness and glare. Ask the child to look at both cards and to point to or touch the card with the picture of the E. The E must be presented randomly, switching from side to side. The child is shown the cards up to 6 times. To pass the test, a child must identify the E correctly in 4 of 6 attempts.

AMERICAN ACADEMY OF PEDIATRICS

CLINICAL REPORT

Guidance for the Clinician in Rendering Pediatric Care

Ted D. Sigrest, MD, and the Committee on Hospital Care

Facilities and Equipment for the Care of Pediatric Patients in a Community Hospital

ABSTRACT. Many children who require hospitalization are admitted to community hospitals that are more accessible for families and their primary care physicians but vary substantially in their pediatric resources. The intent of this clinical report is to provide basic guidelines for furnishing and equipping a pediatric area in a community hospital.

ABBREVIATIONS. AAP, American Academy of Pediatrics; JCAHO, Joint Commission on Accreditation of Healthcare Organizations.

BACKGROUND

Of the 6.4 million admissions of children to hospitals in the United States in 1997, approximately 24% were to children's hospitals. Another 35% were admissions to large, primarily urban pediatric units in municipal or regional medical centers. The remaining 41% of pediatric admissions were to community hospitals that are more accessible and convenient for patients' families and physicians.[1] These smaller hospitals vary in their equipment, staffing, diagnostic resources, and treatment capabilities for pediatric patients. Some smaller hospitals may have no permanently designated pediatric beds and few, if any, staff dedicated exclusively to the care of children. In these smaller facilities, services may be provided by physicians and health care professionals with widely varying levels of expertise in children's health care.

As the number of hospitalized children and average length of stay have decreased, hospitals have been compelled to reassess their commitment to the maintenance of pediatric inpatient units. Some have elected to discontinue their pediatric programs. Others have decreased their services to children, but to remain competitive, continue to attempt to meet patient and community needs. The purpose of this clinical report is to provide guidelines for the basic facilities and equipment needed to adequately care for children in community hospitals with the realization that there are significant budgetary constraints to be acknowledged in the provision of these services. Detailed information on the facilities and equipment needed to care for newborns can be found in the American Academy of Pediatrics (AAP) *Guidelines for Perinatal Care* (see "Resources" section).

THE FACILITY

In addition to recommendations of the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) for facilities used in the provision of care to hospitalized patients, the following is a list of basic facility needs for the care of children from birth to 18 years of age:

- Single- or double-occupancy rooms that comply with guidelines for prevention of nosocomial infections[2] and that are large enough to accommodate parents who stay with their children.
- Patient room configuration and bed positioning that allow convenient observation and supervision of patients by nursing staff, especially if parents are not available.
- Covered electrical outlets, childproof window locks and door latches, padding of sharp edges, and nonslip, easily maintained floor surfaces.
- Age-appropriate furniture, including cribs equipped with safe overhead restraints and beds with covered mechanical or electrical controls.
  - —Beds, cribs, and other furniture should meet Consumer Product Safety Commission standards (http://www.cpsc.gov).
- Area set aside for play, entertainment, education, and other child life activities.
- Separate treatment room for patient assessment and procedures.

Interior design and decor are not addressed in this statement. Information about child-friendly, developmentally appropriate environments may be obtained from the Institute for Family-Centered Care (see "Resources" section).

EQUIPMENT

Essential medical equipment for pediatric care is included in the following list. Additional information on pediatric resuscitation equipment is included in the AAP policy statement "Guidelines for Pediatric Emergency Care Facilities"[3] and in standard pediatric emergency care textbooks.[4]

- Resuscitation cart containing pediatric-specific supplies
  —Common pediatric emergency drugs should be readily accessible and plainly labeled. Drug dosing by weight or length should be easily referenced.
  —The resuscitation cart should also have an appropriate assortment of the various sizes of pediatric oxygen masks, endotracheal tubes, laryngoscope blades, oropharyngeal and nasopharyngeal airways, and self-inflating bags (ie, Ambu bags [Ambu International, Linthicum, MD]) with various sizes of masks. A size-appropriate backboard for resuscitation should be available.
    - A cardiac defibrillator designed for pediatric use with paddles for infants and children.
      —A chart for appropriate joule dosages for weight should be readily available.
    - Cardiorespiratory monitors appropriate for the level of pediatric care provided.
    - Respiratory equipment in appropriate sizes for infants and children.
      —Necessary items include oxygen masks, nasal cannulas, tubing, self-inflating (Ambu) bags and masks, oropharyngeal and nasopharyngeal airways, suctioning equipment and catheters, nebulizers with pediatric-sized face masks, spacer devices and masks for metered-dose inhalers, pulse oximeters with appropriate infant and pediatric probes, and infant and pediatric tracheostomy supplies.
- Intravenous catheters, phlebotomy equipment, and lumbar puncture trays that are size appropriate; extremity warmers, such as chemical packs that warm via exothermic reaction, for improving peripheral blood flow and facilitating blood sampling in infants; papoose boards, adequately padded, of at least 2 sizes for immobilization of infants and children.
- Common neonatal and pediatric intravenous solutions, such as small vials of 10% dextrose, 100 and 250 mL bags of common pediatric intravenous solutions such as 5% dextrose with one-half normal saline or lactated Ringer's solution, 5% dextrose with one-quarter normal saline or lactated Ringer's solution, and intravenous infusion pumps designed for pediatric use with precise administration of small infusion rates.
- Scales and stadiometers for infants and older children.
- Pediatric-appropriate dietary supplies, such as common newborn formulas, pediatric nutritional supplements, and dietary choices that appeal to children; appropriately sized assortment of orogastric and nasogastric feeding tubes and enteral feeding pumps designed for precise administration of small infusion rates.
- Pediatric urine collection devices and appropriately sized urinary catheters.
- Mercury-free thermometers and blood pressure devices (various sizes of blood pressure cuffs).
- Pediatric orthopedic equipment, including wheelchairs, crutches, slings, and splints.
- Infant incubators for small infants with temperature control problems.
- Portable lamps for bedside procedures.
- Developmentally appropriate books, toys, games, and when economically feasible, electronic media such as videocassette players and computers.
  —Toys and equipment should be safe for use by children with impaired mobility.
  —Infection control should be a priority, with all toys, equipment, and play surfaces regularly cleaned with appropriate germicidal solutions.
  —Computers that are available for pediatric patient use should have Internet access limited to child-appropriate sites.

SUPPORT SERVICES

The following therapeutic and diagnostic facilities should be available on a 24-hour basis:

- Routine radiograph imaging, with a radiologist available for reading of emergency films.
  —Availability of computed tomography is strongly recommended.
- Clinical laboratory services appropriate for neonatal and pediatric needs, including hematologic profiles, blood chemistries, blood gas studies, microbiologic profiles, and standard urine studies.
  —Equipment should be available to process all commonly ordered tests such as complete blood cell counts and renal and hepatic function tests using samples of less than 1 mL ("micro" samples).
  —Minimum amounts of blood, urine, and cerebrospinal fluid required for tests should be obtained and posted in the hospital laboratory and pediatric areas.
  —Response times should be appropriate for timely diagnosis and treatment of the child's condition.
  —Topical anesthetics should be available and used before obtaining blood samples whenever possible.
- Pharmacy services providing age- and size-appropriate drug administration and dosing.
  —Commonly used oral suspensions should be immediately available. The equipment necessary to create pediatric liquid formulations, including pill crushers, suspension agents, and flavoring solutions, should be available. Pediatric oral suspension delivery devices, such as oral medication syringes and pacifiers that deliver liquid medications, should be available.
  —Doses of antibiotics that are known to cause ototoxicity or nephrotoxicity, such as vancomycin, tobramycin, and gentamycin, should be calculated using computer programs or calculations based on appropriate neonatal or pediatric pharmacokinetic models. Serum drug concentrations should be obtained to optimize dosage amounts and intervals. Clinical judgment should be used before ordering multiple serum concentrations if the antibiotic is to be discontinued with negative cultures or oral antibiotics

are to be started as soon as the patient is afebrile.
—Current references for pediatric drug dosing and drug interactions should be easily available. A liaison with a tertiary care children's hospital pharmacy is advised to help minimize the possibility of adverse consequences in off-label use of drugs and drug dosing.

The following services should be available as needed: social work services; pastoral services; sign and foreign language interpretation; and respiratory, physical, occupational, and speech therapy. Professionals providing these services should have adequate training and continuing education provided in the pediatric applications of their respective fields. If a child is hospitalized for more than 2 school days, a designated hospital employee, such as nurse, social worker, or child life specialist, should serve as a liaison with the child's school to assist the parents in providing for the child's educational needs. Child life services are recommended whenever feasible.[5] These specialists provide a valuable service in addressing the psychosocial concerns of children and families during hospitalization and provide support for the concept of family-centered care in the medical setting.

CONTINUING EDUCATION

All health care professionals in a pediatric area should be familiar with the unique and changing physical and psychosocial needs of children. Continuing education should be provided to reinforce these concepts. Nurses and physicians should have current certification in pediatric life support techniques. All should know the location of carts and equipment for cardiopulmonary resuscitation and mock codes should be conducted on a regular basis. Instruction on the use of cardiorespiratory monitors and their alarms should be provided on an ongoing basis. If patients are provided with monitors that feature electrocardiogram readouts, appropriate training should be provided. Education sessions and mock codes should be documented for review by hospital quality assurance committees and the JCAHO.

REFERRAL NETWORKS

Community hospitals and physicians providing care for children must have well-established referral networks for timely consultation by pediatric subspecialists and, when necessary, for transfer of patients to a pediatric center that offers more advanced levels of care. This includes access to an air and ground transportation system that is responsive and appropriately equipped and staffed to care for children of all ages. Guidelines for regionalization of care and transfer of injured patients have been published by the AAP[6] and the American College of Surgeons.[7]

ADMISSION AND TRANSFER CRITERIA

Because community hospitals vary significantly in their resources for providing pediatric care, there is no single set of criteria for admission and transfer of pediatric patients that has universal applicability. Each institution must assess its own capabilities and limitations in light of its mission and then formulate guidelines. Once guidelines for transfer of patients have been established, those for admission become less difficult to define. This challenging process requires input from all members of the health care team, including hospital administration. The goal is to ensure that each patient in the facility receives the optimal care that is most appropriate for his or her medical and psychosocial needs.

CLINICAL REPORT

Guidance for the Clinician in Rendering Pediatric Care

Robert W. Block, MD; Nancy F. Krebs, MD; and the Committee on Child Abuse and Neglect, and the Committee on Nutrition

Failure to Thrive as a Manifestation of Child Neglect

ABSTRACT. Failure to thrive is a common problem in infancy and childhood. It is most often multifactorial in origin. Inadequate nutrition and disturbed social interactions contribute to poor weight gain, delayed development, and abnormal behavior. The syndrome develops in a significant number of children as a consequence of child neglect. This clinical report is intended to focus the pediatrician on the consideration, evaluation, and management of failure to thrive when child neglect may be present. Child protective services agencies should be notified when the evaluation leads to a suspicion of abuse or neglect. ***Pediatrics*** **2005;116:1234–1237;** ***failure to thrive, development, child neglect, abuse, nutrition.***

ABBREVIATION. FTT, failure to thrive.

INTRODUCTION

Failure to thrive (FTT) in infants and children results from inadequate nutrition to maintain physical growth and development. An infant or child becoming malnourished as the result of parental or caregiver neglect creates concern about child maltreatment.[1] In its extreme form, FTT secondary to neglect may be fatal. This clinical report is not intended to be a thorough review of FTT but serves as a guide for the assessment, management, and support of children with FTT as a manifestation of child neglect.

DEFINITION OF FTT

FTT is a significantly prolonged cessation of appropriate weight gain compared with recognized norms for age and gender after having achieved a stable pattern (eg, weight-for-age decreasing across 2 major percentile channels from a previously established growth pattern; weight-for-length $<$ 80% of ideal weight). This is often accompanied by normal height velocity.[2,3] Despite these accepted definitions, caution must be applied when diagnosing FTT on the basis of percentile shifts, because growth variants are common.[4] Actual weight $<$70% of predicted weight-for-length requires urgent attention. It is recognized now that earlier distinctions between organic and nonorganic FTT are overly simplistic and not clinically appropriate,[5] because many patients exhibit components of both. See the *Pediatric Nutrition Handbook*[3] from the American Academy of Pediatrics for a thorough discussion of FTT.

INCIDENCE AND CAUSAL FACTORS

The fundamental cause of FTT is nutritional deficiency. Poverty is the greatest single risk factor for FTT worldwide and in the United States.[6,7] FTT can be unintentional, occurring with breastfeeding difficulties, errors in formula preparation, poor diet selection, or improper feeding technique. FTT can also be caused by organic diseases including but not limited to cystic fibrosis, cerebral palsy, HIV infection or AIDS, inborn errors of metabolism, celiac disease, renal disease, lead poisoning, or major cardiac disease. FTT may result if caregivers who are referred for assistance fail to avail themselves of community resources and/or assistance.[8] FTT is often multifactorial, involving some combination of infant organic disease, subtle neurologic and/or behavioral problems, dysfunctional parenting behaviors, and parent-child interactional difficulties.[9] Feeding difficulties, oral-motor dysfunction, food aversion, and/or appetite control often compound the problem.[10,11] The malnutrition in children with FTT can lead not only to impaired growth but also to long-term deficits in intellectual, social, and psychological functioning.[12,13]

When FTT is caused by child neglect, certain risk factors are often present. When considering neglect, the pediatrician should assess each risk factor in the context of each family's unique situation. The parent(s) of an infant with FTT may exhibit inadequate adaptive social interactional behavior and less positive affective behavior. The parent may be an adolescent or may have a history of abuse as a child.[14,15] The infant with FTT is often born preterm or with low birth weight and may have been separated from caregivers because of prolonged hospitalization during the perinatal period. Family and social factors that may contribute to neglect include the lack of available extended family to help with child rearing, social isolation of the family, substance abuse, family violence, single parenthood, and employment instability. Parents in middle-class and affluent circumstances or parents engaged in career development or activities away from home also may lack the emotional strength or maturity to nurture their infants

The guidance in this report does not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

doi:10.1542/peds.2005-2032

appropriately.[14,15] Any of these factors may lead to inconsistent feeding patterns with decreased nutrition, decreased growth, and additional family stress.[16] In toddlers and older children, decrements in the rate of growth in weight and height are more frequently ignored or too easily ascribed to intercurrent illness. Pediatricians should be aware of the potential for neglect of children of any age.

Infant-caregiver attachment issues may be an important component of FTT. Disturbances in attachment may predict several problems in infant and child development.[17] FTT is not synonymous with disturbed attachment; many children fail to thrive without attachment disturbances, and many children with attachment disturbances grow normally. Nevertheless, many factors contributing to FTT (poverty, maternal depression, neglect) also increase the risk of attachment disturbances. Because infants with FTT may be at risk of clinical disturbances of attachment, pediatricians should consider consultation with mental health professionals who can assist in evaluating infant-caregiver attachment.[18–20]

Psychosocial short stature, a variant of FTT, has been described as short stature out of proportion to the decreased weight. This syndrome is thought to result from major emotional and psychological trauma. It has been associated with pituitary and hypothalamic dysfunction, possibly with interactions with nutrient deficiencies, which is frequently reversible when the child is placed in a nurturing environment.[21]

ASSESSMENT

Most children with FTT can be assessed by a general pediatrician with the help of professionals in other disciplines. The clinical evaluation for FTT should include a comprehensive history, physical examination, feeding observation, and a home visit by an appropriate health professional. For breastfed infants, an observation of feeding should include an evaluation of the mother's breastfeeding technique and the infant's response to feeding and be conducted by a professional specifically trained in lactation counseling and assessment. Laboratory and radiologic studies are frequently unnecessary. A multidisciplinary approach involving nursing, social services, and dietetics personnel is essential when children with FTT fail to recover and sustain normal growth velocity after treatment interventions.[22,23]

History

A thorough review of the child's family history should include genetic conditions, growth histories, endocrine disorders, caregivers' knowledge of normal growth and development, family function, eating patterns, types of food available in the home, and family stressors. The child's parents should be queried about personal history of abuse, eating disorders, psychopathology, alcohol use, drug use, domestic violence, and stress; their social skills, nutritional beliefs, and positive assets also should be considered in the evaluation.

The child's medical history should include a general review of systems, current medications, allergy history, feeding history, 72-hour dietary record, gastrointestinal symptoms, travel history, feeding routines, feeding skills, time required to feed, behavior during feedings, sleep patterns, developmental history, daily routine, gestational and prenatal history, and history of organic disease. Information obtained from all child care providers should include a history of eating patterns, interactions, social skills, responses to the providers, and family concerns.

Physical Examination

The physical examination should include documentation of past and present growth parameters, including head circumference, using appropriate growth charts. General examination should include a search for major and minor anomalies, careful neurologic examination, assessment of suck-swallow coordination, and observation of the child's developmental skills and responses and interactive behaviors with parents and examiners.

Feeding Observation

A feeding observation can be performed in the office but is enhanced as part of a home visit. Feeding behavior, the child's oral interest or aversion, and parent-child interactions before, during, and after feeding should be observed and recorded.

Laboratory Testing

When history, comprehensive physical examination, feeding observations, and home visitation do not reveal an obvious cause of FTT, laboratory testing may be performed to rule out organic disease and ascertain nutritional deficits. Testing should be performed if there are concerns arising from the history or physical examination; however, the yield of positive laboratory data are $<1\%$.[23]

RECOGNITION OF FTT SECONDARY TO NEGLECT OR ABUSE

The risk factors that should alert the pediatrician to the possibility of neglect as the cause of FTT include:

- parental depression, stress, marital strife, divorce;
- parental history of abuse as a child;
- mental retardation and psychological abnormalities in the parent(s);
- young and single mothers without social supports;
- domestic violence;
- alcohol or other substance abuse;
- previous child abuse in the family;
- social isolation and/or poverty;
- parents with inadequate adaptive and social skills;
- parents who are overly focused on career and/or activities away from home;
- failure to adhere to medical regimens;
- lack of knowledge of normal growth and development; and/or
- infant with low birth weight or prolonged hospitalization.

Moreover, concerns of abuse or neglect should be raised during the course of intervention and monitored if the following become evident:

- Intentional withholding of food from the child;
- Strong beliefs in health and/or nutrition regimens that jeopardize a child's well-being; and/or
- Family that is resistant to recommended interventions despite multidisciplinary team approach.

TREATMENT AND MANAGEMENT

FTT in the young infant and toddler must be considered a medical emergency if the growth curve documents weight <70% of the predicted weight-for-length.[15] Guidelines on management of less severe cases of FTT are listed in the *Pediatric Nutrition Handbook*[3] from the American Academy of Pediatrics. Because early malnutrition can have severe deleterious effects on early brain development, prompt recognition of severe cases is essential.[24] After resolution of urgent, life-threatening medical conditions, the priority in an evaluation of FTT is a period of observation of at least several weeks to monitor intake, output, growth, feeding style, interactions, and infant/child characteristics. Historically, this has taken place in a hospital but may be better situated in a home environment, possibly including a foster home, until the cause of the FTT is determined.

Despite current economic and managed care constraints, inpatient care is justified for a child with severe FTT and/or if abuse or neglect is suspected. In contrast to other children, a child with FTT secondary to neglect may eagerly eat in the protective and predictable hospital environment. Liberal intake and above-average weight gain observed in the hospital support a diagnosis of neglect as an underlying cause of the FTT. When appropriate, pediatricians should advocate for inpatient care with managed care plan personnel, because hospitalization has been shown to significantly improve outcome in some cases.[25] However, FTT needs to be considered a chronic process, and interventions need to be long-term.

Severely malnourished children may be anorectic and weak. The institution of adequate caloric intake may be difficult. Moreover, institution of increased feedings may initiate significant metabolic problems, known as refeeding syndrome. Guidelines for diagnosis and management of this condition are available elsewhere.[26] Nutritional guidance and occupational and/or oral-motor evaluation by a speech therapist regarding effective feeding techniques are invaluable. Parents should be involved in all aspects of the treatment program and should be provided with support and education, empowering them to fulfill the care plan.

Suspicion of child maltreatment must lead to a report to the appropriate child protective services agency. The pediatrician must adequately document interventions that have been attempted, specific instructions to parents, evidence of parental understanding of the instructions, evidence of parental understanding of the potential adverse consequences to the child, and evidence of parental failure to adhere to nutritional and feeding recommendations.

Intervention by child protective services agencies may increase parental compliance or allow for additional support services such as child care, counseling, and home visitation. If aggressive interdisciplinary intervention fails to correct the weight to safe levels (>80% of predicted weight-for-length) and maintain weight gain, then placement in foster care may be the only alternative. Education and training of foster parents regarding feeding and the importance of close social interaction are mandatory. The involvement of the pediatrician during all phases of protective service intervention is essential.

GUIDANCE FOR THE PEDIATRICIAN

1. Pediatricians are encouraged to recognize that child neglect is among the many causes of FTT.
2. Pediatricians are strongly encouraged to consider child abuse and neglect and to report cases of FTT that do not resolve with appropriate interventions.

CONCLUSIONS

FTT usually can be evaluated by the office-based pediatrician with minimal laboratory tests and medical interventions. However, for infants with FTT who are suspected to be victims of abuse and neglect, aggressive multidisciplinary intervention is required in either an inpatient or outpatient setting. Close follow-up from a multidisciplinary team and home visitors who are respectful and supportive of the family are important components of assessment and treatment. FTT as a consequence of abuse or neglect must be considered in families with profiles indicating a high risk of abuse and in families that consistently fail to adhere to the recommended interventions or are unable to maintain a safe environment for their child.

VIAGRA INGREDIENT MAY AID CHILDREN WITH LUNG DISORDER

"Earlier this month, Pfizer Inc. began shipping to pharmacies a round, white pill called Revatio, a treatment for a rare and life-threatening condition called pulmonary hypertension. The drug, which dilates some of the body's key blood vessels, was approved in June for treating adults with PH, and Pfizer is now studying whether it also can help children with the debilitating illness. In early tests, the drug helped ill children increase by about 60% the distance they could walk in six minutes. But there's another side to Revatio you'd never guess by looking at it. When the same active ingredient, sildenafil, comes at higher doses in a diamond-shaped blue pill, the drug is known by a different name—Viagra . . . Pfizer is now enrolling 332 youngsters, ages 1 to 16, in a placebo-controlled trial to find out if Revatio is as safe and effective in children with the lung disease as in adults."

Falls From Heights: Windows, Roofs, and Balconies

ABSTRACT. Falls of all kinds represent an important cause of child injury and death. In the United States, approximately 140 deaths from falls occur annually in children younger than 15 years. Three million children require emergency department care for fall-related injuries. This policy statement examines the epidemiology of falls from heights and recommends preventive strategies for pediatricians and other child health care professionals. Such strategies involve parent counseling, community programs, building code changes, legislation, and environmental modification, such as the installation of window guards and balcony railings.

ABBREVIATIONS. CPSC, US Consumer Product Safety Commission; AAP, American Academy of Pediatrics.

INTRODUCTION

After motor vehicle–related injuries, falls of all kinds are the second leading cause of death from unintentional injury in the United States, accounting for more than 13 000 deaths during 1998 among persons of all ages, 126 of which were children 14 years and younger.[1] Falls are the leading cause of nonfatal injury, with several hundred thousand hospitalizations annually and almost 9 million persons treated in emergency departments who do not require hospitalization.[2] Although falls are the most common cause of childhood injury, these injuries are rarely fatal, in contrast with a high rate of fall-related mortality among the elderly.[1,3,4] Fatalities occur primarily when children fall from great heights (greater than 2 stories or 6.7 m [22 ft]), or when the head of a child hits a hard surface, such as concrete. Falls from heights greater than 2 stories can include falls from roofs, windows, and balconies.[5–7] The purpose of this statement is to review the epidemiology of falls from heights in children and to suggest strategies for prevention.

Falls from heights are a major problem in urban areas, especially for children living in multiple-story, often deteriorating, low-income housing.[5–7] In some urban areas, falls have represented up to 20% of the deaths of children from unintentional injury, as compared with an average of 1% to 4% nationally.[1,8,9] The majority of fall-related fatalities among children are associated with falls from heights, most from 3 stories or higher. Falls from 1 or 2 stories are more frequently nonfatal, but second-story falls may cause serious injuries (D. Tinsworth, US Consumer Product Safety Commission [CPSC], written communication, June 13, 1994).[5,7] The falls from greater heights tend to cluster in the summer months, presumably because windows are more likely to be open and children are more likely to be playing on fire escapes, roofs, and balconies.[5,7,8,10] Although the average age of patients injured in falls from heights is approximately 5 years, the age distribution is bimodal; preschool children usually fall from windows, and older boys fall from dangerous play areas, such as rooftops and fire escapes.[5,6,8,11] African American and Latino children are overrepresented in published series of falls from heights in which race or ethnicity is reported, probably reflecting their increased likelihood of living in urban, multiple-story low-income housing.[11,12] Overall, fall-related injuries to boys outnumber those to girls by approximately 1.5:1 to 2:1, as with most other injuries.[5,7,8,10–16]

The nature of the injuries to children when they fall from heights has been studied extensively.[11,13–17] Data from the CPSC on the approximately 4700 children who were examined in emergency departments because of falls from windows during 1993 indicate that 90% fall from the first and second stories and that 45% had injuries defined by the CPSC as "serious," such as fractures, internal injuries, concussions, intracranial hematomas, and intracranial hemorrhages. Of those injured, 28% were admitted to the hospital compared with 4% for all consumer product–related injuries reported to the CPSC during 1993. Approximately one third of children sustained only minor injuries, such as contusions, abrasions, and lacerations.[11] These are usually young children who fall 1 or 2 stories. Fractures are the most common of the serious injuries and the radius, ulna, and femur are the most frequent sites.[11,16,17] Rib, spine, pelvis, and calcaneus fractures are much less common among children than among adults. Children tend to use their arms to protect their heads, and they have relatively flexible bones.[11,15,17] Multiple fractures are common, especially those resulting from falls from greater heights. Craniocerebral trauma is frequent, particularly in fatal falls.[15,17] Abdominal and chest injuries are relatively uncommon in falls from 1 or 2 stories, but they are more frequent in falls from greater heights and in fatal falls.[5,10,15,17] In general, the greater the height from which the child falls, the more severe the injury. However, the nature of the surface onto which the child falls (concrete and trash are most common; softer surfaces improve outcome[13,14,18]) and the degree to which the fall is broken on the way down modify the pattern and sever-

PEDIATRICS (ISSN 0031 4005).

ity of injuries.[5,6,11,14–16,18] Children younger than 3 years are much less likely to have serious injuries than older children who fall the same distance. It is thought that, because younger children have more fat and cartilage and less muscle mass than older children, they better dissipate the energy transferred by the fall.[11]

Because witnessed falls of 2 stories or less usually do not result in serious injury, child abuse should be considered in children with serious injuries from falls that were reportedly from lower levels, especially if the fall was unwitnessed.[19–22] One large series reported that about one fourth of the falls were "not accidents"; some children jumped to avoid beatings or fires, some were pushed by siblings or parents, and some attempted suicide (all the suicide attempts were adolescents).[14]

Permanent physical sequelae—primarily orthopedic problems related to fractures and neurologic problems ranging from mild to severe—occur in 4% to 22% of children who survive serious falls.[10,11,13,14,17] One study reported a significant incidence of posttraumatic psychiatric and behavior problems.[14]

The economic costs of these injuries from falls are considerable. In Los Angeles County, where falls are possibly less frequent than in the northeast, the annual hospital charges from 1986 to 1988 were more than $600 000, or about $5000 per child admitted with fall-related injury; almost half of these charges were paid by public assistance.[14] Data compiled by the National Center for Health Statistics National Hospital Ambulatory Medical Care Survey for 1992–1994 revealed a national cost of $958 million for emergency care for children who were seen for falls. Although fewer than 3% were falls from buildings or extreme heights, they would still account for almost $10 million annually, including 26% paid by Medicaid.[23]

Case series have reported predisposing factors for fall injuries: a history of previous major unintentional injury to the patient or siblings; neurologic disorders, such as seizures, developmental delay or hyperactivity; and documented parental neglect.[5,8,10] The families of the victims are more likely than the general population to experience social and demographic factors such as poverty, single-parent households, inadequate child care, and acute stressors such as recent moves, illnesses, and job changes.[8] Some central-city residents may have moved recently from rural areas and may be unfamiliar with the hazards of living in multiple-story dwellings.[5]

PREVENTION

A number of strategies, some of which have documented effectiveness, have been suggested to prevent children falling from heights. Parent counseling has been effective in preventing infant falls and other injuries and should be part of any prevention program.[20,22,24–26]

Considerable success has been reported with modification of the physical environment. Spacing of railings determines how well they function to prevent falls from balconies, decks, porches, and bleachers. Widely spaced rails are ineffective barriers because they permit a child's body to slip through.[27] Virtually all children younger than 6 years can slip through a 6-in opening, and none older than 1 year can pass through a 4-in opening.[27] This information resulted in the adoption of the 4-in spacing by all 3 of the regional building code organizations in the United States. To prevent falls from balconies, the building codes in many communities now require railings through which a child cannot pass.[28] All local building codes dealing with new construction should be made to conform with the national codes that currently recommend 4-in openings between vertical (not horizontal) bars. Because the codes apply only to new construction, retrofitting of older dwellings also should be encouraged. Most codes specify railing heights of 36 in. Although an increase of railing height to 4 to 5 ft would add protection, aesthetic concerns are likely to impede any efforts for change.

Outside fire escapes are unnecessary in modern buildings that use fire-resistant techniques such as internal fire stairs, but it is unlikely that outdoor escapes can be eliminated from older housing, and is it unlikely that urban housing will be air-conditioned, reducing the need to open windows during hot weather. Providing safe ground-level play areas with climbing equipment has been suggested as a strategy for avoiding the falls from heights related to children playing on fire escapes and roofs.[6]

Because the majority of serious injuries are related to falls from windows,[13,14,17] strategies designed to prevent these falls should have a substantial effect. Modern window screens, although easily removable to allow for escape during residential fires, are designed to keep insects out of the house and do not provide a barrier to falls.[24] "Child safety" window screens made of steel are available and are used in new construction in some areas. These screens can withstand 67.5 kg (150 lb) of pressure, similar to the standard for window guards, and need replacing less often, but adding them to existing construction would be costly.

The installation of window guards is a proven preventive strategy. In 1976, the New York City Board of Health, noting that window falls accounted for 12% of deaths from unintentional injury of children younger than 15 years, passed a law requiring the owners of multiple-story dwellings to provide window guards in apartments where children 10 years and younger reside. This law was passed after the implementation of a pilot program combining education with the provision of free window guards. The pilot program resulted in a 35% reduction in deaths attributable to falls from windows and a 50% reduction in incidents; no child fell from a window equipped with a window guard.[7] The mandatory program resulted in a reduction of up to 96% in admissions to local hospitals for the treatment of window-fall-related injuries.[14] Follow-up through 1993 revealed a continuing downward trend.[29] Education is important for teaching the appropriate installation of window guards. Despite the proven effectiveness of window guards, other major cities have been slow to adopt similar codes. The building

code in Chicago requires window guards if the height of the window sill is less than 2 ft above the floor, but enforcement is reportedly ineffective.[10] A voluntary ordinance in Boston encourages but does not mandate landlords to install window guards. The first 2 years' data after initiating this program showed an 83% decrease in hospitalizations for the treatment of injuries attributable to falls from windows, and there were no deaths, compared with 3 deaths during the 2 years preceding the program.[30] A survey of building codes in several states found no regulations requiring window guards, although New Jersey has since passed a law similar to that of New York City.[31] Some states prohibit or limit window guards in the interest of providing fire egress.[13]

One survey of hardware stores found that the only devices available were specifically designed and advertised to keep intruders out; they were recommended for use on first floor windows.[13] These devices were expensive (approximately $50) and difficult to install.[13] Security devices are designed to keep people out, and window guards are designed to keep people in—except for necessary egress in the event of fire. It is easier to find inexpensive window guards (starting at $6) in cities where window guards are required, especially when public health programs have developed networks of stores that offer them. Window stops are available that prevent sliding windows from opening more than 4 inches. They are available at hardware stores for around $2 and are easy to install. Window guards can be obtained to fill the entire opening of a sliding or casement window. However, currently designed window guards are best suited for double-hung (sash-hung) windows. If the guard does not fill the entire opening of the window, additional devices, "L-stops," also are recommended to restrict the opening of the window above the top bar of the guard to no more than 4.5 in. L-stops are not to be used on windows designated for egress, that is, windows that are located less than 75 ft above the ground.[32]

Fire protection professionals have great concerns about the use of *fixed* window bars (security bars) that prevent egress or access by fire fighters. It is important to install *operable* window guards that can be released or removed without the use of a separate key or excessive force. Operable guards must be too difficult for a child to release but easy enough for an adult or teenager to release. Examples of operable guards include built-in bars that appear automatically as the window is raised, guards on a hinge that swing in when a "pin" is released, and a slide-out model that requires the simultaneous depression of 2 pins for removal. Fire codes in some communities prohibit the use of fixed bars on emergency and fire escape windows. Organizations of fire protection professionals decry their use, especially on first and second floors, but data are scarce that would permit the risk-benefit consideration of the use of operable guards, especially on higher floors.[33] Recent data on the New York City experience showed no increase in the number of deaths attributable to residential fires (in fact, there was a decrease) after the introduction of window guards as required by city ordinance.[29]

RECOMMENDATIONS

1. Pediatricians should give the following anticipatory guidance about prevention of falls from heights to parents of children who live in multiple-story dwellings:
   - Supervise small children at all times, especially if windows are open.
   - Install locks on windows to prevent sliding windows not intended for egress from opening more than 4 in.
   - Open double-hung windows from the top only.
   - Fixed guards, commonly used to prevent intrusion, should not be used, because they may prevent egress in the case of fire.
   - Install operable window guards on second- and higher-story windows (unless prohibited by local fire regulations). Window screens are designed to keep insects out, but because they are not strong enough to keep children inside, they will not prevent falls from windows.
   - Discourage or prohibit children from playing on fire escapes, roofs, and balconies, especially those that are not adequately fenced with vertical bars that have openings of 4 in or less. Encourage the use of ground-level safe play areas, such as public parks and playgrounds. Ideally, these areas have been inspected and found safe by a nationally certified playground inspector.
   - Avoid placing furniture, on which children may climb, near windows or on balconies.
2. Pediatricians should advocate for community-wide programs to encourage the use of window guards. Public health authorities, in conjunction with fire prevention officials, should guide such programs so that regulations may be based on concerns about both fire safety and fall prevention.
3. The American Academy of Pediatrics (AAP), state chapters, and local pediatricians should work with manufacturers of windows and window guards to encourage them to develop and make more widely available additional products that can prevent falls and allow egress in fires. Examples are windows that cannot be pushed out or up by a child and window guards with safety catches that can be operated only by adults.
4. Legislation requiring landlords to install releasable window guards or window stops above the ground floor in multiple-story dwellings where children live should be developed. Community outreach and education are important components of programs to prevent falls from heights. In many cities, the local government housing authority, a major landlord for low-income people, along with the AAP state chapters and local pediatricians, should take the lead in encouraging the installation of window guards.
5. Building codes should ensure that balconies, decks, porches, bleachers, roofs, and fire escapes have railings with vertical openings not greater than 4 in.

6. Local communities and recreation departments should develop strategies to reduce the number of children playing in dangerously high places. Such strategies might include the expansion of safe public playground activities, including child care and recreational programs, as well as attempts to make streets and public areas safer for children by implementing programs such as neighborhood watch and crime prevention.
7. Whenever possible, grass or shrubbery should be planted at the bases of tall buildings to soften the impact surface.

Families and Adoption: The Pediatrician's Role in Supporting Communication

ABSTRACT. Each year, more children join families through adoption. Pediatricians have an important role in assisting adoptive families in the various challenges they may face with respect to adoption. The acceptance of the differences between families formed through birth and those formed through adoption is essential in promoting positive emotional growth within the family. It is important for pediatricians to be informed about adoption and to share this knowledge with adoptive families. Parents need ongoing advice with respect to adoption issues and need to be supported in their communication with their adopted children.

ABBREVIATION. AAP, American Academy of Pediatrics.

CHANGING PICTURE OF ADOPTION

There are various types of adoption. In domestic adoptions and some intercountry adoptions, biological families may have continued contact of varying degrees with the child for whom they have chosen an adoption plan, ranging from complete confidentiality to unlimited direct contact.[1] A child may be adopted into a family of the same ethnicity and/or race or into a family with members of different groups.[1] Many children are adopted after having spent time with a family through the foster care system, often after lengthy stays in multiple homes.[1,2] Kinship permanency may be established by grandparents, aunts or uncles, siblings, or other relatives through legalized guardianships or adoptions or through informal nonlegalized agreements within a family.[1] Intercountry adoptions, which also may involve adoptions across ethnic and racial lines, also are increasing in number.[1]

Adoptive families are changing. Increasing numbers of single-parent families, blended families, families with gay or lesbian parents, and families with older parents are providing homes to children through adoption. More children are being placed long-term with relatives, who may or may not formalize the relationship through adoption.[1] Children may have had multiple sets of foster parents before their adoption, some of whom may maintain contact with the child after the adoption. Marked increases in the number of adoptions of children with special needs have been seen in the last 2 decades.[3] There are fewer newborns and more older children being placed for adoption. Sibling groups are often placed together. Many of the children who are in need of adoptive families have complex medical, developmental, behavioral, educational, and psychological challenges. These may be the result of biological or environmental stressors experienced while the child was living with the biological family or may have been initiated or exacerbated while the child was in temporary care.[4]

Modern technology has changed the face of adoption. Although not commonly viewed as such, surrogate parenthood and embryo adoptions are adoptive relationships.[1] The Internet has led to wider dissemination of information about children waiting for permanent families and has established a new system of support among adoptive families. Information about adoption on the Internet may not always be reliable, however, and the broad and instant reach of the World Wide Web also allows great potential for unethical practices in adoption.[5]

MEDICAL ISSUES

Children who join their families through adoption must have a comprehensive medical evaluation to identify medical needs. Standards for the medical care of children in foster care have been published by the American Academy of Pediatrics (AAP)[6] and District II of the AAP.[7] For children adopted internationally, this evaluation includes but is not limited to screening tests and assessment of immunization status as recommended by the AAP Committee on Infectious Diseases in the *Red Book*.[8] Acute and chronic medical problems, vision and hearing loss, and developmental delays should be identified and addressed. Behavioral and emotional concerns need to be evaluated aggressively with appropriate therapy initiated. Pediatricians should help families in accessing mental health and developmental services when needed.

Pediatricians may be asked to review preadoption medical and mental health records to help families understand the current and potential future medical,

The guidance in this report does not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

developmental, and mental health needs of children they plan to adopt. This may include conditions related to complications of pregnancy, poor nutrition, prematurity, lack of prenatal care, and genetic diseases. In counseling families, all attempts should be made to obtain a complete medical and psychological history of the child, particularly in assessing potential special needs of a child. Through comprehensive preplacement assessment, parents should assess their resources and abilities to meet a particular child's needs. With the help of pediatricians, families then may be better able to negotiate adequate adoption subsidies including but not limited to educational needs and mental health insurance coverage.[9]

DEVELOPMENTAL UNDERSTANDING OF ADOPTION

Although parents and children gain so much in becoming a part of an adoptive family, children who join their families through adoption often experience issues of loss relevant to adoption.[10] Although these feelings of loss may be more rooted in societal expectations of genetically based attachments rather than in any inherent biological loss, they nonetheless are experienced by many adopted people.[11]

Just as a child's thinking and self-concept change at various stages of development, so does a child's understanding of the meaning of adoption. Until 3 years of age, most children do not realize there is a difference between their adoptive family and families in which children are reared by their biological parents.[12] From the time a child is adopted, it is appropriate for families to use language on a routine basis that relates to adoption, laying the groundwork for children to later understand these abstract concepts. There are many books on adoption for even young children. Through the use of available resources as well as pictures about a child's own adoption story, parents should relate to children the story of how their family came to be. These foundations are important in the later development of positive attitudes about adoption, a child's birth parents, and himself or herself.[13]

By about 3 years of age, however, children become self-absorbed and may believe that they magically cause all things that happen to them.[13] Children love to hear their adoption stories. At this age, most children begin to ask questions about what adoption means, yet children adopted at a very young age do not understand that they have another family besides the family with whom they live. Separation issues may be more pronounced than they are in peers, especially with children who remember the loss of biological or foster parents, siblings, or other relatives.[13] Children at this age may feel responsible for the loss of their first family as well as for the repeated losses through moves in and out of foster care. They may fear that their adoptive parents will abandon them in the same way once their hidden flaws are discovered.[13] Some children may express yearnings to have been "in the belly" of their adoptive mother.[12]

By the time children enter kindergarten, they realize that most of their peers are not adopted. They also learn that some children may be living with biological parents in circumstances that are similar to those experienced by their own biological parents (eg, single-parent families or conditions of poverty). This, once again, may lead children to feel responsible for their biological parents' decision not to raise them.

School-aged children continue to face issues associated with adoption, although often they deal with them by going "underground." Although children in this stage may not ask questions or initiate discussion of issues related to adoption, they still are most likely thinking about them.[13] When children are 6 to 12 years of age, they realize that, in gaining an adoptive family, they have also lost a biological family.[14] At the same time, school-aged children may identify with their biological families, fantasizing about what life would have been like if an adoption plan had not been made for them. During middle childhood, children (particularly children adopted across racial and/or cultural lines) may become upset by the differences they notice in comparison with other children and may experience denial of these differences as well as of the adoption itself.[13] Self-esteem issues may also complicate emotions and the thinking process during these years, because some children may wonder what flaw in them resulted in their biological parents making an adoption plan. This may be particularly true if the biological parent(s) chose to rear a sibling.

During preschool and elementary school years, peer and school problems may or may not be the manifestation for underlying adoption issues. Behaviors commonly identified as characteristic of attention-deficit/hyperactivity disorder may actually be signs of posttraumatic stress disorder, reactive attachment disorder, bipolar disorder, or sensory integration disorder. Some school assignments may be problematic for children who have joined their family through adoption. Children who have lived in foster care or in another country may not have pictures of themselves from birth or at an early age. Family tree assignments may be difficult, because children may be unsure of how to demonstrate their relationship to their biological family, adoptive family, and foster families. Information about biological ancestors also may be unavailable to the child for such a project. Tracing genetic traits through generations may be difficult even for children who have an ongoing relationship with their biological families. For children adopted by an extended family member, these simple learning assignments may create anxiety by highlighting family differences.[1,13] Communication with educators about adoption issues at this age, as at other ages, may be necessary to help children deal with some of these difficult school assignments and insensitive comments about adoption, family circumstances, culture, race, and ethnicity.

As adolescents develop their identity and begin the task of separation and individuation, adoption issues commonly become very important. At 12 to 16 years of age, many adolescents become angry over the differences between their own life experiences

and society's norm of an intact family. Adolescents may continue to fantasize about their "perfect" biological family. Older adolescents may also struggle with dating issues (as do all adolescents), but in these particular relationships, they may look to identify with their biological families even more. This may include engaging in risk-taking behaviors similar to those that may have led to their conception, such as unprotected sex, or those that played a part in the biological parent's (or parents') decision to make an adoption plan, such as substance abuse. Adolescents may try on identities similar to those of their biological families whether known or imagined. This may include changes in physical appearance, religion, and customs.[13] As adolescents head toward emancipation from their family, separation may come to the forefront. A child who was adopted at an early age may experience emotional uncertainty at the thought of moving away from the adoptive family and home.[13]

LOSSES IN ADOPTION

All members of the adoption triad—the child, the adoptive family, and the biological family—are affected by losses. Children in closed adoptions may lose the sense of their own original identity as well as ties to those with whom they share genetic links. Even children in open and kinship adoptions are aware of the way in which their families are different and will process this knowledge in different ways at different ages. Adoption may also represent loss to adoptive parents. Some adoptive parents have faced infertility, so they too may grieve the loss of genetic links to their child. In confidential adoptions, biological parents have an obvious loss of a relationship with the child they have conceived. Even in open adoption relationships, biological parents may feel the loss of not being in a parenting role with a child they conceived. Some pediatricians may also be involved in supporting a pregnant adolescent who makes an adoption plan. Through understanding and acknowledgment of these losses, adoptive families, children, and biological families are able to adapt better and build healthier families.[15]

COMMUNICATING ABOUT ADOPTION WITH CHILDREN

Even before a child understands the words "adoption," "adopted," and "biological family" or "birth family," it is important that these words be a part of a family's natural conversation, whether the adoption is open or confidential, kinship, or foster-adoptive placement.[13] Families should be discouraged from "waiting until just the right minute" to tell children that they were adopted, because this may leave children feeling betrayed and wondering what else their parents may have hidden from them.[13] Children may also learn information from peers or neighbors, which may impair the trust between parent(s) and child. It is important to share with even very young children their adoption story, starting with their birth, not the adoptive family's initiation of the adoption process.[14] An honest approach in the discussion of a child's biological family and the adoption process will give a child permission to ask questions or to make statements about adoption and at the same time will take away the veil of secrecy that often implies that being adopted is a negative condition.[12]

Some information in a child's past may be private or difficult for the parent to share with the child. Open discussion with a child is important in building bridges of trust and security within a family. Even the most difficult information, such as previous sexual or physical abuse or having been conceived in the context of rape or incest, eventually should be shared with a child at a developmentally appropriate age.[13] The child and parents should be counseled regarding the child's privacy about facts pertinent to the adoption. The parents and the child need to be cautioned that once information is shared, it cannot be taken back.[14] Parents should guide children in what they will share with strangers, friends, and extended family. Facts shared with children about their adoption should always be accurate, and adoptive parents should admit when information is not available.[13] As children age, they should have control over telling their adoption history outside the family.[13]

Some parents who have dealt with infertility may be uncomfortable with the reality that their child has another family, another set of parents.[14] Thus, issues of loss in the adoptive family may continue after the child is adopted into the family.[12] Avoidance of discussion about the biological family will deprive children of the opportunity to ask questions, openly fantasize, or understand having a family outside of the one in which they live and may give children the perception that their thoughts and questions about adoption are bad.[13] It is important to tell a child that he or she was not "given up" but rather that the biological family made an adoption plan in the best interest of the child's future and to the best of their abilities at the time. As children grow in their understanding of the relationship with their biological family, they may become concerned that just as they were "rejected" by their biological family, their adoptive family may also reject them.[12,13] Adoptive parents may need to verbalize their commitment to their child frequently. A "life book," a compilation of all (difficult and happy) that is known about a child's history, can be an effective tool for parents to use in helping a child to process all the thoughts and feelings about his or her adoption story.

RACIAL, ETHNIC, AND CULTURAL DIFFERENCES

Children adopted by parents of a different race, ethnicity, or cultural background may have other concerns specific to their identities. Even children as young as 3 or 4 years of age will be aware of the physical differences between themselves and members of other racial groups.[16] When these children live in communities where they are members of an ethnic minority, the differences in racial identity will be easily apparent to classmates, other parents, and strangers. As these children enter preschool and elementary school, peers may ask questions about their biological and cultural heritage. As children

reach the developmental stage of wanting to be just like their peers, these questions may provoke a variety of responses. Some of these responses might seem to the casual observer to be out of proportion for the information requested. Some remarks may be taunting or intrusive.[13] Children may encounter racist remarks for the first time, particularly in situations in which they are not physically or emotionally safeguarded by their parents.

Families need to acknowledge openly the racial differences that exist between their child and themselves. Relationships with others of the same race or ethnic group, including adults and children, may be very helpful to a child.[16] Whenever possible, an adopted child should be given the opportunity to learn more about the heritage of the country of his birth or of his ethnic group.[13,16] Role-playing with children with respect to stereotypes and racist statements may help them to feel in control when they encounter inevitable comments from strangers, friends, or extended family members.[15] Parents who have not experienced racism personally may need to pay extra attention to teaching their children effective ways to respond to racism.

SPECIAL ISSUES IN KINSHIP ADOPTION

For children who are placed for foster care or adoption within their biological family, separation issues are lessened. At the same time, these relationships present particular challenges for a family. There may be a reluctance of other family members to confirm the adoptive parents as the child's actual parents, and reference may be made within the family setting to a child's "real" parents. Boundaries must be set regarding the type of contact, timing, and granting of parental responsibility to the biological parents. All family members may need to be reminded that the adoptive parent is the responsible parent. Family gatherings may provide particular challenges, especially in cases in which the biological parents' rights have been involuntarily terminated. Many kinship adopters have limited contact with support groups, and there may be a tendency to "keep it in the family," especially with respect to the open discussion of family secrets that led to the placement of the child with a family member. Grandparents who become adoptive parents may grieve the loss of the vision of their own children as parents while coping with the stresses of raising children again and dealing with the circumstances of the reason the child was placed with them.

It is important that pediatricians provide support to these families, particularly in the area of validating the adoptive parents' rights to make decisions for the child. Kinship adoptive parents may be reluctant to share with the child painful information involved in the circumstances leading to the separation from the biological parents. Failing to share the truth with the child will only lead to damaged trust and increase anxiety for the child. The biological parents and kinship adoptive parents must communicate about the sharing of information and what language will be used, keeping in mind the child's developmental stage. Through contact with local child welfare agencies and other community resources, financial assistance, respite care, and support services for families with a kinship adoptive placement, whether formal or informal, may be available.[13]

DIFFICULT TIMES

"Anniversary reactions" often occur in adopted children at certain times of the year.[13] On Mother's Day, children may think about the many mothers they have had, including their adoptive mother, biological mother, and foster mothers.[13] On birthdays and adoption days, children may seem depressed and withdrawn instead of joyful. These anniversaries may trigger thoughts of the biological family, and children may wonder whether their biological parents still love them or even think about them. Sensitivity, particularly at these significant times, may help a child in dealing with difficult adoption issues.[13]

SEARCHING FOR BIOLOGICAL FAMILY AND CULTURAL TIES

As children age into adolescence and adulthood, adoptive children may wish to seek out more information about their biological families.[10] Individuals who joined their families through international adoption may choose to make a trip to the country of their birth. Domestic adoptees may pursue reunification with biological relatives through a reunion registry, may choose to reestablish ties in a lapsed open adoption, or may develop a stronger interest in understanding kinship ties. Although some adoptive parents may view their child's searching for his or her biological family as a sign of rejection, it is actually a sign of healthy emotional growth in the search for an identity.[14] All members of the adoption triad may need the help of mental health professionals to work through these situations. Pediatricians are encouraged to become aware of local community resources for adoptive families, including resources for locating information about biological families, support groups, adoption conferences and services, and mental health professionals.

MODELING POSITIVE ADOPTION LANGUAGE

Pediatricians are encouraged to model positive adoption language for all families. Adoptive families are "real" families; siblings who joined a family through adoption are "real siblings." Biological parents do not "give up a child for adoption," which might imply to the child that he or she was of less worth and was given away. Rather, they "make an adoption plan for a child." A biological mother should not be identified as a "natural parent," as this implies that adoptive families are "unnatural." A child's racial identity, adoption, or birth in another country should never be the identifying characteristics for any child. It is never appropriate to ask how much a child "cost." In modeling positive adoption language, pediatricians can use vocabulary that reflects respect and permanency about children and their families.[13]

As more children each year become part of permanent families through adoption, it is becoming in-

creasingly important for pediatricians to be aware of and knowledgeable about adoption. Pediatricians play an important role in helping families deal with the differences, the losses, and the many other issues surrounding the adoption of a child. Pediatricians are encouraged to have a greater understanding about adoption to be able to advise and support parents as they communicate about adoption with their children. It is also important for a pediatrician to remind families of the importance of forthright communication about adoption. Open acknowledgment of the adoptive relationship helps to nurture a child's self-esteem as he or she grows in the understanding of what it means to join a family through adoption. Effective communication about adoption is important for the long-term mental and physical health and well being of each child and family.

CLINICAL REPORT
Guidance for the Clinician in Rendering Pediatric Care

William L. Coleman, MD, Craig Garfield, MD, and the Committee on Psychosocial Aspects of Child and Family Health

Fathers and Pediatricians: Enhancing Men's Roles in the Care and Development of Their Children

ABSTRACT. Research substantiates that fathers' interactions with their children can exert a positive influence on their children's development. This report suggests ways pediatricians can enhance fathers' caregiving involvement by offering specific, culturally sensitive advice and how pediatricians might change their office practices to support and increase fathers' active involvement in their children's care and development. ***Pediatrics*** **2004;113:1406–1411;** ***father's roles, families, child care, pediatrician's roles.***

Over the last 30 years, fathers' roles in caring for their children have been expanded by rapid and profound socioeconomic changes and by society's evolving perceptions and expectations of fathers' roles. "Father" in the United States means more than "wage earner" or "provider" and now can include stay-at-home dad, caregiver of child, and sharer of child care responsibilities. It even may include a grandfather caring for his grandchild. There is increasing recognition of the benefit to the child of the father's role in providing love and support to the mother or, when the spouse is not the biological mother, the partner. Recent increases in immigration and growing cultural diversity are 2 more sources of change in the roles, expectations, and involvement of fathers. A father may be a biological, foster, or adoptive father; he may be a stepfather, grandfather, adolescent father, father figure, or coparent father in a gay relationship; and he may be custodial or noncustodial, resident or nonresident, near or far. For purposes of this report, father is defined broadly as the male identified as most involved in caregiving and committed to the well-being of the child regardless of living situation or biological relation.

In response to changing expectations, diversity, and changing demographics (ie, more fathers assuming increased child care responsibilities), pediatricians need to broaden their understanding of fathers' roles and fathers' own expectations and appropriately modify their clinical style and office practices to accommodate and support fathers' expanding roles.

A substantial proportion of children in America (ie, 30% of white children, 42% of Hispanic children, and 69% of black children) are born to unwed mothers.[1] In these cases, pediatricians especially need to remind mothers of fathers' unique influence on a child's development, regardless of whether the parents are married, and encourage mothers to include fathers in the next visit(s) and in the care of the child. In addition to the common caregiving tasks, each father makes different and unique contributions to the child-father relationship and to family functioning. Validating, nurturing, and capitalizing on the father's contributions to the child's well-being and to the parents' relationship are major goals for those involved in caring for children.

Despite new expectations, related responsibilities, and evidence-based knowledge (scientific studies) regarding fatherhood, many men still enter fatherhood with little idea of their new role and how it will affect their own lives. They may be unprepared for the challenges of fatherhood yet excited to take up the task. Some may lack role models or previous experience with caregiving responsibilities; others may fail to realize the importance of their involvement to their children and families. Consequently, fathers may or may not be motivated to learn. With appropriate encouragement and specific supports, however, many fathers may become avid, successful learners and providers. Pediatricians are perceived as ideal teachers, role models, moral authorities, and supporters of families in this stage of the family life cycle at which men become fathers.

Pediatricians are necessarily concerned with both the child's and family's well-being, knowing full well that families are the single greatest and most enduring influence on children. They are uniquely positioned to enhance the father's involvement, inform the family about the father's special influence on his children's development, and encourage the father to support the other parent. In so doing, pediatricians enhance and support the multiple roles of fathers in their child's development, the father-child relationship, and healthy family functioning and well-being.

GOALS

The goals of this clinical report are to:

1. Describe the socioeconomic forces that have changed society's expectations of fathers' roles;

2. Explain how fathers' interactions with their children uniquely influence their children's development; and
3. Offer pediatricians specific advice on:
   - How to help fathers increase their caregiving and involvement;
   - How to help fathers and mothers support each other's roles as parents; and
   - How to change their clinical styles and office practices to promote, support, and increase fathers' active involvement in their children's care and development.

THE INCREASING PRESENCE OF FATHERS IN THE LIVES OF CHILDREN: SOCIOECONOMIC FORCES

Pediatricians see more fathers today than they have in the past as more fathers in 2-parent families or in shared-custody arrangements are spending more time with their children and beginning to attend more office visits. This national trend has the potential to strengthen the father-child relationship, stimulate the child's development, ease the mother's or partner's workload, and strengthen the overall family functioning. Several factors contribute to this trend.

- The number of father-only households (no wife or partner in the home) increased almost 25% from 1995 to 1998, to 2.1 million households.[2] The 2000 US Census revealed father-only households increased to 4.3 million, or 4.2% of US households. In Illinois alone, the number of children living in father-only households increased by 109%, from 47 000 in 1985 to 98 000 in 1995.[3] Although the total number is small, the rate of change is significant. Additionally, father-only households seem to be headed by fathers who are highly involved in their children's lives at home and school.[4]
- Economic shifts over the past 30 years increasingly place women in the workplace, often in higher paying jobs than their male partners. Subsequently, many men spend more time at home taking care of their children. For example, most mothers prefer the father to be the child care provider if the mother cannot provide the care.[5] Additionally, married men are likely to be the primary caregivers of their children during the mother's working hours if the family is poor, if the father is unemployed or working part-time, or if the children are younger.[6]
- The average amount of time fathers in 2-parent families spend with their children, directly engaged or accessible, has increased in the last decade to 2.5 hours per weekday and 6.3 hours per weekend.[7]
- In divorced families, a plan for shared-custody arrangements developed by both parents during divorce proceedings increases opportunities for the father to be more involved in his children's care.
- Changing technology in the marketplace, telecommuting from home, and making use of flexible work hours provides more opportunities for fathers to spend more time with their children and families.
- The media and popular culture reflect and positively reinforce fathers' increased involvement in the care and development of their children. Father birthing classes have sprung up in hospitals across the country. General parent magazines, special magazines, Web sites, and newspapers (both paper and Web based) increasingly are targeted at fathers and champion men who have taken to the "daddy track." Many daily and Sunday newspapers feature comic strips based on fathers' involvement and good-hearted foibles at home. Several celebrities, Paul Reiser, Bill Cosby, and Al Roker included, have written books describing their experiences.[8–10] This media emphasis, coupled with cultural image changes and products such as infant-joggers and snugglies that encourage men's participation, reflect the growing trend of fathers caring for and interacting with their children. Meanwhile, scholarly works continue focusing attention on the role and importance of fathers in their children's social and emotional well-being.[11–19]

FATHERS' INFLUENCE ON THEIR CHILDREN'S DEVELOPMENT: SCIENTIFIC EVIDENCE

Fathers' interactions exert a powerful influence on every domain of their children's functioning beginning at infancy. Recent research substantiates how fathers impact their children's social, emotional, and cognitive development. For example, in the first few days of life, many newborn infants turn their heads preferentially to their father's voices versus the voice of a stranger.[20] Premature infants who experience increased visits from their fathers have improved weight gain during hospitalization and score higher during the first 18 months of life on adaptive-behavior and social-development tests, even after controlling for levels of prematurity and hospital stay.[21] In a study of premature black infants, the father's involvement enhanced the child's cognitive and behavioral outcomes.[22]

Mothers and fathers influence their children in similar ways with regard to development of morality, competence in social interactions, academic achievement, and mental health. However, father involvement is of a different nature than mother involvement. In terms of relative frequency, fathers devote more time to playing with their children than do mothers. When children are young (0-4 years old), fathers tend to engage in more tactile physical and stimulating activities. As children enter middle childhood (the school-aged years), fathers engage in more recreational activities such as walks and outings as well as private talks. Fathers also have a strong influence on their children's gender role development and are important role models for both girls and boys.[23,24]

The long-term effects of fathers' direct involvement in the care of their children manifest through childhood and adolescence. For children with a father figure, those who described greater father support had a stronger sense of social competence and fewer depressive symptoms.[25] Although time spent with children is usually less for fathers compared

with mothers, studies show that shared activities between fathers and their children are independently associated with improved academic performance.[7,26] Adolescents who perceive their fathers as encouraging and involved in their lives have higher college entrance examination scores, reach higher economic and educational attainment, show less delinquent behavior, and possess greater psychologic well-being.[27,28]

THE FATHER'S ROLE IN FAMILY FUNCTIONING

Fathers positively influence the behavior and relationships of the mother or other parent, siblings, and other family members. For example, fathers play an important role in the initiation, support, continuation, and ultimate ongoing success of breastfeeding.[29–35] Father involvement also stabilizes and promotes healthy family functioning. Fathers, as much as mothers, can and often do provide affection, nurturing, and comfort to their children. As teachers, disciplinarians, and role models, fathers assume some of the responsibility for teaching their children what they need to know for life-survival skills and for school learning. These lessons may come in the form of teaching about letters, numbers, and shapes; helping the school-aged child with homework; coaching the child in an athletic skill or hobby; teaching manners and social skills; and encouraging a healthy lifestyle. Rituals that involve special time with fathers, such as homework, play, sports activities, bathing routines, bedtime rituals, household chores, shopping, or reading together, also help strengthen the father-child bond. Such involvement may even prove to be protective. In families in which even mild levels of maternal depression exist, for example, a nurturing father-child relationship counteracts behavioral and interactional problems often associated with maternal depression.[36–38]

THE FATHER'S ROLE IN SUPPORTING THE OTHER PARENT IN THEIR RELATIONSHIP

The emotional support a father provides to the other parent helps in practical ways with the care of children. Parents who feel loved, appreciated, and supported as spouses or partners tend to parent with more demonstrations of love, approval, and support and communicate better with their children. Maintaining and nourishing the spousal or partner relationship helps improve the marriage and parenthood (eg, remembering special occasions, bestowing compliments, demonstrating affection, and taking time together as partners).[39–43] When parents are separated or unmarried, a positive, supportive relationship with the mother or other parent is an important predictor of children's successful adjustment to their family structure.

In general, mothers' support and encouragement of fathers is a key predictor of fathers' involvement with their children.[44,45] Mothers may actively oppose or quietly resist involvement or sharing household responsibilities for reasons of efficiency (things are done faster if she does it), quality (she does a better job), sympathy (not wanting to bother the father), admiration (he has done enough), anger (a by-product or after-effect of marital estrangement), or cultural beliefs in gender roles.[45] Thus, in some cases, fathers may desire more involvement, but mothers themselves may discourage greater paternal involvement. Mothers who feel supported themselves as mothers are more likely to support and encourage the father's involvement in the care of the child.

In families experiencing divorce, the relationships between father, mother, and children can become especially strained.[46] Divorce affects children's relationships with their parents and their sense of trust, acceptance, and support, creating feelings of loss and sadness.[47] The quality of the parents' pre- and post-divorce relationship plays a significant role in the child's emotional and social response and the father's involvement with his children. The quality of a father's parenting has been found to be inversely related to sibling conflict, adolescent depression, delinquent behavior, and affiliation with deviant peers.[48] Yet, there is a negative relationship between divorce and the quality of father's parenting; in other words, divorce can lead to less quality parenting by fathers, compounding the aforementioned problems.

There are situations, however, in which divorce can improve paternal involvement. In these situations, positive changes in the father-child bond are a result of increased opportunities to relate to the child in a conflict-free atmosphere.[49] Fathers may find themselves in the role of primary caregiver and, for the first time, engaging the health care system. Keeping both parents apprised of the child's health and involved in the child's life as well as keeping track of the emerging important adult figures in the child's life becomes part of the pediatrician's responsibilities.

THE PEDIATRICIAN'S ROLE

Many fathers want to be more involved in caring for their children. Pediatricians can help fathers learn to play a variety of roles in the family. Expanding on more than the stereotypical roles of the father as financial supporter and offering glimpses into the possibility and benefit of more roles for fathers suggests to the family that these roles are not in competition with those of mothers. In fact, these fathers' roles enhance and support mothers' roles. Furthermore, a father's additional roles serve to support the overall needs of the family and make parenthood more gratifying for both parents. Professionals caring for children need to be aware of these roles and of the greater social and cultural backdrops against which these roles may be played. A father from one family may be expected culturally to meet with the pediatrician and direct most conversations, and another father from a different culture may be expected to meet his child's pediatrician rarely or never. Given these family, social, and cultural variants, it is still largely true that pediatricians seldom get to know fathers as well as they do mothers.

Pediatricians usually see mothers and children in the office and may not be accustomed to or even comfortable with seeing fathers. Pediatricians can easily adapt their practices to accommodate fathers. The following advice will guide pediatricians in en-

couraging a father's involvement and participation in office visits by letting him know he is welcome in the office and the health care system more generally. Pediatricians are encouraged to make special efforts to engage fathers who are separated from the family.

Pediatricians who understand parental expectations and the family's cultural traditions and values and who respectfully explore and encourage the father-child relationship in pediatric visits are more likely to form a good rapport with fathers and make them feel welcome, which in turn conveys to fathers that they are important to their child's development and encourages them to be more active in the care and activities of their children. Encouragement from the child's advocate, the pediatrician, is a powerful message to fathers about their expanded and critical roles in their children's lives.

In this report we have explained some of the socioeconomic factors that place fathers in a changing, often more prominent position in the care and development of their children and in their support of the spousal or partner relationship. Compelling recent evidence reveals that fathers' involvement with their children will continue to increase as more women enter the workforce and men seek greater involvement at home. Pediatricians are uniquely qualified and placed to help fathers by encouragement, by practical advice, and by educating men, women, and their families about the benefits of positive father involvement for 1) the care and development of their children, 2) the other parent's well-being, and 3) healthy family functioning.

ADVICE FOR PEDIATRICIANS

Make Your Practice More Father-Friendly

1. Offer flexible and extended office hours (eg, late afternoons, evenings, weekends, and early mornings) to accommodate parents and encourage their attendance.
2. Actively encourage fathers to come in for at least one of the initial well-infant or acute-illness visits in the infant's first 2 months of life and more if possible.
3. Welcome fathers and express appreciation for their attendance. Speak directly to the father as well as the mother or partner and solicit his opinions. Encourage office staff and nurses to include fathers in the office-visit appointment.
4. Introduce yourself to the father and the mother or other parent. Politely explore the father's relationship to the other parent (eg, married, living together), his cultural traditions, and his own personal beliefs about his role in caring for the child. Assess differences in parenting beliefs and help them negotiate if necessary.
5. Learn something about the father's role and beliefs (eg, how he was parented, expectations and hopes for his children, his previous marriages, other children and how he parented them). Keep the discussions focused on the parenting context and the father's roles and beliefs; minimize small talk.
6. Actively engage the father in the office. For example, tell the father: "As your child's pediatrician, I want to know you and work with you and your child's [mother or other parent] to offer the best care for your child."
7. If the father is not involved in the dialogue, address him directly, asking him if he has specific questions or concerns. Solicit his opinions about child rearing, sharing responsibilities, and his perceived roles. Ask each parent about his or her transition to parenthood. For example, ask: "How is parenting going for each of you?"
8. Ask the parents how they support each other as parents, spouses or partners, and individuals.
9. Recognize that mothers and fathers may not always agree on how best to raise a child. For example, parents may disagree on the approach to discipline or issues of firearm safety. Pediatricians can serve as a mediator in such discussions, meeting with both parents or caregivers together to discuss these and other behavior-management issues and should avoid (whenever possible) siding with one parent or the other on important parenting issues.
10. Participate in educational opportunities (eg, courses, continuing medical education activities, medical literature) devoted to fathers' role issues, parental depression, and family functioning to enhance training and education in this area.

Understand the Family

1. Explore the family composition, cultural beliefs, overall mental and physical health, and delegation and discussions of child care tasks within the family. If parents are not both in the household, discuss living and custody arrangements as well.
2. In addition to discussing the feelings of joy and fulfillment having a child can bring, also be prepared to discuss issues of the allocation of child and sibling care and the common experiences that siblings and parents encounter with conflict, jealousy, and normal disappointments in connection with the arrival of a new infant.
3. Be sensitive to and informed about diverse cultural and ethnic values and customs, especially "traditional" father roles. Pediatricians can determine the extent of the father's responsibilities and presence at home by respectfully exploring these issues with parents.
4. Use a "parenting history" to help parents understand their behaviors by understanding how they themselves were parented. Parents often adopt a parenting style to compensate for their own childhood deficiencies or to emulate childhood experiences depending on their own parenting experiences.
5. Discuss how the couple is adapting to parenthood (with each child). Asking questions such as "How is your relationship (or the family) adjusting to the new infant?" or "How is it living with a teenager?" opens the door to reflection and discussion and can remind parents of the importance of their own partner relationship and the need to nurture and maintain it. Encourage parents to continue to dedicate time for adult activities without children.

Empower, Engage, and Inform Fathers of the Importance of Their Involvement

1. Remind the family that fathers are not only workers or breadwinners and mothers or partners are not only nurturers or primary providers of child care. They share these roles, complementing one another, often to the benefit of the child.
2. As early as in the delivery room or nursery and if culturally appropriate, fathers can be given responsibilities for caring for and making decisions regarding the child.
3. Encourage fathers to assume some roles in the care of the child, and encourage the mother to let the father be involved and learn from his own mistakes. Early time alone with the child helps a father gain confidence and develop his own style of interaction and provides a mother or other parent with much-needed time alone.
4. Determine how comfortable the father is with his parenting skills and whether he has concerns.
5. Explore with the father ways to decrease maternal stress. This might include his helping with meals or household chores, the involvement of other family members with household tasks, or the hiring of household help.
6. Identify institutions and policies that facilitate fathers' involvement and work-family balance. Encourage child care centers, support groups, and schools to involve and include fathers. Promote the use of policies such as the Family Medical Leave Act (codified at 29 CFR §825 [1993]) and flexible work schedules as ways to balance employment and family responsibilities.

Reinforce the Father's Support of the Mother or Partner

1. Inform the family about the normal elation, fatigue, and challenges of being a father. Discuss openly the usual interruptions in sleep for the whole family, the decreases in energy, the alterations in time together as a couple and individual free time, and the changes in intimacy and the sexual relationship. This may be the first time some fathers will have discussed these issues openly.
2. Look for signs of maternal depression (postpartum depression in the newborn period) and be able to offer resources to help.
3. Explore marital stress and inquire about the marriage or partner relationship. For example, you may ask: "How has the birth of this infant affected your relationship?"; "To whom do you turn for advice and support?"; and/or "Would you like a referral to talk to someone else who can help (individual or couples therapy and/or medication)?"
4. Educate fathers about the practicalities of breastfeeding and how to support mothers' nursing.
5. Encourage fathers to provide or protect time for mothers to have time to be alone, exercise, meet friends, or simply relax.

Guidance for the Clinician in Rendering Pediatric Care

Clinical Report—Fever and Antipyretic Use in Children

abstract

Fever in a child is one of the most common clinical symptoms managed by pediatricians and other health care providers and a frequent cause of parental concern. Many parents administer antipyretics even when there is minimal or no fever, because they are concerned that the child must maintain a "normal" temperature. Fever, however, is not the primary illness but is a physiologic mechanism that has beneficial effects in fighting infection. There is no evidence that fever itself worsens the course of an illness or that it causes long-term neurologic complications. Thus, the primary goal of treating the febrile child should be to improve the child's overall comfort rather than focus on the normalization of body temperature. When counseling the parents or caregivers of a febrile child, the general well-being of the child, the importance of monitoring activity, observing for signs of serious illness, encouraging appropriate fluid intake, and the safe storage of antipyretics should be emphasized. Current evidence suggests that there is no substantial difference in the safety and effectiveness of acetaminophen and ibuprofen in the care of a generally healthy child with fever. There is evidence that combining these 2 products is more effective than the use of a single agent alone; however, there are concerns that combined treatment may be more complicated and contribute to the unsafe use of these drugs. Pediatricians should also promote patient safety by advocating for simplified formulations, dosing instructions, and dosing devices. *Pediatrics* 2011;127:580–587

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

INTRODUCTION

Fever is one of the most common clinical symptoms managed by pediatricians and other health care providers and accounts, by some estimates, for one-third of all presenting conditions in children.[1] Fever in a child commonly leads to unscheduled physician visits, telephone calls by parents to their child's physician for advice on fever control, and the wide use of over-the-counter antipyretics.

Parents are frequently concerned with the need to maintain a "normal" temperature in their ill child. Many parents administer antipyretics even though there is either minimal or no fever.[2] Approximately one-half of parents consider a temperature of less than 38°C (100.4°F) to be a fever, and 25% of caregivers would give antipyretics for temperatures of less than 37.8°C (100°F).[1,3] Furthermore, 85% of parents (n = 340) reported awakening their child from sleep to give antipyretics.[1] Unfortunately, as many as one-half of parents administer incorrect doses of antipyretics; approximately 15% of parents give supratherapeutic doses of acetaminophen or ibuprofen.[4] Caregivers who under-

stand that dosing should be based on weight rather than age or height of fever are much less likely to give an incorrect dose.[4]

Physicians and nurses are the primary source of information on fever management for parents and caregivers, although there are some disparities between the views of parents and physicians regarding antipyretic treatment.[1] The most common indications for initiating antipyretic therapy by pediatricians are a temperature higher than 38.3°C (101°F) and improving the child's overall comfort.[5] Although only 13% of pediatricians specifically cite discomfort as the primary indication for antipyretic use,[6] this intent is generally implied in their recommendations. Most pediatricians (80%) believe that a sleeping ill child should not be awakened solely to be given antipyretics.[5]

Antipyretic therapy will remain a common practice by parents and is generally encouraged and supported by pediatricians. Thus, pediatricians and health care providers are responsible for the appropriate counseling of parents and other caregivers about fever and the use of antipyretics.[7]

PHYSIOLOGY OF FEVER

It should be emphasized that fever is not an illness but is, in fact, a physiologic mechanism that has beneficial effects in fighting infection.[8–10] Fever retards the growth and reproduction of bacteria and viruses, enhances neutrophil production and T-lymphocyte proliferation, and aids in the body's acute-phase reaction.[11–14] The degree of fever does not always correlate with the severity of illness. Most fevers are of short duration, are benign, and may actually protect the host.[15] Data show beneficial effects on certain components of the immune system in fever, and limited data have revealed that fever actually helps the body recover more quickly from viral infections, although the fever may result in discomfort in children.[11,16–18] Evidence is inconclusive as to whether treating with antipyretics, particularly ibuprofen alone or in combination with acetaminophen, increases the risks of complications with certain types of infections.[19,20] Potential benefits of fever reduction include relief of patient discomfort and reduction of insensible water loss, which may decrease the occurrence of dehydration. Risks of lowering fever include delayed identification of the underlying diagnosis and initiation of appropriate treatment and drug toxicity.

There is no evidence that children with fever, as opposed to hyperthermia, are at increased risk of adverse outcomes such as brain damage.[7,9,21–23] Fever is a common and normal physiologic response that results in an increase in the hypothalamic "set point" in response to endogenous and exogenous pyrogens.[9,23] In contrast, hyperthermia is a rare and pathophysiologic response with failure of normal homeostasis (no change in the hypothalamic set point) that results in heat production that exceeds the capability to dissipate heat.[9,23] Characteristics of hyperthermia include hot, dry skin and central nervous system dysfunction that results in delirium, convulsions, or coma.[23] Hyperthermia should be addressed promptly, because at temperatures above 41°C to 42°C, adverse physiologic effects begin to occur.[7,9,24] Studies of health care workers, including physicians, have revealed that most believe that the risk of heat-related adverse outcomes is increased with temperatures above 40°C (104°F), although this belief is not justified.[5,23,25–27] A child with a temperature of 40°C (104°F) attributable to a simple febrile illness is quite different from a child with a temperature of 40°C (104°F) attributable to heat stroke. Thus, extrapolating similar outcomes from these different illnesses is problematic.

TREATMENT GOALS

A discussion of the use of antipyretics in febrile children must begin with consideration of the therapeutic end points. When counseling families, physicians should emphasize the child's comfort and signs of serious illness rather than emphasizing normothermia. A primary goal of treating the febrile child should be to improve the child's overall comfort. Most pediatricians observe, with some supporting data from research, that febrile children have altered activity, sleep, and behavior in addition to decreased oral intake.[28] Unfortunately, there is a paucity of clinical research addressing the extent to which antipyretics improve discomfort associated with fever or illness. It is not clear whether comfort improves with a normalized temperature, because external cooling measures, such as tepid sponge baths, can lower the body temperature without improving comfort.[7,29] The use of alcohol baths is not an appropriate cooling method, because there have been reported adverse events associated with systemic absorption of alcohol.[30] Furthermore, antipyretics have other clinical outcomes, including analgesia, which may enhance their overall clinical effect. Regardless of the exact mechanism of action, many physicians continue to encourage the use of antipyretics with the belief that most of the benefits are the result of improved comfort and the accompanying improvements in activity and feeding, less irritability, and a more reliable sense of the child's overall clinical condition. Because these are the most important benefits of antipyretic therapy, it is of paramount importance that parental counseling focus on monitoring of activity, observing for signs of seri-

ous illness, and appropriate fluid intake to maintain hydration.

The desire to improve the overall comfort of the febrile child must be balanced against the desire to simply lower the body temperature. It is well documented that there are significant concerns on the part of parents, nurses, and physicians about potential adverse effects of fever that have led to a description in the literature of "fever phobia."[31] The most consistently identified serious concern of caregivers and health care providers is that high fevers, if left untreated, are associated with seizures, brain damage, and death.[1,25,32,33] It is argued that by creating undue concern over these presumed risks of fever, for which there is no clearly established relationship, physicians are promoting an exaggerated desire in parents to achieve normothermia by aggressively treating fever in their children.

There is no evidence that reducing fever reduces morbidity or mortality from a febrile illness. Possible exceptions to this could be children with underlying chronic diseases that may result in limited metabolic reserves or children who are critically ill, because these children may not tolerate the increased metabolic demands of fever.[34] Finally, there is no evidence that antipyretic therapy decreases the recurrence of febrile seizures.[22,35,36]

Despite insufficient evidence, many pediatricians recommend the routine practice of pretreatment with acetaminophen or ibuprofen before a patient receives immunizations to decrease the discomfort associated with the injections and subsequently at the injection sites and to minimize the febrile response.[9,17,37–39] In addition, results of 1 recent study suggested the possibility of decreased immune response to vaccines in patients treated early with antipyretics.[40]

Although the available literature is limited on the actual risks of fever and the benefits of antipyretic therapy, it is recognized that improvement in patient comfort is a reasonable therapeutic objective. Furthermore, at this time, there is no evidence that temperature reduction, in and of itself, should be the primary goal of antipyretic therapy.

Acetaminophen

After sufficient evidence emerged of an association between salicylates and Reye syndrome, acetaminophen essentially replaced aspirin as the primary treatment of fever. Acetaminophen doses of 10 to 15 mg/kg per dose given every 4 to 6 hours orally are generally regarded as safe and effective. Typically, the onset of an antipyretic effect is within 30 to 60 minutes; approximately 80% of children will experience a decreased temperature within that time (Table 1).

Although alternative dosing regimens have been suggested,[41–43] no consistent evidence has indicated that the use of an initial loading dose by either the oral (30 mg/kg per dose) or rectal (40 mg/kg per dose) route improves antipyretic efficacy. The higher rectal dose is often used in intraoperative conditions but cannot be recommended for use in routine clinical care.[44,45] The use of higher loading doses in clinical practice would add potential risks for dosing confusion leading to hepatotoxicity; therefore, such doses are not recommended.

Although hepatotoxicity with acetaminophen at recommended doses has been reported rarely, hepatoxicity is most commonly seen in the setting of an acute overdose. In addition, there is significant concern over the possibility of acetaminophen-related hepatitis in the setting of a chronic overdose. The most commonly reported scenarios are those of children receiving multiple supratherapeutic doses (ie, >15 mg/kg per dose) or frequent administration of appropriate single doses at intervals of less than 4 hours, which has resulted in doses of more than 90 mg/kg per day for several days.[46,47] Giving an adult preparation of acetaminophen to a child may result in supratherapeutic dosing. In 1 case series,[46] half of the children with hepatotoxicity had received adult preparations of acetaminophen.

One safety concern is the effect of acetaminophen on asthma-related symptoms; although asthma has also been associated with acetaminophen use, causality has not been demonstrated.[48–51]

Ibuprofen

The use of ibuprofen to manage fever has been increasing, because it seems to have a longer clinical effect related to lowering of the body temperature

TABLE 1 Antipyretic Information

Variable	Acetaminophen	Ibuprofen
Decline in temperature, °C	1–2	1–2
Time to onset, h	<1	<1
Time to peak effect, h	3–4	3–4
Duration of effect, h	4–6	6–8
Dose, mg/kg	10–15 every 4 h	10 every 6 h
Maximum daily dose, mg/kg	90 mg/kg[a]	40 mg/kg
Maximum daily adult dose, g/d	4	2.4
Lower age limit, mo[b]	3	6

Data represent approximate averages from referenced sources.[42,43,52,54,71,82]

[a] Label is for 75 mg/kg; 90 mg/kg per day should be limited to less than 3 consecutive days.[83–85]

[b] Unless specifically recommended by a health care provider for the younger patient and, then, only after the infant has been examined by a health care provider.

(Table 1). Studies in which the effectiveness of ibuprofen and acetaminophen were compared have yielded variable results; the consensus is that both drugs are more effective than placebo in reducing fever and that ibuprofen (10 mg/kg per dose) is at least as effective as, and perhaps more effective than, acetaminophen (15 mg/kg per dose) in lowering body temperature when either drug is given as a single or repetitive dose.[52–57] Data also show that the height of the fever and the age of the child (rather than the specific medication used) may be the primary determinants of the efficacy of antipyretic therapy; those who have a higher fever and are older than 6 years show decreased efficacy or response to antipyretic therapy.[54] Studies that compare the effect of ibuprofen versus acetaminophen on children's behavior and comfort are generally lacking.

There is no evidence to indicate that there is a significant difference in the safety of standard doses of ibuprofen versus acetaminophen in generally healthy children between 6 months and 12 years of age with febrile illnesses.[58] Similar to other nonsteroidal anti-inflammatory drugs (NSAIDs), ibuprofen can potentially cause gastritis,[59,60] although no data suggest that this is a common occurrence when used on an acute basis, such as during a febrile illness.[58] However, there have been case reports of bleeding, gastritis, and ulcers of the stomach, duodenum, and esophagus associated with many NSAIDs, including ibuprofen, even when used in typical antipyretic and analgesic doses.[59,60] Ibuprofen does not seem to worsen asthma symptoms.

Concern has been raised over the nephrotoxicity of ibuprofen. In numerous case reports, children with febrile illnesses developed renal insufficiency when treated with ibuprofen or other NSAIDs. Thus, caution is encouraged when using ibuprofen in children with dehydration or with complex medical illnesses.[61–63] In children with dehydration, prostaglandin synthesis becomes an increasingly important mechanism for maintaining appropriate renal blood flow. The use of ibuprofen or any NSAID interferes with the renal effects of prostaglandins, which reduces renal blood flow and potentially precipitates or worsens renal dysfunction.[61,63] However, it is not possible to determine the actual incidence of ibuprofen-related renal insufficiency after short-term use, because it has not been systematically investigated or reported.[64] Children who are at greatest risk of ibuprofen-related renal toxicity are those with dehydration, cardiovascular disease, preexisting renal disease, or the concomitant use of other nephrotoxic agents.[62] Another potential group at risk is infants younger than 6 months because of the possibility of differences in ibuprofen pharmacokinetics and developmental differences in renal function.[65] Data are inadequate to support a specific recommendation for the use of ibuprofen for fever or pain in infants younger than 6 months (there are dosing data for neonatal closure of patent ductus arteriosus[66,67]), although the package insert states to "ask a doctor" for guidance on its use in this population. Another potential risk associated with the use of ibuprofen is the possible association between ibuprofen and varicella-related invasive group A streptococcal infection.[68,69] However, at the time of this report, data were insufficient to support a causal relationship between ibuprofen and invasive group A streptococcal disease.

Alternating or Combination Therapy

A practice frequently used to control fever is the alternating or combined use of acetaminophen and ibuprofen. In a convenience sample survey of 256 parents or caregivers, 67% reported alternating acetaminophen and ibuprofen for fever control, 81% of whom stated that they had followed the advice of their health care provider or pediatrician.[70] Although 4 hours was the most frequent interval, parents reported alternating therapy every 2, 3, 4, and 6 hours, which suggests that there is no consensus on dosing instructions.

At the time of this report, 5 studies had been identified that compared alternating ibuprofen and acetaminophen versus either acetaminophen or ibuprofen as single agents.[71–75] Initially, changes in temperature were similar for all groups in these studies, regardless of therapy. However, 4 or more hours after the initiation of treatment, lower temperature was consistently observed in the combination-treatment groups. For example, 6 and 8 hours after the initiation of the study, a greater percentage of children were afebrile in the combination group (83% and 81%, respectively) compared with those in the group that received ibuprofen alone (58% and 35%, respectively).[71] Only 1 study[72] evaluated issues related to stress and comfort and found lower stress scores and less time missed from child care in the combination-treatment group. Another study[73] showed a trend toward a normalization of fever-related symptoms by 24 and 48 hours after institution of therapy, but these trends disappeared by day 5.

Although the aforementioned studies provide some evidence that combination therapy may be more effective at lowering temperature, questions remain regarding the safety of this practice as well as the effectiveness in improving discomfort, which is the primary treatment end point. The possibility that parents will either not receive or not understand dosing instructions, combined with the wide array of formulations that contain

these drugs, increases the potential for inaccurate dosing or overdosing.[76,77] Finally, this practice may only promote the fever phobia that already exists.

Although there is some evidence that combination therapy may result in a lower body temperature for a greater period of time, there is no evidence that combination therapy results in overall improvement in other clinical outcomes. Also, these studies have not contained adequate numbers of subjects to fully evaluate the safety of this practice. Therefore, there is insufficient evidence to support or refute the routine use of combination treatment with both acetaminophen and ibuprofen. Practitioners who choose to follow this practice should counsel parents carefully regarding proper formulation, dosing, and dosing intervals and emphasize the child's comfort instead of reduction of fever.

INSTRUCTIONS FOR CAREGIVERS

It is critically important for pediatricians to clearly describe the appropriate use (ie, formulation, dose, and dosing interval) of acetaminophen and ibuprofen to caregivers (Table 1). Child safety will be further enhanced by clear labeling and the development of simplified dosing methods, standardized drug concentrations, and standardized delivery devices.[78–80] Cough-and-cold products that contain acetaminophen and ibuprofen should not be given to children because of the possibility that parents may unintentionally give their child simultaneous doses of an antipyretic and a cough-and-cold medication that contains the same antipyretic. In addition, there is a lack of proven efficacy for this class of combination products for children. For children who require liquid preparations, physicians should encourage families to only use 1 formulation. Acetaminophen is the most common single ingredient implicated in emergency department visits for medication overdoses among children, and more than 80% of these emergency visits are a result of unsupervised ingestions[81]; therefore, proper handling and storage of antipyretics should be encouraged.

SUMMARY

Appropriate counseling on the management of fever begins by helping parents understand that fever, in and of itself, is not known to endanger a generally healthy child. In contrast, fever may actually be of benefit; thus, the real goal of antipyretic therapy is not simply to normalize body temperature but to improve the overall comfort and well-being of the child. Acetaminophen and ibuprofen, when used in appropriate doses, are generally regarded as safe and effective agents in most clinical situations. However, as with all drugs, they should be used judiciously to minimize the risk of adverse drug effects and toxicity. Combination therapy with acetaminophen and ibuprofen may place infants and children at increased risk because of dosing errors and adverse outcomes, and these potential risks must be carefully considered. When counseling a family on the management of fever in a child, pediatricians and other health care providers should minimize fever phobia and emphasize that antipyretic use does not prevent febrile seizures. Pediatricians should focus instead on monitoring for signs/symptoms of serious illness, improving the child's comfort by maintaining hydration, and educating parents on the appropriate use, dosing, and safe storage of antipyretics. To promote child safety, pediatricians should advocate for a limited number of formulations of acetaminophen and ibuprofen and for clear labeling of dosing instructions and an included dosing device for antipyretic products.

American Academy of Pediatrics
DEDICATED TO THE HEALTH OF ALL CHILDREN™

POLICY STATEMENT

Financing Graduate Medical Education to Meet the Needs of Children and the Future Pediatrician Workforce

Organizational Principles to Guide and Define the Child Health Care System and/or Improve the Health of All Children

Committee on Pediatric Workforce

ABSTRACT

This policy statement articulates the positions of the American Academy of Pediatrics on graduate medical education and the associated costs and funding mechanisms. It reaffirms the policy of the American Academy of Pediatrics that graduate medical education is a public good and is an essential part of maintaining a high-quality physician workforce. The American Academy of Pediatrics advocates for lifelong learning across the continuum of medical education. This policy statement focuses on the financing of one component of this continuum, namely residency education. The statement calls on federal and state governments to continue their support of residency education and advocates for stable means of funding such as the establishment of an all-payer graduate medical education trust fund. It further proposes a portable authorization system that would allocate graduate medical education funds for direct medical education costs to accredited residency programs on the basis of the selection of the program by qualified student or residents. This system allows the funding to follow the residents to their program. Recognizing the critical workforce needs of many pediatric medical subspecialties, pediatric surgical specialties, and other pediatric specialty disciplines, this statement maintains that subspecialty fellowship training and general pediatrics research fellowship training should receive adequate support from the graduate medical education financing system, including funding from the National Institutes of Health and other federal agencies, as appropriate. Furthermore, residency education that is provided in freestanding children's hospitals should receive a level of support equivalent to that of other teaching hospitals. The financing of graduate medical education is an important and effective tool to ensure that the future pediatrician workforce can provide optimal heath care for infants, children, adolescents, and young adults.

GRADUATE MEDICAL EDUCATION (GME) AS A PUBLIC GOOD

To assure the American public of the competence of its physicians, the path to independent practice of aspiring physicians is a long and arduous one. After graduation from college, a medical student will spend 4 years in medical school, of which approximately 2 years are spent in patient-care settings under close supervision by faculty. After receiving their medical degrees, pediatricians spend an additional 3 to 6 years in residency and subspecialty fellowship training (collectively referred to as graduate medical education [GME]). Pediatricians, thus, spend up to 10 years in medical training to be eligible for board certification in their field. Pediatric surgical specialists likewise spend 5 to 7 years in residency and an additional 1 to 3 years in postgraduate surgical training before entering practice. During GME, these physicians provide essential health care services under supervision and thus facilitate access to care for children.

Residency or GME has been accepted by our society as an essential part of maintaining a high-quality physician workforce.[1] After earning a medical degree, US physicians are required by law in every state to complete an additional 1 to 3 years of GME before receiving a license to practice medicine.[2] This demanding educational process is unique to the medical profession.

Resident physicians provide valuable medical services, frequently to underserved populations and to patients with complex illnesses, under the supervision of experienced physicians. Thus, GME is a public good that ensures the sustained availability of highly skilled physicians and directly provides essential clinical services rendered by resident physicians.

There are many costs associated with GME. Direct costs include salaries and benefits, as well as the overhead costs

of practice for the resident physician, such as licensing fees, medical liability insurance, clinical facility expenses, such as utilities and maintenance, and administrative costs. Because residents must be under supervision for their education, there is also the expense of faculty time for education and supervision. Finally, because they are medical school graduates providing valued health care services, residents also receive salary and fringe benefits, although at a fraction of the income of physicians in independent practice.

In addition, the sponsoring institution incurs indirect costs of training residents. Residents may be less efficient and may perform more diagnostic testing, additional procedures, and require more staff support. Residents, often located at tertiary care centers, may also care for more complex patients. Leaders in managed care believe that services at teaching hospitals cost 5% to 10% more than those at nonteaching hospitals.[3] Thus, for almost 4 decades, the US government has explicitly funded GME, primarily through the Medicare and Medicaid programs.

GRADUATE MEDICAL EDUCATION (GME) AND THE MEDICARE TRUST FUND

GME financing has become a major issue for both Medicare reform and the physician workforce. Medicare is the major explicit financier of GME[4] and related activities in the United States, making payments of more than $8.5 billion each year to teaching hospitals. By virtue of their nonelderly patient populations, freestanding children's hospitals do not receive significant reimbursements from Medicare. However, because 70% of pediatric residents are trained outside of freestanding children's hospitals, Medicare still has the major role in financing pediatric residency training, and its policies on financing for GME, therefore, significantly influence the overall workforce in pediatrics.

Before the enactment of Medicare, GME programs were funded primarily by the sponsoring teaching hospital through patient-care revenues. With the passage of Medicare in 1965, teaching hospitals received pass-through from Part A for the costs of GME, including resident salaries, benefits, and overhead, which are now referred to as direct GME (DGME) payments. In 1965, Congress recognized that hospitals with educational activities enhanced the quality of care offered and that the cost of this education should be borne by society. In the reports accompanying the Medicare legislation, Congress declared[5]:

> Educational activities enhance the quality of care in an institution, and it is intended, until the community undertakes to bear such education costs in some other way, that a part of the net cost of such activities (including stipends of trainees, as well as compensation of teachers and other costs) should be borne to an appropriate extent by the hospital insurance program.

With the implementation of the Medicare diagnosis-related groups (DRG) payment system in 1983, teaching hospitals were given an adjustment factor to their reimbursement rate on the basis of their resident-to-bed ratio.[6] Congress described the purpose of the indirect medical education (IME) adjustment as follows:

> This adjustment is provided in light of doubts . . . about the ability of the DRG case classification system to account fully for factors such as severity of illness of patients, requiring the specialized services and treatment programs provided by teaching institutions and the additional costs associated with the teaching of residents . . . The adjustment for indirect medical education costs is only a proxy to account for a number of factors that may legitimately increase costs in teaching hospitals.[7,8]

In 2001, DGME payments were approximately $3 billion, and in fiscal year 2006, Medicare IME payments were estimated at approximately $5.6 billion. Congress has reduced the IME adjustment several times since its inception, with the most recent prescribed cuts occurring as part of the Medicare Modernization Act of 2003.[9]

There are several important consequences of Medicare's primary role in GME. First, Medicare subsidizes GME as part of the expense of caring for Medicare patients. Thus, freestanding children's hospitals (technically referred to as "Medicare prospective payment system-exempt" hospitals) received, on average, only approximately $374 per resident from Medicare in fiscal year 1997, because they care for very few Medicare patients; predominantly pediatric end-stage renal disease patients. These hospitals must seek other sources of funding for their GME programs. However, many pediatric residents train in general hospitals that receive both DGME and IME payments for these residents; thus, Medicare's GME policies still have a major effect on pediatric residency education. Second, Medicare Part A pays for hospital services. Medicare payment for associated GME costs, therefore, is based on hospital-based services provided by residents. Thus, these reimbursement policies are a major financial disincentive for resident education in nonhospital settings. The Balanced Budget Act of 1997 (BBA) allowed hospitals to count residents in nonhospital settings in determining the IME if the hospital substantially incurs all of the cost of training in that setting[10]; however, it is not clear that this change has increased ambulatory care training. Finally, Medicare provides GME support to any hospital with an accredited residency program. For years, this entitlement created a tremendous financial incentive for hospitals to increase the number of residency positions to increase Medicare reimbursement rates and to benefit from the clinical services provided by the residents. Increasingly fewer resident positions have gone unfilled during the past decade because of the high demand for residency positions in the United States by international medical graduates. Historically, Medicare's GME financing policies constituted an open-ended federal subsidy, although in 1997 Congress also placed a cap on the number of residency positions that Medicare would fund at each hospital. This cap has not only limited the growth of GME positions in the country but also frozen the geographic distribution of GME positions since its implementation. In 2005, the Centers for Medicare and Medicaid Services, authorized by the Medicare Modernization Act of 2003, made a one-time redistribution of resident slots. Hospitals that did not fill all of their resident slots under their BBA cap relinquished them to a subset of those hospitals that

had more resident slots than their BBA cap permitted to be eligible for Medicare GME reimbursement.

The nation's system of GME financing has a tremendous impact on the pediatric workforce and the education of future pediatricians.

CHILDREN'S HOSPITAL GRADUATE MEDICAL EDUCATION PAYMENT PROGRAM (CHGME PP)

The Children's Hospital Graduate Medical Education Payment Program (CHGME PP) was authorized for 2 years by the Health Research and Quality Act of 1999[11] and reauthorized for 4 more years by the Child Health Act of 2000.[12] The program helps Medicare prospective payment system (PPS)-exempt children's hospitals, which, because of their low Medicare patient volume, do not receive significant Medicare GME payments. Only Medicare PPS-exempt children's hospitals that have their own Medicare provider number are eligible for the program.

With enactment of this legislation, Congress recognized that, until comprehensive GME financing reform occurs, CHGME PP funding is essential to provide Medicare PPS-exempt children's hospitals a level of federal GME support equivalent to the Medicare GME support provided to all teaching hospitals. Without it, in today's health care market, Medicare-PPS children's hospitals, which train nearly 30% of all pediatricians, nearly 50% of all pediatric subspecialists, and the majority of pediatric research scientists, would be at significant risk, which would jeopardize the nation's future pediatric workforce.

The Health Resources and Services Administration administers the CHGME PP. It makes DGME and IME payments to ~60 eligible children's hospitals during the federal fiscal year. Congress authorized one third of the funding to go toward DGME payments and the remaining two thirds to go toward IME payments. The DGME payment is based on a standardized national average per resident amount and the average number of Medicare-weighted.* full-time equivalent residents, subject to the resident cap and rolling average established under the BBA. The IME payment varies by hospital, depending on the number of Medicare-unweighted full-time equivalent residents, the area-wage index of the metropolitan area in which the hospital is located, the complexity of its patient population, the volume of patients, the number of Medicare-approved beds, and its teaching intensity.

Unlike Medicare GME funding, Congress must appropriate funds annually for the CHGME PP. From fiscal year 2002 to fiscal year 2004, Congress fully funded the CHGME PP; however, cuts were made in subsequent years. Congress appropriated $303 million for the CHGME PP in fiscal year 2004, $301 million in fiscal year 2005, and $297 million in fiscal year 2006. Given the duration of residency training, the uncertainty of CHGME PP funding levels from year to year is highly problematic.

*When determining the number of full-time-equivalent (FTE) residents for GME funding purposes, Medicare-weighted resident FTEs count residents beyond their initial residency period (i.e. fellows) as 0.5 FTE per current Medicare rules. For Medicare-unweighted counts, all residents (including fellows) are counted equally as 1 FTE.

OTHER SOURCES OF GME FUNDING

Medicaid

Although Medicare is by far the largest explicit national funder of GME, there are other major sources of GME financing. In 2005, Medicaid provided approximately $3.2 billion for GME-related expenses; however, the amount varies widely from state to state and policies for GME use are highly variable. In 2005, 47 states and the District of Columbia paid for GME at some level out of Medicaid funds. Under state budgeting pressures and rising Medicaid costs as of 2005, 4 of these states have decreased the amount of Medicaid funding for GME, and 6 have considered eliminating Medicaid funding for GME altogether. In addition, an increasing number of states are linking Medicaid GME funds to state policy goals regarding the distribution of the health care workforce. It has even been proposed that the federal government not provide Medicaid funds to states for GME.

In total, 46 states and the District of Columbia contributed to GME through their Medicaid fee-for-service programs in 2005. Thirty-one of the states that paid for GME under fee-for-service programs did so through hospital per-case or per-diem rates. Of the 35 states and the District of Columbia that reported capitated Medicaid arrangements, 14 made explicit Medicaid GME payments to teaching hospitals or teaching programs; 10 others included the payments by incorporating them into the capitated rates negotiated in Medicaid managed care contracts with teaching hospitals.[13]

Title VII Programs

Training Grants in Primary Care Medicine and Dentistry, a provision of Title VII of the Public Health Service Act, provide the authority and funding for faculty development, academic administrative units, predoctoral training, and intensive primary care training for residents in diverse ambulatory settings. Title VII helps fund residency education in general pediatrics, internal medicine, and family practice, but this funding was cut by $154.3 million in 2006.

Additional Federal Sources for GME Funding

A number of federal agencies sponsor residency training opportunities and funding outside the normal mechanisms of Medicare, Medicaid, Title VII, and the Children's Hospital GME Payment Program. The National Institutes of Health (NIH), for example, sponsors a limited number of subspecialty training positions, and through research grants, provides funding for some resident research activities. In addition to clinical areas of expertise, the NIH's National Library of Medicine offers predoctoral and postdoctoral research training in biomedical informatics, as well as support for librarians, scientists, health professionals, and others who wish to obtain cross-training to become in-context information specialists. The Agency for Health Care Research and Quality likewise offers a variety of training programs to support predoctoral work. Finally, the Maternal and Child Health Bureau operates a comprehensive program of training opportunities through its MCH Training Pro-

gram, which funds public and private nonprofit institutions of higher learning to provide leadership training in maternal and child health. Although this is not a comprehensive list of training opportunities, it serves to demonstrate the breadth of experiences offered through a number of less well-known federal programs.

Private or Industry-Sponsored GME Funding

More recently, pharmaceutical and medical device companies have supported a few GME positions in particular specialties. In 2006, a program to fund additional dermatology GME positions with funds from both the specialty society and pharmaceutical companies was announced. The program was withdrawn when concerns were raised about the potential influence of industry on residents. The Accreditation Council for Continuing Medical Education (ACCME) has developed and revised Standards of Commercial Support and has grappled with many of the same issues that GME is starting to face.[14] The experiences gleaned from the continuing medical education community can be applied to GME policy development pertaining to funding issues, and thereby further solidify the relationship between these components of lifelong learning.

Cross Subsidy From Patient Care Revenue

The largest source of funding for GME in all specialties, however, continues to be cross-subsidies from patient-care revenue from private payers; however, these funds are not specifically designated for GME. In 2001, the US Bureau of Health Professions estimated Medicare provides 40%, Medicaid provides 10%, and the Bureau of Health Professions provides 1% of GME financing; 49% of GME financing is provided by "other" sources.[15]

Transparency and Decoupling Indirect Medical Education (IME)

Congress recognized the need to increase payment to tertiary care hospitals that care for more severely ill, complex patients because of the limitations of the DRG payment methodology.[16] The ratio of residents to beds was used as a proxy for determining which hospitals cared for these patients. Unfortunately, until there were BBA caps, hospitals were also given a financial incentive to increase the number of residency positions irrespective of whether they cared for more complex patients. Calculating IME on the basis of resident numbers creates financial incentives which can distort GME and the physician workforce. Thus, another mechanism may be more effective at addressing costs because of patient complexity without inducing these unintended consequences.

Care for indigent patients, clinical research, and specialized services and technology for complex patients continue to be important regional and national needs that need adequate financing. Disproportionate share funding provides some support for indigent care at many teaching hospitals serving large proportions of unfunded or public sector patients. However, these funds have also been reduced over time by the BBA. Additional mechanisms should be developed to support the costs of these missions.

Given the substantial public funding directed toward GME, the products of this funding may face increased scrutiny. Traditional measures, such as the knowledge and skills of those being trained, will continue to be relevant. Greater accountability for the quality of care being delivered within GME-funded teaching settings is also likely. Finally, it will be increasingly important to demonstrate that GME funding results in an appropriate supply of physicians, trained in needed specialties and geographically distributed to ensure that the health needs of diverse populations across all U.S. communities are well served.

AN ALL-PAYER GME TRUST FUND

Although society in general and all payers, including Medicare, benefit from GME, Medicare and Medicaid cannot and should not continue to be the only payers to designate substantive funding specifically to support GME. The participation of all payers, both public and private, in financing GME should be encouraged, and a mechanism should be developed to ensure an equitable and openly acknowledged contribution from all parties. Medicare would be able to reduce its burden in financing GME if the private sector began to pay its fair share.

An all-payer GME trust fund has been proposed that will create many benefits.[17] A national GME trust fund could eliminate distortions in the physician workforce caused by the current Medicare funding methodology and develop mechanisms for financing residency positions that will best meet the evolving physician workforce needs of the United States. The total number of residency positions financed can be based on national workforce needs. Funding could be more flexible to support education in ambulatory and community sites for residents in primary care specialties. Also, GME support could be provided to all specialties, including pediatrics, pediatric medical subspecialties, and pediatric surgical specialties, on the basis of need.

Some concerns about a national all-payer GME trust fund include an increase in the cost of employment-based and directly purchased health insurance; these costs are currently being partially borne by Medicare and other payers who support GME. An all-payer trust fund could potentially reduce a teaching hospital's incentive to care for Medicare patients; however, it is very unlikely that a teaching hospital would adopt such a strategy or policy given the dominant role of Medicare as a payer.

Allocation of funds also could be a divisive issue. A centralized planning body that allocates GME funds to each hospital and/or specialty could become highly politicized and also may be insensitive to signals from the health care market, leading to the training of an excessive number of physicians in certain specialties. Use of a market mechanism may be more flexible and responsive to actual societal requirements for physicians.

DISTRIBUTING GME FUNDS TO MEET WORKFORCE NEEDS AND DEMANDS

Using a market mechanism for distributing GME funds has many advantages.[18] Such a system would be responsive to market demand for physicians and make residency programs and their sponsoring institutions more responsive to the educational needs of their residents. This system also may improve accountability of GME expenditures.

A proposed market mechanism would be a portable authorization system that would allocate GME funds for direct medical education costs to accredited residency programs on the basis of the selection of the program by qualified students or residents; thus, the funding would follow the residents to their program. The total number of positions to be funded would be set by a public-private health care workforce policy body on the basis of national workforce requirements. A portable authorization system will not directly address geographic maldistribution of physicians. Thus, continuing support for programs such as the National Health Service Corps and state-level scholarship, loan forgiveness, and incentive programs remain essential to address this problem.

FINANCING PEDIATRIC SUBSPECIALTY GME

Pediatric medical subspecialists and surgical specialists have an essential role in improving pediatric care by generating new knowledge through clinical and basic science research, in educating other pediatric practitioners, and in providing specialized pediatric services. Because of concerns about an excessive number of adult subspecialty physicians, Medicare GME support for subspecialty training was cut in both amount and duration of support, and some have advocated eliminating support altogether. However, not all subspecialties have an excess of physicians, and there is a need for more physicians in some pediatric subspecialties. Thus, stable and reasonable mechanisms of support for subspecialty GME are required.

IF PUBLIC SUPPORT OF GME IS NOT SUSTAINED

Budgetary pressures on the Medicare trust fund and on federal and state governments have led to greater efforts to reduce or eliminate public funding for GME. Policy makers note that Congress intended that the Medicare hospital trust fund's role as the primary funding agent of GME was to be temporary. Elimination of public funding for GME would mean that residency education would have to be supported by cross-subsidies from patient care revenues, leading to a greater focus on service delivery and revenue generation, and resulting in less teaching and less oversight by faculty. Given the high educational debt already owed by medical school graduates, charging tuition for GME would put medical education out of reach for students from poor or middle-class backgrounds and could drive students away from more poorly reimbursed specialties, such as primary care, and from communities with underserved populations.

CONCLUSIONS

GME benefits society through the education of highly skilled physicians and the delivery of clinical services by resident physicians. All payers should support the direct costs of GME through a national GME trust fund. In the absence of an all-payer national GME system, Medicare and Medicaid funding for GME should be maintained, and the CHGME PP should be fully funded. The services of resident physicians who are fully licensed should be reimbursed by all payers for who do not explicitly fund their share of GME costs. Distribution of GME funds across specialties and across training settings should be linked to the health workforce needs of the population. GME programs should be prepared to demonstrate accountability for the quality of resident education/training and the quality of care provided by the residents.

RECOMMENDATIONS

1. Because GME is a public good, federal and state governments should continue their support of GME.

Strategies

A. Until an all-payer GME trust fund is established, the CHGME PP should be fully funded by the federal government at a level of funding that would approach what Medicare provides in DME and IME payments, per resident on average, to all teaching hospitals.

B. Medicare DGME and IME adjustment funding should be maintained.

C. Chapters of the American Academy of Pediatrics should lobby for Medicaid GME funding in their states.

2. Health care services provided by licensed residents should be reimbursed.

Strategy

A. Physicians who are fully licensed and in GME programs should be permitted to bill payers for health care services they provide if the payer does not explicitly fund their share of GME costs.

3. All health care payers, including Medicare and Medicaid, should contribute equitably to a fund that supports the direct costs of GME, including resident salaries and benefits, faculty teaching time, and overhead and patient care expenses directly related to residency education.

Strategies

A. A GME trust fund should be established that is supported by all payers and overseen by a sound, independent, national physician-workforce-planning body with pediatric representation.

B. Subspecialty fellowship training and general pediatrics research fellowship training should receive adequate support from the GME financing system, including funding from the NIH and other federal agencies, as appropriate.

C. Any mechanism for distributing GME funds should ensure that resident physicians are educated in specialties that reflect the needs of the population and should also be sensitive to promoting the educational needs of resident physicians to ensure quality health care in the future. A portable authorization system for use by graduates of accredited US medical schools and other qualified recipients is a potential mechanism to distribute funds to residency programs to finance the direct costs of GME.

4. GME programs in Medicare PPS-exempt children's hospitals should receive a level of support per resident equivalent to that of other teaching hospitals for their GME activities.

Strategies

A. To ensure quality pediatric GME with stable funding, the CHGME PP should be funded as an entitlement or through multiyear, guaranteed appropriation, rather than an annual discretionary appropriations process.

B. Education programs in Medicare PPS-exempt children's hospitals should be included in a reformed national GME financing system.

5. The distribution of GME funds needs to be directed to cover the costs of educational activities and to satisfy public demands for transparency and accountability.

Strategies

A. GME funding should be paid to the entities that incur the costs of residency education, including community sites.

B. GME funds must be directed toward GME, and should not be included in capitation payments for clinical services.

C. Distribution of Medicare IME funds should be uncoupled from the number of residents at a teaching hospital. Funds that primarily support noneducational missions of teaching hospitals, including indigent care, clinical research, and specialized services and treatment programs, should be distributed through alternative mechanisms that provide stable funding for these important missions.

D. Applying the experiences from the Accreditation Council for Continuing Medical Education and the continuing medical education community, the Accreditation Council for GME, the American Medical Association, and other organizations involved in GME should work together to develop guidelines for industry support of GME that assures the quality of GME and protects residents from undue industry influence during residency education.

E. The Accreditation Council on GME and its Pediatric Review Committee and the American Board of Pediatrics should collect educational outcome data to assess the quality of GME and its relationship to GME funding.

6. GME funding should be used to help achieve pediatric workforce goals, as determined by the pediatric community.

Strategies

A. Funding for primary care training programs, such as Title VII, needs to be increased to meet the needs of children in underserved communities.

B. Flexibility in GME funding should be increased to enhance diversity and address geographic maldistribution by mechanisms such as revisiting the BBA caps on residency programs.

C. Because pediatric subspecialty physicians play a critical role in the development and application of new knowledge in health care for children and the education of future pediatricians, mechanisms should be in place to ensure adequate support to educate an appropriate supply of subspecialty physicians.

D. Financial disincentives to education in ambulatory care sites, particularly in underserved communities, should be eliminated.

E. The relationship between GME funding policy and the pediatrician workforce should be studied.

7. Representatives from pediatrics must be active participants in all significant deliberations and decision-making processes pertaining to GME financing.

ACKNOWLEDGMENTS

The Committee wishes to thank Peters D. Willson, Vice President of Public Policy of the National Association of Children's Hospitals and Related Institutions, for his insightful contributions during the development of this policy statement.

DEDICATED TO THE HEALTH OF ALL CHILDREN™

POLICY STATEMENT

Financing of Pediatric Home Health Care*

Organizational Principles to Guide and Define the Child Health Care System and/or Improve the Health of All Children

Committee on Child Health Financing, Section on Home Care

ABSTRACT

In certain situations, home health care has been shown to be a cost-effective alternative to inpatient hospital care. National health expenditures reveal that pediatric home health costs totaled $5.3 billion in 2000. Medicaid is the major payer for pediatric home health care (77%), followed by other public sources (22%). Private health insurance and families each paid less than 1% of pediatric home health expenses. The most important factors affecting access to home health care are the inadequate supply of clinicians and ancillary personnel, shortages of home health nurses with pediatric expertise, inadequate payment, and restrictive insurance and managed care policies. Many children must stay in the NICU, PICU, and other pediatric wards and intermediate care areas at a much higher cost because of inadequate pediatric home health care services. The main financing problem pertaining to Medicaid is low payment to home health agencies at rates that are insufficient to provide beneficiaries access to home health services. Although home care services may be a covered benefit under private health plans, most do not cover private-duty nursing (83%), home health aides (45%), or home physical, occupational, or speech therapy (33%) and/or impose visit or monetary limits or caps. To advocate for improvements in financing of pediatric home health care, the American Academy of Pediatrics has developed several recommendations for public policy makers, federal and state Medicaid offices, private insurers, managed care plans, Title V officials, and home health care professionals. These recommendations will improve licensing, payment, coverage, and research related to pediatric home health services.

INTRODUCTION

The home of the pediatric patient is an appropriate and often preferred site for the provision of health care services to address a wide range of conditions. According to national estimates,[1] more than 500 000 children use home health services in the United States.* Children receiving home health care have a diverse array of diagnoses, severity levels, and complications. The 4 most common diagnoses are cerebral palsy, failure to thrive, developmental delay, and preterm birth, accounting for approximately 15% of the pediatric home health population. Although many children receiving home health care depend on technology, the vast majority do not.[2] Research also reveals that young children are more likely to receive home health care than are older children and adolescents.[1]

Over the past 20 to 30 years, the demand for pediatric in-home services has grown substantially as a result of several factors including the increased survival of preterm infants, trauma patients, and those treated in PICUs; medical and surgical

doi:10.1542/peds.2006-1489

* The Medical Expenditure Panel Survey[1] reports that in 2000, 560 464 children 0 to 18 years of age had home health expenditures. National estimates were based on relatively small sample sizes. The National Survey of Children With Special Health Care Needs (www.cdc.gov/nchs/about/major/slaits/cshcn.htm) reports that 505 459 children with special needs 0 to 18 years of age needed home health care in 2001.

treatment advances; miniaturization and simplification of life-sustaining equipment; family preferences for home versus hospital care; and cost-containment pressures to limit or avoid hospital stays. Moreover, home health care has been shown to be a cost-effective alternative to inpatient hospital care.[3–5] Today, the range of services provided to children in the home has broadened to include not only rehabilitative care but also intravenous administration of antimicrobial agents and other medications, parenteral nutrition, nasogastric or enterostomy feedings, peritoneal dialysis, wound care, oxygen and mechanically assisted ventilation, chronic pain management, complex medical and surgical care, psychosocial support, respite, and hospice care. Registered nurses are the primary providers of pediatric home health care under the direct supervision of the physician.[6] Other health professionals providing in-home care to children are physical and occupational therapists, speech pathologists, medical social workers, nutritionists, licensed practical/vocational nurses, home health aides, and personal care aides.

National health expenditure data reveal that pediatric home health costs totaled $5.3 billion in 2000. This represents one fifth of all home health expenditures but less than 1% of all children's health expenditures. On average, the per-child cost of home health care was $9421 and ranged from a low of $70 to a high of $136 969. By far, Medicaid was the major payer of pediatric home health care (77%), followed by other public sources (22%). Private health insurance and families each paid less than 1% of pediatric home health expenditures.[1]

The American Academy of Pediatrics (AAP) recognizes the growing trend to provide health care services for children in their homes. The AAP has issued a policy statement for the provision of home health care services[6] and also a guide on the management of pediatric patients in the home.[2] To advocate for improvements in the financing of pediatric home health care, the AAP has developed this financing policy statement for its members, public policy makers, federal and state Medicaid officials, private insurers, managed care officials, Title V officials, and home health care professionals. It contains recommendations for improving public and private insurance coverage, payment, and authorization policies.

GENERAL ACCESS PROBLEMS

Access to pediatric home health care services is inadequate throughout most of the United States. The most important factors affecting access to home health care are the inadequate supply of clinicians and ancillary personnel, shortages of home health nurses with pediatric expertise, inadequate payment, and restrictive insurance and managed care policies.[7] As a result, many home health agencies and hospital-run home health programs have reduced or eliminated their pediatric home health capacity in the last few years.

Unfortunately, health care financing policies have not kept pace with the changing demand and complexity of pediatric home health care. As a result, children requiring home health services are at risk of receiving inadequate care at home and experiencing life-threatening disease and other medical complications; serious injury; more frequent readmission to hospitals; higher health care costs; and excessive family burden. Many children must stay in the NICU, PICU, or other pediatric wards and intermediate care areas at a much higher cost because of inadequate pediatric home health care services.

MEDICAID LIMITATIONS

Because more than three fourths of all pediatric home health expenditures are paid for by Medicaid, understanding the limitations of Medicaid's home health care policies is critical. Unlike private health insurance, Medicaid provides a comprehensive home health benefit for children that includes part-time or intermittent nursing services, home health aide services, medical supplies and equipment, and, at states' option, physical, occupational, and speech therapy. Although states are able to limit the amount, duration, and scope of coverage of home health services for adults, these limits, because of requirements in the Early Periodic Screening, Diagnostic, and Treatment (EPSDT) service, cannot apply to children, provided the services are determined by the state to be medically necessary. In addition, states wanting to enhance their home health benefit package or increase eligibility to children from higher-income families can seek a home and community-based waiver. Fifty states are currently implementing such waivers. States also have the option of extending regular Medicaid eligibility to children who would have been eligible for Supplemental Security Income and Medicaid if they received their care in a nursing home or hospital under the "Katie Beckett" or Tax Equity and Fiscal Responsibility Act (TEFRA) eligibility option,[8] and 20 states have elected to use this option.

The main financing problem that pertains to Medicaid is low payment. Specifically, Medicaid agencies have been criticized for paying home health agencies at rates that are insufficient to provide beneficiaries with access to home health services. In many states, families complain that they are unable to secure nurses to fill all of the hours determined to be medically necessary. Correspondingly, home health agencies report difficulties recruiting and retaining qualified nurses because of low payment rates, payment delays, and restrictive policies regarding overtime. Not surprisingly, many home health agencies simply do not accept Medicaid referrals. Faced with these problems, families have attempted to hire their own independent nurses but have reportedly confronted significant payment obstacles. In addition, pedi-

atricians report that state Medicaid agencies and their contracted managed care organizations seldom allow them to bill for home visits, telephone care payment, or the time required for oversight and coordination of home health care plans despite the existence of codes for these services.

Other complaints about pediatric Medicaid concern restrictive interpretations of medical necessity and benefit definitions that follow adult home health care standards. Still other complaints include excessive paperwork and time required for authorization, retrospective denials, and increasingly long waits to gain eligibility for home, community-based, and TEFRA waivers, particularly in the last few years with state budget difficulties.

STATE CHILDREN'S HEALTH INSURANCE PROGRAM LIMITATIONS

Among states operating non-Medicaid State Children's Health Insurance Program (SCHIP) plans, home health coverage is much more generous than private health insurance. Of the 36 states with non-Medicaid SCHIP plans, only 1 state does not cover home health services. Approximately one quarter of these states impose visit limits, and copayments or coinsurance are rarely charged.[9] Little has been written about SCHIP authorization and payment limits, but because most SCHIP plans rely on the same administrative infrastructure as Medicaid, more stringent limits seem inevitable.

PRIVATE HEALTH INSURANCE LIMITATIONS

The extent of home health coverage under employer-sponsored health insurance plans is not well known. A 1998–1999 study of commonly sold health maintenance organization and preferred provider organization products in each state found that almost all plans covered home health services. However, 83% did not cover private-duty nursing, 45% did not cover home health aides, and more than one third did not cover home-based physical, occupational, or speech therapy. In this study, almost half of the plans imposed visit (typically 60 visits) or monetary limits, and the most often used cap was $5000. Condition exclusions were also imposed in two thirds of plans, usually for impairments not caused by illness or injury and less often for developmental disabilities and neurologic or mental health disorders.[10]

Children covered in nongroup plans seldom have home health coverage. Many of these children's parents seek support from their state's Title V program for children with special health care needs and, depending on the child's condition and family income, may be eligible for gap-filling home health services. It is not unusual for families with inadequate private insurance coverage to terminate employment to gain Medicaid eligibility for their child.

Many private health insurance carriers and managed care plans, especially those with strong case management programs, will authorize home health care when it is perceived to be a cost-effective alternative to institutionalization or outpatient treatment. However, authorizations are often for less than the services deemed medically necessary by the child's physician and the home health care agency. As with Medicaid, authorization delays and retroactive denials are common in the private health insurance industry.

RECOMMENDATIONS

Licensure

To ensure that eligible children have access to high-quality pediatric home health care, all states should regulate in-home services through comprehensive licensure laws that define and regulate the provision of all home health services performed by appropriately licensed and pediatric-trained personnel and all personal care services paid for by third-party payers. Until all states have effective licensure laws and regulations for home health agencies, the Joint Commission on Accreditation of Healthcare Organizations and/or Community Health Accreditation Program should enforce the credentialing requirement for contracts with all third-party payers, including Medicaid. Licensure laws should include the following requirements:

1. All home health services must be provided under a physician-approved plan of care that is reviewed every 60 days and revised as often as required by changes in the patient's condition.
2. The roles of attending physicians, home health agency clinical staff, and insurance and plan case managers should be clearly differentially defined. All agency personnel must have training to meet the needs of patients.
3. Physicians, home health agencies, third-party payers, and managed care plans should use the recommendations published by the AAP in *Guidelines for Pediatric Home Health Care*[2] for the purpose of determining the frequency and duration of home health services. Because few scientific studies have been conducted on the effectiveness of home health care for specific pediatric conditions, medical necessity standards should be based on professional standards of care for children or consensus pediatric expert opinion. Coverage of home health care should not be denied unless there is conclusive scientific evidence that proves that the prescribed home health care is ineffective.[11]
4. Licensure for unique community-based programs that compliment care in the home should be adopted to meet the child's needs and provide access to necessary health services. This includes, but is not limited

to, medical day care, respite care, educational centers, and transitional care (hospital-to-home care).

Payment

1. Insurers and plans must adequately reimburse home health agencies, nurses, and physicians for pediatric home health visits and home care planning and oversight. Home health care payments must be increased to permit home health agencies to attract and retain appropriately credentialed clinicians and ancillary personnel for pediatric intermittent care and shift care (private duty) as well as to cover the indirect costs of clinical management and support for in-home staff. Payment adjustments must also take into account the costs associated with preparation and continuing education of nurses in pediatric competencies, intensive care, and technological skills.
2. Insurers and plans must permit physicians to bill for prolonged oversight services, telephone calls, and online consultations to ensure comprehensive and continuous care for vulnerable children when direct patient contact is unnecessary. In addition, insurers and health plans must reimburse for case management to help maintain a medical home.[12]
3. Payment must be offered to home health agencies, nurses, and physicians that is sufficient to enable them to deliver pediatric home health care consistent with pediatric medical standards.
4. The Centers for Medicare and Medicaid Services must conduct a comprehensive analysis of the adequacy of each state's Medicaid home health care payment rates, taking into consideration the complexity of the states' current pediatric home health care patients.
5. Payment for durable medical equipment must not be bundled into payment for visits or into prospective payment arrangements for intermittent care.
6. Payment for community-based care must be provided by Medicaid, SCHIP, and/or private health insurance companies when cost-effectiveness is evident.

Coverage

1. Private health insurers and non-Medicaid SCHIP plans must be encouraged to offer more comprehensive coverage of home health services for children (including foster children), including private-duty nursing, home health aides, therapies, durable medical equipment, and respite care.
2. Enrollment caps and waiting periods in Medicaid and TEFRA must be reduced or eliminated for children who are medically in need of home health services.
3. Arbitrary limits on the number of days of coverage must be eliminated. Services should not be discontinued without the order of a physician.
4. Public and private third-party payers must clarify and standardize their coverage plans/benefit packages for children who need pediatric in-home services with input from the AAP, including the definitions of "medical necessity" and "home and community-based." Medical necessity must be defined to include services that assist in achieving, maintaining, or restoring health and functional capacity; are appropriate for the age and developmental status; and will take into account the specific needs of the child.
5. New and expanded funding mechanisms must be established to support respite care for families with children who have complex medical problems that require long-term home care and families who must continue to work, preferably through Medicaid and Title V. Respite care for primary caregivers must be included in all pediatric home health care benefits.[13] Coverage for "respite" inpatient stays must also be covered at the appropriate level of care when there are no available qualified home health professionals within the geographic area.
6. Coverage of hospice and palliative services must be available in all pediatric home health care benefit packages so that parents of terminally ill children can obtain therapeutic services for their child even though the odds of survival are minimal.
7. Early intervention services must be covered as prescribed by a physician.
8. Medical day care must be covered.

Research

1. The adequacy of Medicare's prospective payment system for home health care should be examined as a model for financing of pediatric home health care under Medicaid and private insurance.
2. A comprehensive analysis of the adequacy of public and private payment rates for pediatric home health care should be conducted.
3. A study of the impact of inadequate access to pediatric home care should be conducted as it relates to hospital and other health care service utilization, rehospitalization rates, costs, family stress, and family satisfaction. Also, a study should be performed to determine if access to quality pediatric home health care will reduce overall costs of care.
4. A study that demonstrates the benefits of home care in relation to the Olmsted Act, which requires states to provide community-based services to individuals for whom institutional care is inappropriate, should be conducted.

5. Support for ongoing development of pediatric home health care standards, including a definition of medical necessity, should be encouraged.

CONCLUSIONS

Pediatric home care involves the delivery of medical care in the home to children who are ill, recovering, or disabled. It can be as simple as dressing changes or as complex as providing mechanical ventilation. The benefits of home care for children are many, including having the child cared for in the familiar surroundings of a home environment, continued access to social support such as friends and siblings, better growth and development, and less cost compared with continued hospitalization. Implementing the recommendations outlined in this statement will enhance access to high-quality pediatric home health care.

Committee on Injury and Poison Prevention

Fireworks-Related Injuries to Children

ABSTRACT. An estimated 8500 individuals, approximately 45% of them children younger than 15 years, were treated in US hospital emergency departments during 1999 for fireworks-related injuries. The hands (40%), eyes (20%), and head and face (20%) are the body areas most often involved. Approximately one third of eye injuries from fireworks result in permanent blindness. During 1999, 16 people died as a result of injuries associated with fireworks. Every type of legally available consumer (so-called "safe and sane") firework has been associated with serious injury or death. In 1997, 20 100 fires were caused by fireworks, resulting in $22.7 million in direct property damage. Fireworks typically cause more fires in the United States on the Fourth of July than all other causes of fire combined on that day. Pediatricians should educate parents, children, community leaders, and others about the dangers of fireworks. Fireworks for individual private use should be banned. Children and their families should be encouraged to enjoy fireworks at public fireworks displays conducted by professionals rather than purchase fireworks for home or private use.

ABBREVIATION. CPSC, US Consumer Product Safety Commission.

OVERVIEW

Fireworks are devices designed for the purpose of producing a visible or audible effect by combustion, deflagration, or detonation.[1] Every year, US residents celebrate the Fourth of July and other festive occasions with fireworks. As a result, in 1999, an estimated 8500 individuals, approximately 45% of them children younger than 15 years, sustained fireworks-related injuries requiring emergency medical treatment.[2,3] Since 1994, the annual number of people receiving emergency medical treatment for fireworks-related injuries has decreased by about one third.[3,4] The hands (40%), eyes (20%), and head and face (20%) are the body areas most often involved.[2] About one third of eye injuries from fireworks result in permanent blindness.[5] Burns account for more than half of fireworks-related injuries,[2] and lacerations, contusions, and abrasions are also common.[1,2,6–8] During 1999, 16 people died as a result of injuries associated with fireworks.[2]

Under regulations promulgated by the US Consumer Product Safety Commission (CPSC) in 1976, any firecracker containing more than 50 mg of explosive material is banned, although aerial devices may contain up to 130 mg of powder charge. In addition, CPSC regulations include fuse burn time limits, cautionary labeling requirements, and criteria to prevent tipover and blowout of devices. Additional regulations address requirements for certain reloadable tube and aerial shell fireworks and the stability of multiple-tube devices.[4]

Consumer fireworks, formerly known as "Class C" fireworks and often inappropriately referred to as "safe and sane" fireworks, include fountains and candles that shoot out sparks or flaming balls, rockets with sticks (called "bottle rockets," because it is customary to stand them in a soda bottle for ignition), other rockets, firecrackers, sparklers, and smoke devices. These are permitted under federal regulation, and their sale is regulated by state and local authorities.[7] At present, 10 states ban all consumer fireworks, and 5 additional states ban all consumer fireworks except sparklers, "snakes," or other novelty items.[9]

In addition to ongoing injury surveillance, the CPSC conducts a special study each year of fireworks-related injuries requiring emergency medical care that occur around the Fourth of July.[2,4,6] The 1999 CPSC study found that one third of the fireworks-related injuries were caused by firecrackers, approximately 10% of which were illegal. Almost 20% of the injuries were from rockets. Notably, sparklers, which are mistakenly believed to be safe by many consumers, caused 10% of these fireworks-related injuries.[2] Although most sparkler-related injuries are minor burns and corneal abrasions, sparklers can reach temperatures greater than 1000°F at the tip and can cause serious burns by igniting clothing.[1,5,8] One study found that two thirds of injuries from sparklers occurred among children 5 years and younger.[8] A case-control study designed to control for the popularity of various devices found firecrackers and aerial devices to be associated with the greatest risk of injury. It also found that the highest chance of injury requiring hospitalization occurred with illegal and homemade devices.[7] Half of the fireworks-related eye injuries and an even higher proportion of those resulting in permanent blindness or enucleation are caused by bottle rockets.[5] Every type of consumer firework has been associated with serious injury or death.[1,8]

Malfunctions of consumer fireworks account for only a small percentage of injuries. In one study, the injured child was a bystander in 26% of cases, and adult supervision was present in 54% of cases.[8] Therefore, not letting children ignite fireworks and

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

PEDIATRICS (ISSN 0031 4005).

providing adult supervision while using fireworks are inadequate injury prevention strategies.

In addition to medical and related costs directly and indirectly attributable to fireworks injuries, fireworks cause significant property damage. In 1997, 20 100 fires, which resulted in $22.7 million in direct property damage, were caused by fireworks.[10] In a typical year, fireworks cause more fires in the United States on the Fourth of July than all other causes of fire combined on that day.[10] The considerable losses of life, health, and property are almost entirely preventable by the removal of all fireworks from the hands of everyone except professional pyrotechnicians. Injuries resulting from public fireworks displays are rare. States that ban all consumer fireworks have significantly lower rates of fireworks-related injuries and fires.[1,5] Where local jurisdictions ban fireworks, there is frequent crossover to nearby communities that permit them, so the effectiveness of such local regulation is limited.[8] Education does not appear to decrease the rate of injuries in states where consumer fireworks are permitted.[7]

RECOMMENDATIONS

1. Pediatricians should educate parents, children, community leaders, and others about the dangers of fireworks. Children and their families should be counseled to attend public fireworks displays rather than purchase fireworks for home use.
2. Public sales, including those by mail or Internet order, of all fireworks should be prohibited. Ideally, this should be done on a national level by federal law or CPSC regulation. International importation of fireworks for private use should also be banned. Sales to professional pyrotechnicians for the purpose of creating public displays would be exempt.
3. The private use of fireworks should be banned. Pediatricians should work to increase the number of communities and states that ban the private use of all fireworks.
4. Accurate surveillance and reporting of fireworks-related injuries, deaths, and fires must be continued.
5. Additional research should be conducted to identify factors that have contributed to the recent decrease in the number of fireworks-related injuries. This information would be helpful in efforts to promote continued improvement in this and perhaps other injury problems.

Committee on Genetics

Folic Acid for the Prevention of Neural Tube Defects

ABSTRACT. The American Academy of Pediatrics endorses the US Public Health Service (USPHS) recommendation that all women capable of becoming pregnant consume 400 μg of folic acid daily to prevent neural tube defects (NTDs). Studies have demonstrated that periconceptional folic acid supplementation can prevent 50% or more of NTDs such as spina bifida and anencephaly. For women who have previously had an NTD-affected pregnancy, the Centers for Disease Control and Prevention (CDC) recommends increasing the intake of folic acid to 4000 μg per day beginning at least 1 month before conception and continuing through the first trimester. Implementation of these recommendations is essential for the primary prevention of these serious and disabling birth defects. Because fewer than 1 in 3 women consume the amount of folic acid recommended by the USPHS, the Academy notes that the prevention of NTDs depends on an urgent and effective campaign to close this prevention gap.

ABBREVIATIONS. NTDs, neural tube defects; USPHS, US Public Health Service; CDC, Centers for Disease Control and Prevention; MRC, Medical Research Council; IOM, Institute of Medicine; AAP, American Academy of Pediatrics.

BACKGROUND

Neural tube defects (NTDs) are among the most common birth defects contributing to infant mortality and serious disability. NTDs, which include anencephaly, spina bifida, and encephalocele, occur in approximately 1 of 1000 births in the United States.[1] An estimated 4000 pregnancies are affected with NTDs each year. More than one third of these pregnancies are spontaneously lost or electively terminated; thus, about 2500 infants per year are born with an NTD. The results of 2 randomized controlled trials and several observational studies showed that 50% or more of NTDs can be prevented if women consume a folic acid–containing supplement before and during the early weeks of pregnancy[2,3] in addition to the folate in their diet. Based on a synthesis of these data, the US Public Health Service (USPHS) and Centers for Disease Control and Prevention (CDC) recommendations were developed.[4,5] Because the evidence for folic acid prevention evolved over time, there are two separate recommendations: one for women who have no history of a previous NTD-affected pregnancy and one for women who have had a previous NTD-affected pregnancy.

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

WOMEN WITH NO HISTORY OF A PREVIOUS NTD-AFFECTED PREGNANCY

Of children with an NTD, 95% are born to couples with no family history of these defects. Evidence to date suggests that supplementation with a multivitamin containing 400 (0.4 mg) μg of folic acid prevents the occurrence of >50% of NTDs when it is taken before conception and continued throughout the first trimester of pregnancy.[5] The USPHS recommends that all women of childbearing age who are capable of becoming pregnant take 400 μg of folic acid daily.[5] Implementing this recommendation may provide the opportunity for primary prevention of 50% or more of these serious disabling birth defects. Regular and ongoing ingestion of folic acid by women of childbearing age is necessary because approximately half of the pregnancies in the United States are unplanned,[6] and neural tube closure occurs during the first 4 weeks of gestation.[7] Despite the publication of the USPHS recommendation in September 1992, a 1998 poll showed that 70% of women aged 18 to 45 years still are not following the USPHS recommendation.[8]

WOMEN WHO HAVE HAD A PREVIOUS NTD-AFFECTED PREGNANCY

Among US couples who have had a child with an NTD, the recurrence risk is 2% to 3% in subsequent pregnancies.[9] In 1991, the Medical Research Council (MRC) Vitamin Study Group reported the results of a well-designed, prospective, randomized trial of folic acid supplementation for the prevention of NTDs in pregnancies of women who had a previous child with an NTD, and the CDC published its recommendations for consumption of 4000 (4 mg) μg of folic acid.[4] The results of the MRC study conclusively demonstrated that a daily dosage of 4000 μg of folic acid, in addition to folate in the diet, before and during early pregnancy resulted in a 71% reduction of recurrence of NTDs. The addition of other vitamins to the dosage of folic acid did not reduce the risk further. Use of multivitamins without folic acid did not result in a reduced risk for NTDs. The MRC study did not explore the possible benefit of a dosage lower than 4000 μg of folic acid. However, an earlier nonrandomized study conducted in the United Kingdom suggested that a lower dosage, 360 μg daily, resulted in a comparable reduction of recurrence of NTDs.[10] Although adverse maternal or fetal effects of a daily 4000 μg dosage of folic acid were

not detected by the MRC study, the small size of the study groups precluded detection of uncommon adverse effects.

FOLATE AND FOLIC ACID

Folic acid, also known as pteroylmonoglutamic acid, is a synthetic compound used in dietary supplements and fortified foods. The term *folate* includes all compounds that have the vitamin properties of folic acid—including folic acid and naturally occurring compounds in food.[11] The average diet in the United States contains 200 μg of naturally occurring food folate, which is less bioavailable than folic acid.[12] Additional intake of foods rich in folate could raise the average intake, but it has not been demonstrated that increased consumption of food folate would prevent NTDs as effectively as a daily vitamin supplement containing 400 μg of folic acid. A small comparison study suggests that blood folate concentrations are increased much more by folic acid supplementation than by naturally occurring food folate in the diet.[13] Economic and social circumstances may make an adequate increase in dietary folate difficult or unlikely, and the behavioral change required among a large fraction of women may take years to achieve.

Folic acid is a water-soluble vitamin that has no known toxicity. However, higher doses of folic acid can correct the anemia of vitamin B_{12} deficiency (pernicious anemia), which might be an important clue to the presence of vitamin B_{12} deficiency in some instances. Folic acid does not prevent the neurologic consequences of vitamin B_{12} deficiency, and, for this reason, the USPHS recommendation cautioned that intake of folate should be not >1000 μg per day. However, the Institute of Medicine (IOM) Food and Nutrition Board recently set the tolerable upper intake limit of synthetic folic acid at 1000 μg, thus eliminating food folate from the calculation.[14] Because pernicious anemia rarely occurs before the age of 50 years, it is likely to be rare among women consuming folic acid during the reproductive years. Folic acid has been consumed by about a quarter of all women for many years and extensively during later pregnancy without apparent adverse effects; however, studies that definitively address the question of maternal and fetal safety of folic acid are not available.

The IOM Food and Nutrition Board's recommended dietary allowance (RDA) for folate is 400 μg for adults and 600 μg for pregnant women.[14] To reduce the risk for NTDs, the IOM recommended that women capable of becoming pregnant consume 400 μg of folic acid daily from fortified foods, vitamin supplements, or a combination of the two. This is in addition to the naturally occurring folate obtained from a varied diet.[14] The majority of multivitamin preparations contain 400 μg of folic acid. These preparations are available over the counter and are already being taken by about 30% of nonpregnant women aged 18 to 45 years in the United States.[8] Tablets containing folic acid alone are available over the counter in dosages up to 800 μg but the availability is very limited when compared with multivitamin preparations. Folic acid tablets in a 1000 μg dose are available by prescription only. This preparation is most frequently utilized by women who are taking 4000 μg because of a previous NTD-affected pregnancy.

In March 1996, the Food and Drug Administration mandated that enriched cereal-grain products be fortified with 140 μg of folic acid per 100 g of flour.[15] This measure increases the proportion of women who consume the USPHS-recommended daily dosage of 400 μg of folic acid only an additional 3%, because this fortification level will provide the average woman only an additional 100 μg of folic acid per day (unpublished data, 1992).

RECOMMENDATIONS

1. ***Prevention for Women With No History of a Previous NTD-Affected Pregnancy.*** The American Academy of Pediatrics (AAP) endorses the USPHS recommendation that all women of childbearing age who are capable of becoming pregnant should consume 400 (0.4 mg) μg of folic acid daily. Because of the high rate of unplanned pregnancies in the United States, the AAP encourages efforts at devising a program of food fortification to provide all women a daily intake of 400 μg of folic acid. In the absence of optimal fortification, the AAP encourages women to consume 400 μg of folic acid daily in addition to eating a healthy diet. At present, the most convenient, inexpensive, and direct way to meet the recommended dosage is by taking a multivitamin containing 400 μg of folic acid, but efforts to increase the availability of folic acid-only supplements should be encouraged for women who prefer not to take multivitamins. Because the risk for NTDs is not totally eliminated by folic acid use, routine prenatal screening for NTDs is still advisable.
2. ***Prevention for Women Who Have Had a Previous NTD-Affected Pregnancy.*** Women with a history of a previous pregnancy resulting in a fetus with an NTD should be advised of the results of the MRC study. During times in which a pregnancy is not planned, these high-risk women should consume 4000 (4 mg) μg of folic acid per day. However, they should be offered treatment with 4000 μg of folic acid per day starting 1 month before the time they plan to become pregnant and throughout the first 3 months of pregnancy, unless contraindicated. Women should be advised not to attempt to achieve the 4000 μg daily dosage of folic acid by taking over-the-counter or prescription multivitamins containing folic acid because of the possibility of ingesting harmful levels of other vitamins, for example, Vitamin A.[17] It should be noted that 4000 μg of folic acid did not prevent all NTDs in the MRC study. Therefore, high-risk patients should be cautioned that folic acid supplementation does not preclude the need for counseling or consideration of prenatal testing for NTDs.
3. ***Prevention for Other High-Risk Persons.*** No intervention or observational studies address prevention for other high-risk persons. Women with a close

relative (eg, sibling, niece, or nephew) who has an NTD (risk is approximately 0.3% to 1.0%), women with type 1 diabetes mellitus (risk is approximately 1%), women with seizure disorders being treated with valproic acid or carbamazepine (risk is approximately 1%), and women or their partners who have an NTD (risk may be 2% to 3%)[18] and are planning a pregnancy should discuss with their physician the risk for an affected child and the advantages and disadvantages of increasing their daily periconceptional folic acid intake to 4000 μg.

4. ***Public Health Programs: Supplementation, Surveillance, and Food Fortification.*** The AAP recommends that the Department of Health and Human Services expeditiously devise and implement an educational program to prevent folic acid–preventable NTDs throughout the use of supplements, fortified foods, or a combination of both. The program should support surveillance of effectiveness and adverse outcomes to further refine the effective folate dose and mechanisms of actions. In light of the recent IOM recommendation, the AAP also encourages additional efforts at devising a program of food fortification with folic acid to provide all women capable of becoming pregnant a daily intake of 400 μg of folic acid.

Follow-up Management of Children With Tympanostomy Tubes

ABSTRACT. The follow-up care of children in whom tympanostomy tubes have been placed is shared by the pediatrician and the otolaryngologist. Guidelines are provided for routine follow-up evaluation, perioperative hearing assessment, and the identification of specific conditions and complications that warrant urgent otolaryngologic consultation. These guidelines have been developed by a consensus of expert opinions.

PROPOSED GUIDELINES

1. The initial postoperative follow-up examination of the child in whom a tympanostomy tube has been placed should be performed by the otolaryngologist to verify the patency and functional status of the tube. This postoperative visit is usually performed within the first month after placement of the tube. Problems related to tubal patency and function can be addressed at this visit, past or present communication needs can be assessed, and a strategy can be outlined regarding the management of future otitis media episodes.
2. The baseline hearing status of any child who has middle ear disease severe enough to warrant the placement of a tympanostomy tube needs to be determined. An audiologic evaluation should be performed postoperatively if normal hearing was not established preoperatively. The techniques and goals of the audiologic evaluation vary depending on the age and cooperation level of the child. Children who are too young to be tested by behavioral audiologic means (generally children 6 months and younger) can be assessed by otoacoustic emission or brainstem auditory evoked response testing. Children with persistent conductive or sensorineural hearing loss after placement of tympanostomy tubes require additional diagnostic workup.
3. Because the average functional duration of a standard "short-term" ventilation tube has been estimated to range between 6 and 18 months with a mean of 13 months, follow-up examinations of children with tympanostomy tubes should be performed at intervals no longer than 6 months. Such interval ear examinations may be performed by the otolaryngologist or the pediatrician with documented communication (eg, letter, fax, e-mail) between the 2 physicians regarding the child's otologic status.
4. Complete tympanic membrane healing, adequate eustachian tube function, and normal hearing after extrusion or removal of the tympanostomy tube should be established before discharge from the otolaryngologist's care.
5. Some children with tympanostomy tubes may require referral to the otolaryngologist before planned interval examinations. These include but are not limited to:

   - Children with chronic, recurrent, or unresponsive otorrhea;
   - Children with hearing deterioration, balance difficulties, or persistent otalgia;
   - Children in whom perforation, cholesteatoma, or other structural disease of the tympanic membrane is suspected (distinguishing such from myringosclerosis can sometimes be difficult);
   - Symptomatic children with documented tympanostomy tube obstruction from cerumen, dry secretions, or granulation tissue;
   - Symptomatic children in whom a previously placed tympanostomy tube cannot be visualized;
   - Children in whom an extruded tympanostomy tube cannot be removed from the ear canal;
   - Children with a documented medialized tympanostomy tube (a tube that has migrated into the middle ear space);
   - Children who have retained a tympanostomy tube for more than 2 years;
   - Children whose ears are difficult to examine because of external ear canal stenosis, as seen in some children with Down syndrome and other craniofacial syndromes; and
   - Children with preexisting sensorineural hearing loss, documented language or developmental delay, or special needs in whom the additional conductive hearing compromise associated with a nonfunctional tympanostomy tube could be particularly debilitating.

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

Forgoing Life-Sustaining Medical Treatment in Abused Children

ABSTRACT. A decision to forgo life-sustaining medical treatment (LSMT) for a critically ill child injured as the result of abuse should be made using the same criteria as those used for any critically ill child. The parent or guardian of an abused child may have a conflict of interest when a decision to forgo LSMT risks changing the legal charge faced by a parent, guardian, relative, or acquaintance from assault to manslaughter or homicide. If a physician suspects that a parent or guardian is not acting in a child's best interest, further review and consultation should be sought in hopes of resolving the conflict. A guardian ad litem who will represent the child's interests regarding LSMT should be appointed in all cases in which a parent or guardian may have a conflict of interest.

ABBREVIATIONS. LSMT, life-sustaining medical treatment; AAP, American Academy of Pediatrics.

Pediatricians, pediatric subspecialists, and pediatric surgeons caring for a severely abused child who is supported with life-sustaining medical treatment (LSMT) face many difficult decisions. One potential concern may be how to proceed when the child apparently will survive with seriously disabling neurologic deficits or with continued reliance on LSMT, such as a ventilator. Moreover, a parent or guardian may have a conflict of interest when a decision to forgo LSMT risks changing the legal charge faced by a parent, guardian, relative, or acquaintance from assault to manslaughter or homicide.

Conflict of interest from a parent or guardian should not arise if a child is declared brain-dead. The declaration of death based on brain death criteria is not dependent on the cause of the brain injury. Brain death is a clinical determination based on established criteria, supplemented (if necessary) by cerebral flow studies, electroencephalograms, and other ancillary tests.[1,2] In cases of abuse, given the likelihood of criminal prosecution, it may be prudent to supplement the clinical determination of brain death with an ancillary test, such as a cerebral flow study.

FORGOING LSMT

LSMT encompasses all interventions that may prolong the life of the patient. These may include cardiopulmonary resuscitation, respiratory and circulatory support, artificially administered nutrition and hydration, and medications, such as antibiotics.[3] Decisions to forgo LSMT for a critically ill child whose injuries are the result of abuse should be made using the same criteria as those used for any critically ill child. These criteria include the reasonable medical certainty that LSMT will fail to maintain the child's life or the disproportionate burden of treatment in the face of irremediable and severe brain or other injury.[3–6] The primary consideration in forgoing LSMT ought to be the best interest of the child after carefully weighing the benefits and burdens of continued treatment. Decisions to forgo LSMT in cases of severe brain injury should not be limited to children in a persistent vegetative state.[3,6]

RESOLUTION OF CONFLICT

The parent or guardian may be suspected or accused of the assault or may be protecting a friend or family member who is suspected or accused of the assault. If a physician suspects that a parent or guardian is not acting in a child's best interest, it is appropriate to seek further review and consultation in hopes of resolving the conflict. The hospital ethics committee may be one mechanism of conflict resolution. However, the complex legal issues may force the conflict into court.[7] Even so, an ethics committee consultation may be useful to assure the hospital administration and other interested parties that the hospital staff has pursued all possible avenues before asking for a court hearing. The hospital attorney also will need to be aware of the conflict to safeguard the interests of the hospital.

Parents and guardians often retain the right of making medical decisions, such as forgoing cardiopulmonary resuscitation or other LSMT, despite being suspected, accused, or even convicted of child abuse. Court proceedings that appoint a guardian ad litem for the purpose of protecting the abused child often limit the role of the guardian to determine appropriate placement of the child after discharge. A separate court proceeding may be necessary to ask for the appointment of a guardian ad litem for medical decisions—an appointment made necessary given the parent or guardian's conflict of interest for making such decisions. The physician should impress on the judge that the request for the appointment of a guardian ad litem does not prejudge the question of forgoing LSMT and that the guardian ad litem could not make an informed decision without visiting the child's bedside to obtain a first-hand understanding of the child's condition.

Prosecutors may not support a decision to forgo LSMT out of concern that the case against the alleged abuser may be weakened. Furthermore, because the

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

prosecutor may bring a charge of manslaughter or murder after the child's death, the prosecutor has an apparent conflict of interest in arguing before the court in favor of forgoing LSMT. It also may be difficult to find a judge who is willing to hear a request for appointing a guardian ad litem for medical decision-making, given the notoriety that such cases often bring. Finally, the application of pertinent child abuse laws varies from state to state, county to county, and judge to judge, making it difficult to predict with any certainty the outcome of such court proceedings. The American Academy of Pediatrics (AAP) recommends the appointment of a guardian ad litem in all cases of child abuse requiring LSMT in which a parent or guardian may have a conflict of interest.

FAMILY SUPPORT

Decisions to forgo LSMT should be based on complete and compassionate communication with the family. The AAP endorses the role of parents of children receiving LSMT in helping to make these determinations, even if one or both parents are suspected of causing the injury.[3,6] Regardless of the cause, nature, and extent of a child's injuries and of the ongoing court proceedings, the parent(s) or guardian(s) should be treated with respect, compassion, and due consideration for privacy. As should be the case for all critically ill children, appropriate support for the parents should be offered, including a bereavement counselor, chaplain, or other persons identified by the parents as providing important psychological and spiritual support.[8]

TISSUE AND ORGAN DONATION

Although forgoing LSMT does not require the permission of the medical examiner or the district attorney, the medical examiner should be involved early and before the removal of LSMT in child abuse cases. There may be physical evidence, such as photographs of the injuries, that preferably would be obtained before the child's death.

Federal and state regulations require that the parent or guardian be given the option of tissue and organ donation. However, the permission of the medical examiner is absolutely necessary for tissue and organ procurement to take place, as valuable evidence may be altered or lost in the process. If tissue and organ donation are options, the physician should introduce the idea and then request that a person who is trained and comfortable in discussing tissue and organ donation describe the options and answer the family's questions. In addition, the medical examiner should be encouraged to attend the tissue and organ procurement to ensure that appropriate evidence is collected rather than routinely deny permission for procurement.[9,10]

RECOMMENDATIONS

1. Pediatricians, pediatric subspecialists, and pediatric surgeons should be aware of the legal and ethical issues in caring for children who have been seriously injured as a result of abuse.
2. Regardless of the cause, nature, and extent of a child's injuries, the parent(s) or guardian(s) should be involved, as appropriate, in all aspects of the child's care and treated with respect and due consideration for their privacy.
3. Decisions to forgo LSMT for a critically ill child whose injuries are the result of abuse should be made using the same guidelines as those used for any critically ill child.
4. A guardian ad litem for medical decision making should be appointed in all cases of child abuse requiring LSMT in which a parent, guardian, or prosecutor of the alleged abuser may have a conflict of interest.
5. The medical examiner's office should be involved early and before forgoing LSMT. Local procedures for collecting evidence and performing postmortem examinations should be developed to allow for organ and tissue donation.

abstract

There is broad consensus that withholding or withdrawing medical interventions is morally permissible when requested by competent patients or, in the case of patients without decision-making capacity, when the interventions no longer confer a benefit to the patient or when the burdens associated with the interventions outweigh the benefits received. The withdrawal or withholding of measures such as attempted resuscitation, ventilators, and critical care medications is common in the terminal care of adults and children. In the case of adults, a consensus has emerged in law and ethics that the medical administration of fluid and nutrition is not fundamentally different from other medical interventions such as use of ventilators; therefore, it can be forgone or withdrawn when a competent adult or legally authorized surrogate requests withdrawal or when the intervention no longer provides a net benefit to the patient. In pediatrics, forgoing or withdrawing medically administered fluids and nutrition has been more controversial because of the inability of children to make autonomous decisions and the emotional power of feeding as a basic element of the care of children. This statement reviews the medical, ethical, and legal issues relevant to the withholding or withdrawing of medically provided fluids and nutrition in children. The American Academy of Pediatrics concludes that the withdrawal of medically administered fluids and nutrition for pediatric patients is ethically acceptable in limited circumstances. Ethics consultation is strongly recommended when particularly difficult or controversial decisions are being considered. *Pediatrics* 2009;124:813–822

INTRODUCTION

Decisions to withhold or withdraw life-sustaining treatment from critically or terminally ill children are commonly made in US and Canadian hospitals.[1–4] Most children who die in American hospitals do so after critical care interventions are withheld or withdrawn.[5–8] The American Academy of Pediatrics (AAP) has stated that it supports allowing the withholding and withdrawing of a medical intervention when the projected burdens of the intervention outweigh the benefits to the child.[9] The AAP has also stated that treatment decisions regarding an infant should be based on the judgment that the infant will derive net benefit, concluding that medical treatment that is judged to be harmful, of no benefit, or "futile" is inappropriate and should not be offered or provided.[10] Although decisions about withholding or withdrawing treatments when death is at hand are difficult, a broad consensus has

emerged that decisions to withhold or withdraw medical interventions are ethically and legally acceptable in many circumstances, and these decisions fall within the authority of parents or guardians in consultation with the child's physician.[9] Nevertheless, the withholding or withdrawing of the medical provision of fluids and nutrition for children remains controversial, in large measure because of the strong emotional and social symbolism associated with feeding children. At the same time, there are situations in which medical provision of fluids and nutrition may fail to benefit a child or create a level of burden that cannot be justified by whatever benefit might accrue. In the treatment of adults, the President's Commission[11] and a number of professional organizations, including the American Medical Association,[12] the American Academy of Neurology,[13] the American Nurses Association,[14] the Hospice and Palliative Nurses Association,[15] and the American Academy of Hospice and Palliative Medicine,[16] support the authority of adult patients or their surrogate decision-makers to withhold or withdraw medically administered fluids and nutrition. The American College of Physicians has declared the medical administration of fluids and nutrition to be a medical intervention subject to the same principles of decision-making as all other medical interventions.[17] Appellate court decisions also consistently equate the decision-making process surrounding medically provided fluids and nutrition with other forms of medical treatment, supporting the authority of surrogates to forgo or withdraw medically provided fluids and nutrition when there is no longer net benefit to the patient.[18] The AAP statement on forgoing life-sustaining treatment mentions medically provided fluids and nutrition among interventions that can be withheld.[9] Nevertheless, pediatricians are often uncertain about the ethical and legal propriety of these decisions, the conditions under which such a decision would be appropriate, and how to communicate about this issue with families, colleagues, and staff. The purpose of this report is to review the medical, social, ethical, and legal issues involved in these decisions and to provide guidance to parents, guardians, and clinicians regarding the conditions under which medically provided fluids and nutrition can be withheld or withdrawn from infants, children, and adolescents who lack decision-making capacity.

USE OF TERMINOLOGY AND SCOPE OF REPORT

Medically provided fluids and nutrition are commonly used in pediatric practice for a wide variety of acute and chronic conditions. Fluids and nutrition provided through intravenous catheters and nasogastric, nasojejunal, and gastrostomy tubes have saved and maintained the lives of countless children. In this report, the provision of fluids and nutrition via medical devices is distinguished from the provision of food and drink to children who are capable of eating and drinking. The AAP considers it a fundamental principle that children who are hungry or thirsty, who are capable of oral intake, and for whom there are no medical contraindications to eating and drinking should be given food and fluids by mouth. The focus of this clinical report is children who depend on fluids and nutrition delivered through medical devices for their survival.

Given this focus, we will use the term "medically provided nutrition" rather than "food" and "withholding medically provided nutrition" rather than "starvation." The term "food" elicits images of eating, chewing, tasting, and swallowing along with the pleasures and social connotations that accompany those actions, failing to distinguish these from the technical process of delivering hydration and nutrition through medical devices. Receiving fluids and nutrition through a tube or intravenous catheter is not the same as eating a meal. Likewise, the term "starvation" fails to accurately characterize the experience of patients for whom medically provided fluids and nutrition are withheld, implying an element of suffering that is rarely present when medically provided nutrition is withdrawn.[19] When medically provided fluids and nutrition are withheld, death does not occur from starvation but as a result of dehydration and the patient's underlying condition. Reports on adult patients who have died after refusing nutrition and hydration have consistently shown that these patients do not appear to suffer but experience peaceful deaths.[20–23] In fact, before the development of medical means for providing nutrition or hydration, the cessation of eating and drinking frequently represented the means by which elderly individuals experienced a "natural" death from old age.[24]

ETHICAL DECISION-MAKING

The clear consensus that has emerged over the last few decades is that medical interventions can be withheld or withdrawn when refused by competent patients or by surrogate decision-makers on behalf of patients who lack decision-making capacity. Surrogate decision-makers are expected to base their decisions on what they believe the patient would have wanted or, in the absence of knowledge of the patient's wishes, a determination of the relative benefits and burdens.

The contemporary test in pediatrics for whether an intervention is ethically appropriate is the best-interest standard—a weighing of expected burdens and benefits of that intervention for a particular child. Although the

benefits, risks, and burdens to family, care providers, and society are relevant considerations in many cases, the primary focus should always be on the child's welfare. Other considerations may become determinative when the intervention offers minimal or no benefit to the child.

A number of commentators have argued that fluids and nutrition are different from other medical interventions, because they represent basic forms of care that can never be withheld or withdrawn, especially from children.[25–29] A mother's letdown reflex at the cry of her infant illustrates the deep and complex bond between parent and child and the importance of feeding offspring as an integral element of nurturing them. Food and water are essential to life, play an important role in social and cultural rituals, and are frequently used to reward, punish, or demonstrate love. For many people, having a well-fed child is a sign of a "good" parent, along with keeping their child warm, clean, and safe.[30,31]

Although the important symbolic meaning of feeding and eating is acknowledged, the provision of fluids and nutrition via medical technology is different in important ways from providing food or drink to a hungry or thirsty child.[23] Children who cannot eat and drink, cannot experience the pleasure of chewing and tasting, cannot enjoy the social aspects of sharing food and the social pleasures of mealtime, cannot detect hunger or thirst, or cannot experience nurturing through feeding have different needs that may or may not be met through the medical provision of fluids and nutrition. The medical provision of fluids and nutrition requires tubes, pumps, special formulas, monitoring for adverse effects and complications, and, frequently, surgical procedures.

Medically provided fluids and nutrition represent medical interventions. Similar to most other medical interventions, the medical provision of fluids and nutrition carries with it the potential for adverse effects and discomfort, including dyspnea, fluid overload, widespread edema with potential skin breakdown, systemic and local infection, fluid and electrolyte imbalance, thrombosis, pain, organ damage, and nutritional excesses and deficiencies. The rate of complications of enteral feeding can be as high as 76%.[32,33]

Similar to other medical interventions, medically provided fluids and nutrition may or may not be appropriate, depending on the goals of treatment.[34] Although the benefits of this technology commonly outweigh its risks when used temporarily as an aid to healing or to maintain a quality of life acceptable to patients and their families, the consideration of burdens and benefits remains the basis for determining the appropriateness of this and all other medical interventions. Therefore, medically provided fluids and nutrition can be withheld or withdrawn under the same 2 conditions that justify the withholding or withdrawing of other medical interventions:

- when a competent person has refused the intervention; or
- in the case of persons who have never possessed decision-making capacity or the absence of some indication of a previously competent patient's preferences, when a surrogate decision-maker, in consultation with the physician, has come to the conclusion that the expected burdens of the intervention to the patient exceed the potential benefit to the patient.

Any determination of relative burdens and benefits related to medically provided fluids and nutrition must occur within the context of other decisions about the appropriate level of medical support, provision of comfort care, and the goals of medical interventions given the patient's underlying condition. This report will not discuss the situation of the person with decision-making capacity who has chosen to forgo medically provided fluids and nutrition, because the response to that situation is clear, and it is infrequently encountered in pediatric practice. However, there are several situations in which medically provided fluids and nutrition might fail to provide a net benefit to the pediatric patient.

SITUATIONS IN WHICH THE BURDENS OF TREATMENT OUTWEIGH THE BENEFITS

The provision of medically provided fluids and nutrition is morally optional if it does not provide a net benefit to the child. This section will discuss several situations in which medically provided fluids and nutrition may not provide net benefit to a child. These situations are offered as examples and are not intended to encompass every possible scenario in which medically provided fluids and nutrition might fail to provide net benefit to a child. The argument that medically provided fluids and nutrition may be forgone in such children is not an argument that it should or must be forgone. In the absence of net benefit to the child, other considerations become relevant, and parents should be granted wide discretion in providing or withholding medically provided fluids and nutrition.

Some children may be unable to eat and drink permanently as the result of severe congenital or acquired central nervous system (CNS) injuries. For children with sufficient awareness to experience benefits from continued existence, long-term medically provided nutritional support might be potentially beneficial. However, for children who never possessed consciousness or fail to regain consciousness, questions may arise about whether long-

term medically provided nutrition and hydration ultimately benefit the child. Although medically provided fluids and nutrition may be beneficial while the diagnosis and prognosis remain uncertain and treatment is provided in hope of recovery, the decision to continue medically provided fluids and nutrition should be based on whether the child ultimately derives a net benefit from the continuation of treatment.[29]

Children who are rendered comatose from a severe CNS injury or disease may transition to a persistent vegetative state, "a clinical condition of complete unawareness of the self and environment, accompanied by sleep-wake cycles with either complete or partial preservation of hypothalamic and brainstem autonomic functions," within several weeks.[35] A defining characteristic of individuals in a persistent vegetative state is the complete lack of awareness of themselves or their environment. Such patients are incapable of experiencing either pleasure or suffering and, thus, do not consciously experience any benefit from continued existence. Recent estimates suggest that there are between 14 000 and 35 000 adult and pediatric patients who are in a vegetative state.[36] Some individuals in a vegetative state may recover consciousness, although the probability decreases substantially over time, and most of the few patients who emerge from a vegetative state remain severely disabled.[37] The term "permanent vegetative state" describes patients who remain vegetative for 12 months after traumatic injury or 3 months after a nontraumatic injury, most commonly an anoxic-ischemic event.[38]

Because individuals in a persistent vegetative state are unaware of themselves and their environment, the provision of medically provided fluids and nutrition does not confer them benefit and may be withdrawn. Emerging social standards seem to support a decision to withhold or withdraw fluids and nutrition from a person in a persistent vegetative state. Population surveys suggest that most Americans would not want medically provided nutrition and hydration should they themselves be in a persistent vegetative state,[39–46] and most physicians knowledgeable in this domain support the option of withdrawing fluids and nutrition for those in a persistent vegetative state.[47] The application of a "reasonable-person" standard would suggest that a large majority of people would not want to be kept alive in a persistent vegetative state via any means, including medically provided fluids and nutrition, and that surrogate decision-makers should, therefore, be permitted to forgo such interventions on their behalf.[48–50] It would be a form of age discrimination to impose on children the burdens and quality of life rejected by the majority of adults merely because they had not achieved legally independent status before their catastrophic injury.

This rationale does not necessarily apply to children in a "minimally conscious state," a relatively new term for patients who have limited consciousness. In this condition, individuals have reproducible ability to respond to some limited environmental stimuli, sometimes exhibiting behaviors such as following a simple command, intelligible verbalization, appropriate smiling or crying, or reaching for an object. These patients have some intermittent awareness of themselves and their surroundings and presumably can experience pleasure and pain, although it may be impossible for observers to assess subjective experiences such as suffering.[51] It is difficult or impossible to understand the subjective experiences of individuals who exist in this condition, and it may be impossible to draw firm conclusions about long-term prognosis. Therefore, it is difficult to draw general conclusions about whether individuals in this state would or would not benefit from long-term technical support.[52] Because these individuals represent a group for whom it might be particularly difficult to assess level of awareness and determine prognosis, decisions regarding the withdrawal or withholding of medical interventions on their behalf should be made carefully, and caution must be exercised that judgments are not inappropriately influenced by prejudice regarding disability.

Infants with congenital CNS malformations or prenatal injury who never possessed the capacity to feed orally represent a third group of neurologically impaired children. Examples include infants with anencephaly, hydranencephaly, or profound perinatal asphyxia resulting in an inability to suck. Artificial fluids and nutrition may be essential to support many such infants until a diagnosis and prognosis are confirmed. If the diagnosis and prognosis indicate that the infant will never possess conscious awareness and the capacity to feed orally, some would argue that the risks and potential burdens of medically provided fluids and nutrition could easily outweigh what minimal benefit they would offer the child.[53]

In any of these groups of children with profound neurologic impairment, continued survival might be considered a benefit by the family members, and they may, therefore, choose to maintain their child's medically provided nutrition and hydration on that basis. Conversely, the mere physical existence of a child who will never recover consciousness or the ability to interact with his or her environment may produce great sorrow and suffering for some parents, siblings, and extended family without any perceived compensatory benefit. Therefore, medical provision of fluids and nutrition in these

circumstances cannot be said to benefit the child (who will never personally be capable of experiencing the benefit of existence) and may not promote the interests of the child's family. Therefore, it is not ethically mandatory to provide medically administered fluids and nutrition to a child in a permanent vegetative state or other condition that results in a permanent lack of conscious awareness. For individuals and parents who do not wish to forgo medically provided fluids and nutrition for ethical, religious, cultural, or medical reasons, a decision to maintain these support measures should be honored. Although a decision to forgo medically provided fluids and nutrition is ethically permissible in some circumstances, it would almost never be ethically required, and parents should be allowed wide discretion in making this decision.

Medically provided fluids and nutrition can also be withheld or withdrawn from children with other medical conditions when the burdens of such interventions are likely to exceed any potential benefits. In the final stages of the dying process, many individuals will lose their ability to take fluids or nutrition by mouth because of compromised mentation, sedation, and/or weakness. If a child is capable of experiencing thirst or hunger, fluids and nutrition can be an essential element of palliative care. However, anorexia is common at the end of life. A clear consensus has emerged on the basis of research and clinical reports that seriously ill or dying patients experience little if any discomfort on withdrawal of tube feedings, parenteral nutrition, or intravenous hydration.[54,55] In fact, the adult experience suggests that fasting, particularly in the setting of terminal illness, may carry significant benefits that include the release of endorphins and creating a feeling of well-being, ketone production leading to hunger reduction, and clearer thinking.[32]

Parents and care providers may wish to consider withholding fluids and nutrition in the setting of terminal illness when medically provided fluids and nutrition do not serve the goals of promoting comfort (eg, in some children with end-stage malignancies who are unable or unwilling to take oral fluids or food). In these circumstances, medically provided fluids and nutrition may not be comforting for the child and may only serve to prolong the dying process.[56] Indeed, providing fluids and nutrition in these circumstances may increase discomfort, and fasting might enhance the well-being of the patient through ketosis and endorphin production, decreasing symptoms such as nausea, vomiting, diarrhea, coughing, respiratory secretions, and urine output and decreasing the metabolic rate.[32] Furthermore, the provision of some forms of fluids and nutrition may be accompanied by other burdens such as ongoing hospitalization rather than home care and blood draws to monitor electrolyte balance, liver function, and evidence of sepsis. Palliative care measures to manage symptoms related to decreased oral intake, such as dry mouth or decreased oral hygiene, are well established and effective.[57]

Infants with a severe gastrointestinal malformation or a disease that is destructive to a large portion of the gastrointestinal tract leading to total intestinal failure represent another group for whom parents or legal guardians might be provided the option of withholding or withdrawing medically provided fluids and nutrition. Although administration of total parenteral nutrition may help such children live for years, long-term total parenteral nutrition, particularly in the absence of any bowel function, is associated with a high rate of complications such as infection and hepatic dysfunction.[58,59] More definitive treatments, such as bowel transplants, are currently associated with a significant rate of severe morbidity and mortality in young children.[60,61] Because in some cases the burdens may outweigh the benefits to the child, withdrawal of medically provided fluids and nutrition is an acceptable, although difficult, option to consider, particularly when technical complications, such as no further central line access sites, confront the caregivers.[29,58] For these patients, it is critical to ensure meticulous attention to prevention and treatment of discomfort.

Other conditions that are incompatible with long-term survival and for which significant burden is associated with continued existence or available treatment options might also create situations in which medically provided fluids and nutrition may ethically be withheld or withdrawn from a child. For example, some infants are born with heart defects that are ultimately incompatible with survival beyond a few months and for which transplant is the only therapeutic option. Parents may decide not to pursue the transplant, choosing instead to optimize their child's comfort during his or her short life. In these cases, medically provided fluids and nutrition may not serve the interests of the child. In particular, when congestive heart failure is present, medically provided fluids and nutrition can induce or worsen fluid overload, leading to dyspnea, uncomfortable abdominal distention and associated nausea and vomiting, chest pain, and massive edema with skin breakdown. Should parents and care providers choose to limit medically provided fluids and nutrition, a comprehensive palliative care regimen would be particularly important for minimizing the suffering of the child.

OTHER ETHICAL CONSIDERATIONS

Although withholding or withdrawing medically provided nutrition and hydration may be in a particular child's interests, children with disabilities must also be protected from discrimination. Many children benefit from medically provided fluids and nutrition. Some individuals and groups worry that "crossing a line" and permitting the withdrawal of medically provided fluids and nutrition in any cases will place these vulnerable children at risk of being neglected or devalued as social standards change. They are concerned that if it seems acceptable to withhold fluids and nutrition in children in a persistent vegetative state today, it may become acceptable in the future to withhold them from children with less severe conditions who might be considered burdensome to families or society. Although this "slippery slope" concern is important, it is not sufficiently weighty to preclude the withdrawal of fluids and nutrition in well-defined circumstances. Prohibiting the withdrawal of fluids and nutrition in all cases to ensure protection against discrimination would subject some children to unwanted and burdensome interventions. Because these difficult decisions to withdraw or withhold medically provided fluids and nutrition are explicitly justified on the basis of the welfare of the child, the risk of abuse is substantially reduced. Disability alone is not a sufficient reason to forgo medically provided fluids and nutrition. Decisions about medically provided fluids and nutrition should be made on the same basis that all other medical decisions are made—a determination that, ultimately, the patient would experience sufficient benefit from the intervention to justify any accompanying burdens. That is, it would not be ethically justifiable to withdraw fluids and nutrition from a child who was clearly benefiting from these measures to reduce burdens on the family, society, or the health care system.

One commonly expressed concern about the withdrawal of fluids and nutrition is that it might cause significant suffering. The clinical data (cited in the previous section) do not support this concern. For patients in a persistent vegetative state or with other conditions marked by the absence of conscious awareness, there can be no experience of suffering. For children in a terminal phase of illness, "forced" feedings or nutrition may cause more discomfort than their withdrawal, particularly when symptoms are carefully addressed through palliative measures.

A final ethical consideration concerns the role of parents or guardians in decision-making about the withdrawal of life-sustaining measures. Parents who are seeking their children's best interests are usually the best decision-makers for their children. Because of the value-laden nature of the decision to withdraw fluids and nutrition, this option should only be pursued with the full knowledge and support of a child's parents or legal guardian. Typically, decisions of this nature are not urgent, so parents, guardians, and care providers can wait to ensure the prognosis is correct and have time to fully consider all of the options and the ramifications of each available option. Parents may want to consult with others, including extended family, clergy, and friends. Parents also may want and should be encouraged to seek second or third opinions about the prognosis and the medical or ethical aspects of their options. Ethics consultation may help address the ethical issues and should be available to families. Decision-making in this situation should be accompanied by a discussion about limiting other interventions (such as cardiopulmonary resuscitation and routine blood draws), the practical aspects and logistics of withdrawing medically provided fluids and nutrition, and how comfort will be ensured for everyone involved. The decision to withhold or withdraw medically provided fluids or nutrition should be understood as an important entry point into a broader palliative care plan.[62–64]

It is also important to emphasize that care providers must work within their own ethical standards, and pediatricians and other health care providers should not be required to participate in treatment plans to which they have personal ethical objections. However, when such an option is legal and ethical by societal standards, parents must be made aware of the option and a referral must be made to caregivers who can assist them to further explore and carry out their wishes. On the other hand, although parental permission for the withdrawal of fluids and nutrition is essential, it is not sufficient if care providers do not believe such a choice is ethically permissible. Care providers may require support in understanding the reasons behind a parent's decision. Ethics consultation or ethics committee involvement may be valuable in these situations. In rare situations in which caregivers have a strong basis for believing that continuing or initiating medically provided fluids and nutrition would be, on balance, excessively burdensome to a child and parents do not support the withholding or withdrawing of medically provided fluids and nutrition, health care providers should seek the involvement of an ethics consultant or ethics committee. Difficult choices are best made when there is consensus between the parents and care providers about the best course of care, and the involvement of an ethics consultant, ethics committee, or palliative care consultant may be especially helpful when

there is disagreement surrounding the appropriateness of medically provided fluids and nutrition.

LEGAL CONSIDERATIONS

Most legal cases that have addressed the issue of withholding or withdrawing fluids and nutrition have involved adults, but several principles developed in these cases apply equally in the pediatric setting. One area of legal consensus is that medically provided nutrition and hydration are medical treatments and may be withheld or withdrawn under the same conditions as any other form of treatment.[65–67] Virtually every court case at the federal appellate level has concluded that provision of artificial nutrition and hydration is a medical procedure, that it may be forgone under appropriate circumstances as may any other procedure, and that the fact that it involves basic sustenance is not relevant to whether it must be administered or may be forgone.[65] In *Cruzan v Director, Missouri Department of Health*, for example, the US Supreme Court affirmed the view that medically provided fluids and nutrition are medical interventions that can be refused by a competent adult.[68] The court thus rejected the "exceptionalism" often afforded to medically provided fluids and nutrition.

Federal regulations relevant to this debate emerged after the public controversy over the case of "Baby Doe" in 1983. Baby Doe was an infant with trisomy 21 who died after the decision by his parents to withhold surgical repair of esophageal atresia. In response, Congress amended the Child Abuse Prevention and Treatment Act (CAPTA) in 1984 to include language requiring state child protective services agencies to have reporting mechanisms for the withholding of treatment from infants with severe disabilities.

The CAPTA stipulates that medical treatment need not be provided "other than appropriate nutrition, hydration, and medication" when, in the physicians' reasonable judgment, any of 3 circumstances apply: (1) the infant is chronically and irreversibly comatose; (2) the provision of such treatment would merely prolong dying, not be effective in ameliorating or correcting all of the infant's life-threatening conditions, or would be "futile" in terms of the infant's survival; or (3) the treatment would be "virtually futile" and "inhumane."[69] Although this language seems to advocate for the provision of appropriate fluids and nutrition in most cases, the AAP argues that medically provided nutrition and hydration are "appropriate" when they serve the interests of the child—in other words, when they are expected to offer a level of benefit to the child that exceeds the potential burden to the child. The purpose of this report is to define the appropriate use of medically provided fluids and nutrition, and in that sense, the CAPTA seems consistent with the guidelines provided in this report.[70] Furthermore, the Baby Doe regulations include no direct enforcement mechanism but make states' receipt of federal child abuse prevention program funds contingent on having a reporting mechanism in place. Therefore, the regulations are directed to state-funded child abuse prevention programs and were not intended as standards of physician or institutional liability.[29]

Although there is no federal prohibition of carefully made decisions to withhold or withdraw medically provided fluids and nutrition from children, individual states may have specific regulations or case law that address this issue. Physicians should be familiar with state laws that may influence their decisions regarding the withholding or withdrawing of medically provided fluids and nutrition (state AAP chapters, state medical associations, or the AAP Division of State Government Affairs can offer assistance in obtaining this information).

CONCLUSIONS

It is ethically permissible to withdraw medically provided fluids and nutrition from infants, children, and adolescents in selected circumstances. As a general rule, medically provided fluids and nutrition can be withheld or withdrawn from a child when there is consensus that the provision of fluids and nutrition do not confer a net benefit to the child. In addition, the AAP offers the following general principles:

1. Children capable of safely eating and drinking who show signs of wanting to eat or drink should be provided food and fluids.
2. Medically provided fluids and nutrition constitute a medical intervention that may be withheld or withdrawn for the same types of reasons that justify the medical withholding or withdrawing of other medical treatments.
3. Decisions about whether medical interventions should be provided to a child, including medically provided fluids and nutrition, should be based on whether the intervention provides net benefit to the child.
4. The primary focus in decision-making should be the interests of the child.
5. Although withholding or withdrawing medically provided fluids and nutrition may be morally permissible, it is not morally required.
6. Medically provided fluids and nutrition may be withdrawn from a child who permanently lacks awareness and the ability to interact with the environment. Examples of such children include children in a persistent vegetative state or children with anencephaly. The diagnosis and prognosis should be

confirmed by a qualified neurologist or other specialist with expertise in the evaluation of children with these conditions.

7. Medically provided fluids and nutrition can be withdrawn from children when such measures only prolong and add morbidity to the process of dying. In these situations, continued fluids and nutrition often provide very limited, if any, benefit and may cause substantial discomfort. Some examples of children in this group include those with terminal illnesses in the final stages of dying, infants born with heart defects that are ultimately incompatible with survival beyond a few months and for which transplant is the only therapeutic option, infants with renal agenesis, or infants with a severe gastrointestinal malformation or a disease that is destructive to a large portion of the gastrointestinal tract, leading to total intestinal failure, and whose parents have opted for palliative care rather than intestinal transplant.
8. Parents or guardians should be fully involved in shared decision-making with the physician and health care team and should support the decision to withhold or withdraw medically provided fluids and nutrition. Parents should be reassured that their child will be kept comfortable and should be informed about the likely course of events, including broad estimates of when the child's death is anticipated. Comprehensive palliative care measures for the child, including appropriate sedation and oral hygiene, should be provided in this situation.
9. Ethics consultation is strongly recommended when particularly difficult or controversial decisions are being considered.

POLICY STATEMENT

AACAP/CWLA FOSTER CARE MENTAL HEALTH VALUES SUBCOMMITTEE- POLICY STATEMENT

PREAMBLE

In the past few years, significant attention has been given to the growing number of children who suffer needlessly because their emotional, behavioral, and developmental needs are not being met. All of us are being urged to take seriously the task of preventing mental health and/or substance use problems and providing services and supports for treating mental illness and/or substance use in children.

Over the last few years, the Surgeon General's Report on Children's Mental Health and the UN Convention on the Rights of the Child have emphasized that treatment should be considered a basic right for children who suffer from an emotional/mental health/substance use problem and their families. This year, President Bush issued an executive order, the "New Freedom Initiative" (NFI) of June 18th, 2001, to identify and remove existing barriers to community living for persons with disabilities, including children with severe emotional disturbances. The NFI highlights the importance of "no wrong door" for accessing services and creating opportunity for children to receive community-based services within their local service systems. The President's announced plan to establish a National Commission on Mental Health will further support addressing the unmet emotional/mental health needs of children.

Children served by the foster care system are coping with the events that precipitated their coming into care, while enduring the personal grief and trauma that accompany the loss of a family. Currently, over 500,000 children reside in foster care in the United States, and 85% of them are estimated to have an emotional disorder and/or substance use problem. Recognizing our common interest, the American Academy of Child and Adolescent Psychiatry (AACAP) and the Child Welfare League of America (CWLA) began an initiative in March 2001, to improve the design, delivery, and outcomes of the mental health and substance use services provided to children in foster care and their families. AACAP and CWLA have been joined by over 30 consumer and professional organizations, which have contributed their expertise and resources to this initiative.

Our examination of the problem and the seriousness, intensity, prevalence, and urgency of the unmet needs of these children and their families substantiates our commitment to this initiative. Drawing on the values and principles already developed through such efforts as the systems of care, which focused on service delivery to children with serious emotional disturbances, the values and principles delineated in this document will guide our efforts to improve policies and practices in the various child-serving systems that

serve children in foster care and their families. We believe such values and principles will drive practice in addressing the mental health and substance use needs of children and their families. This in turn will lead to other reforms in how local communities and the formal systems intersect around mental health, substance use, and child welfare issues to ensure and promote the well-being of children in foster care and their families.

Our mutual interest is the emotional/mental health of children and their families. We must develop innovative and evidence-based assessment tools to identify children's emotional and/or behavioral problems as early as possible and to ensure that all children and their families have access to and receive evidence-based, effective mental health and substance use prevention/treatment services, and supports. We believe it is our professional responsibility to provide the most timely, appropriate, and effective prevention/treatment services and supports to children and their families to ensure the best outcomes. Key strategies for accomplishing these goals are:

- keeping children and their families involved whenever possible;
- providing the children with services and supports in their own community;
- responding to their needs with staff who understand their culture and programs that are culturally relevant to children and their families; and
- treating their mental health and substance use needs in a timely manner with professionals trained in the most effective prevention/treatment approaches.

To this end, we agree to support and advocate for providing mental health and substance use prevention strategies, assessments, treatments, services, and supports designed for children in the foster care system and their families that abide by the following values and principles:

I. **Values**
Overarching Discussion Points:

- Values are infused into a piece of work; principles are the key points that support the infused values.
- Values are what drive the process. Principles result from the values; they make the process operational.
- Values are the "why"; principles are the "how."
- The values focus should be on mental health and substance use issues of children in foster care and their families.

E. Suggested value concepts should support a child-focused approach to ensure that mental health and substance use services and supports are an integral component within foster care.

VALUE: **CHILD-FOCUSED MENTAL HEALTH AND SUBSTANCE USE SERVICES AND SUPPORTS**
Discussion Points:

- Issues of attachment are considered significant to the emotional/mental health of children in all placement decisions.

- The trauma children endure when moved from placement to placement is not conducive to normal development. It can adversely impact children and families.
- When children are placed outside of the home it is important for services and/or supports to be provide not only to the child but also to the family of origin.
- When placing children outside of the home, it is essential to help them create developmentally meaningful new attachments, while at the same time maintaining existing attachments whenever possible.
- Children's view of how their emotional/mental health will be impacted by placement decisions should be represented (either by the child through their words or behavior or through representation by an adult whose primary role is to offer the child's perspective) in all proceedings in keeping with the age and maturity of the child.
- The current child welfare system tends to be focused initially on the physical safety of the child while not adequately considering the impact of removal and placements on the child's emotional/mental health. To do so could prevent further emotional/mental health problems.
- Practice Guidelines must be established to address not only the safety issues but also the emotional/mental/behavioral health need of children.
- Foster care providers need information and resources to address the mental health and substance use needs of the children they serve. A process for monitoring that services are delivered in a timely and appropriate manner is necessary.
- It is important that, while in care, the child and the birth family maintain contact. Assessment decisions need to be made to determine if the birth family can be in immediate and continuing contact (face to face visitation and/or by telephone) in order to decrease the severity of separation trauma. In addition, whenever possible, the birth parents and foster parents and/or other agency caregiver(s) should communicate with each other to maximize continuity and mutuality in accomplishing therapeutic goals.
- Providing mental health intervention at the time of the initial placement and while in care is a means of preventing attachment disorders and/or the progression of already existing mental health and substance use problems. To ensure the child's emotional well-being, assessments should be performed at regular intervals to determine if there are attachment issues emerging to be considered while the child is in care, when moving to another placement and/or moving to their permanent placement (i.e. home, adoption, long-term foster home).

- Reunification with the family of origin may not always be the best option for the child and other options must be considered to ensure the physical and emotional well-being of the child.

F. Suggested value concepts should support a family-driven approach to ensure that mental health and substance use services and supports are an integral component within foster care.

VALUE: **FAMILY-DRIVEN MENTAL HEALTH AND SUBSTANCE USE SERVICES AND SUPPORTS**

Discussion Points:

- For child welfare services, a family-driven policy that does not compromise the child's safety is necessary.
- The foster care system is currently focused on the child. To really meet the needs of the child, it should place greater emphasis on the family of origin. This family-centered approach could result in a major change of cultural/mindset within the current child welfare system.
- The child welfare system is concerned with safety, permanency, and well-being. Every child should have a safe home as soon as possible preferably, but not necessarily with the family of origin.
- To every extent possible, the biological family should be involved even when it is not the custodial family.

G. Suggested value concepts should support a community-based approach.

VALUE: **INTEGRATION, COLLABORATION AND COORDINATION OF COMMUNITY-BASED MENTAL HEALTH AND SUBSTANCE USE SERVICES AND SUPPORTS WITH THE FOSTER CARE SYSTEM**

Discussion Points:

- Mental health and substance use (behavioral health) services and supports should be readily available to children in foster care and their families.
- Identify best practices in providing mental health and substance use services and supports to children in foster care and their families.
- Health and behavioral health care providers must have a clear and defined role, driven by professional expertise and values, in treating children in foster care and their families.
- To ensure child safety and achieve quality services and supports for children and their families, it is crucial to expand and increase the input of both community members and expert professionals.
- In the child welfare system, the child is placed in a foster care environment, which is expected to address the child's safety and well-being. There may be difference in how states define safety.

How local communities participate in setting the community standards further impacts the differences in definition.

- The child's comprehensive health assessment must include the elements of the EPSDT screening and assessment, such as physical, dental, substance use, and mental health evaluations. It must also address issues of co-morbidity.
- Foster parents must be informed of the mental health and substance use needs of the child that they are caring for. They must also be provided with education and information as to effective ways these needs can be met to support the key role foster parents have addressing the mental health and substance use needs of the child.

H. Suggested values concepts should demonstrate sensitivity to cultural competency issues

VALUE: **CULTURALLY COMPETENT, SENSITIVE, RELEVANT, AND STRENGTH-BASED MENTAL HEALTH AND SUBSTANCE USE SERVICES AND SUPPORTS THAT ARE PROVIDED BY KNOWLEDGABLE AND SKILLED STAFF AND SERVICE PROVIDERS WHO ARE AWARE AND UNDERSTAND THE CULTURAL DIVERSITY OF THAT COMMUNITY.**

Discussion Points:

- It is crucial that assessment tools and mental health and substance use services and supports be not only culturally competent, but also culturally sensitive and relevant to children and their families.
- Assessments and mental health and substance use treatment/service/support planning should take into account the strengths of the children and their families.
- Assessment and mental health and substance use treatment/services/supports should take into account the cultural status, economic status, and the diversity of the community and the population being served.
- There should be culturally competent policies and professional competence in procedures, outreach, advocacy, and training throughout the service delivery system.
- To facilitate rapport and successful outcomes, the team engaging and delivering services/supports to children and their families should, to the extent possible, represent the diversity of the community and the population served.
- Cultural competence, sensitivity and relevance is demonstrated through the array of services, the design and delivery system, and by recognizing the importance of existing community-based, informal support networks such as churches, extended kinship networks, and social organizations.

I. Suggested value concepts should support timely access to effective evidence-based quality services and supports

VALUE: **TIMELY, EFFECTIVE, EVIDENCE-BASED, OUTCOME-DRIVEN MENTAL HEALTH AND SUBSTANCE USE SERVICES AND SUPPORTS**

Discussion Points:

- The grief and trauma children experience when they are placed into and within the foster care system must be taken into account when assessing their needs and providing services and supports. An initial mental health and substance use screening should be done within 24 hours of placement. The mental health and substance use screen is intended to identify children in urgent need of emergency mental health and substance use services. This screening would also assess the internalized and externalized levels of distress in the child regarding the separation from their family of origin. A triage intervention to address the child's feelings regarding the separation and help the child cope should be provided as quickly as possible based on the severity and intensity.
- All children in foster care and their families must have a comprehensive mental health and substance use assessment once the child is stabilized but minimally within the timeframes of EPSDT. The assessments should always address the attachment issues for the child as long as the child is in care and be done in a timely fashion especially when there is transition from placement to placement.
- The child welfare system must take into account the difference between a child having a mental disorder and/or substance use problem and a child requiring mental health and substance use intervention to prevent a future disorder and address both. Currently, a mental health and/or substance use assessment is often not done until there is a crisis.
- Just as it is necessary for periodic reviews to be done on individual case plans, it is necessary for systems and providers to perform effective, evidence-based, outcome-driven reviews of results to demonstrate progress in achieving the goals for the children and their families.
- To provide compassionate, relevant services it is essential to reach for and use feedback from the children and their families about the effectiveness of the services offered to address their needs and goals.

II. **Principles generated by the above values**

The principles outlined in this section are infused by the core values mentioned above and provide greater detail for how they are to be implemented.

. **Service coordination and case/care management**

- Coordination/integration among mental health, substance use, physical health, developmental disabilities, legal services, educational services, and child welfare services is essential.
- Children in the foster care system deserve coordinated mental health and substance use services that are designed, screened, assessed, and delivered as part of their foster care services plan.
- Coordination at the systems level can ensure the most appropriate use of limited resources and eliminate the fragmentation currently experienced with different funding streams for the needed services and supports.
- Many children and youth coming into foster care have co-occurring mental health and substance use issues. Service coordination should be provided to ensure that their substance use needs are assessed and treatment services and supports are provided concurrently with the mental health services and supports.
- Coordination must also include the services children are receiving and the services the family member(s) are receiving.
- Coordination should take place to ensure that family members who require services/supports are receiving them.
- Information must be shared on a regular basis among organizations/agencies providing services/support to the child and/or their family. Every effort must be made to eliminate barriers, while complying with the confidentiality requirements in HIPAA. This information should follow the child from placement to placement.

A. **Prevention and early identification**

- Prevention and early identification programs and supports for potential mental health and substance use issues are vital to children in the foster care system and their families.
- Young children (0-3yrs) are of particular concern given they make up a significant percentage of the population of children who are placed in the foster care system. Evidence-based prevention and early intervention programs should be targeted to this population.
- Assessments for children entering the foster care system should include screening for potential mental health and substance use issues.
- While in foster care, children should be reassessed for potential mental health and substance use problems at specific intervals (minimally EPSDT timeframes) or as indicated, so that prevention and/or treatment services and supports can be provided as early as possible. It is recommended that a referral be made for a mental health and substance use assessment by an appropriately trained professional.

B. **Planned and coordinated transitions among agencies and providers and between children, families, and adult systems**

- μ# Children and their families can suffer significant negative impact when transitions and/or discharges are not successful. Therefore, coordination, communication, and effective planning are necessary whenever children are involved in one of the following: changing providers and/or agencies, returning home, changing levels of care, changing placements or moving to their permanent placement, and/or transitioning to self-sufficiency or being transferred to another service system.
- μ# Youth in care making the transition to self-sufficiency may need services provided by the adult system, such as mental health and/or substance use services and housing, financial, health, dental, and educational and/or employment assistance. It is therefore important that effective coordination take place between these child and adult systems.
- μ# Key to ensuring successful transitions and discharges are early planning, ongoing coordination of services to address all needs, effective monitoring of plan implementation, and appropriate sharing of the case record information at the time of transition/discharge.
- μ# Each child leaving the child welfare system must have a developmentally and age appropriate transition and/or discharge plan. Such planning must provide the skills, information, services, and supports that allow young people to successfully transition to adulthood, where they can provide for their own permanency, safety, and well-being.
- μ# Transition can have a significant impact on the child and their family. Therefore, to ensure successful transitions, it is important that the child's needs and wishes (expressed either verbally or through behavior) be considered and take precedence over the system's needs whenever possible. If a child experiences more than two placements, the child welfare system should have a process in place to review the reasons and the impact to the child to ensure attachment issues and the child's mental health and substance use needs are being adequately addressed/considered.
- μ# To minimize the potential negative impact of changes/turnover in workers, it is recommended training be provided to workers on such issues as the impact of removal from home and/or transitions on children and their ability to form attachments, assessing the trauma of removal/placements on the child, effective interventions for dealing with attachment trauma, and signs for when a child should be referred for mental health and substance use treatment/services/supports.

C. **Human rights and responsibilities regarding protection and advocacy**

- μ# All children in foster care have the right to have their views expressed directly through their words and behavior to the extent that is developmentally and age appropriate or have representation

by an adult whose primary role is to offer the child's perspective for the following:

1. Have access to and be provided with quality mental health and substance use services and supports.
2. Have a say in which mental health and substance use services and supports will be of assistance to them based on their own strengths and needs.
3. Have a say in the development, monitoring, and revision of their mental health and substance use treatment plan, which is in keeping with their permanency plan and the family service plan.
4. Have a say in what mental health and substance use services and supports are or are not working for them.
5. Refuse mental health and substance use services and supports unless their refusal would put them at risk of harm.
6. Be provided mental health and substance use services and supports in the least intrusive community-based environment that is possible.
7. Retain their constitutional rights when placed in foster care.
8. Have input into the impact of placement decisions on their emotional/mental health.
9. When very young or developmentally immature, have representation to ensure consideration of the impact of placement decisions on their emotional/mental health.
10. Maintain frequent and regular, ongoing contact with sibling(s) and other family members when the family cannot be maintained as a single unit.

μ# All families with children placed in foster care (except when parental rights are terminated or other legal decisions take precedence while weighing the best interests of the child) have the right to:

1. Have a say and participate in which mental health and substance use treatment services and supports will be of assistance to them and their child based on their strengths and needs.
2. Have a say and participate in the development, monitoring, and revisions of their child's mental health and substance use treatment plan, which is in keeping with their child's permanency plan and their own family service plan.
3. Have a say and participate in decisions about what mental health and substance use services and supports are or are not working for them.
4. Refuse their own mental health and substance use services and supports, when their refusal would not put their child at risk of harm.

5. Have access to and be provided with quality mental health and substance use services and supports.
6. Be provided mental health and substance use services and supports in the least intrusive environment possible.
7. Retain their constitutional rights when their child/children are placed in foster care.

- Through a release of information form, emancipated youth and family members can provide consent on who gets what information.
- Children and their families have the right to be treated in compliance with federal, state, and local policies and standards.
- Children and their families have the right to seek advocacy support.
- Children and their families have the right to make complaints/raise concerns about the mental health and substance use services and supports that they are receiving without retribution. All agencies/providers should have a defined process for how such complaints/concerns can be raised and addressed.
- Children and their families have the right to receive services that are culturally competent/relevant and to choose providers who respect and value their language, culture, and spiritual beliefs.
- Children and their families have the right to access to the courts to address any concerns they might have about the mental health and substance use services they are receiving or believe they should be receiving.

D. **Nondiscrimination in access to services for children in care**

- Discrimination in the provision of services on the basis of race, religion, ethnicity, language, gender, age, sexual preference, marital status, national origin, or disability whether or not illegal.
- Providers should deliver mental health and substance use services and supports to children and their families in compliance with the Americans with Disabilities Act.
- Families can choose mental health and substance use service providers who respect and value their language, culture, and spiritual beliefs.
- As emphasized in the Surgeon General's Report on Children's Mental Health, it is important for public and private providers to ensure services are provided and accessible without any discrimination, including interpreters when necessary.

E. **A comprehensive and accessible array of services**

- Given the complexity of serving children and their families, it is crucial to have a comprehensive array of services available. This would include traditional, faith-based, and non-traditional mental health and substance use services and supports as well as formal and informal supports and services.

- This service array should be appropriate to address the circumstances and treatment needs of children and their families.
- Services chosen from the array should be age and developmentally appropriate.
- This service array should support children and their families in the community whenever possible.
- This service array should take into account the ongoing developing strengths of children and their families.

F. **Individualized service planning**

- Service planning to address the mental health and substance use needs of children should be individualized and include the following:
    1. mental health and substance use services and supports focused on the strengths, desires, interests, values, and goals of the child and the family,
    2. an assessment of the specific and particular mental health substance use needs of the child and the services/supports the family requires to deal with and support a child with these mental health and substance use needs,
    3. measures to address issues of emotional distress arising as a consequence of all placement transitions,
    4. consistency with the permanency plan for the child and the family service plan,
    5. informal as well as formal mental health and substance use services/supports, and
    6. goals articulated in such a way that one can measure progress towards the goals identified by the child and family.
- This individualized service plan should include the continuation of treatment when the child is reunified with his or her family. If a child is not receiving treatment services/supports at the time of reunification then it is an important time to initiate any treatment services that are needed as part of the reintegration process.
- This individualized service plan should be developed in partnership with the child and family and other professionals working with them.
- This individualized service plan should be regularly reviewed and updated to reflect the progress of the child or lack thereof, with input from the child and family when appropriate.
- This individualized service plan should include the discharge and transition plans.

G. **Services in the least intrusive community-based environment**

- Service planning to address the mental health and substance use needs of children should focus on providing these services and supports for children and their families at the appropriate level and

intensity and in the least intrusive environment to increase the child's functioning and physical stability.

- Every effort should be made to keep children in their home community whenever possible. Issues of risk to the child take precedence over the placement that is least intrusive/restrictive even if that means removing a child from their home.
- When services are being designed and developed there should be an easily accessed array of community-based services that support children receiving treatment in the least intrusive manner. Sometimes this might be over a widespread region, in particular in rural areas where it is not financially feasible to have all services in each local community.
- When services are being designed and developed there should be family and community input into the planning process.
- When children need to be placed outside the home community, it is essential that treatment/services/supports be provided to maintain the family connection when there is no indication to the contrary.

H. **Family participation in ALL aspects of planning, service delivery, and evaluation**

- Family is defined (using the Federation of Families definition) as including biological, foster, and adoptive parents, grandparents and their partners, as well as kinship care givers and others who have primary responsibility for providing love, guidance, food, shelter, clothing, supervision, and protection for children and adolescents.
- It is important for the family to be actively invited as part of the engagement process at ALL levels of planning, service delivery, and evaluation: e.g., the system level, organizational level, and individual child level.
- It is important for the family to be appreciated and involved in activities involving the child whenever possible.
- Families should be given the choice as to whether or not they participate.
- The family preference(s) and choice(s) should be considered in all planning for their child outside of situations, which might put the child at risk of harm.
- Families should be provided with advocacy and representation that increases education/communication to families.

I. **Integrated services with coordinated planning across the child-serving system**

- Children in the foster care system with mental health and substance use issues and their families are often involved with multiple child-serving organizations and systems. They require and deserve well coordinated planning and integration of services to address their complex needs.
- To ensure the most appropriate and effective integrated service delivery for children in the foster care system with mental health

and substance use issues and their families, services should be planned and coordinated across the child-serving systems.

- Often children in the foster care system initially access services through primary care. The EPSDT screening process should facilitate integration and coordination of services to meet the identified needs.
- Even when funding streams can not be combined, there is greater potential for integrating services when planning is coordinated across the child-serving systems. Such integrated planning would make better use of limited dollars and reduce the potential duplication of services while increasing the availability of services and supports for the child and family.
- When there are multiple systems involved, it is important for there to be consistency in planning across the various systems to ensure the child and/or family does not hear conflicting messages or has treatment approaches that are counter-indicated. It is the responsibility of all systems to work to mitigate the burden caused by uncoordinated planning between agencies and families.
- The goal is for there to be one document where the plans of various other child-servicing systems are incorporated into the foster care system case plan. The plan should be reasonable, useful, and respectful

GLOSSARY OF TERMS

CHILD - Refers to any child placed in out of home care.

CHILD-FOCUSED - A system is child-focused when both the physical and emotional well-being of the child is central to all levels of decision-making, and a process is in place for resolving conflicts between these two domains. The child's own views expressed, where possible, directly through the child's words and behaviors or, as required, through representation by an adult whose primary role is to offer the child's perspective should be represented along with the viewpoint of members of the child's family (as defined in this document).

CHILD SAFETY - A child is considered safe when an analysis of all available information leads to the conclusion that the child in his of her current living arrangement is not in immediate danger of serious harm, and no safety interventions are necessary.

CULTURAL COMPETENCE - A system is considered culturally competent when there is professional and formalized competence throughout the system in: policies, procedures, outreach, and advocacy efforts, and training. Cultural competence, sensitivity and relevance is demonstrated through the array of services, delivery, framework, and the recognition of the importance of existing community-based, informal support networks such as churches, extended kinship networks, and social organizations. Cultural Competence is demonstrated when there are knowledgeable and skilled staff and service

providers who are aware of cultural issues within the diversity of the community and who reflect and understand the diversity of that community.

FAMILY - Families can include biological, foster and adoptive parents, grandparents and their partners, as well as kinship care givers and other who have primary responsibility for providing love, guidance, food, shelter, clothing, supervision, and protection for children and adolescents. It is the extent of daily interaction and responsibility for a child, not a legal construct that identifies an individual as a family member.

FAMILY-DRIVEN - A system is family-driven when the family (kin and extended) is involved in all levels of decision making. Identification, outreach and engagement of the family receiving services in the foster care system is required so that family experiences and perspectives collectively drive the planning, work and outcome for the foster child.

PREVENTION AND EARLY INTERVENTION - Is inclusive of the following three components:

> **Primary Prevention**: Efforts to avert mental health and substance use problems altogether. For children these efforts include interventions directed at parents and educators and/or other professionals involved with children.
> **Secondary Prevention**: Efforts to detect mental health and/or substance use problems in their early stages of development and to apply techniques to reduce the severity and duration of incipient problems.
> **Tertiary Prevention**: Attempts to arrest further deterioration in individuals who already suffer from severe mental health and/or substance use problems (disorders). Treatment can be considered tertiary prevention.[1]

SYSTEM OF CARE - A system consisting of mental health, substance use, social services, education, medical, physical health, primary care, juvenile justice, and other professional organizations and other formal and informal services/support that work together with the family to meet the child's needs.

SUBSTANCE USE - Refers to the use of alcohol, illicit drugs and the misuse of prescription drugs.

DEDICATED TO THE HEALTH OF ALL CHILDREN™

Policy Statement—The Future of Pediatrics: Mental Health Competencies for Pediatric Primary Care

abstract

Pediatric primary care clinicians have unique opportunities and a growing sense of responsibility to prevent and address mental health and substance abuse problems in the medical home. In this report, the American Academy of Pediatrics proposes competencies requisite for providing mental health and substance abuse services in pediatric primary care settings and recommends steps toward achieving them. Achievement of the competencies proposed in this statement is a goal, not a current expectation. It will require innovations in residency training and continuing medical education, as well as a commitment by the individual clinician to pursue, over time, educational strategies suited to his or her learning style and skill level. System enhancements, such as collaborative relationships with mental health specialists and changes in the financing of mental health care, must precede enhancements in clinical practice. For this reason, the proposed competencies begin with knowledge and skills for systems-based practice. The proposed competencies overlap those of mental health specialists in some areas; for example, they include the knowledge and skills to care for children with attention-deficit/hyperactivity disorder, anxiety, depression, and substance abuse and to recognize psychiatric and social emergencies. In other areas, the competencies reflect the uniqueness of the primary care clinician's role: building resilience in all children; promoting healthy lifestyles; preventing or mitigating mental health and substance abuse problems; identifying risk factors and emerging mental health problems in children and their families; and partnering with families, schools, agencies, and mental health specialists to plan assessment and care. Proposed interpersonal and communication skills reflect the primary care clinician's critical role in overcoming barriers (perceived and/or experienced by children and families) to seeking help for mental health and substance abuse concerns. *Pediatrics* 2009;124:410–421

INTRODUCTION

The purposes of this policy statement are to articulate competencies—skills, knowledge, and attitudes—needed by primary care clinicians (PCCs) to address the mental heath problems prevalent among children and adolescents in the United States and to promote use of the competencies in guiding residency education and continuing education of PCCs.

Definitions and Scope

The term "mental" throughout this statement is intended to encompass "behavioral," "neurodevelopmental," "psychiatric," "psychological," "emotional," and "substance abuse," as well as family context[1–6] and community-related concerns such as child abuse and neglect, separation or divorce of parents, domestic violence, parental or family mental health issues, natural disasters, school crises, military deployment of children's loved ones, and the grief and loss accompanying any of these issues or the illness or death of family members. The term also encompasses somatic manifestations of mental health issues, such as eating disorders and functional gastrointestinal symptoms. This is not to suggest that the full range or severity of all mental health problems falls within the scope of pediatric primary care practice but, rather, that children and adolescents may suffer from the full range and severity of mental health conditions and psychosocial stressors. As such, children with mental health needs, similar to children with special physical and developmental needs, are children for whom pediatricians, family physicians, pediatric nurse practitioners, and physician assistants provide a medical home.[7]

The *Diagnostic and Statistical Manual for Primary Care* (DSM-PC) classification system[8] distinguishes between developmental variations (behaviors that may raise concern but are within the range of expected behaviors for the age of the child), problems (behaviors serious enough to disrupt functioning but not to a level severe enough to warrant the diagnosis of a disorder), and disorders (as defined by the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* [DSM-IV][9]). Because the PCC has a role in providing reassurance and/or care for children with behaviors in each of these categories, all fall within the scope of this document. Authors have used the term "concerns" when referring to behavioral issues not differentiated into 1 of these categories.

Many PCCs engage in mental health screening, assessment, diagnosis, and treatment. The term "mental health specialists" is intended to distinguish PCCs from those who specialize in the assessment and care of children and adolescents with mental health concerns. Thus, the term "mental health specialists," as used in this report, includes physicians and nonphysicians such as psychiatrists, clinical psychologists, clinical social workers, licensed professional substance abuse counselors, nurses with advanced psychiatric training, family therapists, neurologists, early intervention specialists, developmental-behavioral pediatricians, and adolescent medicine specialists. Each of these disciplines has specific training and licensing requirements. Other individuals outside the mental health profession who have an effect on the mental health of children include teachers, counselors, coaches, religious leaders, and community and extended family members. Providers of complementary and alternative (integrative) medicine (CAM), both licensed and unlicensed, also may address children's mental health, and a large number of families self-select CAM treatments for their children's mental health conditions.[10–14] A growing body of literature describes the potential benefits of CAM approaches[15–17] and risks of CAM therapies, including interactions of herbal remedies and dietary supplements with prescription medications.[18,19] Although 1 randomized, controlled trial of St John's wort was conducted with adolescents with depression,[20,21] most studies of herbal medication for mental health disorders have been completed in adults. These developments underscore the importance of knowing the medical evidence and considering CAM therapies and CAM providers in the context of pediatric mental health care.

Need for Statement

The need for this statement was driven by the following forces:

- the recognition that adverse psychosocial experiences in childhood have lifelong adverse effects on mental and physical health and on psychosocial status[22–25];
- the high prevalence of mental health disorders and substance abuse among children and adolescents: an estimated 10% to 11% of children and adolescents have both a mental health disorder and evidence of functional impairment[26];
- the prevalence of children who do not meet DSM-IV criteria for a disorder but who have clinically significant impairment ("problems" in DSM-PC terminology[8]), which is estimated to be equal to twice the prevalence of children with severe emotional disorders[26–28];
- the prevalence of mental health concerns in pediatric populations[29,30];
- the recognition that fully half of the adults in the United States with a mental health disorder had symptoms by the age of 14 years[31];
- the low percentage of children receiving care for their mental health or substance abuse problems (~20%)[26,32];
- the shortage and inaccessibility of specialty mental health services,[33] especially for underserved children from low-income families who do not fall within the target population of public/community mental health services;
- the disproportionate effects of unmet mental health needs on minority populations[34];

- the recognition that unidentified mental health comorbidities, such as anxiety and depression, are a significant force driving utilization of medical services[35]; and
- the growing realization (articulated in the President's New Freedom Commission Report[36]; *Mental Health: A Report of the Surgeon General*[26]; the Future of Pediatric Education II (FOPE II)[37] study; and *Bright Futures: Guidelines for Health Supervision of Infants, Children, and Adolescents, Third Edition*[38]; and by American Academy of Pediatrics [AAP] members [annual leadership forum resolutions]) that PCCs have a critical role to play in meeting children's mental health needs; in fact, at least 1 state is now requiring, by court order, universal mental health screening by PCCs for all children on Medicaid in that state.[39]

RATIONALE FOR COMPETENCIES

Uniqueness of the PCC's Role

PCCs have a role in mental health care that differs substantively from that of mental health specialists, many of whom may be unfamiliar with problems as they present in primary care. The recommended competencies reflect these differences. Children and families who seek care from a mental health specialist do so because they have recognized a mental health need or because some crisis has compelled them. Children and families seeking care at primary care offices typically have not framed the visit as "mental health"–related. They may be seeking routine health supervision, acute care for a physical complaint, help with a challenging behavior, or simply reassurance. Ideally, PCCs would elicit psychosocial and mental health concerns from children and families in each of these situations. They would find ways to support and help the family that is resistant to seeking mental health care and to recognize those emergent situations that compel an immediate intervention. If and when a family is ready to address a problem, PCCs may choose to assess and manage the child himself or herself—in roles similar to those of mental health specialists—or they may choose to guide the family toward appropriate referral sources. Whether providing mental health services alone or collaboratively, PCCs would monitor the child and family's functioning and progress in care, applying chronic care principles as they would for other children and youth with special health care needs.[40] PCCs ideally would be able to provide these mental health services within the constraints of a busy practice without compromising the efficiency and financial viability of the practice.

The Primary Care Advantage

The AAP recognizes the unique strengths of PCCs and the opportunities inherent in the primary care setting—"the primary care advantage"[41]—on which mental health competencies can build:

- a longitudinal, trusting, and empowering therapeutic relationship with children and family members;
- the family-centeredness of the medical home[1–6,42,43];
- unique opportunities to prevent future mental health problems through promoting healthy lifestyles, anticipatory guidance, and timely intervention for common behavioral, emotional, and social problems encountered in the typical course of infancy, childhood, and adolescence (as described in *Bright Futures*)[38,44,45];
- understanding of common social, emotional, and educational problems in the context of a child's development and environment[38];
- experience working with specialists in the care of children with special health care needs and serving as coordinator and case manager through the medical home; and
- familiarity with chronic care principles and practice-improvement methods.

Framework for Behavioral and Mental Health Competencies

In 1999, the Accreditation Council for Graduate Medical Education (ACGME) initiated the Outcome Project.[46] Through it, the ACGME established competencies to serve as the framework for residency curricula, organized into 6 domains: systems-based practice; patient care; medical knowledge; practice-based learning and improvement; interpersonal and communication skills; and professionalism. The competencies proposed in this report build on the ACGME framework with the expectation that they will be useful in setting goals for personal and professional growth in pediatric practice, for future board certification and recertification, and for residency training. Because achievement of system changes necessarily precedes other enhancements in mental health practice, the table of proposed mental health competencies for pediatric PCCs (Appendix 1) departs from the usual ACGME sequence, which includes systems-based practice as the final set of competencies, and instead begins with competencies for systems-based practice.

Assumptions

Traditional concepts of mental health care build on the assumption that treatment must follow diagnosis of a disorder; however, this approach offers only partial help for most children with mental health problems seen in primary care—those with significant dysfunction in the absence of a specific diagnosis.[27] The primary care setting

offers the unique opportunity for patient-clinician interaction to positively influence the clinical outcome of emerging problems, problems that do not meet the criteria of a DSM-IV disorder, and mild or undiagnosed disorders ("problems" in the DSM-PC classification[8]). The proposed competencies assume that PCCs can, in many instances, have a positive effect on a child's mental health problems without knowing precisely the child's diagnosis and in situations in which the child's symptoms do not meet the criteria of a DSM-IV disorder.[47–49]

"Generic" mental health skills proposed in this report are drawn from the literature on "common factors" in mental health care—techniques used to increase patients' optimism, feelings of well-being, and willingness to work toward improvement, regardless of the specific diagnosis or problem identified.[50–56] Other skills target symptoms that occur commonly across multiple mental health problems—feelings of anger, ambivalence, and hopelessness—and the family conflicts frequently associated with these problems. These skills come from family therapy,[6] cognitive therapy,[57] motivational interviewing,[52] family engagement,[58] family-focused pediatrics,[42,43] and solution-focused therapy.[59]

The proposed competencies further assume that collaboration—among PCCs and staff members within the primary care practice and between the PCC/practice and families, mental health specialists, educators, case managers, social service workers, juvenile justice staff, and other agency personnel—is a central requirement in caring for children with mental health problems. Collaboration between PCCs and mental health specialists may take the form of a referral with formal exchange of information, a special referral relationship with regular communication, meeting(s) to discuss cases, meeting(s) of both the PCC and mental health specialist(s) with patients, or full integration of mental health and primary care services.[60] Models in which a licensed mental health specialist is integrated into a primary care practice have shown promise in improving access to services and treatment adherence, increasing efficiency and effectiveness of care, decreasing medical costs, increasing patient functioning and productivity, and improving patient and provider satisfaction.[61–64] A regional network of child psychiatrists[65] offering real-time telephone consultation and referral to PCCs in Massachusetts enhances the capacity of PCCs to care for children with diagnostic comorbidity, complicated attention-deficit/hyperactivity disorder (ADHD), anxiety, and depression. The proposed competencies reflect the importance of clinicians' staying abreast of collaborative approaches applicable to their particular setting and applying the growing body of evidence evaluating the effectiveness of various models.

A final assumption is that PCCs can expand their capacity beyond managing ADHD to care effectively for children with other commonly occurring pediatric mental health problems: anxiety, depression, and substance abuse.[63,66–68] By routinely screening for mental health problems, recognizing symptoms early, educating children and families about self-management strategies, and offering first-line treatment, PCCs have the potential to improve the lives of many children and their families who might otherwise not receive mental health care or receive care only after problems become more severe and impairing.[38] In the case of children with a chronic medical condition and comorbid anxiety and depression, mental health care may also result in improvements in their physical health and decreases in their utilization of emergency department and hospital services.[35]

PROPOSED COMPETENCIES

The proposed competencies are detailed in Appendix 1. A summary follows.

Systems-Based Practice

Systemic changes will necessarily precede other enhancements in mental health practice. Competencies in this area will empower clinicians to work with other mental health advocates toward improving the organizational and financial base of care and, with that base in place, to establish effective coding and billing practices that will sustain mental health services.[69,70]

Another skill set involves building collaborative relationships with individuals and agencies that provide mental health services and with organizations that represent youth and families who are experiencing mental illness. These relationships will enable clinicians to address service gaps, define respective roles, and coordinate services. A final set of systems-based competencies involves selecting tools and establishing systems within the practice to normalize and systematize integration of mental health and to apply medical home principles and the chronic care model to children with mental health problems.

Patient Care

Competencies in this area include clinical skills to build resilience, promote healthy lifestyles, and prevent or mitigate mental health problems in children; identify risk factors and emerging mental health problems in children and their families; screen for mental health issues; conduct an assessment of a child presenting with mental health concerns or a positive screening test; overcome barriers (perceived and/or experienced by children and their families) in seeking help for mental health

concerns; provide guidance to families on managing common behavioral problems and coping with adverse life events; and recognize mental health emergencies. A critical patient care skill is integrating child and family strengths, needs, and preferences; the use of clinicians' own skills (interpersonal, relational, assessment, diagnosis and management); and available resources into developing a care plan for children with mental health problems, involving mental health specialists when appropriate. The proposed competencies suggest that PCCs develop the capacity to provide care to children with ADHD, anxiety, depression, and substance abuse.

Medical Knowledge

This set of competencies focuses on applying current science to the mental health screening and assessment process and to decision-making about pharmacologic and psychosocial interventions in primary care. Foundational elements include the diagnostic classification of mental health variations, problems, and disorders in primary care (DSM-PC)[8] and the evidence base for screening, therapeutic interventions, and behavior change science, as applied to mental health practice.

Practice-Based Learning and Improvement

This skill set enables the clinician to set and achieve learning and practice-improvement goals. Components include development of office protocols for the assessment and care of children with mental health problems and implementation of a quality-improvement program.

Interpersonal and Communication Skills

These skills are central to effective mental health practice within the rapid pace of a primary care practice, including common-factors approaches that are effective across a range of mental health conditions (see "Assumptions"). They also encompass effective exchange of information between PCCs and others involved in the care of the child and family.[71]

Professionalism

These skills build on respect for children and their families and sensitivity to cultural differences. In addition to facilitating child-clinician and family-clinician empathic relationships, which are the heart of effective mental health practice, they enable the clinician to discuss such issues as confidentiality and his or her own professional limitations.[72,73]

RECOMMENDATIONS

PCCs should:

- partner with parents, mental health specialists, and AAP chapter and national leaders to achieve competencies in systems-based practice, such as advocating with insurers for appropriate payment, and with policy makers for funding of mental health services[74,75];
- build relationships with mental health specialists with whom they can collaborate in enhancing their mental health knowledge and skills;
- with necessary system changes in place (eg, payment, collaborative relationships), adopt the goal of achieving the full complement of mental health competencies outlined in Appendix 1;
- advocate for innovations in residency training and continuing medical education activities to increase the knowledge base and skill level of PCCs in accordance with these competencies; and
- pursue educational strategies suited to their own learning style and skill level for achieving the mental health competencies.

EDUCATIONAL STRATEGIES AND IMPLEMENTATION CHALLENGES

These competencies are put forward as goals for all clinicians who serve children. Some clinicians have achieved many, if not most, of these competencies through development of their own knowledge and skills. Some achieve competence through collaborative practice with mental health specialists, as described above. Some are just setting out to achieve competence in mental health practice.

The AAP recognizes the serious maldistribution of mental health resources for children and their families. There are many areas of the country where specialty mental health services are unavailable or inaccessible; in these settings, clinicians may feel a sense of urgency to achieve and apply the full set of mental health competencies. Where mental health specialty services are more readily available, PCCs have the opportunity to establish collaborative relationships with mental health specialist(s), such as a mental health specialists colocated within the primary care setting, a psychiatrist consulting via telephone or videoconference, a mental health specialist providing cognitive behavioral therapy to a child being treated by the PCC with an antidepressant drug, or any number of other collaborative models.[60–63] Such relationships serve to educate the PCC and enhance services to children in their mutual care.

Achieving the proposed competencies will require new educational approaches as well as systems changes. With the exception of ADHD,[76,77] little evidence is available to guide PCCs in the unique aspects of their role as mental health care providers, and few experts in mental health/substance abuse have experience practicing in busy primary care settings within the context of primary care's average 16.3-minute[78] visits and payment realities.

Strategies for Residency Education

Just as mental health practice in primary care settings is collaborative, the process of training PCCs for primary care practice will necessarily be collaborative. Content experts (eg, developmental-behavioral pediatricians, child psychiatrists, adolescent medicine specialists, clinical psychologists, nurses with advanced psychiatric training, social workers) can join with primary care experts—clinicians who are effective in delivering primary medical care and managing children's chronic conditions in partnership with families—to train the next generation of PCCs. For academic generalists who have not received mental health training, collaboration with mental health specialist(s) to train PCCs will be particularly important. This training might take the form of coprecepting in residency continuity clinics, partnering to conduct inpatient rounds, and codeveloping didactic programs. While benefiting from the content expertise of their mental health colleagues, pediatric academicians will have the opportunity to model the collaborative, multidisciplinary relationships that underlie effective mental health practice.

Data from the 2007 AAP Graduating Residents Survey suggest that completion of an elective child psychiatry rotation and more training in mental health assessment, education, and treatment related to children are associated with greater confidence in identifying and treating pediatric mental health problems.[79] Additional research will be necessary to determine which educational methodologies are associated with the best outcomes. These findings have significant implications for the apportionment of time to mental health training within pediatric residency programs. Clearly, the 1-month developmental-behavioral pediatric rotation (often shortened by vacation time) is insufficient to accommodate necessary additions to the curriculum.

Strategies for Education of Experienced Clinicians

Experienced PCCs will benefit from approaches that build on skills they have developed over years of working with children and families. Wissow et al[49] have demonstrated that experienced PCCs can, in appropriate circumstances, provide evidence-based care of children with mental health and substance abuse problems or disorders of mild severity and functional impairment across diagnostic categories. Children treated by PCCs trained in mental health communication techniques have shown modest but significant improvement in mental health functioning, and their parents showed reduction in distress, compared with children treated by clinicians who did not receive training in mental health care.[49] Additional research will be necessary to adapt these techniques to the training of less-experienced clinicians.

Collaborative office rounds have been established in various communities for the purpose of enhancing mental health knowledge and skills of PCCs and their communication with mental health specialists.[80,81] One- to 2-hour sessions typically involve psychiatrists and/or developmental-behavioral pediatricians and PCCs in a case-based discussion.

Several groups of mental health educators have developed comprehensive training to prepare mental health specialists and primary care professionals for their respective roles in collaborative practice.[82,83] The AAP Task Force on Mental Health is collecting information about such trainings on its Web site (www.aap.org/mentalhealth) and has begun the process of keying proposed educational sessions at the National Conference and Exhibition and other AAP events to the mental health competencies put forward in this document. Clinicians may also work toward enhancing mental health competence by monitoring their psychosocial care in maintenance of certification by using such quality-improvement programs as eQIPP (Education in Quality Improvement for Pediatric Practice) and developing relevant pay-for-performance and quality indicators for health plans.

The most fundamental of all the proposed mental health competencies is the capacity to assess one's own knowledge and skills in mental health care and to establish a mechanism to update them, addressing the gaps that inevitably accompany gains in science. A growing number of educational resources developed by the AAP, the American Academy of Family Physicians, the National Association of Pediatric Nurse Practitioners, the American Psychiatric Association, the National Association of Social Workers, the American Academy of Child and Adolescent Psychiatry, and the American Psychological Association are available on their respective Web sites (Appendix 2). A powerful educational strategy is the cross-fertilization that occurs through a PCC's relationship with mental health specialists—authentic collaboration in the assessment and management of children in their mutual care and regular exchange of information about the child's and family's progress. This type of collaboration, together with openness to applying new science, will be essential for achieving and maintaining competence in mental health practice.

CONCLUSIONS

Attainment of the mental health competencies proposed in this report is a future goal, not a current expectation. It will require systemic changes,

new methods of financing, practice enhancements, new (or honed) skills, access to reliable sources of information about existing evidence and new science, and innovative educational methods. These changes will be incremental and will require substantial investments by the AAP and its partner organizations and by clinicians working at both the community and practice levels. Gains are also likely to be substantial, including the improved well-being of children and their families and enhanced satisfaction of PCCs.

APPENDIX 1 Proposed Mental Health Competencies for Pediatric PCCs

"Systems-based practice": clinicians providing primary care to children and adolescents should be able to do the following

"Improve the organizational and financial base of care"

1. Apply collaborative strategies applicable to advocating with insurers and payers for appropriate payment to PCCs and mental health specialists for their mental health services
2. Utilize appropriate coding and billing practices to support mental health services

"Build community collaborations"

3. Establish collaborative relationships with support groups; professionals available within the community (eg, early intervention specialists, school personnel, child care professionals, mental health specialists); and/or community agencies (eg, departments of social services, juvenile justice system, nonprofit agencies providing mental health and substance abuse services to children and families) and define respective roles in assessment, treatment, coordination of care, exchange of information, and family support
4. Participate in multidisciplinary meetings, appropriately applying such skills as reflective listening, mediation, and leadership skills
5. Apply collaborative approaches involving parents and mental health specialists to advocate for services and educational resources relevant to the full range of children's/adolescents' and families' mental health needs, including those of special populations, such as abused children, children in foster care, homeless children, children of international political refugees and other recent immigrants, children with physical or mental disabilities, children displaced by disasters, children of separated and divorced parents, children of parents deployed for military service, and youth involved in the juvenile justice system

"Enhance the practice"

6. Establish systems within their practice to support mental health services; elements include
   a. a directory of mental health and substance abuse referral sources and family support resources in the region
   b. established procedures for
      promoting healthy lifestyles, including exercise, sleep, optimal nutrition, stress management, decreasing exposure to environmental toxins and stressors, and seeking support within the community
      eliciting a history of patients' involvement in mental health specialty care
      requesting consent to collect information from collateral sources such as mental health professionals, schools, and social service agencies
      obtaining and documenting the child's and family's psychosocial history
      managing psychiatric emergencies
      screening for occult mental health problems
   c. registries of patients with mental health problems (including children for whom psychopharmacologic agents have been prescribed and children/families not prepared to take action on mental health concerns)
   d. evidence-based protocols and monitoring/tracking mechanisms for the care of children with mental health problems
   e. culturally and linguistically appropriate educational materials on mental health topics for children and families
   f. tools for facilitating coding and billing specific to mental health
7. Establish a practice environment that normalizes integration of mental health and incorporates medical home principles for the care of children with mental health concerns as for children and youth with other special health care needs

"Patient care": clinicians providing primary care to children and adolescents should be able to do the following

1. Promote mental health resilience through reinforcing child and family strengths and counseling families in healthy lifestyles (eg, nutrition, exercise, play, limited screen time, sleep, family time, stress management, decreased exposure to environmental toxins, and promotion of social capital)
2. Integrate a brief psychosocial update into acute care visits
3. Select, use, and interpret tools appropriate to the primary care setting for such purposes as screening for mental health problems, functional assessment of children and families, collection of information from collateral sources (eg, schools, agencies, juvenile justice system, other health professionals), and diagnostic assessment
4. Conduct history, physical assessment, and observations of parent-child interaction indicated by presenting mental health concerns and/or positive screening test(s) results
5. Differentiate normal behavioral variations, mental health problems and disorders, physical conditions with mental health manifestations, and adverse medication effects
6. Identify potential behavioral, mental health, and/or learning differences/problems reflected in report cards, academic test results, Individualized Family Service Plans, or Individualized Education Plans
7. Recognize common mental health comorbidities in children with physical and cognitive disabilities, chronic medical conditions, and mental health disorders
8. Plan diagnostic assessment, alone or in collaboration with mental health specialists, of children and youth with special health care needs who have comorbid mental health issues; infants and young children manifesting difficulties with communication and/or attachment; and children and adolescents presenting with anxious or avoidant behaviors, inattention and hyperactivity, depressive or withdrawn behaviors, oppositional or aggressive behaviors, problems with eating, substance use, exposure to trauma or loss, learning differences, and poor academic performance
9. Analyze results from mental health screening, history, and physical assessment to determine a child's/family's need for further assessment and/or intervention
10. Provide guidance to families on managing common mental health problems; on coping with adverse life events such as parental separation and illness or death of a loved one; and on use of educational resources appropriate to their literacy level and cultural and individual needs
11. Recognize mental health emergencies, severe functional impairment, and complex mental health symptoms that require mental health specialty care
12. Assist families in seeking and using care of a mental health specialist and/or facility that provides evidence-based services appropriate to a child's/family's needs and preferences
13. Develop a contingency or crisis plan for a child or adolescent with an urgent mental health problem
14. Apply strategies to monitor adverse and positive effects of nonpharmacologic and pharmacologic therapy
15. Integrate child/family strengths, needs, and preferences; clinician's own skills; and available resources into development of a care plan for children with mental health problems, alone or in collaboration with mental health specialists (including further assessment; child/family education about the condition[s]; evidence-based nonpharmacologic and, if indicated, pharmacologic interventions; communication with family and collaborating professionals; monitoring mechanisms; and routine health supervision)

APPENDIX 1 Continued

16. Initiate the process of care, alone or in collaboration with other clinicians, for children experiencing functional impairment from ADHD, anxiety, depression, or substance use/abuse, as desired by the child or family

"Medical knowledge": clinicians providing primary care to children and adolescents should be able to do the following

1. Access current data about the safety and efficacy of common pharmacologic and psychosocial interventions in children and adolescents
2. Access current data about interactions between prescription drugs and dietary supplements commonly used for mental health problems
3. Apply the DSM-PC criteria for the diagnoses of ADHD, major depressive disorder, and other disorders for which the clinician considers pharmacologic therapy
4. Use evidence-based interventions for children and adolescents with anxiety disorders (including posttraumatic stress disorder), ADHD, depression, and substance abuse
5. Apply principles of behavior-change science to mental health practice

"Practice-based learning and improvement": clinicians providing primary care to children and adolescents should be able to do the following

1. "Identify strengths, deficiencies, and limits in one's own knowledge and expertise" concerning mental health and substance abuse assessment and care
2. "Set learning and improvement goals"
3. "Identify and perform appropriate learning activities"
4. "Locate, appraise, and assimilate evidence from scientific studies related to their patients' problems"
5. "Use information technology to optimize learning"
6. Apply learning to development of office protocols for the assessment and care of children with mental health disorders
7. "Systematically analyze practice, using quality improvement methods, and implement changes with the goal of practice improvement" in mental health care

"Interpersonal and communication skills": clinicians providing primary care to children and adolescents should be able to do the following

1. Elicit mental health concerns from a child or adolescent and family
2. Explore the cultural context of a child and family's symptoms or concerns
3. Collaborate with child/adolescent and family to establish the agenda for an outpatient visit involving a mental health issue
4. Identify and address barriers preventing a child and/or family from seeking or accepting help for a mental health problem (eg, sense of hopelessness, inadequate insurance or financial resources, family conflict, stigma)
5. Manage resistance or anger in child/adolescent and/or family
6. Apply motivational interviewing techniques, family engagement strategies, and behavioral contracts to seek consensus on a mental health plan of action and to prepare the family for a mental health consultation
7. Interpret to families current evidence related to the safety and efficacy of relevant therapeutic options
8. Promote healthy lifestyles that contribute to mental health
9. "Communicate effectively with physicians, other health professionals, health-related agencies" and educators in the mutual care of children and adolescents
10. Clarify and discuss psychological test results, mental health findings, and concerns to children, adolescents, and families in language that is appropriate for age, education level, and cultural norms
11. Bring a mental health visit to a close in a supportive, efficient manner

"Professionalism": clinicians providing primary care to children and adolescents should be able to do the following

1. "Demonstrate compassion, integrity, and respect" for all children and family members
2. Demonstrate sensitivity to cultural differences and family preferences in addressing mental health concerns
3. Establish clear expectations in children, adolescents, and their families about conditional confidentiality (specific to state laws), exchange of protected health information, and business practices
4. Discuss one's professional limitations in knowledge and skills as part of the referral process

The ACGME has published "general competencies," which in some cases overlap those outlined in this document but bear restatement in the context of mental health care. ACGME wording is shown in quotes. The AAP recognizes that achievement of the competencies proposed in this table is a long-term goal, requiring training and resources that have yet to be developed. The AAP is committed to the development of the resources and training needed to assist pediatricians in achieving these competencies.

MMWR™

Morbidity and Mortality Weekly Report

Recommendations and Reports | December 1, 2006 / Vol. 55 / No. RR-15

General Recommendations on Immunization

Recommendations of the Advisory Committee on Immunization Practices (ACIP)

INSIDE: Continuing Education Examination

DEPARTMENT OF HEALTH AND HUMAN SERVICES
CENTERS FOR DISEASE CONTROL AND PREVENTION

The *MMWR* series of publications is published by the Coordinating Center for Health Information and Service, Centers for Disease Control and Prevention (CDC), U.S. Department of Health and Human Services, Atlanta, GA 30333.

Suggested Citation: Centers for Disease Control and Prevention. [Title]. MMWR 2006;55(No. RR-#):[inclusive page numbers].

CONTENTS

Disclosure of Relationship

CDC, our planners, and our presenters wish to disclose they have no financial interests or other relationships with the manufacturers of commercial products, suppliers of commercial services, or commercial supporters.

This report will not include any discussion of the unlabeled use of a product or a product under investigational use with the exception of the discussion of:

1. The nonsimultaneous administration of yellow fever vaccine and inactivated vaccines.
2. Progressive neurologic disorders are a precaution for the use of tetanus-reduced diphtheria acellular pertussis vaccine for adolescents and adults.
3. Contact allergy to latex is neither a contraindication nor a precaution to the use of meningococcal vaccine in the absence of an anaphylactic allergy.
4. Meningococcal conjugate vaccine should be administered intramuscularly, but if administered subcutaneously, repeating the dose is unnecssary.
5. Use of immune globulin, intravenous for postexposure prophylaxis or varicella.
6. Use of VariZIG for postexposure prophylaxis of varicella (unlicensed).

General Recommendations on Immunization

Recommendations of the Advisory Committee on Immunization Practices (ACIP)

Prepared by
Andrew T. Kroger, MD[1]
William L. Atkinson, MD[1]
Edgar K. Marcuse, MD[2]
Larry K. Pickering, MD[3]
[1]*Immunization Services Division, National Center for Immunization and Respiratory Diseases (proposed)*
[2]*Children's Hospital and Regional Medical Center, Seattle, Washington*

Summary

This report is a revision of General Recommendations on Immunization and updates the 2002 statement by the Advisory Committee on Immunization Practices (ACIP) (CDC. General recommendations on immunization: recommendations of the Advisory Committee on Immunization Practices and the American Academy of Family Physicians. MMWR 2002;51[No. RR-2]). This report is intended to serve as a general reference on vaccines and immunization. The principal changes include 1) expansion of the discussion of vaccination spacing and timing; 2) an increased emphasis on the importance of injection technique/age/body mass in determining appropriate needle length; 3) expansion of the discussion of storage and handling of vaccines, with a table defining the appropriate storage temperature range for inactivated and live vaccines; 4) expansion of the discussion of altered immunocompetence, including new recommendations about use of live-attenuated vaccines with therapeutic monoclonal antibodies; and 5) minor changes to the recommendations about vaccination during pregnancy and vaccination of internationally adopted children, in accordance with new ACIP vaccine-specific recommendations for use of inactivated influenza vaccine and hepatitis B vaccine. The most recent ACIP recommendations for each specific vaccine should be consulted for comprehensive discussion. This report, ACIP recommendations for each vaccine, and other information about vaccination can be accessed at CDC's National Center for Immunization and Respiratory Diseases (proposed) (formerly known as the National Immunization Program) website at http//:www.cdc.gov/nip.

Introduction

This report provides technical guidance about common vaccination concerns for clinicians and other health-care providers who administer vaccines to infants, children, adolescents, and adults. Vaccine recommendations are based on characteristics of the immunobiologic product, scientific knowledge about the principles of active and passive immunization, epidemiology and burden of diseases (i.e., morbidity, mortality, costs of treatment, and loss of productivity), vaccine safety considerations, cost analysis of preventive measures, published and unpublished studies, and expert opinion of public health officials and specialists in clinical and preventive medicine.

The material in this report was prepared for publication by the National Center for Immunization and Respiratory Diseases, Anne Schuchat, MD, Director; and the Immunization Services Division, Lance E. Rodewald, MD, Director.
Corresponding author: Andrew T. Kroger, MD, National Center for Immunization and Respiratory Diseases (proposed), CDC, 1600 Clifton Road, NE, MS E-52, Atlanta, GA 30333. Telephone: 404-639-1958; Fax: 404-639-8828; E-mail: akroger@cdc.gov.

Benefits and risks are associated with using all immunobiologics (i.e., an antigenic substance or antibody-containing preparation). No vaccine is completely safe or effective. Benefits of vaccination include partial or complete protection against infection for the vaccinated person and overall benefits to society as a whole. Benefits include protection from symptomatic illness, improved quality of life and productivity, and prevention of death. Societal benefits include creation and maintenance of herd immunity against communicable diseases, prevention of disease outbreaks, and reduction in health-care–related costs. Vaccination risks range from common, minor, and local adverse effects to rare, severe, and life-threatening conditions. Therefore, recommendations for vaccination practices balance scientific evidence of benefits for each person and to society against the potential costs and risks for vaccination for the individual and programs.

Standards for child and adolescent vaccination practices and standards for adult vaccination practices (*1,2*) have been published to assist with implementing vaccination programs and maximizing their benefits. Any person or institution that provides vaccination services should adopt these standards to improve vaccination delivery and protect infants, children, adolescents, and adults from vaccine-preventable diseases.

To maximize the benefits of vaccination, this report provides general information about immunobiologics and provides practical guidelines about vaccine administration and technique. To minimize risk from vaccine administration, this report delineates situations that warrant precautions or contraindications to using a vaccine. These recommendations are intended for use in the United States because vaccine availability and use and epidemiologic circumstances differ in other countries. Individual circumstances might warrant deviations from these recommendations.

The relative balance of benefits and risks can change as diseases are controlled or eradicated. For example, because wild poliovirus transmission has been interrupted in the United States since 1979, the only indigenous cases of paralytic poliomyelitis reported since that time have been caused by live oral poliovirus vaccine (OPV) (*3*). In 1999, to eliminate the risk for vaccine-associated paralytic poliomyelitis (VAPP), exclusive use of inactivated poliovirus vaccine (IPV) was recommended for routine vaccination in the United States. However, because of superior ability to induce intestinal immunity and to prevent spread among close contacts, OPV remains the vaccine of choice for areas where wild poliovirus is still present (*4*). Until worldwide eradication of poliovirus is accomplished, continued vaccination of the U.S. population against poliovirus will be necessary.

Timing and Spacing of Immunobiologics

General Principles for Vaccine Scheduling

Optimal response to a vaccine depends on multiple factors, including the nature of the vaccine and the age and immune status of the recipient. Recommendations for the age at which vaccines are administered are influenced by age-specific risks for disease, age-specific risks for complications, ability of persons of a certain age to respond to the vaccine, and potential interference with the immune response by passively transferred maternal antibody. Vaccines are recommended for members of the youngest age group at risk for experiencing the disease for whom efficacy and safety have been demonstrated.

Certain products, including inactivated vaccines, toxoids, recombinant subunit, and polysaccharide conjugate vaccines, require administering 2 or more doses for development of an adequate and persisting antibody response. Tetanus and diphtheria toxoids require periodic reinforcement or booster doses to maintain protective antibody concentrations. Unconjugated polysaccharide vaccines do not induce T-cell memory, and booster doses are not expected to produce substantially increased protection. Conjugation with a protein carrier improves the effectiveness of polysaccharide vaccines by inducing T-cell–dependent immunologic function. Vaccines that stimulate both cell-mediated immunity and neutralizing antibodies (e.g., live-attenuated virus vaccines) usually can induce prolonged immunity, even if antibody titers decline over time (*5*). Subsequent exposure to infection usually does not lead to viremia but to a rapid anamnestic antibody response.

Approximately 90%–95% of recipients of a single dose of certain live vaccines administered by injection at the recommended age (i.e., measles, rubella, and yellow fever) have protective antibody (generally within 2 weeks of the dose). For varicella and mumps vaccines, 80%–85% of vaccinees are protected after a single dose. However, because a limited proportion of recipients (5%–15%) of measles-mumps-rubella (MMR) or varicella vaccine fail to respond to 1 dose, a second dose is recommended to provide another opportunity to develop immunity (*6*). The majority of persons who fail to respond to the first dose of MMR or varicella vaccine respond to a second dose (*7,8*).

The Recommended Childhood and Adolescent Immunization Schedule and the Recommended Adult Immunization Schedule are revised annually. Physicians and other healthcare providers should ensure that they are following the most up-to-date schedules, which are available from CDC's National Center for Immunization and Respiratory Diseases (proposed) website (http://www.cdc.gov/nip).

Spacing of Multiple Doses of the Same Antigen

Vaccination providers should adhere as closely as possible to recommended vaccination schedules. Recommended ages and intervals between doses of multidose antigens provide optimal protection or have the best evidence of efficacy. Recommended vaccines and recommended intervals between doses are provided in this report (Table 1).

In certain circumstances, administering doses of a multidose vaccine at shorter than the recommended intervals might be necessary. This can occur when a person is behind schedule and needs to be brought up-to-date as quickly as possible or when international travel is impending. In these situations, an accelerated schedule can be implemented that uses intervals between doses shorter than those recommended for routine vaccination. Although the effectiveness of all accelerated schedules has not been evaluated in clinical trials, ACIP believes that when accelerated intervals are used, the immune response is acceptable and will lead to adequate protection. The accelerated or minimum intervals and ages that can be used for scheduling catch-up vaccinations are provided in this report (Table 1). Vaccine doses should not be administered at

TABLE 1. Recommended and minimum ages and intervals between vaccine doses of routinely recommended vaccines*

Vaccine and dose no.	Recommended age for this dose	Minimum age for this dose	Recommended interval to next dose	Minimum interval to next dose
Hepatitis B (HepB)-1[À]	Birth	Birth	1ï 4 months	4 weeks
HepB-2	1ï 2 months	4 weeks	2ï 17 months	8 weeks
HepB-3[Ä]	6ï 18 months	24 weeks	ð	ð
Diphtheria-tetanus-acellular pertussis (DTaP)-1[À]	2 months	6 weeks	2 months	4 weeks

Rotavirus (RV)-1*****	2 months	6 weeks	2 months	4 weeks
RV-2	4 months	10 weeks	2 months	4 weeks
RV-3	6 months	14 weeks	ð	ð
Zoster[ÀÀÀÀÀ]	60 years	60 years	ð	

* Combination vaccines are available. Use of licensed combination vaccines is preferred over separate injections of their equivalent component vaccines (**Source:** CDC. Combination vaccines for childhood immunization: recommendations of the Advisory Committee on Immunization Practices (ACIP), the American Academy of Pediatrics (AAP), and the American Academy of Family Physicians (AAFP). MMWR 1999;48[No. RR-5]). When administering combination vaccines, the minimum age for administration is the oldest age for any of the individual components; the minimum interval between doses is equal to the greatest interval of any of the individual components.

TABLE 1. (*Continued*) Recommended and minimum ages and intervals between vaccine doses of routinely recommended vaccines*

Vaccine and dose no.	Recommended age for this dose	Minimum age for this dose	Recommended interval to next dose	Minimum interval to next dose

† Combination vaccines containing the Hepatitis B component are available (HepB-Hib, DTaP-HepB-IPV, and HepA-HepB). These vaccines should not be administered to infants aged <6 weeks because of the other components (i.e., Hib, DTaP, HepA, and IPV).

‡ HepB-3 should be administered at least 8 weeks after HepB-2 and at least 16 weeks after HepB-1 and should not be administered before age 24 weeks.

§ Calendar months.

** The minimum recommended interval between DTaP-3 and DTaP-4 is 6 months. However, DTaP-4 need not be repeated if administered at least 4 months after DTaP-3.

†† For Hib and PCV, children receiving the first dose of vaccine at age ≥7 months require fewer doses to complete the series (CDC. Recommended childhood and adolescent immunization scheduleð United States, 2006. MMWR 2005; 54 [Nos. 51 & 52]:Q1-Q4).

‡‡ If PRP-OMP (Pedvax-HibÈ, Merck Vaccine Division) was administered at age 2 and 4 months, a dose at age 6 months is not required.

§§ Combination measles-mumps-rubella-varicella (MMRV) vaccine can be used for children aged 12 monthsï 12 years.

*** The minimum interval from VAR-1 to VAR-2 for persons beginning the series at age ≥13 years is 4 weeks.

††† Two doses of influenza vaccine are recommended for children aged <9 years who are receiving the vaccine for the first time. Children aged <9 years who have previously received influenza vaccine, and persons aged ≥9 years require only 1 dose per influenza season.

‡‡‡ The minimum age for inactivated influenza vaccine varies by vaccine manufacturer. Only Fluzone (manufactured by sanofi pasteur) is approved for children aged 6ï 35 months. The minimum age for Fluvirin (manufactured by Novartis) is 4 years. For Fluarix and FluLeval (manufactured by GlaxoSmithKline), the minimum age is 18 years.

§§§ Certain experts recommend a second dose of MPSV 3 years after the first dose for persons at increased risk for meningococcal disease.

**** A second dose of meningococcal vaccine is recommended for persons previously vaccinated with MPSV who remain at high risk for meningococcal disease. MCV4 is preferred when revaccinating persons aged 11ï 55 years, but a second dose of MPSV is acceptable. (**Source:** CDC. Prevention and control of meningococcal disease: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 2005;54[No. RR-7]).

†††† Only 1 dose of Tdap is recommended. Subsequent doses should be administered as Td. If vaccination to prevent tetanus and/or diphtheria disease is required for children aged 7ï 9 years, Td should be administered (minimum age for Td is 7 years). For one brand of Tdap, the minimum age is 11 years. The preferred interval between Tdap and a previous dose of Td is 5 years. In persons who have received a primary series of tetanus-toxoidï containing vaccine, for management of a tetanus-prone wound, the minimum interval after a previous dose of any tetanus-containing vaccine is 5 years.

‡‡‡‡ A second dose of PPV is recommended for persons at highest risk for serious pneumococcal infection and those who are likely to have a rapid decline in pneumococcal antibody concentration. Revaccination 3 years after the previous dose can be considered for children at highest risk for severe pneumococcal infection who would be aged <10 years of age at the time of revaccination. (**Source:** CDC. Prevention of pneumococcal disease: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1997;46[No. RR-8]).

§§§§ HPV is approved only for females aged 9ï 26 years.

***** The first dose of RV must be administered at age 6ï 12 weeks. The vaccine series should not be started at age ≥13 weeks. RV should not be administered to children aged ≥33 weeks regardless of the number of doses received at age 6ï 32 weeks.

†††††† Herpes zoster vaccine is approved as a single dose for persons who are aged ≥60 years with a history of varicella.

intervals less than these minimum intervals or earlier than the minimum age.*

In clinical practice, vaccine doses occasionally are administered at intervals less than the minimum interval or at ages younger than the minimum age. Doses administered too close together or at too young an age can lead to a suboptimal immune response. However, administering a dose a limited number of days earlier than the minimum interval or age is unlikely to have a substantially negative effect on the immune response to that dose. Therefore, ACIP recommends that vaccine doses administered 4 or fewer days before the minimum interval or age be counted as valid.† However, because of its unique schedule, this recommendation does not apply to the rabies vaccine (*9*). Doses administered 5 or more days earlier than the minimum interval or age of any vaccine should not be counted as valid doses and should be repeated as age-appropriate. The repeat dose should be spaced after the invalid dose by the recommended minimum interval (Table 1). For example, if *Haemophilus influenzae* type b (Hib) doses one and two were administered only 2 weeks apart, because the minimum interval from dose one to dose two is 4 weeks, dose two is invalid and should be repeated. The repeat dose should be administered 4 or more weeks after the invalid (second) dose. The repeat dose would be counted as the second valid dose. Doses administered 5 or more days before the minimum age should be repeated on or after the child reaches the minimum age and 4 or more weeks after the invalid dose. For example, if the first dose of varicella vaccine were administered at age 10 months, the repeat dose would be administered no earlier than the child's first birthday. If the first dose of varicella vaccine were administered at age 11 months and 2 weeks, the repeat dose could be administered 2 weeks after the first birthday.

Certain vaccines produce increased rates of local or systemic reactions in certain recipients when administered too frequently (e.g., adult tetanus-diphtheria toxoid [Td]; pedi-

*During measles outbreaks, if cases are occurring among infants aged <12 months, measles vaccination of infants as young as 6 months can be undertaken as an outbreak control measure. However, doses administered at ages <12 months should not be counted as part of the series (**Source**: CDC. Measles, mumps, and rubella vaccine use and strategies for elimination of measles, rubella, and congenital rubella syndrome and control of mumps: recommendations of the Advisory Committee on Immunization Practices [ACIP]. MMWR 1998;47[No. RR-8]).

†In certain situations, local or state requirements might mandate that doses of selected vaccines be administered on or after specific ages. For example, a school entry requirement might not accept a dose of MMR or varicella vaccine administered before the child's first birthday. ACIP recommends that physicians and other health-care providers comply with local or state vaccination requirements when scheduling and administering vaccines.

atric diphtheria-tetanus toxoid [DT]; tetanus toxoid; and tetanus, reduced diphtheria acellular pertussis vaccine for adolescents and adults) (*10,11*). Such reactions might result from formation of antigen-antibody complexes. Optimal record keeping, maintaining patient histories, and adhering to recommended schedules can decrease the incidence of such reactions without adversely affecting immunity.

Simultaneous Administration

Experimental evidence and extensive clinical experience provide the scientific basis for administering vaccines simultaneously (i.e., during the same office visit, not combined in the same syringe). Simultaneously administering all vaccines for which a person is eligible is critical, including for childhood vaccination programs, because simultaneous administration increases the probability that a child will be vaccinated fully at the appropriate age (*1*). A study conducted during a measles outbreak demonstrated that approximately one third of measles cases among unvaccinated but vaccine-eligible preschool children could have been prevented if MMR had been administered at the same visit when another vaccine was administered (*12*). Simultaneous administration also is critical when preparing for foreign travel and/or if uncertainty exists that a person will return for further doses of vaccine.

Simultaneously administering the most widely used live and inactivated vaccines have produced seroconversion rates and rates for adverse reactions similar to those observed when the vaccines are administered separately (*13–16*). Routinely administering all age-appropriate doses of vaccines simultaneously is recommended for children for whom no specific contraindications exist at the time of the visit. Administering combined MMR (or measles-mumps-rubella-varicella [MMRV] vaccine) yields safety and immunogenicity results similar to administering individual measles, mumps, and rubella vaccines at different sites. Therefore, no medical basis exists for administering these vaccines separately for routine vaccination instead of the preferred MMR combined vaccine (*6*). Administering separate antigens would result in a delay in protection for the deferred components. Response to MMR and varicella vaccines administered on the same day is identical to vaccines administered a month apart (*17*), and administration of MMRV combined vaccine is similar to administration of MMR and varicella vaccines on the same day (*18*). No evidence exists that oral rotavirus vaccine (RV) interferes with live vaccines administered by injection or intranasally (e.g., MMR and live-attenuated influenza vaccine [LAIV]). RV can be administered simultaneously or at any interval before or after injectable or intranasal live vaccines (*19*). No data exist about the immunogenicity of oral Ty21a typhoid vaccine when administered concurrently or within 30 days of other live virus vaccines. In the absence of such data, if typhoid vaccination is warranted, administration should not be delayed because of administration of live-attenuated virus vaccines (*20*).

Simultaneously administering pneumococcal polysaccharide vaccine (PPV) and inactivated influenza vaccine elicits a satisfactory antibody response without increasing the incidence or severity of adverse reactions (*21*). Simultaneously administering PPV and inactivated influenza vaccine is recommended for all persons for whom both vaccines are indicated.

Hepatitis B vaccine (HepB) administered with yellow fever vaccine is as safe and immunogenic as when these vaccines are administered separately (*22*). Measles and yellow fever vaccines have been administered safely at the same visit and without reduction of immunogenicity of each of the components (*23,24*).

Depending on vaccines administered in the first year of life, children aged 12–15 months might receive up to nine injections during a single visit (MMR, varicella, Hib, pneumococcal conjugate, diphtheria and tetanus toxoids and acellular pertussis [DTaP], IPV, hepatitis A, HepB, and influenza [seasonal] vaccines). To reduce the number of injections at the 12–15-month visit, the IPV and HepB series can be expedited and completed before the child's first birthday. MMRV can be administered as soon as possible on or after the first birthday and the fourth dose of DTaP administered at age 15 months. The majority of children aged 1 year who have received 2 (polyribosylribitol phosphate-meningococcal outer membrane protein [PRP-OMP]) or 3 (PRP-tetanus [PRP-T], diphtheria CRM197 [CRM, cross-reactive material] protein conjugate [HbOC]) previous doses of Hib vaccine and 3 previous doses of DTaP and pneumococcal conjugate vaccine (PCV) have had protection (*25,26*). The third (PRP-OMP) or fourth (PRP-T, HbOC) dose of the Hib series, and the fourth doses of DTaP and PCV are critical in boosting antibody titer and ensuring continued protection (*26–29*). However, the booster dose of the pneumococcal conjugate series can be deferred until age 15–18 months for children who are likely to return for future visits. The fourth dose of DTaP is recommended at age 15–18 months but can be administered as early as age 12 months under certain circumstances (*27*). For infants at low risk for infection with hepatitis B virus (i.e., the mother tested negative for hepatitis B surface antigen [HBsAg] at the time of delivery), the HepB series can be completed at any time for children aged 6–18 months. With use of certain HepB combination vaccines (i.e., combination Hib-HepB vaccine), the minimum age of administration of the final dose is 12 months because of the minimum age requirement for the last dose of the Hib series (*30*). Recommended spacing of doses should be maintained (Table 1).

Use of combination vaccines can reduce the number of injections required at an office visit. Licensed combination vaccines can be used whenever any components of the combination are indicated and its other components are not contraindicated and if licensed by the Food and Drug Administration (FDA) for that dose in the series. Use of licensed combination vaccines is preferred to separate injection of their equivalent component vaccines to reduce the number of injections and missed opportunities to protect through vaccination (*31*). Only combination vaccines licensed by FDA should be used. Individual vaccines should never be mixed in the same syringe unless they are approved specifically for mixing by FDA. Only one vaccine (DTaP and PRP-T Hib vaccine, marketed as TriHIBit® [manufactured by sanofi pasteur]) is licensed by FDA for mixing in the same syringe. This vaccine should not be used for primary vaccination in infants aged 2, 4, and 6 months, but it can be used as the last dose of the Hib vaccine series on or after age 12 months.

Nonsimultaneous Administration

No evidence exists that inactivated vaccines interfere with the immune response to other inactivated vaccines or to live vaccines. An inactivated vaccine can be administered either simultaneously or at any time before or after a different inactivated vaccine or live vaccine (Table 2).

Data are limited about interference between live vaccines. The immune response to one live-virus vaccine might be impaired if administered within 30 days of another live-virus vaccine (*32,33*). In a study conducted in two U.S. health maintenance organizations, persons who received varicella vaccine <30 days after MMR vaccination had an increased risk for varicella vaccine failure (i.e., varicella disease in a vaccinated person) of 2.5-fold compared with persons who received varicella vaccine before or >30 days after MMR (*34*). In comparison, another study determined that the response to yellow fever vaccine is not affected by monovalent measles vaccine administered 1–27 days earlier (*23*). The effect of nonsimultaneously administering rubella, mumps, varicella, and yellow fever vaccines is unknown.

TABLE 2. Guidelines for spacing of live and inactivated antigens

Antigen combination	Recommended minimum interval between doses
Two or more inactivated*	Can be administered simultaneously or at any interval between doses
Inactivated and live	Can be administered simultaneously or at any interval between doses
Two or more live intranasal or injectable[Â]	4-week minimum interval, if not administered simultaneously

*Certain experts suggest a 1-month interval between tetanus toxoid, reduced diphtheria toxoid, and reduced acellular pertussis vaccine and quadrivalent meningococcal conjugate vaccine if they are not administered simultaneously.

[Â]Live oral vaccines (e.g., Ty21a typhoid vaccine and rotavirus vaccine) can be administered simultaneously or at any interval before or after inactivated or live injectable vaccines.

Source: American Academy of Pediatrics. Pertussis. In: Pickering LK, Backer, CJ, Long SS, McMillan J, eds., Red Book: 2006 Report of the Committee on Infectious Diseases. 27th ed. Elk Grove Village, IL: American Academy of Pediatrics.

To minimize the potential risk for interference, injectable or nasally administered live vaccines not administered on the same day should be administered >4 weeks apart whenever possible (Table 2). If injectable or nasally administered live vaccines are separated by <4 weeks, the vaccine-administered second should not be counted as a valid dose and should be repeated. The repeat dose should be administered >4 weeks after the last invalid dose. Yellow fever vaccine can be administered at any time after single-antigen measles vaccine. Oral vaccines (Ty21a typhoid vaccine and RV) can be administered simultaneously or at any interval before or after other live vaccines (injectable or intranasal) if indicated.

Spacing of Vaccines and Antibody-Containing Products

Live Vaccines

Ty21a typhoid, yellow fever, and LAIV vaccines can be administered at any time before, concurrent with, or after administering any immune globulin, hyperimmune globulin, or intravenous immune globulin (IGIV). Blood (e.g., whole blood, packed red blood cells, and plasma) and other antibody-containing blood products (e.g., immune globulin, hyperimmune globulin, and IGIV) can inhibit the immune response to measles and rubella vaccines for 3 or more months. The effect of blood and immune globulin preparations on the response to mumps and varicella vaccines is unknown, but commercial immune globulin preparations contain antibodies to these viruses. Blood products available in the United States are unlikely to contain a substantial amount of antibody to yellow fever vaccine virus. The length of time that interference with injectable live vaccination (except yellow fever vaccine) can persist after the antibody-containing product is a function of the amount of antigen-specific antibody contained in the product (*35–37*). Therefore, after an antibody-containing product is received, live vaccines (except yellow fever vaccine, oral Ty21a typhoid vaccine, and LAIV) should be delayed until the passive antibody has degraded (Table 3). If a dose of injectable live-virus vaccine (except yellow fever vaccine) is administered after an antibody-containing product but at an interval shorter than recommended in this report, the vaccine dose should be repeated unless serologic testing is feasible and indicates a response to the vac-

TABLE 3. Guidelines for administering antibody-containing products* and vaccines

Simultaneous administration

Combination	Recommended minimum interval between doses
Antibody-containing products and inactivated antigen	Can be administered simultaneously at different sites or at any time interval between doses.
Antibody-containing products and live antigen	Should not be administered simultaneously.[À] If simultaneous administration of measles-containing vaccine or varicella vaccine is unavoidable, administer at different sites and revaccinate or test for seroconversion after the recommended interval.

Nonsimultaneous administration

Product administered		
First	Second	Recommended minimum interval between doses
Antibody-containing products	Inactivated antigen	Not applicable
Inactivated antigen	Antibody-containing products	Not applicable
Antibody-containing products	Live antigen	Dose-related[À,Ä,Æ]
Live antigen	Antibody-containing products	2 weeks[À]

* Blood products containing substantial amounts of immunoglobulin include intramuscular and intravenous immune globulin, specific hyperimmune globulin (e.g., hepatitis B immune globulin, tetanus immune globulin, varicella zoster immune globulin, and rabies immune globulin), whole blood, packed red cells, plasma, and platelet products.

[À] Yellow fever, oral Ty21a typhoid vaccine, and live-attenuated influenza vaccine are exceptions to these recommendations. These live-attenuated vaccines can be administered at any time before, after, or simultaneously with an antibody-containing product without substantially decreasing the antibody response.

[Ä] Rotavirus vaccine (RV) should be deferred for 6 weeks after receipt of an antibody-containing product if possible. However, if the 6-week deferral would cause the first dose of RV to be scheduled for age ≥13 weeks, a shorter deferral interval should be used to ensure the first dose of RV is administered no later than age 13 weeks.

[Æ] The duration of interference of antibody-containing products with the immune response to the measles component of measles-containing vaccine, and possibly varicella vaccine, is dose-related.

cine. The repeat dose or serologic testing should be performed after the interval indicated for the antibody-containing product (Table 4).

Although passively acquired antibodies can interfere with the response to rubella vaccine, the low dose of anti-Rho(D) globulin administered to postpartum women has not been demonstrated to reduce the response to the RA27/3 strain rubella vaccine (*38*). Because of the importance of rubella and varicella immunity among childbearing-aged women (*6,39*), the postpartum vaccination of women without evidence of immunity to rubella or varicella with single-antigen rubella, MMR, varicella, or MMRV vaccine should not be delayed because of receipt of anti-Rho(D) globulin or any other blood product during the last trimester of pregnancy or at delivery. These women should be vaccinated immediately after delivery and, if possible, tested 3 or more months later to ensure immunity to rubella and, if appropriate, to measles (*6*).

Interference can occur if administering an antibody-containing product becomes necessary after administering MMRV or its individual components. Usually, vaccine virus replication and stimulation of immunity will occur 1–2 weeks after vaccination. If the interval between administering any of these vaccines and subsequent administration of an antibody-containing product is <14 days, vaccination should be repeated after the recommended interval (Tables 3 and 4), unless serologic testing indicates an antibody response. RV should be deferred for 6 weeks after receipt of an antibody-containing product if possible. However, if the 6-week deferral would cause the first dose of RV to be scheduled for a child aged ≥13 weeks, a shorter deferral interval should be used to ensure the first dose of RV is administered no later than age 13 weeks (*19*).

A humanized mouse monoclonal antibody product (palivizumab) is available for prevention of respiratory syncytial virus infection among infants and young children. This product contains only antibody to respiratory syncytial virus and will not interfere with immune response to currently licensed live or inactivated vaccines.

Inactivated Vaccines

Antibody-containing products interact less with inactivated vaccines, toxoids, recombinant subunit, and polysaccharide vaccines than with live vaccines (*40*). Therefore, administering inactivated vaccines and toxoids either simultaneously with or at any interval before or after receipt of an antibody-containing product should not substantially impair development of a protective antibody response (Table 3). The vaccine or toxoid and antibody preparation should be administered at different sites by using the standard recommended dose. Increasing the vaccine dose volume or number of vaccinations is not indicated or recommended.

TABLE 4. Suggested intervals between administration of antibody-containing products for different indications and measles-containing vaccine and varicella-containing vaccine*

Product/indication	Dose, including mg immunoglobulin G (IgG)/ kg body weight*	Recommended interval before measles or varicella-containing vaccine administration (months)
Respiratory syncytial virus immune globulin (IG) monoclonal antibody (Synagis[Ê])[Â]	15 mg/kg intramuscularly (IM)	None
Tetanus IG	250 units (10 mg IgG/kg) IM	3
Hepatitis A IG		
Contact prophylaxis	0.02 mL/kg (3.3 mg IgG/kg) IM	3
International travel	0.06 mL/kg (10 mg IgG/kg) IM	3
Hepatitis B IG	0.06 mL/kg (10 mg IgG/kg) IM	3
Rabies IG	20 IU/kg (22 mg IgG/kg) IM	4
Measles prophylaxis IG		
Standard (i.e., nonimmunocompromised) contact	0.25 mL/kg (40 mg IgG/kg) IM	5
Immunocompromised contact	0.50 mL/kg (80 mg IgG/kg) IM	6
Blood transfusion		
Red blood cells (RBCs), washed	10 mL/kg negligible IgG/kg intravenously (IV)	None
RBCs, adenine-saline added	10 mL/kg (10 mg IgG/kg) IV	3
Packed RBCs (hematocrit 65%)[Ä]	10 mL/kg (60 mg IgG/kg) IV	6
Whole blood (hematocrit 35%ï 50%)[Ä]	10 mL/kg (80ï 100 mg IgG/kg) IV	6
Plasma/platelet products	10 mL/kg (160 mg IgG/kg) IV	7
Cytomegalovirus intravenous immune globulin (IGIV)	150 mg/kg maximum	6
IGIV		
Replacement therapy for immune deficiencies[Æ]	300ï 400 mg/kg IV[Æ]	8
Immune thrombocytopenic purpura	400 mg/kg IV	8
Postexposure varicella prophylaxis**	400 mg/kg IV	8
Immune thrombocytopenic purpura	1000 mg/kg IV	10
Kawasaki disease	2 g/kg IV	11

* This table is not intended for determining the correct indications and dosages for using antibody-containing products. Unvaccinated persons might not be fully protected against measles during the entire recommended interval, and additional doses of immune globulin or measles vaccine might be indicated after measles exposure. Concentrations of measles antibody in an immune globulin preparation can vary by manufacturer's lot. Rates of antibody clearance after receipt of an immune globulin preparation also might vary. Recommended intervals are extrapolated from an estimated half-life of 30 days for passively acquired antibody and an observed interference with the immune response to measles vaccine for 5 months after a dose of 80 mg IgG/kg.

[Â] Contains antibody only to respiratory syncytial virus

[Ä] Assumes a serum IgG concentration of 16 mg/mL.

[Æ] Measles and varicella vaccinations are recommended for children with asymptomatic or mildly symptomatic human immunodeficiency virus (HIV) infection but are contraindicated for persons with severe immunosuppression from HIV or any other immunosuppressive disorder.

** The investigational product VariZIG, similar to licensed VZIG, is a purified human immune globulin preparation made from plasma containing high levels of anti-varicella antibodies (immunoglobulin class G [IgG]). When indicated, health-care providers should make every effort to obtain and administer VariZIG. In situations in which administration of VariZIG does not appear possible within 96 hours of exposure, administration of immune globulin intravenous (IGIV) should be considered as an alternative. IGIV also should be administered within 96 hours of exposure. Although licensed IGIV preparations are known to contain anti-varicella antibody titers, the titer of any specific lot of IGIV that might be available is uncertain because IGIV is not routinely tested for antivaricella antibodies. The recommended IGIV dose for postexposure prophylaxis of varicella is 400 mg/kg, administered once. For pregnant women who cannot receive VariZIG within 96 hours of exposure, clinicians can choose either to administer IGIV or closely monitor the women for signs and symptoms of varicella and institute treatment with acyclovir if illness occurs. (**Source:** CDC. A new product for postexposure prophylaxis available under an investigational new drug application expanded access protocol. MMWR 2006;55:209ï 10).

Interchangeability of Vaccines from Different Manufacturers

Certain vaccines are available from different manufacturers, and these vaccines usually are not identical in antigen content or amount or method of formulation. Manufacturers use different production processes, and their products might contain different concentrations of antigen per dose or a different stabilizer or preservative.

Available data indicate that infants who receive sequential doses of different Hib conjugate, HepB, and hepatitis A (HepA) vaccines produce a satisfactory antibody response after a complete primary series (*41–44*). All brands of Hib conjugate, HepB,[§] and HepA vaccines are interchangeable within

[§] The exception is the 2-dose HepB vaccination series for adolescents aged 11–15 years. Only Recombivax HB® (Merck Vaccine Division) should be used in this schedule. Engerix-B® (GlaxoSmithKline) is not approved by FDA for this schedule.

their respective series. If different brands of Hib conjugate vaccine are administered, 3 doses are considered adequate for the primary series among infants. If PRP-OMP is used, the primary series consists of 2 doses. After completing the primary series, any Hib conjugate vaccine can be used for the booster dose at age 12–18 months.

Data are limited about the safety, immunogenicity, and efficacy of using acellular pertussis (e.g., DTaP) vaccines from different manufacturers for successive doses of the pertussis series. Data from one study indicate that, for the first 3 doses of the DTaP series, 1–2 doses of Tripedia® followed by Infanrix® for the remaining doses(s) is comparable to 3 doses of Tripedia with regard to immunogenicity, as measured by antibodies to diphtheria, tetanus, and pertussis toxoid, and filamentous hemagglutinin (*45*). However, in the absence of a clear serologic correlate of protection for pertussis, the relevance of these immunogenicity data for protection against pertussis is unknown. Whenever feasible, the same brand of DTaP vaccine should be used for all doses of the vaccination series. If vaccination providers do not know or have available the type of DTaP vaccine previously administered to a child, any DTaP vaccine should be used to continue or complete the series. For vaccines in general, vaccination should not be deferred because the brand used for previous doses is not available or is unknown (*27,46*).

Lapsed Vaccination Schedule

Vaccination providers should administer vaccines as close to the recommended intervals as possible. However, longer-than-recommended intervals between doses do not reduce final antibody concentrations, although protection might not be attained until the recommended number of doses has been administered. With the exception of oral typhoid vaccine, an interruption in the vaccination schedule does not require restarting the entire series of a vaccine or toxoid or addition of extra doses.

Unknown or Uncertain Vaccination Status

Vaccination providers frequently encounter persons who do not have adequate documentation of vaccinations. Providers should only accept written, dated records as evidence of vaccination. With the exception of influenza vaccine and PPV (*47,48*), self-reported doses of vaccine without written documentation should not be accepted. Although vaccinations should not be postponed if records cannot be found, an attempt to locate missing records should be made by contacting previous health-care providers, reviewing state or local immunization information systems (IIS), and searching for a personally held record. If records cannot be located, these persons should be considered susceptible and should be started on the age-appropriate vaccination schedule. Serologic testing for immunity is an alternative to vaccination for certain antigens (e.g., measles, rubella, hepatitis A, and tetanus).

Contraindications and Precautions

Contraindications and precautions to vaccination dictate circumstances when vaccines should not be administered. The majority of precautions are temporary, and the vaccination can be administered later. A contraindication is a condition in a recipient that increases the risk for a serious adverse reaction. A vaccine should not be administered when a contraindication is present. For example, administering influenza vaccine to a person with an anaphylactic allergy to egg protein could cause serious illness in or death of the recipient.

National standards for pediatric vaccination practices have been established and include true contraindications and precautions to vaccination (Table 5) (*1*). The only contraindication applicable to all vaccines is a history of a severe allergic reaction after a previous dose of vaccine or to a vaccine constituent (unless the recipient has been desensitized). In addition, severely immunocompromised persons should generally not receive live vaccines. Children who experience encephalopathy within 7 days after administration of a previous dose of diphtheria and tetanus toxoids and whole-cell pertussis vaccine (DTP), DTaP, or Tdap not attributable to another identifiable cause should not receive further doses of a vaccine that contains pertussis. Because of the theoretical risk for the fetus, women known to be pregnant should generally not receive live-attenuated virus vaccines.

A precaution is a condition in a recipient that might increase the risk for a serious adverse reaction or that might compromise the ability of the vaccine to produce immunity (e.g., administering measles vaccine to a person with passive immunity to measles from a blood transfusion). A person might experience a more severe reaction to the vaccine than would have otherwise been expected; however, the risk for this happening is less than expected with a contraindication. In general, vaccinations should be deferred when a precaution is present. However, a vaccination might be indicated in the presence of a precaution because the benefit of protection from the vaccine outweighs the risk for an adverse reaction. For example, caution should be exercised in vaccinating a child with DTaP who, within 48 hours of receipt of a previous dose of DTP or DTaP, experienced fever of >104°F (>40.5°C); had persistent, inconsolable crying for 3 or more hours; collapsed or experienced a shock-like state; or had a seizure <3 days after receiving the previous dose of DTP or DTaP. How-

TABLE 5. Contraindications and precautions* to commonly used vaccines

Vaccine	True contraindications and precautions*	Untrue (vaccines can be administered)
General for all routine vaccines, including diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP); pediatric diphtheria-tetanus toxoid (DT); adult tetanus-diphtheria toxoid (Td); tetanus-reduced-diphtheria toxoid and acellular pertussis vaccine (Tdap), inactivated poliovirus vaccine (IPV); measles-mumps-rubella vaccine (MMR); *Haemophilus influenzae* type b vaccine (Hib); hepatitis A vaccine; hepatitis B vaccine; varicella vaccine; Rotavirus vaccine, pneumococcal conjugate vaccine (PCV); inactivated influenza vaccine (TIV); live-attenuated influenza vaccine (LAIV) pneumococcal polysaccharide vaccine (PPV); meningococcal conjugate vaccine (MCV4); meningococcal polysaccharide vaccine (MPSV); human papillomavirus vaccine (HPV); and herpes zoster vaccine (HZ)	**Contraindications** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component **Precautions** Moderate or severe acute illness with or without fever	Mild acute illness with or without fever Mild-to-moderate local reaction (i.e., swelling, redness, and soreness); low-grade or moderate fever after previous dose Lack of previous physical examination in well-appearing person Current antimicrobial therapy† Convalescent phase of illness Preterm birth (hepatitis B vaccine is an exception in certain circumstances)† Recent exposure to an infectious disease History of penicillin allergy, other nonvaccine allergies, relatives with allergies, receiving allergen extract immunotherapy Breast feeding
DTaP	**Contraindications** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component Encephalopathy (e.g., coma, decreased level of consciousness; prolonged seizures) not attributable to another identifiable cause within 7 days of administration of previous dose of DTP or DTaP Progressive neurologic disorder, including infantile spasms, uncontrolled epilepsy, progressive encephalopathy: defer DTaP until neurologic status clarified and stabilized **Precautions** Temperature of ≥105ÁF (≥40.5ÁC) for ≤48 hours after vaccination with a previous dose of DTP or DTaP Collapse or shock-like state (i.e., hypotonic hyporesponsive episode) ≤48 hours after receiving a previous dose of DTP/DTaP Seizure ≤3 days after receiving a previous dose of DTP/DTaP§ Persistent, inconsolable crying lasting ≥3 hours within 48 hours after receiving a previous dose of DTP/DTaP Guillain-Barr® syndrome (GBS) <6 weeks after previous dose of tetanus toxoid-containing vaccine Moderate or severe acute illness with or without fever	Temperature of ≤104ÁF (<40.5ÁC), fussiness, or mild drowsiness after a previous dose of diphtheria toxoid-tetanus toxoid-pertussis vaccine (DTP/DTaP) Family history of seizures§ Family history of sudden infant death syndrome Family history of an adverse event after DTP or DTaP administration Stable neurologic conditions (e.g., cerebral palsy, well-controlled seizure disorder, developmental delay)
DT, Td	**Contraindications** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component **Precautions** GBS <6 weeks after previous dose of tetanus toxoid-containing vaccine Moderate or severe acute illness with or without fever	

TABLE 5. (*Continued*) Contraindications and precautions* to commonly used vaccines

Vaccine	True contraindications and precautions*	Untrue (vaccines can be administered)
Tdap	**Contraindications** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component Encephalopathy (e.g., coma, decreased level of consciousness, and prolonged seizures) not attributable to another identifiable cause within 7 days of administration of previous dose of DTP, DTaP or Tdap **Precautions** Moderate or severe acute illness with or without fever GBS ≤6 weeks after a previous dose of tetanus toxoid containing vaccine Progressive or unstable neurological disorder, uncontrolled seizures or progressive encephalopathy until a treatment regimen has been established and the condition has stabilized History of arthus-type hypersensitivity reactions following a previous dose of tetanus toxoid-containing vaccine. Defer vaccination until at least 10 years have elapsed since the last tetanus toxoid-containing vaccine	Temperature of >104ÁF (>40.5ÁC) for ≤48 hours after vaccination with a previous dose of DTP or DTaP Collapse or shock-like state (i.e., hypotonic hyporesponsive episode) ≤48 hours after receiving a previous dose of DTP/DTaP Seizure ≤3 days after receiving a previous dose of DTP/DTaPÆ Persistent, inconsolable crying lasting ≥3 hours within 48 hours after receiving a previous dose of DTP/DTaP History of extensive limb swelling after DTP/DTaP/Td that is not an arthus-type reaction Stable neurologic disorder Brachial neuritis Latex allergy that is not anaphylactic Breast feeding Immunosuppression
IPV	**Contraindications** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component **Precautions** Pregnancy Moderate or severe acute illness with or without fever	Previous receipt of one or more doses of oral polio vaccine
MMR**	**Contraindications** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component Pregnancy Known severe immunodeficiency (e.g., hematologic and solid tumors; receiving chemotherapy; congenital immunodeficiency; long-term immunosuppressive therapy;ÄÄ or patients with human immunodeficiency virus [HIV] infection who are severely immunocompromised) **Precautions** Recent (≤11 months) receipt of antibody-containing blood product (specific interval depends on product)ÆÆ History of thrombocytopenia or thrombocytopenic purpura Moderate or severe acute illness with or without fever	Positive tuberculin skin test Simultaneous tuberculosis skin testingÄÄ Breast feeding Pregnancy of recipientÕs mother or other close or household contact Recipient is childbearing-age female Immunodeficient family member or household contact Asymptomatic or mildly symptomatic HIV infection Allergy to eggs
Hib	**Contraindications** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component Aged <6 weeks **Precautions** Moderate or severe acute illness with or without fever	

TABLE 5. (*Continued*) Contraindications and precautions* to commonly used vaccines

Vaccine	True contraindications and precautions*	Untrue (vaccines can be administered)
Hepatitis B	**Contraindication** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component **Precautions** Infant weighing <2000 g[Ä] Moderate or severe acute illness with or without fever	Pregnancy Autoimmune disease (e.g., systemic lupus erythematosis or rheumatoid arthritis)
Hepatitis A	**Contraindications** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component **Precautions** Pregnancy Moderate or severe acute illness with or without fever	
Varicella	**Contraindications** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component Substantial suppression of cellular immunity Pregnancy **Precautions** Recent (≤11 months) receipt of antibody-containing blood product (specific interval depends on product)[ÆÆE] Moderate or severe acute illness with or without fever	Pregnancy of recipientŝ mother or other close or household contact Immunodeficient family member or household contact*** Asymptomatic or mildly symptomatic HIV infection Humoral immunodeficiency (e.g., agamma-globulinemia)[ÀÀÀ]
PCV	**Contraindications** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component **Precaution** Moderate or severe acute illness with or without fever	
TIV	**Contraindication** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component **Precaution** Moderate or severe acute illness with or without fever	Nonsevere (e.g., contact) allergy to latex or thimerosal Concurrent administration of coumadin or aminophylline
LAIV	**Contraindications** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component Pregnancy Known severe immunodeficiency (e.g., hematologic and solid tumors; receiving chemotherapy; congenital immunodeficiency; long-term immunosuppressive therapy;[ÀÀ] or patients with human immunodeficiency virus [HIV] infection who are severely immunocompromised) Previous history of GBS Certain chronic medical conditions[ÄÄÄ] **Precaution** Moderate or severe acute illness with or without fever	

TABLE 5. (*Continued*) Contraindications and precautions* to commonly used vaccines

Vaccine	True contraindications and precautions*	Untrue (vaccines can be administered)
PPV	**Contraindication** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component **Precaution** Moderate or severe acute illness with or without fever	History of invasive pneumococcal disease or pneumonia
MCV4	**Contraindications** Severe allergic reaction (e.g., anaphylaxis) after a previous vaccine dose or to a vaccine component **Precautions** Moderate or severe acute illness with or without fever History of Guillain-Barr® syndrome (if not at high risk for meningococcal disease)	
MPSV	**Contraindications** Severe allergic reaction after a previous dose or to a vaccine component **Precautions** Moderate or severe acute illness with or without fever	
HPV	**Contraindications** Severe allergic reaction after a previous dose or to a vaccine component **Precautions** Moderate or severe acute illness with or without fever Pregnancy	
Rotavirus	**Contraindications** Severe allergic reaction after a previous dose or to a vaccine component **Precautions** Moderate or severe acute illness with or without fever Immunosuppression Receipt of an antibody-containing blood product within 6 weeks[ÆÆ] Preexisting gastrointestinal disease Previous history of intussusception	Preterm births Immunosuppression in household contacts Pregnant household contacts

* Events or conditions listed as precautions should be reviewed carefully. Benefits of and risks for administering a specific vaccine to a person under these circumstances should be considered. If the risk from the vaccine is believed to outweigh the benefit, the vaccine should not be administered. If the benefit of vaccination is believed to outweigh the risk, the vaccine should be administered. Whether and when to administer DTaP to children with proven or suspected underlying neurologic disorders should be decided on a case-by-case basis.

[À] Antibacterial drugs and mefloquine might interfere with Ty21a oral typhoid vaccine, and certain antiviral drugs might interfere with varicella-containing and live-attenuated influenza virus vaccine.

[Ä] Hepatitis B vaccination should be deferred for infants weighing <2000 g if the mother is documented to be hepatitis B surface antigen (HBsAg)-negative at the time of the infantÕs birth. Vaccination can commence at chronological age 1 month. For infants born to HBsAg-positive women, hepatitis B immunoglobulin and hepatitis B vaccine should be administered at or soon after birth, regardless of weight.

[Æ] Acetaminophen or other appropriate antipyretic can be administered to infants and children with a history of previous seizures at the time of DTaP vaccination and every 4 hours for 24 hours thereafter to reduce the possibility of postvaccination fever (**Source:** American Academy of Pediatrics. Active immunization. In: Pickering LK, Baker CJ, Long SS, McMillan J. eds. 2006 red book: report of the Committee on Infectious Diseases. 27th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2006).

** MMR and varicella vaccines can be administered on the same day. If not administered on the same day, these vaccines should be separated by at least 28 days.

[ÀÀ] Substantially immunosuppressive steroid dose is considered to be ≥2 weeks of daily receipt of ≥20 mg or ≥2 mg/kg body weight of prednisone or equivalent.

[ÄÄ] Measles vaccination might suppress tuberculin reactivity temporarily. Measles-containing vaccine can be administered on the same day as tuberculin skin testing. If testing cannot be performed until after the day of MMR vaccination, the test should be postponed for ≥4 weeks after the vaccination. If an urgent need exists to skin test, do so with the understanding that reactivity might be reduced by the vaccine.

[ÆÆ] See text for details

TABLE 5. (*Continued*) Contraindications and precautions* to commonly used vaccines

Vaccine	True contraindications and precautions*	Untrue (vaccines can be administered)

*** If a vaccinee experiences a presumed vaccine-related rash 7ï 25 days after vaccination, avoid direct contact with immunocompromised persons for the duration of the rash, if possible.

ÀÀÀVaccine should be deferred for the appropriate interval if replacement IG products are being administered (Table 4).

ÄÄÄFor details, see CDC. Prevention and control of influenza: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR 2006;55:No. RR-10.

ÆÆÆRotavirus vaccine (RV) should be deferred for 6 weeks after receipt of an antibody-containing product if possible. However, if the 6-week deferral would cause the first dose of RV to be scheduled for age ≥13 weeks, a shorter deferral interval should be used to ensure the first dose of RV is administered no later than age 13 weeks.

ever, administering a pertussis-containing vaccine should be considered if the risk for pertussis is increased (e.g., during a pertussis outbreak) (*27*). These precautions do not apply to administration of tetanus-reduced-diphtheria-acellular-pertussis vaccine for adolescents and adults. The presence of a moderate or severe acute illness with or without a fever is a precaution to administration of all vaccines (Table 5).

Clinicians or other health-care providers might inappropriately consider certain conditions or circumstances to be true contraindications or precautions to vaccination. This misconception results in missed opportunities to administer recommended vaccines (*49*). Likewise, clinicians and other health-care providers might fail to understand what constitutes a true contraindication or precaution and might administer a vaccine when it should be withheld. This practice can result in an increased risk for an adverse reaction to the vaccine. Among the most common conditions often inappropriately considered contraindications are diarrhea, minor upper-respiratory tract illnesses (including otitis media) with or without fever, mild-to-moderate local reactions to a previous dose of vaccine, current antimicrobial therapy, and the convalescent phase of an acute illness (Table 5).

The decision to administer or delay vaccination because of a current or recent acute illness depends on severity of symptoms and etiology of the disease. All vaccines can be administered to persons with minor acute illness (e.g., diarrhea or mild upper-respiratory tract infection with or without fever). Studies indicate that failure to vaccinate children with minor illnesses can seriously impede vaccination efforts (*50–52*). Among persons whose compliance with medical care cannot be ensured, use of every opportunity to provide appropriate vaccinations is critical.

The safety and efficacy of vaccinating persons who have mild illnesses have been documented (*53–56*). Vaccination should not be delayed because of the presence of mild respiratory tract illness or other acute illness with or without fever.

Persons with moderate or severe acute illness should be vaccinated as soon as the acute illness has improved, after screening for contraindications. This precaution avoids superimposing adverse effects of the vaccine on the underlying illness or causing diagnostic confusion between manifestations of the underlying illness and possible adverse effects of vaccination.

Routine physical examinations and procedures (e.g., measuring temperatures) are not prerequisites for vaccinating persons who appear to be healthy. Asking the parent or guardian if the child is ill and then postponing vaccination for children with moderate-to-severe illness or proceeding with vaccination if no contraindications exist are appropriate procedures in childhood vaccination programs.

A family history of seizures or other central nervous system disorders is not a contraindication to administration of pertussis or other vaccines. However, delaying pertussis vaccination for infants and children with a history of previous seizures until the child's neurologic status has been assessed is prudent. Pertussis vaccine should not be administered to infants with evolving neurologic conditions until the condition has stabilized (Table 5) (*27*).

Vaccine Administration

Infection Control and Sterile Technique

Persons administering vaccines should follow appropriate precautions to minimize risk for spread of disease. Hands should be cleansed with an alcohol-based waterless antiseptic hand rub or washed with soap and water between each patient contact (*57*). Occupational Safety and Health Administration (OSHA) regulations do not require gloves to be worn when administering vaccinations, unless persons administering vaccinations are likely to come into contact with potentially infectious body fluids or have open lesions on their hands. Needles used for injections must be sterile and disposable to minimize the risk for contamination. A separate needle and syringe should be used for each injection. Changing needles between drawing vaccine from a vial and injecting it into a recipient is not necessary. Different vaccines should never be mixed in the same syringe unless specifically licensed for such use, and no attempt should be made to transfer between syringes.

To prevent inadvertent needle-stick injury or reuse, needles and syringes should be discarded immediately after use in labeled, puncture-proof containers located in the same room where the vaccine is administered. Needles should not be recapped before being placed in the container. Safety needles or needle-free injection devices should be used if available to reduce the risk for injury.

Injection Route and Injection Site

With the exception of Bacillus Calmette-Guerin (BCG) vaccine, injectable vaccines are administered by the intramuscular and subcutaneous route. The method of administration of injectable vaccines is determined, in part, by the presence of adjuvants in some vaccines. The term adjuvant refers to a vaccine component distinct from the antigen that enhances the immune response to the antigen. The majority of vaccines containing an adjuvant (e.g., DTaP, DT, Td, Tdap, PCV, Hib, HepA , HepB, and human papillomavirus [HPV]) should be injected into a muscle because administration subcutaneously or intradermally can cause local irritation, induration, skin discoloration, inflammation, and granuloma formation. Anthrax vaccine, an inactivated vaccine with adjuvant, is an exception to this rule and is recommended to be administered subcutaneously. Routes of administration are recommended by the manufacturer for each immunobiologic (Table 6). Deviation from the recommended route of administration might reduce vaccine efficacy (*58,59*) or increase local adverse reactions (*60–62*).

Intramuscular Injections and Needle Length

Injectable immunobiologics should be administered where local, neural, vascular, or tissue injury is unlikely. Use of longer needles has been associated with less redness or swelling than occurs with shorter needles because of injection into deeper muscle mass (*60*). Appropriate needle length depends on age and body mass.

TABLE 6: Dose and route of administration for selected vaccines

Vaccines	Dose	Route
Diphtheria, tetanus, pertussis (DTaP, DT, Td, Tdap)	0.5 mL	Intramuscular (IM)
Diphtheria, tetanus, acellular pertussis, inactivated polio, hepatitis B vaccine (DTaP-IPV-HepB)	0.5 mL	IM
Diphtheria, tetanus, acellular pertussis, *haemophilus influenza* type b vaccine (DTaP-Hib)	0.5 mL	IM
Haemophilus influenzae type b (Hib)	0.5 mL	IM
Haemophilus influenzae type b ï Hepatitis B (Hib-HepB)	0.5 mL	IM
Hepatitis A (HepA)	≤18 yrs: 0.5 mL ≥19 yrs: 1.0 mL	IM
HepB	≤19 yrs: 0.5 mL* ≥20 yrs: 1.0 mL	IM
HepA/HepB	≥18 yrs: 1.0 mL	IM
Influenza, live attenuated	0.5 mL	Intranasal spray
Influenza, trivalent inactivated	6ï 35 mos: 0.25 mL ≥3 yrs: 0.5 mL	IM
Measles, mumps, rubella	0.5 mL	Subcutaneous (SC)
Measles, mumps, rubella, varicella	0.5 mL	SC
Meningococcal conjugate	0.5 mL	IM
Meningococcal polysaccharide	0.5 mL	SC
Pneumococcal conjugate	0.5 mL	IM
Pneumococcal polysaccharide	0.5 mL	IM or SC
Human papillomavirus	0.5 mL	IM
Polio, inactivated	0.5 mL	IM or SC
Rotavirus	2.0 mL	Oral
Varicella	0.5 mL	SC
Zoster	0.7 mL	SC

* Persons aged 11ï 15 years can be administered Recombivax HB^{È} (Merck) 1.0 mL (adult formulation) on a 2-dose schedule.
Adapted from: Immunization Action Coalition (http://www.immunize.org).

For all intramuscular injections, the needle should be long enough to reach the muscle mass and prevent vaccine from seeping into subcutaneous tissue, but not so long as to involve underlying nerves, blood vessels, or bone (*59,63–65)*. Vaccinators should be familiar with the anatomy of the area into which they are injecting vaccine. Intramuscular injections are administered at a 90-degree angle to the skin, preferably into the anterolateral aspect of the thigh or the deltoid muscle of the upper arm, depending on the age of the patient (Table 7).

Decision on needle size and site of injection must be made for each person on the basis of the size of the muscle, the thickness of adipose tissue at the injection site, the volume of the material to be administered, injection technique, and the depth below the muscle surface into which the material is to be injected (Figure 1). Aspiration before injection of vaccines or toxoids (i.e., pulling back on the syringe plunger after needle insertion, before injection) is not required because no large blood vessels exists at the recommended injection sites.

Infants (Aged <12 Months)

For the majority of infants, the anterolateral aspect of the thigh is the recommended site for injection because it provides a large muscle mass (Figure 2). The muscles of the buttock have not been used for administration of vaccines in infants and children because of concern about potential injury to the sciatic nerve, which is well documented after injection of antimicrobial agents into the buttock. If the gluteal muscle must be used, care should be taken to define the ana-

tomic landmarks.[¶] Injection technique is the most important parameter to ensure efficient intramuscular vaccine delivery. If the subcutaneous and muscle tissue are bunched to minimize the chance of striking bone (*63*), a 1-inch needle is required to ensure intramuscular administration in infants. For the majority of infants, a 1-inch, 22–25-gauge needle is sufficient to penetrate muscle in an infant's thigh. For newborn (first 28 days of life) and premature infants, a 5/8 inch long needle usually is adequate if the skin is stretched flat between thumb and forefinger and the needle inserted at a 90-degree angle to the skin (*65*).

Toddlers and Older Children (Aged 12 Months–10 Years)

The deltoid muscle should be used if the muscle mass is adequate. The needle size for deltoid site injections can range from 22–25 gauge and from 5/8 to 1 inch on the basis of the size of the muscle and the thickness of adipose tissue at the injection site (Figure 3). A 5/8-inch needle is adequate only for the deltoid muscle and only if the skin is stretched flat between thumb and forefinger and the needle inserted at a 90-degree angle to the skin. For toddlers, the anterolateral thigh can be used, but the needle should be at least 1 inch in length.

Adolescents and Adults (Aged >11 Years)

For adults and adolescents, the deltoid muscle is recommended for routine intramuscular vaccinations. The anterolateral thigh also can be used. For men and women weighing <130 lbs (<60 kg) a 5/8–1-inch needle is sufficient to ensure intramuscular injection. For women weighing 130–200 lbs (60–90 kg) and men 130–260 lbs (60–118kg), a 1–1½-inch needle is needed. For women weighing >200 lbs (>90 kg) or men weighing >260 lbs (>118 kg), a 1½-inch needle is required (Table 7) (*64*).

[¶]If the gluteal muscle is chosen, injection should be administered lateral and superior to a line between the posterior superior iliac spine and the greater trochanter or in the ventrogluteal site, the center of a triangle bounded by the anterior superior iliac spine, the tubercle of the iliac crest, and the upper border of the greater trochanter.

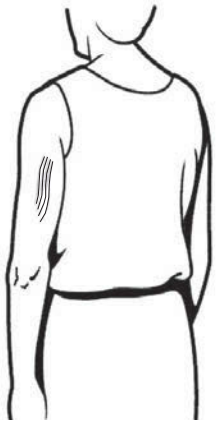
FIGURE 3. Intramuscular site of administration: deltoid

Adapted from Minnesota Department of Health

Subcutaneous Injections

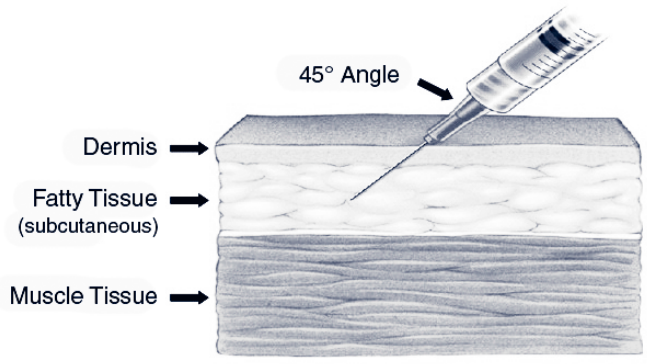
Subcutaneous injections are administered at a 45-degree angle usually into the thigh for infants aged <12 months and in the upper-outer triceps area of persons aged ≥12 months. Subcutaneous injections can be administered into the upper-outer triceps area of an infant, if necessary. A 5/8-inch, 23–25-gauge needle should be inserted into the subcutaneous tissue (Figures 4 and 5).

FIGURE 4. Subcutaneous site of administration: triceps



Adapted from Minnesota Department of Health

FIGURE 5. Subcutaneous needle insertion



Adapted from California Immunization Branch

Multiple Vaccinations

If multiple vaccines are administered at a single visit, administration of each preparation at a different anatomic site is desirable. For infants and younger children, if more than two vaccines must be injected in a single limb, the thigh is the preferred site because of the greater muscle mass; the injections should be sufficiently separated (i.e., 1 inch or more if possible) so that any local reactions can be differentiated (*60,66*). For older children and adults, the deltoid muscle can be used for more than one intramuscular injection. If a vaccine and an immune globulin preparation are administered simultaneously (e.g., Td/Tdap and tetanus immune globulin [TIG], HepB and hepatitis B immunoglobulin [HBIG]), separate anatomic sites should be used for each injection. The location of each injection should be documented in the patients' medical record.

Jet Injection

Jet injectors (JIs) are needle-free devices that drive liquid medication through a nozzle orifice, creating a narrow stream under high pressure that penetrates skin to deliver a drug or vaccine into intradermal, subcutaneous, or intramuscular tissues (*67,68*). JIs have the potential to reduce the frequency of needle-stick injuries to health-care workers (*69*) and to overcome the improper reuse and other drawbacks of needles and syringes in economically developing countries (*70–72*). JIs have been safe and effective for administering different live and inactivated vaccines for viral and bacterial diseases (*72*). The immune responses generated are equivalent to, and occasionally greater than, immune responses induced by needle injection. However, local reactions or injury (e.g., redness, induration, pain, blood, and ecchymosis at the injection site) can be more frequent when vaccines are delivered by JIs compared with needle injection (*68,72*).

In the 1990s, a new generation of JIs was introduced with disposable cartridges serving as dose chambers and nozzle (*72*). With the provision of a new sterile cartridge for each patient and correct use, these devices avoid the safety concerns for multiple-use–nozzle devices (*72–76*). These devices should be used in accordance with their labeling for intradermal, subcutaneous, or intramuscular administration.

Methods for Alleviating Discomfort and Pain Associated with Vaccination

Comfort measures, such as distraction (e.g., playing music or pretending to blow away the pain), ingestion of sweet liquids, breast feeding, cooling of the injection site, and topical or oral analgesia, can help infants or children cope with the discomfort associated with vaccination (*77,78*). Pretreatment (30–60 minutes before injection) with 5% topical lidocaine-prilocaine emulsion can decrease the pain of vaccination by causing superficial anesthesia (*79,80*). Evidence indicates that this cream does not interfere with the immune response to MMR (*81*). Topical lidocaine-prilocaine emulsion should not be used on infants aged <12 months who are receiving treatment with methemoglobin-inducing agents because of the possible development of methemoglobinemia (*82*).

Acetaminophen has been used among children to reduce the discomfort and fever associated with DTP vaccination (*83*). However, acetaminophen can cause formation of methemoglobin and might interact with lidocaine-prilocaine cream if used concurrently (*82*). Use of a topical refrigerant (vapocoolant) spray immediately before vaccination can reduce the short-term pain associated with injections and can be as effective as lidocaine-prilocaine cream (*84*).

Nonstandard Vaccination Practices

Recommendations for route, site, and dosage of immunobiologics are derived from data from clinical trials, from practical experience, and from theoretical considerations. ACIP discourages variations from the recommended route, site, volume, or number of doses of any vaccine.

Variation from the recommended route and site can result in inadequate protection. In adults but not in infants (*85*), the immunogenicity of HepB is substantially lower when the gluteal rather than the deltoid site is used for administration (*58*). HepB administered intradermally can result in a lower seroconversion rate and final titer of hepatitis B surface antibody than when administered by the deltoid intramuscular route (*86,87*). HepB administered by any route other than intramuscularly, or in adults at any site other than the deltoid or anterolateral thigh, should not be counted as valid and should be repeated. Similarly, doses of rabies vaccine administered in the gluteal site should not be counted as valid doses and should be repeated (*88*). Meningococcal conjugate vaccine (MCV4) should be administered intramuscularly; however, revaccination is not necessary when administered subcutaneously (*89*). Inactivated influenza vaccine is immunogenic when administered in a lower than standard dose by the intradermal (ID) route to healthy adult volunteers (*90*). However, the immunogenicity for persons aged ≥60 years is inadequate, and variance from the recommended route and dose is not recommended.

Live-attenuated injectable vaccines (e.g., MMR, varicella, and yellow fever) and certain inactivated vaccines (e.g., meningococcal polysaccharide and anthrax) are recommended by the manufacturers to be administered by subcutaneous injec-

tion. PPV and IPV are recommended by the manufacturer to be administered by the subcutaneous or intramuscular route. Response to vaccines recommended by the subcutaneous route probably will not be affected if the vaccines are administered by the intramuscular rather than subcutaneous route. Repeating doses of vaccine administered by the intramuscular route rather than by the subcutaneous route is not necessary.

Administering volumes smaller than that recommended (e.g., split doses) can result in inadequate protection. Using larger than recommended dosages can be hazardous because of excessive local or systemic concentrations of antigens or other vaccine constituents. Using reduced doses administered at multiple immunization visits that equal a full dose or using smaller divided doses are not endorsed or recommended. Any vaccination using less than the standard dose should not be counted, and the person should be revaccinated according to age, unless serologic testing indicates that an adequate response has been achieved.

Preventing Adverse Reactions

Vaccines are intended to produce active immunity to specific antigens. An adverse reaction is an untoward effect that occurs after a vaccination that is extraneous to the vaccine's primary purpose of producing immunity. Vaccine adverse reactions are classified by three general categories: local, systemic, and allergic (*91*). Local reactions are usually the least severe and most frequent. Systemic reactions (e.g., fever) occur less frequently than local reactions. Serious allergic reactions (e.g., anaphylaxis) are the most severe and least frequent. Severe adverse reactions are rare.

Persons who administer vaccines should screen their patients for contraindications and precautions to the vaccine before each dose of vaccine is administered (Table 5). Screening can be facilitated by consistent use of screening questionnaires, which are available from certain state vaccination programs and other sources (e.g., the Immunization Action Coalition at http://www.immunize.org).

Syncope (vasovagal or vasodepressor reaction) can occur after vaccination, most commonly among adolescents and young adults. During 1990–2004, a total of 3,168 reports to Vaccine Adverse Event Reporting System (VAERS) were coded as syncope; 35% of these episodes were reported among persons aged 10–18 years (CDC, unpublished data, 2005). Approximately 14% of reported syncopal episodes resulted in hospitalization because of injury or medical evaluation. Serious injury, including skull fracture and cerebral hemorrhage, has resulted from syncopal episodes after vaccination (*92*). A review of syncope after vaccination indicated that 63% of syncopal episodes occurred ≤5 minutes after vaccination, and 89% occurred within 15 minutes after vaccination (*93*). Although syncopal episodes are uncommon and severe allergic reactions are rare, vaccine providers should strongly consider observing patients for 15 minutes after they are vaccinated (*94*). If syncope develops, patients should be observed until the symptoms resolve.

Managing Acute Vaccine Reactions

Although rare after vaccination, the immediate onset and life-threatening nature of an anaphylactic reaction require that all personnel and facilities providing vaccinations have procedures in place for managing a reaction. All vaccine providers should be familiar with the office emergency plan and be certified in cardiopulmonary resuscitation. Epinephrine and equipment for maintaining an airway should be available for immediate use.

Anaphylaxis usually begins within minutes of vaccine administration (*95,96*). Rapidly recognizing and initiating treatment are required to prevent possible progression to cardiovascular collapse. If flushing, facial edema, urticaria, itching, swelling of the mouth or throat, wheezing, difficulty breathing, or other signs of anaphylaxis occur, the patient should be placed in a recumbent position with the legs elevated. Treatment options for management of anaphylaxis using pharmaceuticals have been recommended (Table 8) (*94,97*). Maintenance of an airway and oxygen administration might be necessary. Arrangements should be made for immediate transfer to an emergency facility for further evaluation and treatment.

Occupational Safety Regulations

Bloodborne diseases (e.g., hepatitis B, hepatitis C, and human immunodeficiency virus [HIV]) are occupational hazards for physicians and other health-care providers. To reduce the incidence of needle-stick injury and the consequent risk for bloodborne diseases acquired from patients, the Needlestick Safety and Prevention Act was enacted in November 2000. The Act directed OSHA to strengthen its existing bloodborne pathogen standards. Those standards were revised and became effective in April 2001 (*69*). These federal regulations require that safer injection devices (e.g., needle-shielding syringes or needle-free injectors) be used for injectable vaccination in all clinical settings. The rules also require that records be kept documenting injuries caused by medical sharps and that nonmanagerial employees be involved in the evaluation and selection of safer devices to be procured.

Needle-shielding or needle-free devices that might satisfy the occupational safety regulations for administering inject-

TABLE 8. Treatment of anaphylaxis with intramuscular or oral pharmaceuticals

Drug	Dosage
Child	
Primary regimen	
Epinephrine 1:1000 (aqueous) (1 mg/mL)*	0.01 mg/kg up to 0.5 mg (administer 0.01 mL/kg/dose up to 0.5 mL) intramuscularly (IM) repeated every 10ï 20 minutes up to 3 doses
Secondary regimen	
Diphenhydramine	1ï 2 mg/kg oral, IM, or intraveneously (IV), every 4ï 6 hours (maximum single dose: 100 mg)
Hydroxyzine	0.5ï 1 mg/kg oral, IM, every 4ï 6 hours (maximum single dose: 100 mg)
Prednisone	1.5ï 2 mg/kg oral (maximum single dose: 60 mg); use corticosteroids as long as needed
Adult	
Primary regimen	
Epinephrine 1:1000 (aqueous)*	0.01 mg/kg up to 0.5 mg (give 0.01 mL/kg/dose up to 0.5 mL) IM repeated every 10ï 20 minutes up to 3 doses
Secondary regimen	
Diphenhydramine	1ï 2 mg/kg up to 100 mg IM or oral, every 4ï 6 hours

* If agent causing anaphylactic reaction was administered by injection, epinephrine can be injected into the same site to slow absorption.

able vaccines are available in the United States (*72,98,99*).** Additional information about implementation and enforcement of these regulations is available from OSHA (http://www.osha.gov/pls/oshaweb).

Storage and Handling of Immunobiologics

Failure to adhere to recommended specifications for storage and handling of immunobiologics can reduce their potency, resulting in an inadequate immune response in the recipient. Recommendations in the product package inserts, including methods for reconstitution of the vaccine, should be followed carefully. Vaccine quality is the shared responsibility of all handlers of vaccines from the time a vaccine is manufactured until administration. All vaccines should be inspected upon delivery and monitored during storage to ensure that the cold chain has been maintained. Vaccines should continue to be stored at recommended temperatures immediately upon receipt until use.

Storage Temperature

The majority of recommended vaccines require storage temperatures of 35°F–46°F (2°C–8°C), and they must not be exposed to freezing temperatures (*100*). Certain vaccines are sensitive to freezing temperatures because they contain an aluminum adjuvant (e.g., anthrax, DTaP, DT, Td, Tdap, Hib [PRP-OMP], HepA, HepB, PCV, rabies, and HPV) that precipitates when exposed to temperatures of ≤32°F (≤0°C) (*100,101*). Other vaccines (e.g., MMR, varicella, MMRV, LAIV, and yellow fever) lose potency when exposed to increased temperature because they contain live viruses (Table 9).

Vaccine storage units must be carefully selected, used properly, and consistently monitored to ensure that recommended temperatures are maintained. Refrigerators without freezers and stand-alone freezers (either manual defrost or automatic defrost) usually perform best at maintaining the precise temperatures required for vaccine storage, and such single-purpose units sold for home use are less expensive alternatives to medical specialty equipment (*100*). A combination refrigerator/freezer unit sold for home use is acceptable for storage of limited quantities of vaccines if the refrigerator and freezer compartments each have a separate external door. In these units, a freezer thermostat usually controls the freezer temperature and a refrigerator thermostat controls the volume of freezer temperature air entering the refrigerator, possibly resulting in different temperature zones within the refrigerator. In such units, vaccines should not be stored on the top shelf near the cold air outlet from the freezer to the refrigerator (usually located at the top of the refrigerator compartment). Any refrigerator or freezer used for vaccine storage must maintain the required temperature range year-round, be large enough to hold the year's largest inventory, and be dedicated to storage of biologics. Before use of the refrigerator for vaccine storage, the temperature should be measured in various

**Internet sites with device listings are identified for information purposes only. CDC, the U.S. Public Health Service, and the Department of Health and Human Services do not endorse any specific device or imply that the devices listed would all satisfy the needle-stick prevention regulations.

TABLE 9. Vaccine storage temperature recommendations

Vaccines	Vaccine storage temperature	Diluent storage temperature	Instructions
Diphtheria-tetanus, or pertussis-containing vaccines	35Áï 46ÁF (2ÁCï 8ÁC) Do not freeze	No diluent*	Aluminum adjuvant ï irreversible loss of potency with exposure to freezing temperature

locations within the refrigerator compartment to document that a stable temperature can be maintained (Table 9) within the compartment (*102*). The refrigerator temperature should be set at the midpoint of the recommended range (i.e., 40°F [5°C]) (*103,104*). Frequent opening and closing of doors can cause fluctuations of storage temperature; food, beverages, and clinical specimens should not be stored in vaccine storage units.

Temperature Monitoring

Temperature monitoring is a critical component of cold chain management. One person in the office should be assigned primary responsibility for maintaining temperature logs (Figure 6), with a second person assigned as backup. Temperatures for both the refrigerator and freezer should be documented twice a day and recorded. The backup person should review the log each week. Temperature logs should be maintained for 3 years unless state or local statutes mandate a longer time period. An automated monitoring system that alerts staff when a temperature deviation occurs is optimal. However, even if an automated monitoring system is used, temperatures should still be manually checked and recorded twice a day.

Thermometers should be placed in a central location in each compartment near the vaccine. Different types of thermometers can be used, including standard fluid-filled, minimum-maximum, and continuous chart recorder thermometers (Table 10). Standard fluid-filled thermometers are the simplest and least expensive products, but some models might

perform poorly. Product temperature thermometers (i.e., those encased in biosafe liquids) generally reflect refrigerator temperature more accurately. Minimum-maximum thermometers monitor the temperature range. Continuous chart recorder thermometers monitor temperature range and duration and can be recalibrated at specified intervals. All thermometers used for monitoring vaccine storage temperatures should be calibrated and certified by an appropriate agency (e.g., National Institute of Standards and Technology or the American Society for Testing and Materials). Because all thermometers are calibrated as part of the manufacturing process, this recommendation refers to a second calibration process that occurs after manufacturing but before marketing and is documented with a certificate that comes with the product.

Response to Out-of-Temperature-Range Storage

An out-of-range temperature reading should prompt immediate action. A plan should be developed to transfer vaccine to a predesignated alternative emergency storage site if a temperature problem cannot be resolved immediately (i.e., unit unplugged or door left open). Vaccine should be marked "do not use" and moved to the alternate site. After the vaccine has been moved, determine if the vaccine is still useable by contacting the manufacturer or state/local health department. Changes to vaccine exposed to temperatures outside of the recommended range and that affects its immunogenicity usually are not apparent visually.

Expiration Dates and Windows

All vaccines have an expiration date determined by the manufacturer that must be observed. When vaccines are removed from storage, physicians and health-care providers should note whether an expiration window exists for vaccine stored at room temperature or at an intermediate temperature. For example, live-attenuated influenza vaccine that is stored frozen must be discarded after 60 hours at refrigerator temperature. An expiration window also applies to vaccines that have been reconstituted. For example, after reconstitution, MMR vaccine must be administered within 8 hours and must be kept at refrigerator temperature during this time. Doses of expired vaccines that are administered inadvertently generally should not be counted as valid and should be repeated. Additional information about expiration dates is available at http://www.cdc.gov/nip.

Multidose Vials

Certain vaccines (i.e., DT, Td, Typhoid Vi, meningococcal polysaccharide vaccine [MPSV], TIV, JE, MMR, IPV, and yellow fever) might be distributed in multidose vials. For multidose vials that do not require reconstitution, after entering the vial, the remaining doses in a multidose vial can be administered until the expiration date printed on the vial or vaccine packaging if the vial has been stored correctly and the vaccine is not visibly contaminated, unless otherwise specified by the manufacturer. Multidose vials that require reconstitution must be used within an interval specified by the manufacturer. After reconstitution, the new expiration date should be written on the vial.

Prefilling Syringes

ACIP discourages the routine practice of prefilling syringes because of the potential for administration errors. The majority of vaccines have a similar appearance after being drawn into a syringe. Vaccine doses should not be drawn into a syringe until immediately before administration. When the syringes are filled, the type of vaccine, lot number, and date of filling must be labeled on each syringe, and the doses should be administered as soon as possible after filling. In certain circumstances in which a single vaccine type is being used (e.g., in advance of a community influenza vaccination campaign), filling a small number of syringes can be considered. Unused syringes filled by the end user (i.e., not filled by the manufacturer) should be discarded at the end of the vaccination session. In addition to administration errors, prefilling of syringes is a concern because FDA does not license administration syringes for vaccine storage. When in doubt about the appropriate handling of a vaccine, vaccination providers should contact the manufacturer.

As a general rule, vaccines that have been mishandled or stored at inappropriate temperatures should not be administered. Guidance for specific situations is available from the state health department or CDC. For certain vaccines (i.e., MMR, MMRV, or varicella vaccine), a serologic test can be performed and, if evidence of immunity can be documented for all antigens, revaccination is not necessary.

Altered Immunocompetence

General Principles

Altered immunocompetence is a term often used synonymously with immunosuppression and immunocompromise that includes conditions commonly classified as primary immunodeficiency and secondary immunodeficiency.

Primary immunodeficiencies generally are inherited and include conditions defined by an absence or quantitative deficiency of cellular and/or humoral components that provide immunity. Examples include congenital immunodeficiency diseases (e.g., X-linked agammaglobulinemia), severe combined immunodeficiency disease, and chronic granulomatous disease. Secondary immunodeficiency generally is acquired and is defined by loss or qualitative deficiency in cellular and humoral immune components that occurs as a result of a disease process or its therapy. Examples of secondary immune deficiency include HIV infection, hematopoetic malignancies, treatment with radiation, and treatment with immunosuppressive drugs, including alkylating agents and antimetabolites. The degree to which immunosuppressive drugs cause clinically significant immunodeficiency generally is dose-related and varies by drug. Primary and secondary immunodeficiencies might display a combination of deficits in both cellular and humoral immunity. In this report, the general term altered immunocompetence also will be used to include conditions such as asplenia and chronic renal disease and treatments with therapeutic monoclonal antibodies (specifically the tumor-necrosis-factor alpha inhibitors) (*105–110*) and prolonged high-dose corticosteroids.

Determination of altered immunocompetence is important to the vaccine provider because the incidence or severity of certain vaccine-preventable diseases is higher in persons with altered immunocompetence; therefore, certain vaccines (e.g., inactivated influenza and pneumococcal vaccines) are recommended specifically for persons with these diseases (*47,111–113*). Vaccines might be less effective during the period of altered immunocompetence. Live vaccines generally should be deferred until immune function has improved. Inactivated vaccines administered during the period of altered immunocompetence might need to be repeated after immune function has improved. Finally, persons with altered immunocompetence might be at increased risk for an adverse reaction after administration of live-attenuated vaccines because of reduced ability to mount an effective immune response.

The degree of altered immunocompetence in a patient should be determined by a physician. The challenge for clinicians and other health-care providers is in assessing the safety and effectiveness of vaccines for conditions associated with primary or secondary immunodeficiency, especially when new therapeutic modalities are being used and information about the safety and effectiveness of vaccines has not been characterized fully in persons receiving these drugs (Table 11). Laboratory studies can be useful for assessing the effects of a disease or drug on the immune system. Tests useful to assess humoral immunity include immunoglobulin (and immunoglobulin subset) levels and specific antibody levels (tetanus, diphtheria, and response to pneumococcal vaccine). Tests that demonstrate the status of cellular immunity include lymphocyte numbers (i.e., a complete blood count with differential), a test that delineates concentrations and proportions of lymphocyte subsets (i.e., B and T-lymphocytes, CD4+ versus CD8+ lymphocytes), and tests that measure T-lymphocyte proliferation in response to specific or nonspecific stimuli (e.g., lymphocyte proliferation assays) (*114–115*). The ability to characterize a drug or disease condition as affecting cellular or humoral immunity is only the first step; using this information to draw inferences about whether particular vaccines are indicated or whether caution is advised with use of live or

TABLE 11. Vaccination of persons with primary and secondary immune deficiencies

Category	Specific immunodeficiency	Contraindicated vaccines*	Risk-specific recommended vaccines*	Effectiveness and comments
Primary				
B-lymphocyte (humoral)	Severe antibody deficiencies (e.g., X-linked agammaglobulinemia and common variable immunodeficiency)	Oral poliovirus (OPV)[À] Smallpox Live-attenuated influenza vaccine (LAIV) BCG Ty21a (live oral typhoid)	Pneumococcal Influenza (TIV) Consider measles and varicella vaccination	The effectiveness of any vaccine will be uncertain if it depends only on the humoral response; intravenous immune globulin interferes with the immune response to measles vaccine and possibly varicella vaccine
	Less severe antibody deficiencies (e.g., selective IgA deficiency and IgG subclass deficiency)	OPV[À] Other live-vaccines appear to be safe	Pneumococcal Influenza (TIV)	All vaccines probably effective. Immune response may be attenuated
T-lymphocyte (cell-mediated and humoral)	Complete defects (e.g., severe combined immunodeficiency [SCID] disease, complete DiGeorge syndrome)	All live vaccines [Ä,Æ]	Pneumococcal Influenza (TIV)	Vaccines may be ineffective
	Partial defects (e.g., the majority of patients with DiGeorge syndrome, Wiskott-Aldrich syndrome, ataxia- telangiectasia)	All live vaccines [Ä,Æ]	Pneumococcal Meningococcal *Haemophilus influenza* type b (Hib) (if not administered in infancy) Influenza (TIV)	Effectiveness of any vaccine depends on degree of immune suppression
Complement	Deficiency of early components (C1, C2, C3, and C4)	None	Pneumococcal Meningococcal Influenza (TIV)	All routine vaccines probably effective
	Deficiency of late components (C5-C9) and C3, properdin, factor B	None	Pneumococcal Meningococcal Influenza (TIV)	All routine vaccines probably effective
Phagocytic function	Chronic granulomatous disease, leukocyte adhesion defect, and myeloperoxidase deficiency	Live bacterial vaccines[Ä]	Pneumococcal** Influenza (TIV) (to decrease secondary bacterial infection)	All inactivated vaccines safe and probably effective Live viral vaccines probably safe and effective
Secondary				
	Human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS)	OPV Smallpox BCG LAIV Withhold MMR and varicella in severely immunocompromised persons	Influenza (TIV) Pneumococcal Consider Hib (if not administered in infancy) and meningococcal vaccination.	Measles, mumps, rubella (MMR, varicella, and all inactivated vaccines, including inactivated influenza, might be effective[ÄÄ]
	Malignant neoplasm, transplantation, immunosuppressive or radiation therapy	Live viral and bacterial, depending on immune status	Influenza (TIV) Pneumococcal	Effectiveness of any vaccine depends on degree of immune suppression

TABLE 11. (*Continued*) Vaccination of persons with primary and secondary immune deficiencies

Secondary				
	Asplenia	None	Pneumococcal Meningococcal Hib (if not administered in infancy)	All routine vaccines probably effective.
	Chronic renal disease	LAIV	Pneumococcal Influenza (TIV) Hepatitis B	All routine vaccines probably effective.

* Other vaccines that are universally or routinely recommended should be administered if not contraindicated.
† OPV is no longer available for routine use in the United States.
§ Live bacterial vaccines: BCG, and Ty21a *Salmonella typhi* vaccine.
¶ Live viral vaccines: MMR, OPV, LAIV, yellow fever, and varicella, including MMRV and HZ vaccine, and vaccinia (smallpox). Smallpox vaccine is not recommended for children or the general public.
†† Pneumococcal vaccine is not indicated for children with chronic granulomatous disease.
§§ HIV-infected children should receive IG after exposure to measles, and can receive varicella and measles vaccine if CD4+ lymphocyte count is >15%.
Modified from American Academy of Pediatrics. Passive Immunization. In: Pickering LK, ed. Red Book: 2006 Report of the Committee on Infectious Diseases. 27th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2006, and CDC. Use of vaccines and immune globulins in persons with altered immunocompetence: recommendations of the Advisory Committee on Immunization Practices (ACIP). MMWR 1993:42 (No. RR-4).

inactivated vaccines is more complicated and might require consultation with an infectious disease or immunology specialist.

Altered Immunocompetence as an Indication to Receive a Vaccine

Persons with altered immunocompetence generally are advised to receive TIV and polysaccharide-based vaccines (i.e., PCV, PPV, MCV4, MPSV, and Hib vaccines) on the basis of demonstrated effectiveness and an increased risk for disease if the vaccine is withheld.

Pneumococcal Vaccines

Two types of vaccine against invasive pneumococcal disease are available in the United States: PCV and PPV. PCV is routinely recommended for all children beginning at age 2 months. PCV is not recommended for persons aged >59 months. PPV is approved for persons aged ≥2 years with certain underlying medical conditions (including altered immunocompetence) and routinely for persons aged ≥65 years. Complete recommendations on use of PCV and PPV are available in the Recommended Child and Adolescent Immunization Schedule and the Recommended Adult Immunization Schedule (*113,116*).

Influenza Vaccine

Two types of influenza vaccine are available in the United States: TIV and LAIV. Vaccination with TIV is indicated specifically for persons with altered immunocompetence, including HIV infection. LAIV usually is contraindicated for persons with altered immunocompetence, although healthy persons with anatomic or functional asplenia and household and other close contacts of persons with altered immunocompetence can receive this vaccine.

Meningococcal Vaccine

Two types of meningococcal vaccine are available in the United States: MCV4 and MPSV. Persons with asplenia, C3 complement deficiency (*117*), or terminal complement component deficiency are at increased risk for meningococcal disease and should receive MCV4 or MPSV. Persons with HIV infection can elect to receive MCV4 or MPSV. MCV4 is licensed for persons aged 11–55 years[††]; children aged 2–10 years or persons aged ≥56 years should receive MPSV.

Haemophilus influenzae type b Vaccine

Hib conjugate vaccines are available in single or combined antigen preparations. Hib vaccine is recommended routinely for all children through age 59 months. However, a single dose of Hib vaccine also can be considered for asplenic older children, adolescents, and adults who did not receive the vaccine series in childhood. Clinicians and other health-care providers might consider use of Hib vaccine among persons with HIV infection who did not receive the vaccine as an infant or in childhood (*112*).

[††] A supplement to the original MCV4 vaccine Biologics License Agreement was submitted to FDA in March 2005, for use of MCV4 in children aged 2–10 years.

Vaccination of Contacts of Persons with Altered Immunocompetence

Household and other close contacts of persons with altered immunocompetence should receive all age-appropriate vaccines, with the exception of live OPV and smallpox vaccine. MMR, varicella, and rotavirus vaccines should be administered to susceptible household and other close contacts of immunocompromised patients when indicated. MMR vaccine viruses are not transmitted to contacts, and transmission of varicella vaccine is rare (*6,118*). No special precautions are needed unless the varicella vaccine recipient has a rash after vaccination, in which case direct contact with susceptible household contacts should be avoided until the rash resolves (*8,119*). To minimize potential rotavirus transmission, all members of the household should employ hand hygiene measures after contact with feces of a rotavirus-vaccinated infant for at least 1 week (*19*). Household and other close contacts of persons with altered immunocompetence should receive annual influenza vaccination. LAIV can be administered to otherwise eligible contacts (*47*).

Vaccination with Inactivated Vaccines

All inactivated vaccines can be administered safely to persons with altered immunocompetence whether the vaccine is a killed whole organism or a recombinant, subunit, toxoid, polysaccharide, or polysaccharide protein-conjugate vaccine. If inactivated vaccines are indicated for persons with altered immunocompetence, the usual doses and schedules are recommended. However, the effectiveness of such vaccinations might be suboptimal.

Except for influenza vaccine, which should be administered annually (*47*), vaccination during chemotherapy or radiation therapy should be avoided if possible because antibody response might be suboptimal. However, administration of inactivated vaccines during chemotherapy or radiation is not contraindicated. Patients vaccinated within 2 weeks before starting immunosuppressive therapy or while receiving immunosuppressive therapy should be considered unvaccinated and should be revaccinated at least 3 months after therapy is discontinued if immune competence has been restored.

Vaccination with Live-Attenuated Vaccines

Severe complications have followed vaccination with live-attenuated viral and live-attenuated bacterial vaccines among persons with altered immunocompetence (*120–127*). Persons with most forms of altered immunocompetence should not receive live vaccines (MMR, varicella vaccine, LAIV, yellow fever vaccine, oral typhoid, BCG, and rotavirus) except in certain circumstances. Patients with leukemia, lymphoma, or other malignancies whose disease is in remission and whose chemotherapy has been terminated for at least 3 months can receive live-virus vaccines.

Children with defects in phagocyte function (e.g., chronic granulomatous disease or myeloperoxidase deficiency) can receive live-attenuated viral vaccines in addition to inactivated vaccines, but should not receive live-attenuated bacterial vaccines (e.g., BCG and Ty21a oral typhoid vaccine). Children with deficiencies in complement or with asplenia can receive live-attenuated viral and live-attenuated bacterial vaccines (*94*).

Persons with severe cell-mediated immune deficiency should not receive live attenuated vaccines. However, children with HIV infection are at increased risk for complications of primary varicella and herpes zoster compared with immunocompetent children (*118,128*). Limited data among HIV-infected children (specifically CDC class N1, N2, A1, A2, B1, or B2) with age-specific $CD4^+$ lymphocyte percentages of >15% indicate that varicella vaccine is immunogenic, effective, and safe (*129*). Varicella vaccine should be considered for children meeting these criteria. Eligible children should receive 2 doses of varicella vaccine with a 3-month interval between doses (*118*).

Persons with HIV infection are at increased risk for severe complications if infected with measles. No severe or unusual adverse events have been reported after measles vaccination among HIV-infected persons who did not have evidence of severe immunosuppression (*130–133*). Therefore, MMR vaccination is recommended for all asymptomatic HIV-infected persons who do not have evidence of severe immunosuppression (age-specific $CD4^+$ lymphocyte percentages of >15%) and for whom measles vaccination would otherwise be indicated. Similarly, MMR vaccination should be considered for mildly symptomatic (Pediatric Category A1, A2 or Adolescent/adult Category A) (*129,134*) HIV-infected persons who do not have evidence of severe immunosuppression (age-specific CD4+ lymphocyte percentages of >15%) for whom measles vaccination would otherwise be indicated.

HIV-infected persons who are receiving regular doses of IGIV might not respond to varicella vaccine or MMR or its individual component vaccines because of the continued presence of passively acquired antibody. However, because of the potential benefit, MMR and varicella vaccines should be considered approximately 2 weeks before the next scheduled dose of IGIV (if not otherwise contraindicated), although an optimal immune response might not occur depending on the dose and interval since the previous dose of IGIV. Unless serologic testing indicates that specific antibodies have been produced,

vaccination should be repeated (if not otherwise contraindicated) after the recommended interval (Table 4). An additional dose of IGIV should be considered for persons on maintenance IGIV therapy who are exposed to measles or varicella 3 or more weeks after administering a standard dose (100–400 mg/kg body weight) of IGIV.

Persons with impaired humoral immunity (e.g., hypogammaglobulinemia or dysgammaglobulinemia) should receive varicella vaccine (*118,135*). However, the majority of persons with these disorders also receive periodic doses of IGIV. Appropriate spacing should be maintained between administration of IGIV and varicella vaccine to prevent an inadequate response to vaccination caused by the presence of neutralizing antibodies from the IGIV. Household and other close contacts of persons with altered immunocompetence should receive all age appropriate vaccines, with the exception of live OPV and smallpox vaccine.

Recipients of Hematopoietic Stem Cell Transplant

Hematopoietic stem cell transplantation (HSCT) results in immunosuppression from the hematopoietic ablative therapy preceding transplant, from drugs used to prevent or treat graft-versus-host disease, and in certain cases from the underlying disease process necessitating transplantation (*136*). HSCT involves ablation of the bone marrow with reimplantation of the person's own stem cells or stem cells from a donor. Antibody titers to vaccine-preventable diseases (e.g., tetanus, poliovirus, measles, mumps, rubella, and encapsulated bacteria) decline 1–4 years after autologous or allogeneic HSCT if the recipient is not revaccinated. HSCT recipients of all ages are at increased risk for certain vaccine-preventable diseases, including diseases caused by encapsulated bacteria (i.e., pneumococcal, meningococcal, and Hib infections). As a result, HSCT recipients should be revaccinated routinely after HSCT, regardless of the source of the transplanted stem cells (*136*). Revaccination with inactivated vaccines should begin 12 months after HSCT, except inactivated influenza vaccine, which should be administered beginning at least 6 months after HSCT and annually thereafter for the life of the patient. PPV should be administered at 12 and 24 months after HSCT. Data are limited about the use of heptavalent PCV in this population. Sequential administration of 2 doses of heptavalent pneumococcal conjugate vaccine followed by a dose of pneumococcal polysaccharide vaccine (with 8 weeks between doses) can be considered, especially for children aged <60 months. A 3-dose regimen of Hib vaccine should be administered at ages 12, 14, and 24 months after transplantation for all age groups (*136*). MMR vaccine should be administered 24 months after transplantation if the HSCT recipient is immunocompetent. Because of insufficient experience using varicella vaccine among HSCT recipients, physicians should assess the immune status of each recipient on a case-by-case basis and determine the risk for infection before using these vaccines. If a decision is made to vaccinate with varicella vaccine, the vaccine should be administered a minimum of 24 months after transplantation if the HSCT recipient is presumed to be immunocompetent (*137*).

Situations in Which Some Degree of Immunodeficiency Might be Present

Asplenia and use of corticosteroids or certain drugs have the potential to be immunosuppressive and in each, some degree of altered immunocompetence is presumed to exist.

Anatomic or Functional Asplenia

Persons with anatomic (e.g., surgical removal or congenital absence) or functional (as occurs with sickle cell disease) asplenia are at increased risk for infection by encapsulated bacteria, especially with *S. pneumoniae* (pneumococcus), *N. meningitidis* (meningococcus), and Hib (*26,48,117*). Persons with anatomic or functional asplenia should receive pneumococcal vaccine, depending on their age and previous pneumococcal vaccination status, as recommended (*29,48,113,116*).

Meningococcal vaccine is recommended for persons with anatomic or functional asplenia. Children aged 2–10 years and persons aged ≥56 years should receive MPSV. MCV4 is approved for persons aged 11–55 years[††] and is preferred for persons in this age group, but MPSV is an acceptable alternative (*117*). A second dose of MPSV can be considered at least 5 years after the initial dose. The duration of immunity after MCV4 is not known, but is thought to be long-lasting like other conjugate vaccines, and revaccination is not recommended.

No efficacy data are available on which to base a recommendation about use of Hib vaccine for older children and adults with the chronic conditions associated with an increased risk for Hib disease. However, studies suggest good immunogenicity in patients who have sickle cell disease or have had splenectomies; administering Hib vaccine to these patients is not contraindicated (*112*).

Pneumococcal, meningococcal, and Hib vaccines should be administered at least 2 weeks before elective splenectomy, if possible. If vaccines are not administered before surgery, they should be administered as soon as the person's condition stabilizes after the procedure.

Corticosteroids

The amount of systemically absorbed corticosteroids and the duration of administration needed to suppress the immune system of an otherwise immunocompetent person are not well defined. Corticosteroid therapy usually is not a contraindication to administering live-virus vaccine when administration is short-term (i.e., <2 weeks); a low-to-moderate dose (<20 mg or prednisone or equivalent per day); long-term, alternate-day treatment with short-acting preparations; maintenance physiologic doses (replacement therapy); or administered topically (skin or eyes), inhaled, or by intra-articular, bursal, or tendon injection (*138*). No evidence of increased severity of reactions to live-attenuated vaccines has been reported among persons receiving corticosteroid therapy by aerosol, and such therapy is not a reason to delay vaccination. The immunosuppressive effects of steroid treatment vary, but the majority of clinicians consider a dose equivalent to either >2 mg/kg of body weight or 20 mg/day of prednisone or equivalent for persons who weigh >10 kg when administered for ≥2 weeks as sufficiently immunosuppressive to raise concern about the safety of vaccination with live-virus vaccines (*112,138*). Corticosteroids used in greater than physiologic doses also can reduce the immune response to vaccines. Vaccination providers should wait at least 1 month after discontinuation of high dose systemically absorbed corticosteroid therapy administered for more than 2 weeks before administering a live-virus vaccine.

Other Immunosuppressive Drugs

Whenever feasible, clinicians should provide all indicated vaccines to all persons before initiation of chemotherapy, before treatment with other immunosuppressive drugs, and before radiation or splenectomy. Persons receiving chemotherapy or radiation for leukemia and other hematopoetic malignancies, solid tumors, or after solid organ transplant should be assumed to have altered immunocompetence. Live-attenuated vaccines should not be administered for at least 3 months after such immunosuppressive therapy. Inactivated vaccines administered during chemotherapy might need to be readministered after immune competence is regained. Persons vaccinated before chemotherapy for leukemia, lymphoma, other malignancies, or radiation generally are thought to retain immune memory after treatment, although revaccination following chemotherapy for acute lymphoblastic leukemia might be indicated (*139*). Revaccination of a person after chemotherapy or radiation therapy is not thought to be necessary if the previous vaccination occurred before therapy and not during the therapy, with the exception of recipients of HSCT, who should be revaccinated as recommended previously. Determination of the level of immune memory and the need for revaccination should be made by the treating physician.

Inactivated vaccines can be administered during low dose intermittent or maintenance therapy of immunosuppressive drugs. The safety and efficacy of live-attenuated vaccines during such therapy is unknown. Physicians should carefully weigh the risks for and benefits of providing injectable live vaccines to adult patients on low-dose therapies for chronic autoimmune disease. The safety and efficacy of live-attenuated vaccines administered concurrently with recombinant human immune mediators and immune modulators is unknown. Evidence that use of therapeutic monoclonal antibodies, especially the antitumor necrosis factor agents adalimumab, infliximab, and etanercept, causes reactivation of latent tuberculosis infection and tuberculosis disease and predisposes to other opportunistic infections suggests caution in the use of live vaccines in patients receiving these drugs (*105–110*). Until additional information becomes available, avoidance of live attenuated vaccines during intermittent or low dose chemotherapy or other immunosuppressive therapy is prudent, unless the benefit of vaccination outweighs the hypothetical increased risk for an adverse reaction after vaccination.

Special Situations

Concurrently Administering Antimicrobial Agents and Vaccines

With limited exceptions, using an antimicrobial agent is not a contraindication to vaccination. Antimicrobial agents have no effect on the response to live-attenuated vaccines, except live oral Ty21a typhoid vaccine, and have no effect on inactivated, recombinant subunit, or polysaccharide vaccines or toxoids. Ty21a typhoid vaccine should not be administered to persons receiving antimicrobial agents until 24 hours after any dose of antimicrobial agent (*20*).

Antiviral drugs used for treatment or prophylaxis of influenza virus infections have no effect on the response to inactivated influenza vaccine (*47*). However, live-attenuated influenza vaccine should not be administered until 48 hours after cessation of therapy using antiviral influenza drugs. If feasible, antiviral medication should not be administered for 2 weeks after LAIV administration (*47*). Antiviral drugs active against herpesviruses (e.g., acyclovir or valacyclovir) might reduce the efficacy of live-attenuated varicella vaccine. These drugs should be discontinued at least 24 hours before administration of varicella-containing vaccines, if possible.

The antimalarial drug mefloquine could affect the immune response to oral Ty21a typhoid vaccine if both are taken si-

multaneously (*140*). To minimize this effect, administering Ty21a typhoid vaccine at least 24 hours before or after a dose of mefloquine is prudent.

Tuberculosis Screening and Skin Test Reactivity

Measles illness, severe acute or chronic infections, HIV infection, and malnutrition can create a relatively anergic state during which the tuberculin skin test (TST) (previously referred to as purified protein derivative [PPD] skin test) might give a false negative reaction (*141–143*). Although any live attenuated measles vaccine can theoretically suppress TST reactivity, the degree of suppression is probably less than that occurring from acute infection from wild-type measles virus. Although routine TST screening of all children is no longer recommended, TST screening is sometimes needed at the same time as administering a measles-containing vaccine (e.g., for well-child care, school entrance, or for employee health reasons).

TST and measles-containing vaccine can be administered at the same visit (preferred option). Simultaneously administering TST and measles-containing vaccine does not interfere with reading the TST result at 48–72 hours and ensures that the person has received measles vaccine.

If the measles-containing vaccine has been administered recently, TST screening should be delayed for at least 4 weeks after vaccination. A delay in performing TST will remove the concern of any theoretical but transient suppression of TST reactivity from the vaccine.

TST screening can be performed and read before administering the measles-containing vaccine. This option is the least favored because it will delay receipt of the measles-containing vaccine.

No data exist for the potential degree of TST suppression that might be associated with other injectable, live-attenuated virus vaccines (e.g., varicella and yellow fever). However, in the absence of data, following guidelines for measles-containing vaccine when scheduling TST screening and administering other live-attenuated virus vaccines is prudent. If the opportunity to vaccinate might be missed, vaccination should not be delayed only because of these theoretical considerations. Because of similar concerns about smallpox vaccine and TST suppression, a TST should not be performed until four weeks after smallpox vaccination (*144*).

TST reactivity in the absence of tuberculosis disease is not a contraindication to administration of any vaccine, including live-attenuated virus vaccines. Tuberculosis disease is not a contraindication to vaccination, unless the person is moderately or severely ill. Although no studies have reported the effect of MMR vaccine on persons with untreated tuberculosis, a theoretical basis exists for concern that measles vaccine might exacerbate the disease tuberculosis (*6*). As a result, before administering MMR to persons with untreated active tuberculosis, initiating antituberculosis therapy is advisable (*7*). Considering if concurrent immunosuppression (e.g., immunosuppression caused by HIV infection) is a concern before administering live attenuated vaccines also is prudent.

Severe Allergy to Vaccine Components

Vaccine components can cause allergic reactions among certain recipients. These reactions can be local or systemic and can include mild-to-severe anaphylaxis or anaphylactic-like responses (e.g., generalized urticaria or hives, wheezing, swelling of the mouth and throat, difficulty breathing, hypotension, and shock). Allergic reactions might be caused by the vaccine antigen, residual animal protein, antimicrobial agents, preservatives, stabilizers, or other vaccine components (*145*). Components of each vaccine are listed in the respective package insert. An extensive listing of vaccine components, their use, and the vaccines that contain each component has been published *(146)* and is also available from CDC's National Center for Immunization and Respiratory Diseases (proposed) (http://www.cdc.gov/nip).

The most common animal protein allergen is egg protein, which is found in influenza and yellow fever vaccines, which are prepared using embryonated chicken eggs. Ordinarily, persons who are able to eat eggs or egg products safely can receive these vaccines; persons with histories of anaphylactic or anaphylactic-like allergy to eggs or egg proteins should generally not receive these vaccines. Asking persons if they can eat eggs without adverse effects is a reasonable way to determine who might be at risk for allergic reactions from receiving yellow fever and influenza vaccines. A regimen for administering influenza vaccine to children with egg hypersensitivity and severe asthma has been developed (*147*).

Measles and mumps vaccine viruses are grown in chick embryo fibroblast tissue culture. Persons with a serious egg allergy can receive measles- or mumps-containing vaccines without skin testing or desensitization to egg protein (*6*). Rubella and varicella vaccines are grown in human diploid cell cultures and can safely be administered to persons with histories of severe allergy to eggs or egg proteins. The rare serious allergic reactions after measles or mumps vaccination or MMR are not believed to be caused by egg antigens, but to other components of the vaccine (e.g., gelatin) (*148–151*). MMR, MMRV, and their component vaccines and other vaccines contain hydrolyzed gelatin as a stabilizer. Extreme caution should be used when administering vaccines that contain

gelatin to persons who have a history of an anaphylactic reaction to gelatin or gelatin-containing products. Before administering gelatin-containing vaccines to such persons, skin testing for sensitivity to gelatin can be considered. However, no specific protocols for this approach have been published.

Certain vaccines contain trace amounts of antimicrobial agents or other preservatives (e.g., neomycin or thimerosal) to which patients might be severely allergic. The information provided in the vaccine package insert should be reviewed carefully before deciding if the rare patient with such allergies should receive the vaccine. No licensed vaccine contains penicillin or penicillin derivatives.

Certain vaccines contain trace amounts of neomycin. Persons who have experienced anaphylactic reactions to neomycin should not receive these vaccines. Most often, neomycin allergy is a contact dermatitis, a manifestation of a delayed type (cell-mediated) immune response, rather than anaphylaxis (*152,153*). A history of delayed type reactions to neomycin is not a contraindication for administration of these vaccines.

Thimerosal is an organic mercurial compound in use since the 1930s and is added to certain immunobiologic products as a preservative. A joint statement issued by the U.S. Public Health Service and the American Academy of Pediatrics (AAP) in 1999 (*154*) and agreed to by the American Academy of Family Physicians (AAFP) later in 1999, established the goal of removing thimerosal as soon as possible from vaccines routinely recommended for infants. Although no evidence exists of any harm caused by low levels of thimerosal in vaccines and the risk was only theoretical (*155*), this goal was established as a precautionary measure.

The public is concerned about the health effects of mercury exposure of any type, and the elimination of mercury from vaccines was judged a feasible means of reducing an infant's total exposure to mercury in a world where other environmental sources of exposure are more difficult or impossible to eliminate (e.g., common foods like tuna). Since mid-2001, vaccines routinely recommended for infants have been manufactured without thimerosal as a preservative. Live-attenuated vaccines have never contained thimerosal. Thimerosal-free formulations of inactivated influenza vaccine are available. Inactivated influenza vaccine also is available in formulations with trace thimerosal, in which thimerosal no longer functions as a preservative, and in formulations that contain thimerosal. Thimerosal that acts as a preservative is present in certain other vaccines that can be administered to children (e.g., Td and DT). Information about the thimerosal content of vaccines is available from FDA (http://www.fda.gov/cber/vaccine/thimerosal.htm).

Receiving thimerosal-containing vaccines might lead to induction of allergy. However, limited scientific basis exists for this assertion (*145*). Allergy to thimerosal usually consists of local delayed type hypersensitivity reactions (*156–158*). Thimerosal elicits positive delayed type hypersensitivity patch tests in 1%–18% of persons tested, but these tests have limited or no clinical relevance (*159–160*). The majority of persons do not experience reactions to thimerosal administered as a component of vaccines even when patch or intradermal tests for thimerosal indicate hypersensitivity (*160*). A localized or delayed type hypersensitivity reaction to thimerosal is not a contraindication to receipt of a vaccine that contains thimerosal.

Latex Allergy

Latex is sap from the commercial rubber tree. Latex contains naturally occurring impurities (e.g., plant proteins and peptides) that might be responsible for allergic reactions. Latex is processed to form natural rubber latex and dry natural rubber. Dry natural rubber and natural rubber latex might contain the same plant impurities as latex but in lesser amounts. Natural rubber latex is used to produce medical gloves, catheters, and other products. Dry natural rubber is used in syringe plungers, vial stoppers, and injection ports on intravascular tubing. Synthetic rubber and synthetic latex also are used in medical gloves, syringe plungers, and vial stoppers. Synthetic rubber and synthetic latex do not contain natural rubber or natural latex and do not contain the impurities linked to allergic reactions. Latex or dry natural rubber used in vaccine packaging is generally noted in the manufacturer's package insert.

The most common type of latex sensitivity is contact-type (type 4) allergy, usually as a result of prolonged contact with latex-containing gloves (*161*). However, injection-procedure–associated latex allergies among patients with diabetes mellitus have been described (*162–164*). Allergic reactions (including anaphylaxis) after vaccination procedures are rare (*165*). Only one known report of an allergic reaction after administering HepB to a patient with known severe allergy (anaphylaxis) to latex has been published (*166*).

If a person reports a severe (anaphylactic) allergy to latex, vaccines supplied in vials or syringes that contain natural rubber should not be administered unless the benefit of vaccination outweighs the risk for a potential allergic reaction. For latex allergies other than anaphylactic allergies (e.g., a history of contact allergy to latex gloves), vaccines supplied in vials or syringes that contain dry natural rubber or natural rubber latex can be administered.

Vaccination of Preterm Infants

In the majority of cases, infants born prematurely, regardless of birthweight, should be vaccinated at the same chronological age and according to the same schedule and precautions as full-term infants and children. Birthweight and size are not factors in deciding whether to postpone routine vaccination of a clinically stable preterm infant (*167–171*), except for HepB. The full recommended dose of each vaccine should be used. Divided or reduced doses are not recommended (*173*).

Decreased seroconversion rates might occur among certain preterm infants with low birthweights (i.e., <2,000 g) after administration of HepB at birth (*173*). However, by chronological age 1 month, all preterm infants, regardless of initial birth weight or gestational age, are likely to respond as adequately as older and larger infants (*174–176*). Preterm infants born to HBsAg-positive mothers and mothers with unknown HBsAg status must receive immunoprophylaxis with HepB and HBIG within 12 hours after birth. If these infants weigh <2,000 g at birth, the initial vaccine dose should not be counted towards completion of the HepB series, and 3 additional doses of HepB should be administered, beginning when the infant is aged 1 month. Preterm infants weighing <2,000 g and born to HBsAg-negative mothers should receive the first dose of the HepB series at chronological age 1 month or at hospital discharge. (*30*)

Breast Feeding and Vaccination

Neither inactivated nor live vaccines administered to a lactating woman affect the safety of breast feeding for women or their infants. Breast feeding does not adversely affect immunization and is not a contraindication for any vaccine, with the exception of smallpox vaccine. Limited data indicate that breast feeding can enhance the response to certain vaccine antigens (*177*). Breast-fed infants should be vaccinated according to recommended schedules (*178–180*).

Although live vaccines multiply within the mother's body, the majority have not been demonstrated to be excreted in human milk (*181*). Although rubella vaccine virus might be excreted in human milk, the virus usually does not infect the infant. If infection does occur, it is well-tolerated because the virus is attenuated (*182*). Inactivated, recombinant, subunit, polysaccharide, conjugate vaccines and toxoids pose no risk for mothers who are breast feeding or for their infants.

Vaccination During Pregnancy

Risk for a developing fetus from vaccination of the mother during pregnancy primarily is theoretical. No evidence exists of risk from vaccinating pregnant women with inactivated virus or bacterial vaccines or toxoids (*183,184*). Live vaccines pose a theoretical risk to the fetus. Benefits of vaccinating pregnant women usually outweigh potential risks when the likelihood of disease exposure is high, when infection would pose a risk to the mother or fetus, and when the vaccine is unlikely to cause harm.

Recommendations for vaccination during pregnancy can be found in the adult immunization schedule (*113*). Pregnant women should receive Td vaccine if indicated. Previously vaccinated pregnant women who have not received a Td vaccination within the last 10 years should receive a booster dose. Pregnant women who are not vaccinated or only partially immunized against tetanus should complete the primary series (*28,112*). Women for whom the vaccine is indicated but who have not completed the recommended 3-dose series during pregnancy should receive follow-up after delivery to ensure the series is completed. Pregnant adolescents and adults who received the last tetanus-containing vaccine <10 years previously are generally recommended to receive Tdap after delivery. To prevent neonatal tetanus, pregnant adolescents who received the last dose of tetanus-toxoid containing vaccine ≥10 years previously should generally receive Td in preference to Tdap while they are pregnant (*28*), although Tdap is not contraindicated during pregnancy.

Women in the second and third trimesters of pregnancy are at increased risk for hospitalization from influenza. Therefore, routine influenza vaccination is recommended for all women who will be pregnant (in any trimester) during influenza season (usually November–March in the United States) (*47*).

IPV can be administered to pregnant women who are at risk for exposure to wild-type poliovirus infection (*4*). HepB is recommended for pregnant women at risk for hepatitis B virus infection (*30*). HepA, pneumococcal polysaccharide, meningococcal conjugate, and meningococcal polysaccharide vaccines should be considered for women at increased risk for those infections (*48,117,185*). Pregnant women who must travel to areas where the risk for yellow fever is high should receive yellow fever vaccine because the limited theoretical risk from vaccination is substantially outweighed by the risk for yellow fever infection (*24,186*).

Pregnancy is a contraindication for smallpox (vaccinia), measles, mumps, rubella, and varicella-containing vaccines. Smallpox (vaccinia) vaccine is the only vaccine known to cause harm to a fetus when administered to a pregnant woman. In addition to the vaccinee herself, smallpox (vaccinia) vaccine should not be administered to a household contact of a pregnant woman (*144*). Although of theoretical concern, no cases of congenital rubella or varicella syndrome or abnormalities

attributable to fetal infection have been observed among infants born to susceptible women who received rubella or varicella vaccines during pregnancy (*6,187*). Because of the importance of protecting women of childbearing age against rubella and varicella, reasonable practices in any vaccination program include asking women if they are pregnant or might become pregnant in the next 4 weeks; not vaccinating women who state that they are or plan to be pregnant; explaining the theoretical risk for the fetus if MMR, varicella, or MMRV vaccine were administered to a women who is pregnant; and counseling women who are vaccinated not to become pregnant during the 4 weeks after MMR, varicella, or MMRV vaccination (*6,39,188*). Routine pregnancy testing of women of childbearing age before administering a live-virus vaccine is not recommended (*6*). If vaccination of an unknowingly pregnant woman occurs or if she becomes pregnant within 4 weeks after MMR or varicella vaccination, she should be counseled about the theoretical basis of concern for the fetus; however, MMR or varicella vaccination during pregnancy should not be regarded as a reason to terminate pregnancy (*6,8,189*).

Persons who receive MMR vaccine do not transmit the vaccine viruses to contacts (*6*). Transmission of varicella vaccine virus to contacts is extremely rare (*118*). MMR and varicella vaccines should be administered when indicated to the children and other household contacts of pregnant women (*6,8*).

All pregnant women should be evaluated for immunity to rubella and varicella and be tested for the presence of HBsAg in every pregnancy (*6,30,39*). Women susceptible to rubella and varicella should be vaccinated immediately after delivery. A woman found to be HBsAg-positive should be followed carefully to ensure that the infant receives HBIG and begins the hepatitis B vaccine series no later than 12 hours after birth and that the infant completes the recommended HepB vaccine series on schedule (*30*). No known risk exists for the fetus from passive immunization of pregnant women with immune globulin preparations.

Persons Vaccinated Outside the United States, Including Internationally Adopted Children

The ability of a clinician to determine that a person is protected on the basis of their country of origin and their records alone is limited. Vaccines administered outside the United States can generally be accepted as valid if the schedule was similar to that recommended in the United States (i.e., minimum ages and intervals). Only written documentation should be accepted as evidence of previous vaccination. Written records are more likely to predict protection if the vaccines, dates of administration, intervals between doses, and the person's age at the time of vaccination are comparable to U.S. recommendations. Although vaccines with inadequate potency have been produced in other countries (*190,191*), the majority of vaccines used worldwide is produced with adequate quality control standards and are potent.

The number of U.S. families adopting children from outside the United States has increased substantially in recent years (*192*). Adopted children's birth countries often have vaccination schedules that differ from the recommended childhood immunization schedule in the United States. Differences in the U.S. immunization schedule and those used in other countries include the vaccines administered, the recommended ages of administration, and the number and timing of doses.

Data are inconclusive about the extent to which an internationally adopted child's vaccination record reflects the child's protection. A child's record might indicate administration of MMR vaccine when only single-antigen measles vaccine was administered. A study of children adopted from orphanages in the People's Republic of China, Russia, and Eastern Europe determined that 67% of children with documentation of more than 3 doses of DTP before adoption had nonprotective titers to these antigens. By contrast, children adopted from these countries who received vaccination in the community (not only from orphanages) and who possessed records of 1 or more doses of DTP exhibited protective titers 67% of the time (*193*). However, antibody testing was performed by using a hemagglutination assay, which tends to underestimate protection and cannot directly be compared with antibody concentration (*194*). Data are likely to remain limited for countries other than the People's Republic of China, Russia, and Eastern Europe because of the limited number of adoptees from other countries.

Clinicians and other health-care providers can follow one of multiple approaches if a question exists about whether vaccines administered to an international adoptee were immunogenic. Repeating the vaccinations is an acceptable option. Doing so usually is safe and avoids the need to obtain and interpret serologic tests. If avoiding unnecessary injections is desired, judicious use of serologic testing might be helpful in determining which vaccinations are needed. For some vaccines, the most readily available serologic tests cannot document protection against infection. These recommendations provide guidance on possible approaches to evaluation and revaccination for each vaccine recommended universally for children in the United States (Table 12). Clinicians and other health-care providers should ensure that household contacts of internationally adoptees are adequately vaccinated, particularly for measles and hepatitis B.

TABLE 12. Approaches to the evaluation and vaccination of internationally adopted children with no or questionable vaccination records

Vaccine	Recommended approach	Alternative approach
Measles, mumps, and rubella (MMR)	Revaccinate with MMR	Serologic testing for immunoglobulin G (IgG) antibody to measles, mumps, and rubella
Haemophilus influenzae type b (Hib)	Age-appropriate revaccination	ð
Hepatitis A	Age-appropriate revaccination	Serologic testing for IgG antibody to hepatitis A virus
Hepatitis B (Hep B)	Age-appropriate revaccination and serologic testing for HBsAg*	ð
Poliovirus	Revaccinate with inactivated poliovirus vaccine (IPV)	Serologic testing for neutralizing antibody to poliovirus types 1, 2, and 3 (limited availability)
Diphtheria and tetanus toxoids and acellular pertussis (DTaP)	Revaccination with DTaP, with serologic testing for specific IgG antibody to tetanus and diphtheria toxins in the event of a severe local reaction	Children whose records indicate receipt of ≥3 doses: serologic testing for specific IgG antibody to diphtheria and tetanus toxins before administering additional doses (see text), or administer a single booster dose of DTaP, followed by serological testing after 1 month for specific IgG antibody to diphtheria and tetanus toxins with revaccination as appropriate
Varicella	Age-appropriate vaccination of children who lack evidence of varicella immunity	ð
Pneumococcal conjugate	Age-appropriate vaccination	ð

* Very rarely, Hep B vaccine can give a false positive HBsAg result up to 18 days following vaccination; therefore, blood should be drawn to test for HBsAg before vaccinating (CDC. A comprehensive immunization strategy to eliminate transmission of hepatitis B virus infection in the United States: Recommendations of the Advisory Committee on Immunization Practices [ACIP]; Part I: Immunization in Infants, Children, and Adolescents. MMWR 2005;54[No. RR-16]).

MMR Vaccine

The simplest approach to resolving concerns about MMR vaccination among internationally adopted children is to revaccinate with 1 or 2 doses of MMR vaccine, depending on the child's age. Serious adverse events after MMR vaccinations are rare (*6*). No evidence indicates that administering MMR vaccine increases the risk for adverse reactions among persons who are already immune to measles, mumps, or rubella as a result of previous vaccination or natural disease. Doses of measles-containing vaccine administered before the first birthday should not be counted as part of the series (*6*). Alternatively, serologic testing for immunoglobulin G (IgG) antibody to vaccine viruses indicated on the vaccination record can be considered. Serologic testing is widely available for measles and rubella IgG antibody. A child whose record indicates receipt of monovalent measles or measles-rubella vaccine on or after the first birthday and who has protective antibody against measles and rubella should receive 1 or 2 doses of MMR or MMRV as age-appropriate to ensure protection against mumps and varicella (and rubella if measles vaccine alone had been used). If a child whose record indicates receipt of MMR at age ≥12 months has a protective concentration of antibody to measles, no additional vaccination is needed unless required for school entry.

Hib Vaccine

Interpretation of a serologic test to verify protection from Hib bacteria for children vaccinated >2 months previously can be difficult to interpret. Because the number of vaccinations needed for protection decreases with age and adverse events are rare (*26*), age-appropriate vaccination should be provided. Hib vaccination is not recommended routinely for children aged ≥5 years (*116*).

Hepatitis A Vaccine

Children without documentation of HepA vaccination or serologic evidence of immunity should be vaccinated on arrival if aged ≥12 months (*185*).

Hepatitis B Vaccine

Children not known to be vaccinated for hepatitis B should receive an age-appropriate series of HepB. A child whose records indicate receipt of 3 or more doses of vaccine can be considered protected, and additional doses are not needed if 1 or more doses were administered at age ≥24 weeks. Chil-

dren who received their last HepB dose at age <24 weeks should receive an additional dose at age ≥24 weeks. Children who have received fewer than 3 doses of vaccine should complete the series at the recommended intervals and ages.

All foreign-born persons and immigrants, refugees, and internationally adopted children born in Asia, the Pacific Islands, Africa, and other regions in which HBV is highly endemic should be tested for HBsAg, regardless of vaccination status. Those determined to be HBsAg-positive should be monitored for development of liver disease. Household members of HBsAg-positive children or adults should be vaccinated if not already immune.

Poliovirus Vaccine

The simplest approach is to revaccinate internationally adopted children with IPV according to the U.S. schedule. Adverse events after IPV are rare (*4*). Children appropriately vaccinated with 3 doses of OPV in economically developing countries might have suboptimal seroconversion, including to type 3 poliovirus (*180*). Serologic testing for neutralizing antibody to poliovirus types 1, 2, and 3 can be obtained commercially and at certain state health department laboratories. Children with protective titers against all three types do not need revaccination and should complete the schedule as age-appropriate.

DTaP Vaccine

Vaccination providers can revaccinate a child with DTaP vaccine without regard to recorded doses; however, one concern about this approach is that data indicate increased rates of local adverse reactions after the fourth and fifth doses of DTP or DTaP (*46*). If a revaccination approach is adopted and a severe local reaction occurs, serologic testing for specific IgG antibody to tetanus and diphtheria toxins can be measured before administering additional doses. Protective concentration[§§] indicates that further doses are unnecessary and subsequent vaccination should occur as age-appropriate. No established serologic correlates exist for protection against pertussis.

For a child whose record indicates receipt of 3 or more doses of DTP or DTaP, serologic testing for specific IgG antibody to both diphtheria and tetanus toxin before additional doses is a reasonable approach. If a protective concentration is present, recorded doses can be considered valid, and the vaccination series should be completed as age-appropriate. Indeterminate antibody concentration might indicate immunologic memory but antibody waning; serology can be repeated after a booster dose if the vaccination provider wants to avoid revaccination with a complete series.

Alternately, for a child whose records indicate receipt of 3 or more doses, a single booster dose can be administered, followed by serologic testing after 1 month for specific IgG antibody to both diphtheria and tetanus toxins. If a protective concentration is obtained, the recorded doses can be considered valid and the vaccination series completed as age-appropriate. Children with indeterminate concentration after a booster dose should be revaccinated with a complete series.

Varicella Vaccine

Varicella vaccine is not administered in the majority of countries. A child who lacks reliable evidence of varicella immunity should be vaccinated as age-appropriate (*8,116*).

Pneumococcal Vaccines

PCV and PPV are not administered in the majority of countries and should be administered as age-appropriate or as indicated by the presence of underlying medical conditions (*29,48*).

Vaccinating Persons with Bleeding Disorders and Persons Receiving Anticoagulant Therapy

Because of the risk for hematoma formation after injections, intramuscular injections are often avoided among persons with bleeding disorders by using the subcutaneous or intradermal routes for vaccines that are administered normally by the intramuscular route. HepB administered intramuscularly to 153 persons with hemophilia by using a 23-gauge needle or smaller, followed by steady pressure to the site for 1–2 minutes, resulted in a 4% bruising rate with no patients requiring factor supplementation (*195*). Whether antigens that produce more local reactions (e.g., pertussis) would produce an equally low rate of bruising is unknown.

When HepB or any other intramuscular vaccine is indicated for a patient with a bleeding disorder or a person receiving anticoagulant therapy, the vaccine should be administered intramuscularly if, in the opinion of a physician familiar with the patient's bleeding risk, the vaccine can be administered with reasonable safety by this route. If the patient receives antihemophilia or similar therapy, intramuscular vaccinations can be scheduled shortly after such therapy is administered. A fine needle (23 gauge or smaller) should be used for the vaccination and firm pressure applied to the site, without rubbing, for at least 2 minutes. The patient or family should be instructed concerning the risk for hematoma from the injection.

[§§]Enzyme immunoassay tests are available. Physicians should contact the laboratory performing the test for interpretive standards and limitations. Protective concentrations for antibody to diphtheria and tetanus toxins are defined as ≥0.1 IU/mL.

Vaccination Records

Consent to Vaccinate

The National Childhood Vaccine Injury Act of 1986 (42 U.S.C. § 300aa-26) requires that all health-care providers in the United States who administer any vaccine covered by the Act[¶] must provide a copy of the relevant, current edition of the vaccine information materials that have been produced by CDC before administering each dose of the vaccine. Vaccine information statements (VIS) are available at http://www.cdc.gov/nip/publications/VIS/default.htm and http://www.immunize.org/vis. VIS must be provided to the parent or legal representative of any child or to any adult to whom the physician or other health-care provider intends to administer the vaccine. The act does not require that a signature be obtained, but documentation of consent is recommended or required by certain state or local authorities.

Provider Records

Documentation of patient vaccinations helps ensure that persons in need of a vaccine receive it and that adequately vaccinated patients are not administered excess doses, possibly increasing the risk for local adverse events (e.g., tetanus toxoid). Serologic test results for vaccine-preventable diseases (e.g., those for rubella screening and antibody to hepatitis B surface antigen) and documented episodes of adverse events also should be recorded in the permanent medical record of the vaccine recipient.

Health-care providers who administer vaccines covered by the National Childhood Vaccine Injury Act are required to ensure that the permanent medical record of the recipient (or a permanent office log or file) indicates the date the vaccine was administered; the vaccine manufacturer; the vaccine lot number; and the name, address, and title of the person administering the vaccine. In addition, the provider is required to record the edition date of the VIS distributed and the date those materials were provided. In the Act, the term health-care provider is defined as any licensed health-care professional, organization, or institution, whether private or public (including federal, state, and local departments and agencies), under whose authority a specified vaccine is administered. This same information should be kept for all vaccines, not just for those required by the National Childhood Vaccine Injury Act.

[¶]As of May 2006, vaccines covered by the act include diphtheria, tetanus, pertussis, measles, mumps, rubella, poliovirus, HepB, Hib, varicella, pneumococcal conjugate, HepA, trivalent inactivated influenza vaccine, and pentavalent RV.

Patients' Personal Records

Official childhood vaccination records have been adopted by every state, territory, and the District of Columbia to encourage uniformity of records and to facilitate assessment of vaccination status by schools and child care centers. The records also are key tools in vaccination education programs aimed at increasing parental and patient awareness of the need for vaccines. A permanent vaccination record card should be established for each newborn infant and maintained by the parent or guardian. In certain states, these cards are distributed to new mothers before discharge from the hospital. Using vaccination record cards for adolescents and adults also is encouraged. Standardized adult vaccination records are available at http://www.immunize.org.

Immunization Information Systems

IISs are confidential, population-based, computerized information systems that collect and consolidate vaccination data from multiple health-care providers within a geographic area. IISs are a critical tool that can increase and sustain increased vaccination coverage by consolidating vaccination records of children from multiple providers, generating reminder and recall vaccination notices for each child, and providing official vaccination forms and vaccination coverage assessments (*196*). A fully operational IIS also can prevent duplicate vaccinations, limit missed appointments, reduce vaccine waste, and reduce staff time required to produce or locate vaccination records or certificates. The National Vaccine Advisory Committee strongly encourages development of community- or state-based IISs and recommends that vaccination providers participate in these systems whenever possible (*196*). One of the national health objectives for 2010 is 95% participation of children aged <6 years in a fully operational population-based IIS (objective 20.1) (*197*).

Reporting Adverse Events after Vaccination

Modern vaccines are safe and effective; however, adverse events have been reported after administration of all vaccines (*91*). These events range from frequent, minor, local reactions to extremely rare, severe, systemic illness (e.g., anaphylaxis). Establishing evidence for cause-and-effect relations on the basis of case reports and case series alone is impossible because temporal association alone does not necessarily indicate causation. Unless the symptom or syndrome that occurs after vaccination is clinically or pathologically distinctive, more detailed epidemiologic studies to compare the incidence of

the event among vaccinees with the incidence among unvaccinated persons are necessary. Reporting adverse events to public health authorities, including serious events, is a key stimulus to developing studies to confirm or refute a causal association with vaccination. More complete information about adverse reactions to a specific vaccine is available in the ACIP recommendations for that vaccine and in a specific statement on vaccine adverse reactions (*91*).

The National Childhood Vaccine Injury Act requires health-care providers to report selected events occurring after vaccination to VAERS. Events for which reporting is required appear in the Reportable Events Table.*** Persons other than health-care providers also can report adverse events to VAERS. All clinically significant adverse events other than those that must be reported or that occur after administration of vaccines not covered by the Act also should be reported to VAERS, even if the physician or other health-care provider is uncertain they are related causally to vaccination. VAERS forms and instructions are available in the FDA Drug Bulletin by contacting VAERS (800-822-7967), or from the VAERS website (http://www.vaers.hhs.gov/vaers.htm).

National Vaccine Injury Compensation Program

The National Vaccine Injury Compensation Program, established by the National Childhood Vaccine Injury Act, is a no-fault system in which persons thought to have suffered an injury or death as a result of administration of a covered vaccine can seek compensation. The program became operational on October 1, 1988, and is intended as an alternative to civil litigation under the traditional tort system in that negligence need not be proven. Claims arising from covered vaccines must first be adjudicated through the program before civil litigation can be pursued.

The program relies on a Reportable Events Table listing the vaccines covered by the program and the injuries, disabilities, illnesses, and conditions (including death) for which compensation might be awarded. The table defines the time during which the first symptom or substantial aggravation of an injury must appear after vaccination. Successful claimants receive a legal presumption of causation if a condition listed in the table is proven, thus avoiding the need to prove actual causation in an individual case. Claimants also can prevail for conditions not listed in the table if they prove causation. Injuries after administration of vaccines not listed in the legislation authorizing the program are not eligible for compensation through the program. Additional information is available from the National Vaccine Injury Compensation Program, Health Resources and Services Administration, Parklawn Building, Room 11C-26, 5600 Fishers Lane, Rockville, MD 20857; telephone: 800-338-2382; Website: http://www.hrsa.gov/osp/vicp.

Persons wanting to file a claim for vaccine injury should contact the following: U.S. Court of Federal Claims, 717 Madison Place, N.W., Washington, DC 20005; telephone: 202-357-6400.

Benefit and Risk Communication

Parents, guardians, legal representatives, and adolescent and adult patients should be informed about the benefits of and risks for vaccines in understandable language. Opportunity for questions should be provided before each vaccination. Discussion of the benefits of and risks for vaccination is sound medical practice and is required by law.

The National Childhood Vaccine Injury Act requires that vaccine information materials be developed for each vaccine covered by the Act. These materials, known as Vaccine Information Statements, must be provided by all public and private vaccination providers each time a vaccine is administered. Copies of Vaccine Information Statements are available from state health authorities responsible for vaccination, or they can be obtained from CDC's National Center for Immunization and Respiratory Disease (proposed) website (http://www.cdc.gov/nip). Translations of Vaccine Information Statements into languages other than English are available from certain state vaccination programs and from the Immunization Action Coalition website (http://www.immunize.org).

Health-care providers should anticipate that certain parents or patients will question the need for or safety of vaccination, refuse certain vaccines, or even reject all vaccinations. A limited number of persons might have religious or personal objections to vaccinations. Others might want to enter into a dialogue about the risks for and benefits of certain vaccines. Having a basic understanding of how patients view vaccine risk and developing effective approaches in dealing with vaccine safety concerns when they arise is imperative for vaccination providers.

Each person understands and reacts to vaccine information on the basis of different factors, including previous experience, education, personal values, method of data presentation, perceptions of the risk for disease, perceived ability to control those risks, and their risk preference. Increasingly, through the media and nonauthoritative Internet sites, decisions about risk are based on inaccurate information. Only through direct dialogue with parents and by using available

***The Reportable Events Table can be obtained from the Vaccine Injury Compensation Program Internet site at http://vaers.hhs.gov/reportable.htm.

resources can health-care providers prevent acceptance of media reports and information from nonauthoritative Internet sites as scientific fact.

When a parent or patient initiates a discussion about a vaccine controversy, the health-care provider should discuss the specific concerns and provide factual information, using appropriate language. Effective, empathetic vaccine risk communication is essential in responding to misinformation and concerns, recognizing that for certain persons, risk assessment and decision-making are difficult and confusing. Certain vaccines might be acceptable to the resistant parent. Their concerns should then be addressed using the VIS and offering other resource materials (e.g., information available on the National Center for Immunization and Respiratory Diseases (proposed) website [http://www.cdc.gov/nip]).

Although a limited number of providers might exclude from their practice those patients who question or refuse vaccination, the more effective public health strategy is to identify common ground and discuss measures that need to be followed if the patient's decision is to defer vaccination. As part of a strong recommendation, health-care providers can reinforce key points about each vaccine, including safety, and emphasize risks encountered by unvaccinated children. Parents should be advised of state laws pertaining to school or child-care entry, which might require that unvaccinated children be excluded from school or child care during outbreaks. Documentation of these discussions in the patient's record, including the refusal to receive certain vaccines (i.e., informed refusal), might reduce any potential liability if a vaccine-preventable disease occurs in the unvaccinated patient.

Vaccination Programs

The best way to reduce vaccine-preventable diseases is to have a highly immune population. Universal vaccination is a critical part of quality health care and should be accomplished through routine and intensive vaccination programs implemented in physicians' offices and in public health clinics. Programs should be established and maintained in all communities to ensure vaccination of all children at the recommended age. In addition, appropriate vaccinations should be available for all adolescents and adults.

Physicians and other pediatric vaccination providers should adhere to the standards for child and adolescent vaccination practices (*1*). These standards define appropriate vaccination practices for both the public and private sectors. The standards provide guidance on practices that will result in eliminating barriers to vaccination. These include practices aimed at eliminating unnecessary prerequisites for receiving vaccinations, eliminating missed opportunities to vaccinate, improving procedures to assess vaccination needs, enhancing knowledge about vaccinations among parents and providers, and improving the management and reporting of adverse events. In addition, the standards address the importance of recall and reminder systems and using assessments to monitor clinic or office vaccination coverage levels. Physicians and other health-care providers should simultaneously administer as many vaccine doses as possible, as indicated on the Recommended Child and Adolescent Immunization Schedule (*116*).

Standards of practice also have been published to increase vaccination coverage among adults (*2*). These standards include ensuring vaccine availability, routine review of vaccination status, communicating risks for and benefits to the patient, using standing orders, and recommending simultaneous administration of all indicated doses according to the Recommended Adult Immunization Schedule (*113*).

Every visit to a physician or other health-care provider can be an opportunity to update a patient's vaccination status with needed vaccinations. Official health agencies should take necessary steps, including, when appropriate, developing and enforcing child care and school vaccination requirements, to ensure that students at all grade levels (including college) and children in day care centers are protected against vaccine-preventable diseases. Agencies also should encourage institutions (e.g., hospitals and long-term–care facilities) to adopt policies about the appropriate vaccination of patients, residents, and employees (*198*).

Dates of vaccination (day, month, and year) should be recorded on institutional vaccination records (e.g., records kept in schools and day care centers). These records will facilitate assessments that a primary vaccination series has been completed according to an appropriate schedule and that needed booster doses have been administered at the appropriate time.

The independent, nonfederal Task Force on Community Preventive Services (the Task Force), whose membership is appointed by CDC, provides public health decision-makers with recommendations on population-based interventions to promote health and prevent disease, injury, disability, and premature death. The recommendations are based on systematic reviews of the scientific literature about effectiveness and cost-effectiveness of these interventions. In addition, the Task Force identifies critical information about the other effects of these interventions and the applicability to specific populations and settings and the potential barriers to implementation. This information is available at http://www.thecommunityguide.org.

Beginning in 1996, the Task Force systematically reviewed published evidence on the effectiveness and cost-effectiveness

of population-based interventions to increase coverage of vaccines recommended for routine use among children, adolescents, and adults. A total of 197 articles were identified that evaluated a relevant intervention, met inclusion criteria, and were published during 1980–1997. Reviews of 17 specific interventions were published in 1999 (*199–202*). Using the results of their review, the Task Force made recommendations about the use of these interventions (*202*). Several interventions were identified and recommended on the basis of published evidence. The interventions and the recommendations are summarized in this report (Table 13).

Vaccine Information Sources

In addition to these general recommendations, other sources are available that contain specific and updated vaccine information.

CDC-INFO Contact Center

The CDC-INFO contact center is supported by CDC's National Center for Immunization and Respiratory Diseases (proposed) and provides public health-related information, including vaccination information, for health-care providers and the public, 24 hours a day, seven days a week (Telephone [English and Spanish]: 800-232-4636; Telephone [TTY]: 800-232-6348).

CDC's National Center for Immunization and Respiratory Diseases (proposed)

CDC's National Center for Immunization and Respiratory Diseases (proposed) website provides direct access to immunization recommendations of ACIP, vaccination schedules, vaccine safety information, publications, provider education and training, and links to other vaccination-related websites (http://www.cdc.gov/nip).

MMWR

ACIP recommendations regarding vaccine use, statements of vaccine policy as they are developed, and reports of specific disease activity are published by CDC in the *MMWR* series. Electronic subscriptions are free (http://www.cdc.gov/subscribe.html). Printed subscriptions are available at

TABLE 13. Summary of recommendations for interventions to improve coverage of vaccines recommended for routine use among children, adolescents, and adults*

Intervention	Recommendations
Interventions that increase community demand for immunization	
Client reminder or recall systems	Strongly recommended
Multicomponent interventions, including education	Strongly recommended
School, day care, and college-entry requirements	Recommended
Community education alone	Insufficient evidence
Clinic-based education	Insufficient evidence
Patient or family incentives or sanctions	Insufficient evidence
Client-held medical records	Insufficient evidence
Interventions that enhance access to vaccination services	
Reducing out-of-pocket costs	Strongly recommended
Enhancing access through the U.S. Department of Agriculture's Women, Infants, and Children program	Recommended
Home visits, outreach, and case management	Recommended
Enhancing access at day care centers	Insufficient evidence
Enhancing access at schools	Recommended
Expanding access in health-care settings	Recommended as part of multicomponent interventions only
Interventions that target providers	
Reminder or recall systems	Strongly recommended
Assessment and feedback	Strongly recommended
Standing orders	Strongly recommended
Provider education alone	Insufficient evidence

Am J Prev Med 2000;18:92ï 6, and Task Force on Community Preventive Services. Recommendations to improve targeted vaccination coverage among high-risk adults. Am J Prev Med 2005;28:231ï 7.

American Academy of Pediatrics (AAP)

Every 3 years, AAP issues the *Red Book: Report of the Committee on Infectious Diseases*, which contains a composite summary of AAP recommendations concerning infectious diseases and immunizations for infants, children, and adolescents (Telephone: 888-227-1770; Website: http://www.aap.org).

American Academy of Family Physicians (AAFP)

Information from the professional organization of family physicians is available at http://www.aafp.org.

Immunization Action Coalition

This source provides extensive free provider and patient information, including translations of Vaccine Information Statements into multiple languages. Printed materials are reviewed by CDC for technical accuracy (http://www.immunize.org and http://vaccineinformation.org).

National Network for Immunization Information

This information source is an affiliation of the Infectious Diseases Society of America, the Pediatric Infectious Diseases Society, AAP, the American Nurses Association, the AAFP, the National Association of Pediatric Nurse Practitioners, the American College of Obstetricians and Gynecologists and the University of Texas Medical Branch. This source seeks to provide the public, health professionals, policy makers, and the media with up-to-date, scientifically valid information (http://www.immunizationinfo.org).

Vaccine Education Center

Located at the Children's Hospital of Philadelphia, this source provides patient and provider information (http://www.vaccine.chop.edu).

Institute for Vaccine Safety

Located at Johns Hopkins University School of Public Health, this source provides information about vaccine safety concerns and objective and timely information to physicians and health-care providers and parents (http://www.vaccinesafety.edu).

Group on Immunization Education of the Society of Teachers of Family Medicine

This organization provides information for clinicians, including the free personal digital assistant software called "Shots" which includes the childhood and adult schedule for Palm OS and for Windows handhelds (http://www.immunizationed.org).

State and Local Health Departments

State and local health departments provide technical advice through hotlines, electronic mail, and Internet sites, including printed information regarding vaccines and immunization schedules, posters, and other educational materials.

Acknowledgments

The members of the Advisory Committee on Immunization Practices are grateful for the contributions of Lorry Rubin, MD, Schneider Children's Hospital, New Hyde Park, New York, Deborah Wexler, MD, Immunization Action Coalition; Stephan L. Foster, PharmD, University of Tennessee, Memphis, Geoffrey Evans, MD, Health Resources and Services Administration, Rockville, Maryland; Richard Zimmerman, MD, University of Pittsburgh School of Medicine, Pennsylvania, and Richard Clover, MD, University of Louisville School of Public Health, Kentucky.

VICP	Vaccine Injury Compensation Program
VIS	Vaccine Information Statement

Definitions Used in This Report

Adverse event. An untoward event that occurs after a vaccination that might be caused by the vaccine product or vaccination process. It includes events that are 1) vaccine-induced: caused by the intrinsic characteristic of the vaccine preparation and the individual response of the vaccinee; these events would not have occurred without vaccination (e.g., vaccine-associated paralytic poliomyelitis); 2) vaccine-potentiated: the events would have occurred anyway, but were precipitated by the vaccination (e.g., first febrile seizure in a predisposed child); 3) programmatic error: the event was caused by technical errors in vaccine preparation, handling, or administration; 4) coincidental: the event was associated temporally with vaccination by chance or caused by underlying illness. Special studies are needed to determine if an adverse event is a reaction to the vaccine or the result of another cause (**Sources:** Chen RT. Special methodological issues in pharmacoepidemiology studies of vaccine safety. In: Strom BL, ed. Pharmacoepidemiology. 3rd ed. Sussex, England: John Wiley & Sons; 2000:707–32; and Fenichel GM, Lane DA, Livengood JR, Horwitz SJ, Menkes JH, Schwartz JF. Adverse events following

immunization: assessing probability of causation. Pediatr Neurol 1989;5:287–90).

Adverse reaction. An undesirable medical condition that has been demonstrated to be caused by a vaccine. Evidence for the causal relation is usually obtained through randomized clinical trials, controlled epidemiologic studies, isolation of the vaccine strain from the pathogenic site, or recurrence of the condition with repeated vaccination (i.e., rechallenge); synonyms include side effect and adverse effect.

Immunobiologic. Antigenic substances (e.g., vaccines and toxoids) or antibody-containing preparations (e.g., globulins and antitoxins) from human or animal donors. These products are used for active or passive immunization or therapy. The following are examples of immunobiologics:

Vaccine. A suspension of live (usually attenuated) or inactivated microorganisms (e.g., bacteria or viruses) or fractions thereof administered to induce immunity and prevent infectious disease or its sequelae. Some vaccines contain highly defined antigens (e.g., the polysaccharide of *Haemophilus influenzae* type b or the surface antigen of hepatitis B); others have antigens that are complex or incompletely defined (e.g., *Bordetella pertussis* antigens or live-attenuated viruses).

Toxoid. A modified bacterial toxin that has been made nontoxic, but retains the ability to stimulate the formation of antibodies to the toxin.

Immune globulin. A sterile solution containing antibodies, which are usually obtained from human blood. It is obtained by cold ethanol fractionation of large pools of blood plasma and contains 15%–18% protein. Intended for intramuscular administration, immune globulin is primarily indicated for routine maintenance of immunity among certain immunodeficient persons and for passive protection against measles and hepatitis A.

Intravenous immune globulin. A product derived from blood plasma from a donor pool similar to the immune globulin pool, but prepared so that it is suitable for intravenous use. Intravenous immune globulin is used primarily for replacement therapy in primary antibody-deficiency disorders, for treatment of Kawasaki disease, immune thrombocytopenic purpura, hypogammaglobulinemia in chronic lymphocytic leukemia, and certain cases of human immunodeficiency virus infection (Table 4).

Hyperimmune globulin (specific). Special preparations obtained from blood plasma from donor pools preselected for a high antibody content against a specific antigen (e.g., hepatitis B immune globulin, varicella-zoster immune globulin, rabies immune globulin, tetanus immune globulin, vaccinia immune globulin, cytomegalovirus immune globulin, botulism immune globulin).

Monoclonal antibody. An antibody product prepared from a single lymphocyte clone, which contains only antibody against a single antigen.

Antitoxin. A solution of antibodies against a toxin. Antitoxin can be derived from either human (e.g., tetanus immune globulin) or animal (usually equine) sources (e.g., diphtheria and botulism antitoxin). Antitoxins are used to confer passive immunity and for treatment.

Vaccination and immunization. The terms vaccine and vaccination are derived from vacca, the Latin term for cow. Vaccine was the term used by Edward Jenner to describe material used (i.e., cowpox virus) to produce immunity to smallpox. The term vaccination was used by Louis Pasteur in the 19th century to include the physical act of administering any vaccine or toxoid. Immunization is a more inclusive term, denoting the process of inducing or providing immunity by administering an immunobiologic. Immunization can be active or passive. Active immunization is the production of antibody or other immune responses through administration of a vaccine or toxoid. Passive immunization means the provision of temporary immunity by the administration of preformed antibodies. Although persons often use the terms vaccination and immunization interchangeably in reference to active immunization, the terms are not synonymous because the administration of an immunobiologic cannot be equated automatically with development of adequate immunity.

Advisory Committee on Immunization Practices

Membership List, February 2006

Chairman: Jon S. Abramson, MD, Weston M. Kelsey, Professor and Chair, Department of Pediatrics, Wake Forest University School of Medicine, Winston-Salem, North Carolina.

Executive Secretary: Larry K. Pickering, MD, Senior Advisor to the Director, National Center for Immunization and Respiratory Diseases (proposed), CDC, Atlanta, Georgia.

Members: Ban Mishu Allos, MD, Vanderbilt University School of Medicine, Nashville, Tennessee; Robert L. Beck, Consumer Representative, Palmyra, Virginia; Judith Campbell, MD, Baylor College of Medicine, Houston, Texas; Reginald Finger, MD, Colorado Springs, Colorado; Janet R. Gilsdorf, M.D., University of Michigan, Ann Arbor, Michigan; Harry Hull, MD, Minnesota Department of Health, Minneapolis, Minnesota; Tracy Lieu, MD, Harvard Pilgrim Health Care and Harvard Medical School, Boston, Massachusettes; Edgar K. Marcuse, MD, Children's Hospital and Regional Medical Center, Seattle, Washington; Dale L. Morse, MD, New York State Department of Health, Albany, New York; Julia Morita, MD, Chicago Department of Public Health, Chicago, Illinois; Gregory A. Poland, MD, Mayo Clinic and Foundation, Rochester, Minnesota; Patricia Stinchfield, The Children's Immunization Project, Children's Hospitals and Clinics, St. Paul, Minnesota; John J. Treanor, MD, University of Rochester, Rochester, New York; Robin J. Womeodu, MD, University of Tennessee Health Science Center, Memphis, Tennessee.

Ex-Officio Members: James Cheek, MD, Indian Health Service, Albuquerque, New Mexico; Wayne Hachey, DO, Department of Defense, Falls Church, Virginia; Geoffrey S. Evans, MD, Health Resources and Services Administration, Rockville, Maryland; Bruce Gellin, MD, National Vaccine Program Office, Washington, DC; Linda Murphy, Centers for Medicare and Medicaid Services, Baltimore, Maryland; George T. Curlin, MD, National Institutes of Health, Bethesda, Maryland; Norman Baylor, PhD, Food and Drug Administration, Rockville, Maryland; Kristin Lee Nichol, MD, Department of Veterans Affairs, Minneapolis, Minnesota.

Liaison Representatives: American Academy of Family Physicians, Jonathan Temte, MD, Madison, Wisconsin; Doug Campos-Outcalt, MD, Phoenix, Arizona; American Academy of Pediatrics, Keith Powell, MD, Akron, Ohio; Carol Baker, MD, Houston, Texas; America's Health Insurance Plans, Andrea Gelzer, MD, Hartford, Connecticut; American College Health Association, James C. Turner, MD, Charlottesville, Virginia; American College of Obstetricians and Gynecologists, Stanley Gall, MD, Louisville, Kentucky; American College of Physicians, Kathleen M. Neuzil, MD, Seattle, Washington; American Medical Association, Litjen Tan, PhD, Chicago, Illinois; American Pharmacists Association, Stephan L. Foster, PharmD, Memphis, Tennessee; Association of Teachers of Preventive Medicine, Paul W. McKinney, MD, Louisville, Kentucky; Biotechnology Industry Organization, Clement Lewin, PhD, Orange, Connecticut; Canadian National Advisory Committee on Immunization, Monica Naus, MD, Vancouver, British Columbia, Canada; Healthcare Infection Control Practices Advisory Committee, Steve Gordon, MD, Cleveland, Ohio; Infectious Diseases Society of America, Samuel L. Katz, MD, Durham, North Carolina; London Department of Health, David Salisbury, MD, London, England, United Kingdom; National Association of County and City Health Officials, Nancy Bennett, MD, Rochester, New York; Jeffrey Duchin, MD, Seattle, Washington; National Coalition for Adult Immunization, David A. Neumann, PhD, Alexandria, Virginia; National Foundation for Infectious Diseases, William Schaffner, MD, Nashville, Tennessee; National Immunization Council and Child Health Program, Mexico, Romeo S. Rodriquez, Mexico; National Medical Association, Patricia Whitley-Williams, MD, New Brunswick, New Jersey; Pharmaceutical Research and Manufacturers of America, Peter Paradiso, PhD, Collegeville, Pennsylvania; Society for Adolescent Medicine, Amy B. Middleman, MD, Houston, Texas.

Members of the General Recommendations on Immunization Working Group

Advisory Committee on Immunization Practices (ACIP), Edgar K. Marcuse, MD; Patricia Stinchfield; ACIP Liaison and Ex-Officio Members, Geoffrey S. Evans, MD, Health Resources and Services Administration; Stephan L. Foster, PharmD, American Pharmacists Association; CDC staff members, Andrew T. Kroger, MD, William L. Atkinson, MD, Larry K. Pickering, MD; other members and consultants, Lorry Rubin, MD, Schneider Children's Hospital; Deborah Wexler, MD, Immunization Action Coalition; Richard Zimmerman, MD, University of Pittsburgh School of Medicine; Richard D. Clover, MD, University of Louisville School of Public Health.

MMWR™

Morbidity and Mortality Weekly Report

Recommendations and Reports | December 1, 2006 / Vol. 55 / No. RR-15

Continuing Education Activity Sponsored by CDC

General Recommendations on Immunization: Recommendations of the Advisory Committee on Immunization Practices (ACIP)

EXPIRATION — December 1, 2009

You must complete and return the response form electronically or by mail by **December 1, 2009**, to receive continuing education credit. If you answer all of the questions, you will receive an award later for 2.75 hours Continuing Medical Education (CME) credit; .25 Continuing Education Units (CEUs); 2.75 Continuing Nursing Education (CNE) credits; 3.0 Continuing Health Education Specialist (CHES) contact hours; or .25 Continuing Pharmacy Education (CPE) hours. If you return the form electronically, you will receive educational credit immediately. If you mail the form, you will receive educational credit in approximately 30 days. No fees are charged for participating in this continuing education activity.

INSTRUCTIONS

By Internet

1. Read this *MMWR* (Vol. 55, RR-15), which contains the correct answers to the questions beginning on the next page.
2. Go to the *MMWR* Continuing Education Internet site at http://www.cdc.gov/mmwr/cme/conted.html.
3. Select which exam you want to take and select whether you want to register for CME, CEU, or CNE credit.
4. Fill out and submit the registration form.
5. Select exam questions. To receive continuing education credit, you must answer all of the questions. Questions with more than one correct answer will instruct you to "Indicate all that apply."
6. Submit your answers no later than **December 1, 2009**.
7. Immediately print your Certificate of Completion for your records.

By Mail or Fax

1. Read this *MMWR* (Vol. 55, RR-15), which contains the correct answers to the questions beginning on the next page.
2. Complete all registration information on the response form, including your name, mailing address, phone number, and e-mail address, if available.
3. Indicate whether you are registering for CME, CEU, or CNE credit.
4. Select your answers to the questions, and mark the corresponding letters on the response form. To receive continuing education credit, you must answer all of the questions. Questions with more than one correct answer will instruct you to "Indicate all that apply."
5. Sign and date the response form or a photocopy of the form and send no later than **December 1, 2009**, to
   Fax: 404-498-2388
   Mail: MMWR CE Credit
   Coordinating Center for Health Information and Service, MS E-90
   Centers for Disease Control and Prevention
   1600 Clifton Rd, N.E.
   Atlanta, GA 30333
6. Your Certificate of Completion will be mailed to you within 30 days.

ACCREDITATION

Continuing Medical Education (CME). CDC is accredited by the Accreditation Council for Continuing Medical Education to provide continuing medical education for physicians. CDC designates this educational activity for a maximum of 2.75 hours in category 1 credit toward the AMA Physician's Recognition Award. Each physician should claim only those hours of credit that he/she actually spent in the educational activity.

Continuing Education Unit (CEU). CDC has been reviewed and approved as an Authorized Provider by the International Association for Continuing Education and Training (IACET) 1620 I Street, NW, Suite 615, Washington, DC 2006. CDC has awarded .25 CEU's to participants who successfully complete this program.

Continuing Nursing Education (CNE). CDC is accredited as a provider of continuing nursing education by the American Nurses Credentialing Center's Commission on Accreditation. CDC will award 2.75 contact hour(s) in CNE credit.

Certified Health Education Specialist (CHES). CDC is a designated provider of continuing education contact hours (CECH) in health education by the National Commission for Health Education Credentialing, Inc. This program is a designated event for CHESs to receive 3.0 category I contact hour(s) in health education. The CDC provider number is **GA0082.**

Continuing Pharmacy Education (CPE). CDC is accredited by the Accreditation Council for Pharmacy Education as a provider of continuing pharmacy education. This program is a designated event for pharmacists to receive .25 contact hour(s) in pharmacy education. The universal program number is *387-000-06-46-H01.*

DEPARTMENT OF HEALTH AND HUMAN SERVICES
CENTERS FOR DISEASE CONTROL AND PREVENTION

Goals and Objectives

This *MMWR* provides general guidelines on immunization. The goal of this report is improve vaccination practices in the United States. Upon completion of this educational activity, the reader should be able to 1) identity valid contraindications for commonly used vaccines, 2) identify the minimum spacing between doses for vaccines routinely used in the United States, 3) describe recommended methods for administration of vaccines, and 4) identify evidence-based interventions shown to improve vaccination rates among children.

To receive continuing education credit, please answer all of the following questions.

1. If a second dose of a live virus vaccine is determined to be invalid, when should another dose be administered?
- A. As soon as possible.
- B. 28 days after the most recent valid dose.
- C. 28 days from the invalid dose or a minimum interval from the invalid dose, whichever is longer.
- D. A minimum interval from the most recent valid dose.
- E. Never. You must start the series over.

2. Which of the following is a permanent contraindication for all vaccines?
- A. Progressive neurologic disorder.
- B. Pregnancy.
- C. Severe allergic reaction to a previous dose of vaccine.
- D. Family history of asthma.
- E. Fever.

3. Which factor is an important criterion for needle length for a subcutaneous injection?
- A. Body mass.
- B. Site of injection.
- C. Sex.
- D. Age.
- E. None of the above.

4. Which test is NOT considered a suitable test to assess the level of altered immunocompetence?
- A. Immunoglobulin subclasses.
- B. Pertussis titers.
- C. Lymphocyte proliferation assays.
- D. T-cell counts.
- E. Antibody response to adult tetanus-diphtheria toxoid antigen.

5. The combination measles-mumps-rubella-varicella (MMRV) vaccine...
- A. is an inactivated vaccine.
- B. is contraindicated in pregnancy.
- C. is recommended if a person has a contraindication to one of the single-antigen vaccines (like monovalent varicella vaccine).
- D. must be refrigerated.
- E. requires more injections than measles-mumps-rubella (MMR) vaccine.

6. Which of the following strategy is not specifically recommended to improve vaccination coverage in children?
- A. Provision of vaccines at child care centers.
- B. Enhancing access to vaccines at schools.
- C. Laws requiring vaccines for school entry.
- D. Enhancing access to vaccines through the Women, Infants, and Children program.
- E. Reminder and recall systems.

7. The minimum intervals for vaccines should be used...
- A. to schedule a patient's next visit.
- B. to avoid simultaneous administration of vaccines.
- C. to catch-up children that are behind on vaccine doses.
- D. to avoid giving two injections at the same site.
- E. by vaccine registries to construct recall messages for providers.

8. Which is an acceptable way of alleviating the pain and discomfort of children as part of the vaccination process?
- A. Combining acetaminophen with topical EMLA therapy.
- B. Distraction methods (e.g., blowing away the pain).
- C. Telling children that vaccination doesn't hurt.
- D. Assurance that most adverse reactions are mild.
- E. None of the above.

9. Which of the following is a contraindication to MMR vaccine?
- A. Positive tuberculin skin test (TST) skin test.
- B. Simultaneous testing using TST.
- C. Allergy to eggs.
- D. Pregnancy.
- E. A household contact with altered immunocompetence.

10. If a storage unit has been found to be maintained at temperatures outside the recommended range for the vaccines contained within, which of the following would be an appropriate action?
- A. Discard all vaccines contained in the unit.
- B. Continue using the vaccine after it has been transferred to another storage unit.
- C. Mark the vaccine "Do not use" until more can be determined about the usability of the vaccine.
- D. Shorten the expiration date by 1 month.
- E. Recalibrate the thermometer.

11. Which best describes your professional activities?
- A. Physician.
- B. Nurse.
- C. Health educator.
- D. Office staff.
- E. Other.

12. I plan to use these recommendations as the basis for …(*Indicate all that apply.*)
- A. health education materials.
- B. insurance reimbursement policies.
- C. local practice guidelines.
- D. public policy.
- E. other.

13. Overall, the length of the journal report was…
- A. much too long.
- B. a little too long.
- C. just right.
- D. a little too short.
- E. much too short.

14. After reading this report, I am confident I can identify valid contraindications for commonly used vaccines.
- A. Strongly agree.
- B. Agree.
- C. Undecided.
- D. Disagree.
- E. Strongly disagree.

15. After reading this report, I am confident I can identify the minimum spacing between doses for vaccines routinely used in the United States.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

16. After reading this report, I am confident I can describe recommended methods for administration of vaccines.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

17. After reading this report, I am confident I can identify evidence-based interventions shown to improve vaccination rates among children.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

18. The learning outcomes (objectives) were relevant to the goals of this report.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

19. The instructional strategies used in this report (text, tables, and figures) helped me learn the material.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

20. The content was appropriate given the stated objectives of the report.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

21. The content expert(s) demonstrated expertise in the subject matter.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree

22. Overall, the quality of the journal report was excellent.
A. Strongly agree.
B. Agree.
C. Undecided.
D. Disagree.
E. Strongly disagree.

***MMWR* Response Form for Continuing Education Credit**
December 1, 2006/Vol. 55/No. RR-15

General Recommendations on Immunization: Recommendations of the Advisory Committee on Immunization Practices (ACIP)

To receive continuing education credit, you must
1. provide your contact information (**please print or type**);
2. indicate your choice of CME, CME for nonphysicians, CEU, CNE, or CPE credit;
3. answer all of the test questions;
4. sign and date this form or a photocopy;
5. submit your answer form by **December 1, 2009**.

Failure to complete these items can result in a delay or rejection of your application for continuing education credit.

Check One
☐ CME Credit
☐ CME for nonphysicians Credit
☐ CEU Credit
☐ CNE Credit
☐ CHES Credit
☐ CPE Credit

Last Name (**print or type**) First Name

Generic Prescribing, Generic Substitution, and Therapeutic Substitution (RE7091)

AMERICAN ACADEMY OF PEDIATRICS

Committee on Drugs

Pressures generated by a constellation of professional, consumer, legislative, and health care provider groups in this era of increasing health care costs have led to enactment of generic substitution laws in 50 states. The general acceptance of this concept, despite conflicting evidence that it has reduced the cost of prescription items to the consumer, has led to the concept of therapeutic substitution. Considerable confusion exists among health care professionals regarding the precise meaning of these concepts.

Generic prescribing is the prescribing of a drug by a physician using the generic name. This leaves the choice of brand to the dispensing pharmacist. Generic substitution is a pharmacist-initiated act by which a different brand or an unbranded drug product is dispensed instead of a drug brand that was prescribed by the physician. This means substituting the same chemical entity in the same dosage form for one marketed by a different company. Therapeutic substitution is a pharmacist-initiated act by which a pharmaceutical or therapeutic alternate for the physician-prescribed drug is dispensed without consulting the physician. This denotes replacement of the prescribed drug with a chemically different drug within the same therapeutic category, eg, hydrochlorothiazide for furosemide; ranitidine for cimetidine; chloramphenicol for erythromycin.

In 1976, the AAP Committee on Drugs published a commentary in *Pediatrics* (1976;57:275-277) on generic prescribing and concluded that "the lack of data on bioavailability and bioequivalence in children precludes blanket support of generic prescribing for infants and children." The Committee recently reviewed this issue and concluded that the situation has changed little during the past decade. The Committee supports prescribing the least costly drug if therapeutic efficacy and safety are not compromised. This may involve generic prescribing when, based on the physician's knowledge and experience, the generic choices are considered to be therapeutically equivalent. Because the physician is ultimately responsible for the care of the patient, the choice and/or selection of the drug must be under the physician's control

Generic substitution is based on the supposition that therapeutic equivalence, palatibility, and equivalent safety/adverse reactions exist among the various brands of a prescribed drug. However, there is little evidence to support the assumption of bioequivalence for most therapeutic agents in infants and children. Therefore, the Committee does not support a blanket recommendation for generic substitution.

The Committee strongly opposes therapeutic substitution. Therapeutic substitution constitutes abrogation by the physician of prescribing prerogatives to the dispensing pharmacist. Therapeutic decisions reached by physicians are based on a complex body of medical information relevant to a specific patient. Therapeutic failure or toxicity may result from substitution of a drug that is chemically different from that prescribed by the physician.

RECOMMENDATIONS

1. The Committee on Drugs of the American Academy of Pediatrics supports the concept of prescribing the least costly medication if safety and efficacy are not compromised.
2. Generic prescribing may be appropriate when, in the judgment of the physician, different brands of the same drug will provide equivalent efficacy and safety.
3. The Committee does not support a blanket recommendation for generic substitution.
4. The Committee opposes therapeutic substitution and any legislation that would permit it.

Barry H. Rumack, MD
Wayne Snodgrass, MD
Stephen P. Spielberg, MD, PhD

AHA Scientific Statement

Genetic Basis for Congenital Heart Defects: Current Knowledge

A Scientific Statement From the American Heart Association Congenital Cardiac Defects Committee, Council on Cardiovascular Disease in the Young

Endorsed by the American Academy of Pediatrics

Mary Ella Pierpont, MD, PhD, Chair; Craig T. Basson, MD, PhD, FAHA; D. Woodrow Benson, Jr, MD, PhD, FAHA; Bruce D. Gelb, MD; Therese M. Giglia, MD; Elizabeth Goldmuntz, MD; Glenn McGee, PhD; Craig A. Sable, MD; Deepak Srivastava, MD; Catherine L. Webb, MD, MS, FAHA

Abstractð The intent of this review is to provide the clinician with a summary of what is currently known about the contribution of genetics to the origin of congenital heart disease. Techniques are discussed to evaluate children with heart disease for genetic alterations. Many of these techniques are now available on a clinical basis. Information on the genetic and clinical evaluation of children with cardiac disease is presented, and several tables have been constructed to aid the clinician in the assessment of children with different types of heart disease. Genetic algorithms for cardiac defects have been constructed and are available in an appendix. It is anticipated that this summary will update a wide range of medical personnel, including pediatric cardiologists and pediatricians, adult cardiologists, internists, obstetricians, nurses, and thoracic surgeons, about the genetic aspects of congenital heart disease and will encourage an interdisciplinary approach to the child and adult with congenital heart disease. **(*Circulation*. 2007;115:3015-3038.)**

Key Words: AHA Scientific Statements ■ congenital heart disease ■ genetics

The goal of this review is to provide more information for clinicians on the expanding knowledge of the involvement of genetic contributions to the origin of congenital heart disease (CHD). There has been a long-standing clinical view that most CHD occurs as isolated cases. On the basis of studies of recurrence and transmission risks, a hypothesis of multifactorial etiology was proposed.[1] In this type of inheritance, the genetic predisposition of the individual interacts with the environment to cause the congenital heart defect. In recent years, separate environmental[2] and genetic causes have been identified. Classic mendelian transmission of congenital heart defects in some families has been described in the literature. In the past decade, molecular genetic studies have exploited these observations of families with multiple affected individuals and have provided insights into the genetic basis of several forms of CHD, such as atrial septal defect or patent ductus arteriosus.[3,4] These initial discoveries demonstrate that the genetic contribution to CHD has been significantly underestimated in the past. This review includes descriptions of the currently available diagnostic tools and their applications. Some syndromes, including DiGeorge syndrome, Williams-Beuren syndrome, Alagille syndrome, Noonan syndrome (NS), and Holt-Oram syndrome, have been highlighted in the text for the purpose of illustrating some of these new technologies. For further clinical details, interested readers are referred to a genetics textbook such as *Smithõs Recognizable Patterns of Human Malformation*.[5]

In reading this review, it is important to remember that human cardiovascular genetics is in the early phase of gene discovery; consequently, the field is changing rapidly. Ge-

The American Heart Association makes every effort to avoid any actual or potential conflicts of interest that may arise as a result of an outside relationship or a personal, professional, or business interest of a member of the writing panel. Specifically, all members of the writing group are required to complete and submit a Disclosure Questionnaire showing all such relationships that might be perceived as real or potential conflicts of interest.

Circulation **is available at http://www.circulationaha.org** **DOI: 10.1161/CIRCULATIONAHA.106.183056**

netic testing of embryos, fetuses, children, and adults, in both research and clinical settings, is expanding more quickly than are regulatory and surveillance programs. As part of these changes, clinically available genetic tests for various forms of CHD move from the research laboratory to the bedside or clinic at variable speeds. The pace of discovery is such that todayôs state of the art quickly becomes outdated. As a means of keeping abreast of the latest genes and availability of testing, the reader is referred to online resources such as Online Mendelian Inheritance in Man (http://www.ncbi.nlm.nih.gov/omim/) and GeneTests (http://www.genetests.org/), which are updated regularly.

Prevalence of CHD

Cardiac malformations present at birth are an important component of pediatric cardiovascular disease and constitute a major percentage of clinically significant birth defects, with an estimated prevalence of 4 to 50 per 1000 live births. For example, it is estimated that 4 to 10 liveborn infants per 1000 have a cardiac malformation, 40% of which are diagnosed in the first year of life.[6,7] The true prevalence, however, may be much higher. For example, bicuspid aortic valve, the most common cardiac malformation, is usually excluded from this estimate. Bicuspid aortic valve is associated with considerable morbidity and mortality later in life and by itself occurs in 10 to 20 per 1000 in the general population.[8] Recent studies are finding a high degree of heritability of bicuspid aortic valve, alone and with other cardiovascular anomalies, especially left ventricular outflow tract obstructive disorders.[9ï11] When isolated aneurysm of the atrial septum and persistent left superior vena cava, each of which occurs in 5 to 10 per 1000 live births, are taken into account, the incidence of cardiac malformations approaches 50 per 1000 live births.[12] The incidence of ventricular septal defect (VSD) has also been demonstrated to be as high as 5% in 2 independent cohorts of 5000 serial newborns and 5000 serial premature infants in Israel.[13,14] In light of the above considerations, an incidence of CHD of 50 per 1000 live births is a conservative estimate.[15,16]

In the year 2000, the prevalence of CHD in the pediatric population was estimated at approximately 623 000 (320 000 with simple lesions, 165 000 with moderately complex disease, and 138 000 with highly complex CHD).[16] Tremendous advances in medical and surgical care of children with CHD over the past decade have made survival into adulthood a reality. At the time of the Bethesda Conference in 2000, an estimated total of 787 000 adults were living with CHD (368 800 with simple disease, 302 500 with moderately complex disease, and 117 000 with highly complex disease).[17,18] This assessment of prevalence in the adult population is likely low, because many adult patients, particularly minorities, have been lost to follow-up. It has been estimated that the population of adults with CHD is growing by ≈5% per year, which predicts that the total adult CHD population likely reached 1 million by 2005.[19] This means that the number of adults living with CHD has for the first time surpassed the number of children with CHD. Clearly, it is imperative that many disciplines within the medical community, including adult cardiologists and thoracic surgeons, internists, obstetricians, family practitioners, and ancillary healthcare personnel, acquire an understanding of CHD and its inheritance so that proper lifetime care can be provided for this burgeoning patient population, which to date has been largely unfamiliar to all but pediatricians and pediatric cardiologists.

Importance of Identifying the Genetic Basis of CHD

Extraordinary diagnostic precision and definitive therapies with relatively low morbidity and mortality characterize the state of the art in the management of most CHD (eg, the arterial switch operation for transposition of the great arteries or device closure of intracardiac shunts). These types of therapies indicate that more and more individuals with CHD are going to live to adulthood and may have the opportunity to reproduce. Although there have been tremendous advances in diagnosis and treatment of CHD, our knowledge of the causes of CHD has been limited but has advanced in recent years. Despite the many advanced therapies currently available for a number of heart defects, significant morbidity and mortality are still associated with some types of CHD, for example, hypoplastic left heart syndrome. Improved understanding of possible causes will permit insight into the pathobiological basis of the congenital heart problem and allow definition of disease risk, 2 critical elements for disease prevention. For the clinician caring for a child with CHD, it is very important to determine whether there is an underlying genetic pattern (eg, deletions, duplications, or mutations), for the following reasons: (1) there may be other important organ system involvement; (2) there may be prognostic information for clinical outcomes; (3) there may be important genetic reproductive risks the family should know about; and (4) there may be other family members for whom genetic testing is appropriate. The following sections describe currently available techniques for evaluating infants and children with CHD.

Current Genetic Techniques for Evaluation of Congenital Heart Defects

Congenital heart defects often occur in the setting of multiple congenital anomalies, including abnormal facial features, or in association with limb anomalies, other organ malformations, developmental abnormalities, or growth abnormalities. We now have a number of genetic tests that can assist the clinician in diagnosing genetic alterations in the child with CHD. These include cytogenetic techniques, fluorescence in situ hybridization (FISH), and DNA mutation analysis. After discussion of these techniques, some syndromes that illustrate the use of these genetic techniques will be highlighted, and finally, a suggested approach for comprehensive assessment of these children is provided with an algorithm.

Chromosome Analysis

Before the availability of advanced cytogenetic techniques such as FISH, standard chromosome analysis revealed chromosomal aberration in 8% to 13% of neonates with CHD.[20] With improved resolution in cytogenetic analysis and the availability of molecular techniques, the prevalence of chromosomal abnormalities in selected congenital heart defects is now estimated to be much higher.[21] In contrast, of all children with chromosomal abnormalities, at least 30% have a con-

genital heart defect, with the incidence varying from that of the general population to nearly 100%, as in trisomy 18.[22] Therefore, chromosomal analyses in children with various types of CHD, especially if they have other organ system anomalies, is currently an important part of their medical evaluation (Appendix 1).

The standard metaphase karyotype (450 to 550 bands) is diagnostic for many chromosomal disorders, especially those of chromosome number such as trisomy (trisomy 21) or monosomy (45,X or Turner syndrome). A more sensitive test, high-resolution banding, evaluates chromosomes in prometaphase, which allows for the visualization of a greater number of bands (550 to 850 bands) than the standard karyotype. This technique better defines chromosomal structural abnormalities such as duplications, translocations between chromosomes, and interstitial or terminal deletions.[23] In most centers, 7 to 14 days is required for standard karyotyping and up to 3 weeks for high-resolution banding. More advanced cytogenetic techniques, such as FISH, are required to diagnose more subtle structural abnormalities, such as microdeletions, tiny duplications, and/or subtle translocations. FISH probes (see below) for chromosomes 13, 18, and 21 are currently available for use on interphase (nondividing) cells to diagnose chromosomal trisomies in a more timely fashion, ie, 1 to 2 days, as would be helpful if one of these trisomies were suspected in a neonate.[24]

Chromosomes can be analyzed from a number of sources, including peripheral blood lymphocytes, cord blood, skin fibroblasts, amniotic fluid, chorionic villi, and bone marrow, with peripheral blood most commonly used. Prior blood product transfusions are not likely to interfere with chromosome testing considering the small volume of the transfusion in relation to the total blood volume of the patient, and especially if leukoreduced and/or irradiated blood products have been used.[25]

Amniotic fluid cells are the primary means of prenatal chromosomal diagnosis. Amniocentesis is routinely performed at 15 to 16 weeksô gestation. Amniotic fluid cells, however, take 1 to 2 weeks to grow and harvest before karyotyping can be done. Chorionic villus sampling involves the biopsy of tissue from the villous area of the chorion transcervically or transabdominally, between 10 and 12 weeksô gestation. These results are usually available in 10 to 14 days. The major advantage of chorionic villus sampling compared with midtrimester amniocentesis is that chorionic villus sampling allows the results to be available at an earlier stage of the pregnancy, which reduces the period of uncertainty.

In the current era of in vitro fertilization, preimplantation genetic diagnosis for chromosomal abnormalities/aneuploidies and single-gene defects has recently become possible.[26] Preimplantation genetic diagnosis provides chromosomal and mutational analysis of blastocysts that result from in vitro fertilization before implantation. Preimplantation genetic diagnosis is primarily used by patients choosing assisted reproductive services who have concerns regarding risks of specific genetic disorders. The techniques used for prenatal or preimplantation diagnosis have inherent risks and benefits, which should be discussed on an individual basis with the treating physician. For more detail, the reader is referred to recent reviews of prenatal or preimplantation diagnosis.[27,28]

FISH Technology

FISH is a method by which biotinylated test and control DNA probes are hybridized with metaphase chromosomes to determine whether 1 (deletion), 2 (normal), or 3 (duplication) copies of the test region are present.[29] Specific DNA probes can be located by fluorescence microscopy and will identify well-known deletion syndromes such as del 5p (cri-du-chat). Other fluorescent DNA probes are useful in determining microdeletion syndromes that cannot be detected visually. Several disorders, including Williams-Beuren, Alagille, and the 22q11 deletion syndromes, have been associated with a consistent microdeletion that frequently can be detected only by FISH technology. This technology is widely available in almost every cytogenetics laboratory for the syndromes noted.

Telomere Analysis by Subtelomere FISH

Tiny deletions, duplications, or subtle translocations involving the most distal ends of each chromosome (telomeres) may be quite difficult to detect by standard or high-resolution karyotype techniques. Newly developed fluorescent DNA probes for many interstitial chromosomal regions now provide the ability to detect abnormalities that involve the subtelomere-telomere regions (subtelomere FISH). The distal segments of the chromosomal telomeres are composed of telomere-associated repeat sequences, and these extend 100 to 300 kb from the terminal repeat sequences.[30] Chromosome-specific unique sequences are present in these terminal regions, and fluorescent DNA probes can be specifically targeted to these areas. The subtelomere regions are thought to contain a very high concentration of genes; thus, rearrangements in these regions may have a significant impact on the phenotype of the individual.[31] Subtelomere FISH probes with fluorescent DNA have been commercially developed for each end of the chromosome arms except for the short arms of the acrocentric (centromere near 1 end) chromosomes.[32] If the karyotype is normal in a patient with dysmorphic facial features, congenital anomalies, developmental delay, and mental retardation, then the clinician should consider ordering subtelomere FISH studies for further genetic evaluation.

Cardiac malformations reported to date in children with subtelomere chromosomal rearrangements include aortic arch anomalies, VSD, atrial septal defect, mitral valve insufficiency, and concomitant pulmonary stenosis with VSD.[33,34] Most of the published studies of subtelomere abnormalities indicate that a 4% to 9% prevalence of subtle chromosome rearrangements can be detected in children or adults with microcephaly, hydrocephaly, tracheoesophageal fistula, skeletal anomalies, multiple congenital anomalies, polycystic kidney, duodenal atresia, syndactyly, epilepsy, mental retardation, developmental delay, and/or dysmorphic facial features.[30,35]

The use of subtelomeric FISH analysis has significant utility in individuals with normal karyotypes, especially if there are multiple congenital anomalies that include mental

retardation or CHD.[36] By finding a tiny deletion, duplication, or unbalanced translocation, further investigation of other family members can uncover the exact genetic risks faced by the family and the affected individual. As many as 50% of families can have other individual members with subtelomeric abnormalities.[37] Because some polymorphic variants and cross-hybridizations of subtelomeric FISH probes are known,[30] families in whom a subtelomeric abnormality is identified should be seen by a medical genetics specialist to provide appropriate evaluation and counseling.

Methods of Gene Discovery

Initial strategies of gene discovery were directed toward isolating a protein of interest, sequencing a portion of it, and then cloning the gene that produces that protein. This approach works well for disorders for which the function of the target protein is obvious and facilitates its identification, eg, Pompe disease (acid α-glucosidase deficiency). Currently, disease gene discovery can be accomplished by positional cloning, a candidate gene approach, or a combination of these 2 methods.[38] Positional cloning has been referred to as reverse genetics. In this paradigm, investigators study families with affected individuals to identify a position on a chromosome that must contain the disease gene of interest, utilizing linkage analysis. That disease gene is then identified from among the set of all genes residing in that chromosomal region through cloning techniques. An example of the successful use of this strategy was the identification of the *NKX2.5* gene, for which the locus was defined from linkage analysis of large families.[3] Some investigators have used this approach to identify a CHD gene in a syndromic disorder that is a single-gene trait. This approach is far less robust for finding disease genes when the disorder arises in a more complex genetic fashion or is heterogeneous, for example, patent ductus arteriosus.[4] This may be the case for many forms of CHD. Using the candidate gene approach, investigators look for mutations in genes that encode proteins with relevance to the process in question. For CHD, this means that genes that control the formation and development of the heart (also known as cardiogenic genes) are candidates. A combination of these 2 methods, or the positional candidate approach, uses linkage analysis or identification of karyotypic abnormalities to find a region of a chromosome likely to contain the gene of interest. Candidate genes (cardiogenic) in that particular chromosomal region are then evaluated for mutations.

DNA Mutation Analysis

The cytogenetic methods described above identify large changes in chromosome number or structure. However, in certain disorders, changes occur at the level of a single gene and must be detected by alternative techniques. Genes are complex structures that include not only regions coding for the protein itself but also other sequences involved in regulation of gene activity. Currently, the coding region for the protein is evaluated for sequence changes for which the biological significance of an altered coding sequence can generally be interpreted. In contrast, the regulatory domains are not usually studied for sequence changes, because the regulatory domains for the gene may not be known, and the biological significance of the altered sequence is difficult to interpret.

Mutation analysis identifies changes in the coding sequence of the gene, including small deletions, insertions, or substitutions of nucleotides that alter the encoded amino acid and consequently protein structure. Most methods employ polymerase chain reactionï based assays. Indirect screening methods, such as denaturing high-performance liquid chromatography[39] or single-strand conformation polymorphism,[40] have been used extensively. More expensive exon-by-exon sequencing of genomic DNA has recently emerged. Additionally, newer, more cost-effective direct sequence analysis methods have become available.[41] Such testing is usually done on DNA obtained from peripheral blood lymphocytes, but other tissues, such as skin, liver, muscle, buccal cells, or saliva, can be used, depending on their availability. DNA testing technology does have some limitations. For example, several types of mutations, including large deletions, other chromosomal structural abnormalities, and some changes that cause splicing errors, are difficult to detect by these approaches.

Once a sequence variation is identified, it is important to consider whether this variation is disease related. The basic criteria used to establish the disease-causing potential of the nucleotide sequence change are that it (1) is predicted to alter the gene coding sense, gene splice site, or regulatory region of the encoded protein; (2) segregates with disease in a kindred; and (3) is not found in unrelated, unaffected control chromosomes. The occurrence of a change in an evolutionarily conserved sequence domain provides additional support that the sequence change is disease causing. Although each of these criteria should be met by any disease-causing mutation, supporting evidence will come from the demonstration that affected individuals from other unrelated families have mutations in the same gene.

Another major problem is the interpretation of the biological importance of mutations. In many instances, little is known of the role of the normal gene product in cardiac development or function, and in some instances, genes were not known to have any role in the heart before mutation identification (eg, in Alagille syndrome). To date, a variety of mutations that cause pediatric cardiovascular disease, including missense and frameshift mutations, have been identified. The extent and heterogeneity of the genes and the mutations identified thus far suggest that they are associated with a variety of pathogenetic mechanisms, including loss of expression, inactivation, or loss of function or gain of function of the mutated allelic products. The challenge of the future is to define the pathogenesis of disease-causing mutations, which in turn will provide opportunities to develop diagnostic and therapeutic strategies as alternatives to those now used.

Loci and Genes Associated With Congenital Heart Defects Identified to Date

Deletion Syndromes Identified by FISH Technology

DiGeorge Syndrome

DiGeorge syndrome was originally considered to be a rare developmental field defect encompassing derivatives of the branchial arch/pharyngeal pouch system.[42,43] The syndrome is characterized by aplasia or hypoplasia of the thymus, aplasia or hypoplasia of the parathyroid glands, cardiac malformations, and specific facial features. Infants present with CHD, hypocalcemia, immunodeficiency, and facial dysmorphia. Ten to twenty percent of patients with DiGeorge syndrome have visible alterations that result in the loss of the proximal long arm of 1 copy of chromosome 22.[44] On FISH, ≈90% of patients with the DiGeorge phenotype have a microdeletion of part of 1 copy of chromosome 22.[45] The prevalence of the 22q11 deletion has been estimated at 1 per 5950 live births.[46]

Subsequently, it has been shown that patients with the clinical diagnosis of DiGeorge, velocardiofacial (Shprintzen), or conotruncal anomaly face syndromes most often share a common genetic origin, namely, a 22q11 deletion.[47] Not all patients with the clinical features of these syndromes have a 22q11 deletion, consistent with heterogeneous causes for the clinical features. For instance, some patients with similar clinical features may have a small deletion of the short arm of chromosome 10, or some of these features may also result from maternal diabetes mellitus or maternal alcohol use.

The clinical features of the 22q11 deletion syndrome are highly variable between affected individuals, even when they are related.[48] The most common features include cardiovascular anomalies, palate anomalies, feeding disorders, speech and learning disabilities, renal anomalies, and behavioral disorders. Other abnormalities may include hypocalcemia, immunodeficiency, skeletal abnormalities, and growth hormone deficiency. Typical facial features may also include tubular nose, hypoplastic alae nasi, bulbous tip nose, low-set and/or dysplastic ears, and myopathic facies. A 22q11 deletion is inherited in an autosomal dominant fashion from a parent in approximately 6% to 28% of cases.[48] In many familial cases, one of the parents is found to have a 22q11 deletion only after their child with CHD has been diagnosed as affected. All parents affected with 22q11 deletions are then found on further analysis to have subtle syndromic features that were not recognized previously.[48,49] Also, given that approximately 6% to 28%[48] of parents are found to carry the deletion, this has significant implications for future pregnancies, because there is a 50% chance that the deletion-bearing chromosome from an affected parent will be transmitted to the offspring. This is very important information for genetic family counseling.

The most common cardiovascular defects associated with a 22q11 deletion include tetralogy of Fallot, interrupted aortic arch type B, truncus arteriosus, conoventricular VSDs, and aortic arch anomalies.[50–52] Pulmonary stenosis, atrial septal defects, heterotaxy syndrome, and hypoplastic left heart syndrome have also been reported.

TABLE 1. Estimated 22q11 Deletion Frequency in Congenital Heart Disease

Cardiac Defect	Estimated Deletion Frequency, %	Reference(s)
Interrupted aortic arch	50–89	56, 57
VSDs	10	58
With normal aortic arch*	3	
With aortic arch anomaly†	45	
Truncus arteriosus	34–41	51, 56, 59–61
Tetralogy of Fallot	8–35	51, 56, 59, 61, 62
Isolated aortic arch anomalies	24	55
Double-outlet right ventricle	<5	51, 56, 59
Transposition of the great arteries	<1	51, 59

*Left-sided aortic arch with normal branching pattern.

†Includes right aortic arch and/or abnormal branching pattern, cervical location, and/or discontinuous branch pulmonary arteries.

Several studies have demonstrated that a 22q11 deletion is commonly found in a subset of patients with specific types of CHD (Table 1). Individuals with both a cardiac defect and an aortic arch anomaly (right aortic arch, cervical location, or abnormal branching pattern) are more likely to have a 22q11 deletion, as are a subset of patients with tetralogy of Fallot associated with absent pulmonary valve syndrome or aortopulmonary collaterals.[53–55] Children with double-outlet right ventricle or transposition of the great arteries are rarely found to have a 22q11 deletion (Table 1).[51,55–62]

It is important to identify the cardiac patient with a 22q11 deletion by FISH testing to evaluate for associated noncardiac features of the syndrome in a timely fashion and to offer accurate genetic counseling. Additionally, a higher operative mortality in some individuals with a 22q11 deletion has been documented,[63,64] and the clinician and surgeon should be aware of this when planning surgery and postoperative care, particularly as related to calcium metabolism or immunologic issues.

Discussions have centered around which cardiac patients should be routinely tested for a 22q11 deletion and at what age. It appears reasonable to test all infants with interrupted aortic arch type B or truncus arteriosus for a 22q11 deletion given the high frequency of a 22q11 deletion in those patients (Table 1). Using the same logic, data also support the testing of all infants with tetralogy of Fallot and one of the following associated features: absent pulmonary valve syndrome, aortic arch anomalies (including right aortic arch), pulmonary artery anomalies, or aortopulmonary collaterals (Table 1).[53–55] A high frequency of 22q11 deletion also supports testing of patients with both perimembranous VSD and associated aortic arch abnormalities[58] or those with isolated aortic arch abnormalities[55] (Table 1).

Much debate on testing strategies has focused on infants with tetralogy of Fallot who have a normal aortic arch and branching pattern. This subset comprises a large patient population, of which 6% are estimated to have a 22q11 deletion.[51] To clinically detect the deletion-bearing patient, the infant should be evaluated for hypocalcemia, thymic size, typical facial features, palate anatomy, or nasal regurgitation

TABLE 2. Age-Related Features of the 22q11 Deletion Syndrome

Newborn/infant age group
Specific types of congenital heart disease (interrupted aortic arch, truncus arteriosus, tetralogy of Fallot, VSD, aortic arch anomaly)
Aortic arch anomaly or discontinuous branch pulmonary arteries
Overt or submucous cleft palate, high arched palate, bifid uvula
Absent, hypoplastic, or abnormally located thymus
Hypocalcemia
Nasal regurgitation of feeds
Feeding disorders/failure to thrive/gastroesophageal reflux
Facial dysmorphia (especially abnormal ear or nose)
Toddler/school-aged child
Findings detailed above
Feeding disorders
Delayed emergence in speech
Hypernasal speech
Learning disabilities
Behavioral disorders, including attention deficit hyperactivity disorder (ADHD)
Adolescent/adult
Findings detailed above
Psychiatric disorders, including bipolar disorders and/or schizophrenia

with feeding on a routine examination (Table 2). The older child with a suspected 22q11 deletion could be evaluated for speech and learning disabilities, endocrine abnormalities, immune dysfunction, or other recognized syndromic abnormalities (Table 2). However, clinical assessment for syndrome features alone of the at-risk individual may not consistently identify the infant carrying a 22q11 deletion. Therefore, more routine FISH testing of at-risk infants is likely warranted.

In particular, facial features may be the only associated syndromic finding in the newborn and can be difficult to detect in that age group.[62] Such patients may be uncommon and would presumably be identified at an older age when other syndromic features and symptoms became more apparent. But these data also argue for a more comprehensive testing strategy to identify all infants with tetralogy of Fallot and a 22q11 deletion. Ultimately, early diagnosis of the patient with a 22q11 deletion allows for appropriate treatment of associated noncardiac anomalies, including appropriate handling of blood products at the time of surgery (leukocyte-depleted and cytomegalovirus-negative blood for the immunocompromised patient). In addition, accurate and timely genetic counseling can be provided to the family, including information on recurrence issues. Other family members can then be tested appropriately. Therefore, early FISH testing in patients with specific types of CHD is currently suggested as outlined in Table 3.

Finally, prenatal testing for a 22q11 deletion should be strongly considered in the fetus with either interrupted aortic arch, truncus arteriosus, tetralogy of Fallot, VSD (perimembranous, conoseptal hypoplasia, or malalignment types only), or aortic arch anomaly.[51,55,58] In the fetus, it is much more difficult to diagnose the 22q11 deletion syndrome by clinical appearance alone, because other features, such as facial dysmorphia, will not be sufficiently apparent to exclude the diagnosis. Appropriate genetic and family counseling is of critical importance in this situation.

TABLE 3. Suggested Testing Strategy for a 22q11 Deletion in the Congenital Heart Disease Population

All newborns/infants with:
IAA
TA
TOF
VSD* with AAA
Isolated AAA
Discontinuous branch pulmonary arteries
Any newborn/infant/child with CHD and another feature of the 22q11 deletion syndrome
Any child/adolescent/adult with TOF, TA, IAA, VSD, or AAA not previously tested who has 1 other feature of the 22q11 deletion syndrome (see Table 2)
All fetuses with IAA, TAA, TOF, VSD, or AAA (if amniocentesis performed for diagnostic purposes)
Consider all newborns/infants with VSD with normal aortic arch

IAA indicates interrupted aortic arch; TA, truncus arteriosus; TOF, tetralogy of Fallot; and AAA, aortic arch anomaly.

*Perimembranous, conoseptal hypoplasia or malalignment VSD.

Williams-Beuren Syndrome

Williams-Beuren syndrome (Williams syndrome) is an autosomal dominant disorder characterized by specific cardiovascular defects, infantile hypercalcemia, skeletal and renal anomalies, cognitive deficits, ñsocial personality,ò and elfin facies. Most cases arise de novo due to a chromosomal microdeletion. As with other deletion syndromes, Williams syndrome has a broad range of clinical presentations. Typical cardiovascular anomalies include supravalvular aortic stenosis, often in conjunction with supravalvular pulmonary stenosis and peripheral pulmonary stenosis. These arterial abnormalities constitute an elastin arteriopathy or vasculopathy caused by deletion of the elastin gene.[65] The degree of cardiovascular involvement and the involvement of the pulmonic or aortic vessels varies widely. The supravalvular aortic stenosis has been shown to progress in many cases, whereas the supravalvular pulmonary stenosis or peripheral pulmonary artery stenosis usually regresses with time.[66,67]

Approximately 90% of individuals with a clinical diagnosis of Williams syndrome have been found by FISH to have a microdeletion at chromosome 7q11.23.[65,68] Molecular analyses comparing clinical phenotype to genotype have demonstrated that this syndrome is a contiguous gene-deletion syndrome, ie, the deletion or alteration of specific genes in the deleted region corresponds with specific clinical features. Deletion of 1 copy of the elastin gene corresponds with the development of vascular manifestations of this disorder. Deletion of different genes in the region accounts for different manifestations of the disorder. Larger deletions, particularly deletions visible cytogenetically, can be associated with more severe clinical phenotypes, including seizures, which

TABLE 4. Clinical Features of Williams-Beuren Syndrome

Cardiovascular
Supravalvular aortic stenosis

Endocrine
Hypercalcemia
Hypercalciuria
Hypothyroidism
Adult diabetes mellitus
Renal/bladder disorders
Chronic urinary tract infections
Structural anomalies
Nephrocalcinosis

are not typically seen in Williams syndrome. Given the clinical variability of Williams syndrome and the fact that many aspects of Williams syndrome are not particularly evident in a young infant or child, especially characteristic facial features, it is appropriate to consider testing all patients with supravalvular aortic or pulmonic stenosis for this specific microdeletion by FISH at the time of diagnosis of the cardiac disease. In addition, if peripheral pulmonary stenosis persists beyond infancy, it is also appropriate to assess these patients with FISH analysis for the Williams syndrome critical region.

Early diagnosis of Williams syndrome is important to initiate treatment for other potential medical problems (Table 4). In particular, hypercalcemia, which often occurs in the first year of life along with hypercalciuria, can be treated with appropriate diet or medication. Because hypercalcemia can be a risk factor for the development of nephrocalcinosis, making this diagnosis is important for prevention of extensive kidney damage, which can lead to renal failure. Screening for thyroid and renal anomalies will uncover anomalies that are unsuspected clinically.[69] Routine follow-up of blood pressure measurements is needed because at least half of adults with Williams syndrome have systemic hypertension, and this can often be detected in childhood or adolescent years.[70] Early identification of Williams syndrome is also essential for planning educational strategies that can enhance learning and development in children with Williams syndrome. The detection of a deletion also adds diagnostic certainty for the family and the responsible clinician. Appropriate testing of other family members and genetic counseling can then occur.

Single-Gene Disorders

In the past 15 years, considerable progress has been made toward identifying molecular genetic causes of selected congenital heart defects. As illustrated in the first part of Table 5, a number of selected congenital heart defects have been found to be associated with mutations in a variety of single genes.[3,4,71–104] Some cardiac defects are related to mutations in >1 gene. It is highly likely that additional single-gene abnormalities (mutations) will be defined in the future. DNA testing for most of the genes for isolated congenital heart defects is unavailable except on a research basis at this time; however, testing of some of these genes is transitioning from the research laboratory to clinical availability. The clinician is advised to consult the Gene Tests Web site (http://www.genetests.org), a publicly funded medical genetics information resource, for updates on what testing is currently available.

The identification of causative gene mutations for genetic syndromes is also occurring at a rapid pace. A select group of syndromes in which the underlying single gene has been discovered is also listed in Table 5. For illustration purposes, Alagille syndrome, NS, and Holt-Oram syndrome will be discussed in greater detail. These single-gene disorders reflect the recent identification of genes responsible for congenital heart defects and for multiple other clinical features.

Alagille Syndrome

Alagille syndrome, an autosomal dominant disorder, was originally defined as the presence of bile duct paucity on liver biopsy in conjunction with 3 of the 5 following characteristics: cholestasis; cardiovascular, skeletal, or ocular anomalies; or typical facial features. Cardiovascular anomalies occur in >90% of individuals with Alagille syndrome.[79] The most common cardiovascular features include peripheral pulmonary hypoplasia, tetralogy of Fallot, and pulmonary valve stenosis, although left-sided lesions and septal defects are also seen. Liver disease is highly variable from patient to patient and also within affected members of the same family.[105] It is characterized by a paucity of intrahepatic bile ducts and can include chronic cholestasis, minimal liver enzyme elevation, hypercholesterolemia, or liver failure. Additional clinical features of Alagille syndrome are listed in Table 6.

A subset of Alagille patients (3% to 7%) have deletions of chromosome 20p12 detectable by karyotype or FISH analysis.[106] The gene *JAG1*, which encodes a Notch ligand protein product, has been mapped into the commonly deleted region of 20p12. Mutations of *JAG1* have been identified in patients with a broad spectrum of clinical phenotypes of Alagille syndrome, including patients with a predominant cardiac phenotype.[89]

TABLE 5. Genes Associated With Congenital Heart Defects in the Young

Condition	Gene(s)	Chromosome Location	Reference(s)

ASD indicates atrial septal defect; D-TGA, D-transposition of great arteries; DORV, double-outlet right ventricle; PPS, peripheral pulmonary stenosis; PDA, patent ductus arteriosus; and CHARGE, coloboma, heart anomaly, choanal atresia, retardation, and genital and ear anomalies.

Patients suspected of having Alagille syndrome should undergo a karyotype and FISH analysis to check for a 20p12 rearrangement or deletion. Karyotype and FISH analysis are readily available in most cytogenetics laboratories, and the finding of a deletion or chromosomal rearrangement can be diagnostic for Alagille syndrome. If this diagnosis is confirmed by the cytogenetic testing, the child can be evaluated for other important features of Alagille syndrome, such as liver disease or additional vascular involvement.[107] In addition, the cytogenetic results will most likely have a significant impact on the reproductive decisions some families will make in the future.

More than 90% of individuals with the classic phenotype of Alagille syndrome have a *JAG1* mutation when the most sensitive and rigorous methods for mutation detection are used.[108] *JAG1* mutation analysis is now clinically available for those patients whose karyotype and FISH analyses are normal. Growing evidence suggests that patients with a strong family history of right-sided defects, such as peripheral pulmonary stenosis, valvar pulmonary stenosis, or tetralogy of Fallot, who do not otherwise fulfill the criteria for Alagille syndrome may also be appropriate for testing in this specific region.[109,110] The finding of peripheral pulmonary stenosis or hypoplasia of the branch pulmonary arteries in a child, alone or in combination with tetralogy of Fallot, should prompt consideration of testing for Alagille syndrome. All patients with documented *JAG1* mutations or suspected Alagille syndrome should have cardiac, hepatic, ophthalmologic (anterior chamber defects, pigmentary retinal anomalies, posterior embryotoxon), orthopedic (butterfly vertebrae), hematologic (bleeding tendency), and renal (structural, cysts, tubular acidosis) evaluations.[111] The finding of a *JAG1* mutation in an individual establishes the diagnosis and allows for further testing of appropriate family members in whom the diagnosis

has not yet been suspected. This is helpful to make appropriate arrangements for comprehensive evaluation of clinical issues and to provide appropriate genetic counseling to the family regarding recurrence risk.

Noonan Syndrome

NS is a genetic multiple malformation disorder that includes short stature, typical facial dysmorphism, webbed neck, chest deformity, and cardiovascular abnormalities.[112] The cardiac involvement is observed in 80% to 90% of affected individuals, with valvar pulmonic stenosis and hypertrophic cardiomyopathy being the most common.[112,113] Other congenital heart defects observed in NS are secundum atrial septal defect, atrioventricular septal defect, mitral valve abnormalities, aortic coarctation, and tetralogy of Fallot. Other noncardiac features of NS include cryptorchidism, bleeding diathesis, and developmental delay. Additional features are listed in Table 7. Population prevalence has been estimated at

Lymphangiectasia

1 per 1000 to 1 per 2500 live births. The trait is inherited in an autosomal dominant fashion, although a substantial fraction of cases are sporadic.

NS is genetically heterogeneous, which means that there are at least 3 NS disease genes, *PTPN11*, *SOS1*, and *KRAS*.[92,114–116] With genetic linkage analysis and then positional candidacy, an NS disease gene on chromosome 12 was identified.[90] It is *PTPN11*, which encodes a protein tyrosine phosphatase called SHP-2. SHP-2 plays an important role in signal transduction for a wide variety of biological processes, including the formation of the semilunar valves.[117,118] Mutations in the *PTPN11* gene are observed in 40% to 50% of NS patients and are more prevalent among familial cases and among NS patients with pulmonary valve stenosis.[91] NS patients with hypertrophic cardiomyopathy are unlikely to harbor a *PTPN11* mutation. Otherwise, there does not appear to be a strong correlation between the presence or absence of a *PTPN11* mutation and most other aspects of the NS phenotype (eg, mental retardation). Disease penetrance is nearly complete among those with *PTPN11* mutations, although phenotypic variability within families can be substantial.

Clinical mutation testing for *PTPN11*, *SOS1*, and *KRAS* is now available in the United States and elsewhere. These DNA tests can confirm the diagnosis of NS but cannot exclude it due to the genetic heterogeneity (ie, the individual could harbor a mutation in another NS gene that has not been identified as yet). Molecular confirmation is useful in borderline cases, especially in neonates and adults in whom the facial features of NS may not be obvious. Prenatal testing can be done when the fetus is at risk for inheriting a defined *PTPN11* mutation from an affected parent. Similar testing of suspicious prenatal, sporadic cases (eg, a fetus with cystic hygroma and pulmonic stenosis) suffers from the uncertainty that arises from the genetic heterogeneity.

There are 3 NS-related conditions for which *PTPN11* mutations can be found: LEOPARD syndrome, Noonan-like with multiple giant cell lesions, and certain hematopoietic disorders. LEOPARD syndrome is also a multiple malformation disorder; the name is an acronym that designates the cardinal features: multiple lentigines, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, retardation of growth, and sensorineural deafness. A high percentage of affected individuals have *PTPN11* mutations with certain missense defects that appear to be specific for LEOPARD syndrome rather than NS.[119,120] Noonan-like with multiple giant cell lesions includes all of the features of NS plus the giant cell lesions of bone. The proclivity for involving the maxilla with expansile lesions leads to this disorder being a form of cherubism. Cardiac involvement appears to be highly similar to NS. Unlike LEOPARD syndrome, the *PTPN11* mutations have no specificity in predicting this disorder versus NS.[91,120]

Holt-Oram Syndrome

Holt-Oram syndrome is an autosomal dominant ñheart-handò syndrome that is characterized by congenital heart defects in patients with upper-limb deformities.[122] This syndrome occurs in approximately 1 per 100 000 individuals, and although it can be inherited in a mendelian fashion, a significant portion of cases are sporadic.[123] All patients have preaxial radial ray malformation (eg, triphalangeal, hypoplastic, or absent thumb and/or radial dysplasia), and three fourths of patients have septation (atrial and/or ventricular) defects and/or progressive atrioventricular conduction disease.[124–126] Human genetic linkage analyses and positional cloning studies of affected families revealed that Holt-Oram syndrome is caused by mutations in the *TBX5* transcription factor gene (chromosome 12q24.1).[87,124,126,127] The *TBX5* transcription factor has proven to be a key regulator, particularly in combination with other transcription factors such as *NKX2.5* and *GATA-4*, of gene expression during embryogenesis, and loss of its activity markedly impairs development of the heart and limb.[81,128,129]

Although there is significant genetic heterogeneity to the broader class of heart-hand syndromes,[130] there is little if any genetic heterogeneity among Holt-Oram patients. Mutational analyses of the *TBX5* gene-coding regions will detect mutations in approximately three fourths of such patients, and the remainder are likely to have mutations in regulatory regions or to have deletions/insertions not detectable by current mutational analysis.[131] Some studies find that fewer than half of Holt-Oram patients have *TBX5* mutations, which suggests genetic heterogeneity.[126,127,132] However, these studies have been confounded by aggregation of patients who have other heart-hand syndromes with those who have Holt-Oram.[133] Thus, careful and detailed clinical evaluations of the cardiovascular and other organ systems are essential to distinguish other such clinical syndromes (eg, Rothmund-Thomson syndrome, Okihiro syndrome, thrombocytopenia absent radius syndrome, and VACTERL association [vertebral anomalies, anal atresia, cardiac defect, tracheoesophageal fistula, renal abnormalities, and limb abnormalities]) that share features with Holt-Oram syndrome but are nonetheless clinically and genetically distinct.[134–136]

Key to the accurate diagnosis of Holt-Oram syndrome is the uniform presence of upper-limb radial ray defects, which may be symmetrical or asymmetrical (even unilateral) regardless of the presence or absence of cardiovascular disease. Such limb deformity, for example, altered structure of a single carpal bone, may be quite subtle and only detectable radiographically, but individuals without such radial ray defects do not have Holt-Oram syndrome.[124,137] Other limb malformations (eg, syndactyly of digits other than the thumb, polydactyly, or lower-limb defects), craniofacial abnormalities, and/or evidence of noncardiac visceral organ abnormalities (including heterotaxy) make Holt-Oram syndrome unlikely.[124,125,131,138] Most Holt-Oram structural cardiac defects are either ostium secundum atrial septal defects or muscular VSDs. Complex congenital heart defects have been seen in Holt-Oram syndrome patients with *TBX5* mutations, but they are rare events.[87,88,139] Therefore, the demonstration of ostium primum atrial septal defects, membranous VSDs, or congenital valvular disease should at least prompt further detailed clinical evaluations of other organ systems and consideration of other diagnoses.

Among those individuals with Holt-Oram syndrome, most will have *TBX5* mutations that are nonsense or frameshift

mutations that are predicted to produce a 50% reduction in *TBX5* gene dosage, that is, haploinsufficiency. Interestingly, there have been several reports[140–142] of individuals with duplications of chromosome 12q segments encompassing *TBX5* (and therefore potentially *TBX5* overexpression), and such patients have clinical phenotypes that overlap with Holt-Oram syndrome.[87] A minority of Holt-Oram syndrome is due to missense *TBX5* mutations that do not alter the geneôs dosage. Although large family-based studies have suggested that many such missense *TBX5* mutations have their greatest impact on either heart or limb development, compared with haploinsufficient *TBX5* mutations that markedly deform both organ systems, these genotype-phenotype associations are not necessarily evident in the individual patient with Holt-Oram syndrome and are not clinically useful for predicting the individual patientôs phenotype.[88,132]

Thus, in the setting of careful clinical evaluations of patients with suspected Holt-Oram syndrome, there is a rather limited role for *TBX5* mutational analyses. When diagnostic clarity is not achieved clinically, *TBX5* mutational analyses can provide adjunctive information. However, due to technical limitations of genetic assays used, the absence of a detected *TBX5* mutation in an individual with a typical clinical presentation does not preclude a diagnosis of Holt-Oram syndrome. Thus, the most valuable setting for *TBX5* genetic testing may be in establishing diagnoses for family members of a patient with previously established Holt-Oram syndrome and a known *TBX5* mutation. For instance, McDermott et al[131] used genetic testing to rule out Holt-Oram syndrome in an individual with tetralogy of Fallot whose cousin had well-established Holt-Oram syndrome. *TBX5* genetic testing has also been a useful addition to our assisted reproductive armamentarium.[26] When in vitro fertilization is used as a reproductive strategy for an individual affected by Holt-Oram syndrome, blastocysts can be subjected to preimplantation genetic testing in vitro before their transfer back to the mother. If the affected parentôs *TBX5* mutation is established before the in vitro fertilization cycle is begun, mutational analyses can occur in a sufficiently rapid and sensitive fashion that they can be the basis for embryo selection to achieve offspring who will not carry the *TBX5* mutation and will therefore be unaffected by Holt-Oram syndrome.

Nonsyndromic Single-Gene Disorders

Studies have recently shown that nonsyndromic CHD can result from single-gene defects. Schott et al[3] identified mutations in *NKX2.5* in 4 kindreds with atrial septal defects and atrioventricular conduction delay without other apparent syndromic features. The mutations were found only in affected individuals, were not present in control samples, and were demonstrated to change protein structure or function. Given that some members of these kindreds had either isolated atrioventricular conduction delay or other types of CHD, investigators subsequently studied additional kindred and sporadic cases with isolated atrioventricular conduction delay or CHD for *NKX2.5* mutations. These studies identified likely disease-related mutations in a subset of cases with atrioventricular conduction delay and additional sequence alterations in patients with selected types of CHD.[71,72,143–145] The gene changes in patients with sporadic CHD were not identified in control subjects, and it was difficult to demonstrate their functional significance; thus, their relationship to the disease may not be proved. These studies demonstrate the complexity of the biological interpretation of some alterations and the likely complexity of the genetic contribution to CHD.

Investigators have also identified mutations of *GATA4* in 2 kindreds with septal defects and no apparent syndromic features.[81] Once again, the mutations identified were found in affected individuals but not in control samples and were shown to confer changes in protein function. Mutations in additional kindreds and subjects with septal defects have been reported subsequently.[146–148] It remains to be seen whether mutations of *GATA4* will be identified widely in patients with septal defects or in other sporadic cases of CHD; however, these studies highlight the utility of studying large kindreds to identify novel disease genes for CHD, and they demonstrate that single-gene disorders may be found in a subset of CHD. In addition, these studies identify critical molecular pathways involved in cardiovascular development and disease, given that the proteins encoded by *NKX2.5*, *GATA4*, and *TBX5* are known to interact with one another in experimental systems.

Many cases of nonsyndromic CHD are unlikely to result from simple single-gene disorders. Instead, many cases of CHD are likely the result of multiple genetic alterations that increase susceptibility to CHD and interact with environmental factors. Already there is evidence of decreased penetrance and marked variability in expressivity of identical genetic alterations. For example, only 40% to 50% of children with trisomy 21 have CHD, and patients with a 22q11 deletion or even a single-gene defect (eg, *JAG1*) can present with markedly variable features. Such variable expressivity and penetrance is presumably explained by other genetic and environmental factors. These observations and the marked genetic heterogeneity already evident demonstrate the complexity of deciphering the genetic basis of CHD.

Evaluation for Genetic Basis in Children With CHD

Chromosome analysis and FISH testing for specific deletions are now accepted tools for the clinician. If the clinician finds a specific chromosome abnormality, it will provide the family with a clear explanation of the cause, allow the clinician to provide appropriate counseling about recurrence or lack of recurrence, and prompt the physician to investigate other potential medical problems known to be associated with the particular chromosomal anomaly.

Despite the rapidly advancing fund of knowledge, a genetic defect can only be identified through available testing in a minority of patients with CHD.[149] Many of these children have abnormalities of other organ systems that indicate the presence of a known phenotype. In some cases, there may be a single-gene defect for which no testing is clinically available. In other instances, polygenic inheritance with or without an additive environmental component may be implicated. A complete understanding of the interactions between abnormal cardiac physiology and derangements in other organs is important for appropriate management and counseling in such patients. Therefore, it is useful for the physician caring

for these patients to have an algorithm based on the initial presentation to assess for the presence of noncardiac abnormalities (Appendix 2).

The approach to the newly diagnosed patient with CHD should include routine examination of all relatives for a potential genetic contribution. Identification of some genetic causes of CHD has highlighted the importance of obtaining an accurate medical history of other family members and documenting an extended pedigree. In some forms of cardiovascular disease, for example, hypertrophic cardiomyopathy and Marfan syndrome, the familial nature (autosomal dominant inheritance) is well recognized; however, for other problems, for example, bicuspid aortic valve, family clustering has not been widely appreciated in the past. Recent studies have shown that a familial bicuspid aortic valve is likely to be inherited as an autosomal dominant condition with reduced penetrance.[9,150] There is a 24% prevalence of bicuspid aortic valve in first-degree relatives of patients with left ventricular outflow tract obstruction.[150] Increasingly, medical practice is evolving toward a recommendation that other family members undergo clinical evaluation, which may include an electrocardiogram and echocardiogram.

Specific assessment for physical features is warranted. The physical examination should focus on dysmorphic facies, eye and ear abnormalities, limb reduction defects, polydactyly, other skeletal defects, gastrointestinal and urologic defects, and neurological status. This assessment may be more difficult in the newborn who is intubated and/or sedated, and it may be more fruitful before rather than after cardiac surgery. In these situations, it is helpful and important to have a geneticist perform a complete examination to help uncover more subtle abnormalities. Other consultants, for example, from neurology, ophthalmology, orthopedic surgery, and otolaryngology, may be needed based on the suspected diagnoses.

Chest radiographs are performed in all newborn inpatients and many older patients who are diagnosed with CHD. Particular attention should be paid to skeletal defects and cardiac aortic arch, pulmonary, liver, and stomach situs. Additional radiographic tests that may also be indicated include abdominal/renal ultrasound, upper gastrointestinal series, liver-spleen scan, head ultrasound, and brain computed tomography or magnetic resonance imaging.

Cytogenetic testing should be considered in the following situations:

1. Any infant or child with the phenotype of a recognizable chromosomal syndrome (eg, trisomy 21 or 18)
2. Because not all chromosomal abnormalities result in a clinically recognizable syndrome, any infant or child with a congenital heart defect combined with (a) dysmorphic features, (b) growth retardation that cannot be explained by the heart defect, (c) developmental delay or mental retardation, or (d) multiple congenital anomalies
3. Infants or children with a family history of multiple miscarriages and/or siblings with birth defects
4. If major cardiac and/or other visceral organ malformations are documented by prenatal ultrasound and/or fetal echocardiogram

Genetic consultation is recommended in the presence of mental retardation, multiple congenital anomalies, or facial dysmorphia or if the standard karyotype is normal despite the clinical suspicion of a genetic abnormality (ie, normal karyotype in the presence of dysmorphism, mental retardation, and/or multiple congenital anomalies that include cardiac defects). In this situation, high-resolution banding or more advanced cytogenetic techniques may be indicated (FISH for specific defects or telomeric and subtelomeric probes). In addition, chromosome analysis is warranted as described above. Consultation with a clinical geneticist is recommended when a chromosomal abnormality is discovered so that appropriate counseling and evaluation of family members may be undertaken.

It is anticipated that the emphasis in the evaluation of patients with CHD will increasingly focus on the family in addition to the patient. Given the regularity with which the phenomenon of variable expression (ie, phenotype variation in individuals carrying the same gene mutation) is being recognized, the evaluations may need to be very comprehensive. For example, the evaluation may extend to noncardiac organs (eg, upper-extremity [Holt-Oram syndrome, *TBX5* mutations] and liver, skeleton, or eyes [Alagille syndrome, *JAG1* mutations]).

Impact on Patients and Families

For individuals with CHD and their families, identification of a genetic cause is very beneficial. This allows confidence in the diagnosis and allows the physician to explain the exact genetic mechanisms to the family. It also alerts the clinician to investigate other organ systems that may be involved in the syndrome and broadens the context of evaluation from the individual to other family members. In instances where a genetic cause such as Alagille syndrome has been identified in a family, genotyping may be very useful for stratifying ñasymptomaticò family members into groups who should have cardiac evaluations and those for whom it is not necessary. Genotype-negative individuals have a low risk of developing pediatric cardiovascular disease, and clinical evaluation of such patients is not warranted. On the other hand, serial evaluation of genotype-positive individuals is essential to monitor development of the phenotype.

Ethical Considerations

Predictive genetic testing of children and adolescents has been the subject of numerous recommendations.[151ï153] Although there is no universal agreement about acceptable practices in pediatric genetic testing, consensus exists that pediatric genetic testing should not take place unless there are clinical benefits to be reaped as a direct result of testing before the patient reaches the age of majority. In addition, the struggle to obtain the pediatric analogue of informed consent is particularly important in genetic testing, in part because the long-term social and legal risks of genetic testing for pediatric patients are difficult to predict, and the risks are more difficult for a child to judge. On the other hand, genetic testing may determine a genetic mechanism of disease that provides an important opportunity for genetic counseling that benefits the entire family.

Summary

Ongoing research is now demonstrating that variations or alterations in genes contribute to the origin of CHD to a greater degree than previously suspected. This review has summarized the current knowledge of the genetics of CHD and has provided guidelines and algorithms to aid the clinician in making diagnoses and planning care. Many types of genetic testing are currently clinically available; other testing is still in the research phase. Awareness of this rapidly advancing field is important for all clinicians, and a multidisciplinary team approach to the child with CHD is necessary for comprehensive, state-of-the-art care. In addition to physicians and surgeons with expertise in CHD, a geneticist is a highly important member of this team.

Patients with CHD require multidisciplinary care. Their families deserve up-to-date genetic information as it relates to their childôs prognosis and to the kindredôs risk for future inheritance of genetic abnormalities associated with cardiac defects. Obstetricians will have involvement in these issues if prenatal echocardiography demonstrates CHD or if preimplantation genetic diagnosis and in vitro fertilization are requested. Pediatricians require knowledge about these issues in caring for multiple organ systems in children with genetic syndromes that include CHD. Families of these children will need information about recurrence risk. Pediatric cardiologists and pediatric cardiac surgeons are currently well equipped to care for patients with CHD, but they need to constantly update their understanding of the contribution of genetic abnormalities to these birth defects. As children grow into adulthood, internists, obstetricians, cardiologists, and thoracic surgeons will step in to care for CHD as it is superimposed on adult medical issues.

Research discoveries regarding the genetics and inheritance of CHD are rapidly occurring. As in all genetic research, ethical considerations for children with heart disease demand thorough and thoughtful reflection. It is hoped that dissemination of the information in the present report will result in improved diagnoses and care for children and adults with congenital cardiac disease. Through multidisciplinary care and research, the goal to prevent and improve clinical outcomes in CHD will guide future investigations.

Appendix 1

Representative Chromosomal Disorders Associated With Congenital Heart Defects

Chromosomal Disorder	Main Features	Percent With CHD	Heart Anomaly	Reference(s)
Deletion 4p (Wolf-Hirschhorn syndrome)	Pronounced microcephaly, widely spaced eyes, broad nasal bridge (Greek helmet appearance), downturned mouth, micrognathia, preauricular skin tags, elongated trunk and fingers, severe mental retardation and seizures; 1/3 die in infancy	50–65	ASD, VSD, PDA, LSVC, aortic atresia, dextrocardia, TOF, tricuspid atresia	22, 154
Deletion 5p (cri-du-chat)	Catlike cry, prenatal and postnatal growth retardation, round face, widely spaced eyes, epicanthal fold, simian crease, severe mental retardation, long survival	30–60	VSD, ASD, PDA	22, 155, 156
Deletion 7q11.23 (Williams-Beuren syndrome)	Infantile hypercalcemia, skeletal and renal anomalies, cognitive deficits, "social" personality, elfin facies	53–85	Supravalvar AS and PS, PPS	67, 157, 158
Trisomy 8 mosaicism	Skeletal/vertebral anomalies, widely spaced eyes, broad nasal bridge, small jaw, high arched palate, cryptorchidism, renal anomalies (50%), long survival	25	VSD, PDA, CoA, PS, TAPVR, truncus arteriosus	22, 159–162
Deletion 8p syndrome	Microcephaly, growth retardation, mental retardation, deep-set eyes, malformed ears, small chin, genital anomalies in males, long survival	50–75	AVSD, PS, VSD, TOF	163–165
Trisomy 9	Severe prenatal and postnatal growth retardation, marked microcephaly, deep-set eyes, low-set ears, severe mental retardation; 2/3 die in infancy	65–80	PDA, LSVC, VSD, TOF/PA, DORV	22, 166
Deletion 10p	Frontal bossing, short down-slanting palpebral fissures, small low-set ears, micrognathia, cleft palate, short neck, urinary/genital, upper-limb anomalies	50	BAV, ASD, VSD, PDA, PS, CoA, truncus arteriosus	22, 167, 168
Deletion 11q (Jacobsen syndrome)	Growth retardation, developmental delay, mental retardation, thrombocytopenia, platelet dysfunction, widely spaced eyes, strabismus, broad nasal bridge, thin upper lip, prominent forehead	56	HLHS, valvar AS, VSD, CoA, Shone's complex	169
Trisomy 13 (Patau syndrome)	Polydactyly, cleft lip and palate, scalp defects, hypotelorism, microphthalmia or anophthalmia, colobomata of irides, holoprosencephaly, microcephaly, deafness, profound mental retardation, rib abnormalities, omphalocele, renal abnormalities, hypospadias, cryptorchidism, uterine abnormalities; 80% die in first year	80	ASD, VSD, PDA, HLHS, laterality defects, atrial isomerism	170, 171
Trisomy 18 (Edwards syndrome)	IUGR, polyhydramnios, micrognathia, short sternum, hypertonia, rocker-bottom feet, overlapping fingers and toes, TEF, CDH, omphalocele, renal anomalies, biliary atresia, profound mental retardation; 90% die in first year	90–100	ASD, VSD, PDA, TOF, DORV, D-TGA, CoA, BAV, BPV, polyvalvular nodular dysplasia	22, 172, 173
Deletion 20p12 (Alagille syndrome)	Bile duct paucity, cholestasis, skeletal or ocular anomalies, broad forehead, widely spaced eyes, underdeveloped mandible	85–94	Peripheral PA, hypoplasia, TOF, PS, (left-sided heart lesions and septal defects less common)	79, 174
Trisomy 21 (Down syndrome)	Hypotonia, hyperextensibility, epicanthal fold, simian crease, clinodactyly of fifth finger, brachydactyly, variable mental retardation, premature aging	40–50	AVSD, VSD, ASD, (TOF, D-TGA less common)	22, 175–180
Deletion 22q11 (DiGeorge, velocardiofacial, and conotruncal anomaly face syndrome)	Hypertelorism, micrognathia, low-set posteriorly rotated ears, "fish mouth," thymic and parathyroid hypoplasia, hypocalcemia, feeding/speech/learning/behavioral disorders, immunodeficiency, palate/skeletal/renal anomalies	75	IAA-B, truncus arteriosus, isolated aortic arch anomalies, TOF, conoventricular VSD	181, 182
Monosomy X (Turner syndrome, 45,X)	Lymphedema of hands and feet, widely spaced hypoplastic nipples, webbed neck, primary amenorrhea, short stature, normal intelligence	25–35	CoA, BAV, valvar AS, HLHS, aortic dissection	22, 183–187
Klinefelter syndrome (47,XXY)	Usually normal appearing, tall stature, small testes, delayed puberty, emotional and behavioral problems common, variable mental retardation	50	MVP, venous thromboembolic disease, PDA, ASD	22, 188

CHD indicates congenital heart defects; ASD, atrial septal defect; VSD, ventricular septal defect; PDA, patent ductus arteriosus; LSVC, persistent left superior vena cava; TOF, tetralogy of Fallot; AS, aortic stenosis; PS, pulmonic stenosis; PPS, peripheral pulmonary stenosis; CoA, coarctation of the aorta; TAPVR, total anomalous pulmonary venous return; AVSD, atrioventricular septal defect; TOF/PA, tetralogy of Fallot with pulmonary atresia; DORV, double-outlet right ventricle; BAV, bicuspid aortic valve; HLHS, hypoplastic left heart syndrome; IUGR, intrauterine growth retardation; TEF, tracheoesophageal fistula; CDH, congenital diaphragmatic hernia; D-TGA, D-transposition of the great arteries; BPV, bicuspid pulmonary valve; PA, pulmonary artery; IAA-B, interrupted aortic arch type B; and MVP, mitral valve prolapse.

Appendix 2

Genetic Algorithms for Cardiac Defects

I. Pulmonary outflow obstruction
- A. Pulmonary valve stenosis
  - 1. Noonan syndrome
    - a) Autosomal dominant
    - b) 25% to 70% of cases result from de novo mutation
    - c) More likely if pulmonary valve is dysplastic
    - d) Also associated with hypertrophic cardiomyopathy (right and/or left ventricle)
    - e) Noncardiac phenotype features
      - (1) Male or female
      - (2) Short stature
      - (3) Broad or webbed neck
      - (4) Unusual chest shape
      - (5) Characteristic facies
      - (6) Developmental delay
      - (7) Cryptorchidism
    - f) Genetic testing clinically available
      - (1) *PTPN11* gene mutation analysis
      - (2) *KRAS* gene mutation analysis
      - (3) *SOS1* gene mutation analysis
  - 2. Alagille syndrome (see below)
  - 3. Costello syndrome
    - a) Sporadic occurrence
    - b) Also associated with hypertrophic cardiomyopathy
    - c) Noncardiac phenotype features
      - (1) Failure to thrive
      - (2) Feeding difficulties
      - (3) Mental retardation
      - (4) Increased risk of malignancy
      - (5) Coarse facial features with thick lips
      - (6) Loose skin
      - (7) *HRAS* mutations
  - 4. LEOPARD syndrome
    - a) Autosomal dominant
    - b) Noncardiac phenotype features
      - (1) Hearing loss
      - (2) Lentigines
      - (3) Short stature
      - (4) Similarities with Noonan syndrome
    - c) Genetic testing clinically available
      - (1) *PTPN11* gene mutation analysis
  - 5. Other chromosomal anomalies
    - a) Deletions of chromosome 1p, 8p, 10p, 22q
    - b) Duplications of chromosome 6q, 15q, 19q
    - c) Trisomy 8
- B. Pulmonary artery branch stenosis
  - 1. Alagille syndrome
    - a) Autosomal dominant
    - b) 50% to 60% of cases result from de novo mutation
    - c) Noncardiac phenotype features
      - (1) Bile duct paucity
      - (2) Cholestasis
      - (3) Eye findings (posterior embryotoxon)
      - (4) Vertebral anomalies
      - (5) Characteristic facies
      - (6) Growth retardation
    - d) Genetic testing clinically available:
      - (1) Microdeletion in chromosome locus 20p12 detectable by FISH
      - (2) *JAG1* gene mutation analysis
  - 2. Williams-Beuren syndrome (see below)
  - 3. Other
    - a) Congenital rubella
    - b) Ehlers-Danlos syndrome
    - c) Noonan syndrome (see above)
    - d) LEOPARD syndrome (see above)
- C. Pulmonary valve atresia (intact ventricular septum)
  - 1. Ring 9 chromosome abnormality

II. Aortic outflow obstruction
- A. Aortic valve stenosis
  - 1. Chromosome abnormalities
    - a) Deletion of chromosome 11q (Jacobsen syndrome)
    - b) Autosomal trisomies (13, 18)
    - c) Deletion of 10q
    - d) Duplications of 1q, 2p, 2q, 6q, 11q
  - 2. Noonan syndrome (see above)
  - 3. Turner syndrome (see below)
- B. Supravalvular aortic stenosis
  - 1. Williams-Beuren syndrome
    - a) Autosomal dominant
    - b) Most cases result from de novo mutation
    - c) Noncardiac phenotype features
      - (1) Characteristic elfin facies
      - (2) Loquacious personality
      - (3) Hypercalcemia
      - (4) Developmental delay/cognitive defects
      - (5) Connective tissue abnormalities
      - (6) Renal anomalies
      - (7) Thyroid disorder
    - d) Genetic testing clinically available:
      - (1) Microdeletion in chromosome 7q11 (elastin gene) detectable by FISH (>95% of cases)
    - e) Rare translocations involving 7q11 locus
  - 2. Isolated supravalvular aortic stenosis, Eisenberg type
    - a) Distinct entity from Williams syndrome
    - b) Abnormal facies and mental retardation absent
    - c) Elastin gene mutations
- C. Coarctation of the aorta
  - 1. Turner syndrome
    - a) Noncardiac phenotype features
      - (1) Female
      - (2) Unusual chest shape
      - (3) Widely spaced nipples
      - (4) Webbed neck
      - (5) Lymphedema
      - (6) Short stature
      - (7) Streak ovaries

Appendix 2. Continued

- b) Karyotype is diagnostic: 45,X or mosaics (45,X/46,XX)
- 2. Other chromosomal abnormalities
  - a) Deletion of 18p
  - b) Duplications of 4p, 4q, 6q, 10p
  - c) Autosomal trisomies 8, 9
- 3. Familial aggregation of left-sided obstructive heart defects
  - a) Frequent occurrence in first-degree relatives (9.4%)

D. Aortic atresia/hypoplastic left heart syndrome

- 1. Chromosomal anomalies
  - a) Deletion of 11q (Jacobsen syndrome)
  - b) Turner syndrome
  - c) Trisomy 13, 18
  - d) Deletion of 4p (Wolf-Hirschhorn)
- 2. Familial aggregation of left-sided obstructive heart defects
  - a) Frequent association with bicuspid aortic valve in a parent (5%)
  - b) Sibling recurrence risk (2% to 9%)
  - c) Proposed inheritance patterns
    - (1) Multifactorial
    - (2) Autosomal dominant with reduced penetrance
    - (3) Autosomal recessive

E. Bicuspid aortic valve

- 1. Very common cardiac anomaly (incidence 0.9% to 1.36% in population)
- 2. Association with familial aggregation of left-sided obstructive heart defects
  - a) Frequent finding of bicuspid aortic valve in parents of children with other left-sided obstructive anomalies
  - b) Frequent association of cardiac anomalies in first-degree relatives (19.3%)
- 3. Familial bicuspid aortic valve
  - a) Autosomal dominant with reduced penetrance
  - b) Prevalence 24% in first-degree relatives
- 4. Turner syndrome (see above)
- 5. Chromosomal anomalies
  - a) Autosomal trisomies 13, 18
  - b) Deletion 10p
  - c) Duplication 6q

III. Laterality defects (heterotaxy, asplenia/polysplenia)

A. Phenotype

- 1. Asplenia syndrome (also known as right atrial isomerism)
  - a) Cardiac defects
    - (1) Right atrial isomerism
    - (2) Complex conotruncal defects
    - (3) AVSD
    - (4) Anomalous location of inferior vena cava (on same side as abdominal aorta)
  - b) Pattern of visceral organs
    - (1) Asplenia: 99% of patients, more severe than polysplenia
    - (2) Bilateral “right-sidedness”
    - (3) Symmetrical liver
    - (4) Gastrointestinal malrotation
    - (5) Right-sided stomach
    - (6) Genitourinary, bronchopulmonary, axial skeletal, and central nervous system abnormalities
- 2. Polysplenia syndrome (also known as left atrial isomerism)
  - a) Cardiac defects
    - (1) Left atrial isomerism
    - (2) Septal defects
    - (3) Interrupted inferior vena cava
    - (4) Bilateral superior vena cavae
    - (5) Partial anomalous pulmonary venous return
  - b) Pattern of visceral organs
    - (1) Polysplenia: 90% of patients
    - (2) Bilateral “left-sidedness”
    - (3) Symmetrical or inverted (larger lobe on left) liver
    - (4) Gastrointestinal malrotation
    - (5) Two or more spleens, can be functionally asplenic
    - (6) Extrahepatic biliary atresia
    - (7) Genitourinary, bronchopulmonary, axial skeletal, and central nervous system abnormalities

B. Genotype

- 1. No well-described genetic syndromes with clinical testing available
- 2. Reported chromosomal abnormalities
  - a) Autosomal
    - (1) Chromosome 2 (*CFC1* gene encoding CRYPTIC protein)
    - (2) Chromosome locus 6q (*HTX3* gene)
  - b) X-linked: locus Xq26.2 (*ZIC3* gene)

IV. Atrial septal abnormalities

A. Secundum ASD

- 1. Holt-Oram syndrome
  - a) Autosomal dominant
  - b) Variable expression
  - c) Also associated with VSD, variable other defects
  - d) Noncardiac phenotype features
    - (1) No sex predilection
    - (2) Variable preaxial limb defects
    - (3) Absent, hypoplastic, or triphalangeal thumbs
  - e) Mutations of *TBX5* gene on 12q24.1
- 2. Familial ASD and progressive atrioventricular block
  - a) Autosomal dominant
  - b) No demographics known
  - c) Variable onset of conduction abnormality
  - d) Other cardiac anomalies can include VSD, tetralogy of Fallot, and others
  - e) No noncardiac features reported
  - f) Mutations or haploinsufficiency of *NKX2.5* gene on chromosome 5
- 3. Familial ASD without progressive atrioventricular block
  - a) Other cardiac anomalies can include VSD or pulmonary stenosis
    - (1) *GATA 4* mutations
- 4. Ellis-van Creveld syndrome
  - a) Autosomal recessive
  - b) Often single atrium
  - c) Noncardiac features
    - (1) Male or female
    - (2) Polydactyly
    - (3) Deformity of upper lip
    - (4) Dwarfism with narrow thorax

Appendix 2. Continued

(5) Mutations have been described in Ellis-van Creveld gene at 4p16.1
5. Noonan syndrome (see above)
6. Other chromosomal abnormalities
a) Deletions of 1, 4, 4p, 5p, 6, 10p, 11, 13, 17, 18, and 22
b) Trisomy 18, 21
c) Klinefelter syndrome
7. Other syndromes
a) Rubinstein-Taybi syndrome
b) Kabuki syndrome
c) Williams syndrome
d) Goldenhar syndrome
e) Thrombocytopenia–absent radius syndrome
f) Marfan syndrome (rare)

B. Single atrium (see Ellis-van Creveld syndrome)
C. Ostium primum ASD (see atrioventricular septal abnormalities)

V. Ventricular septal abnormalities
A. VSD
1. Holt-Oram syndrome (see under ASD)
2. Familial ASD and progressive atrioventricular block (see ASD)
3. Familial ASD without progressive atrioventricular block
a) Other cardiac anomalies can include VSD or pulmonary stenosis
b) *GATA 4* mutation
4. Chromosome abnormalities
a) Deletions of many chromosomes
b) Duplications of many chromosomes
c) Autosomal trisomies 13, 18, and 21
5. Other syndromes
a) Rubinstein-Taybi syndrome
b) Goldenhar syndrome
c) VACTERL association
d) Costello syndrome
e) Williams syndrome (see above)
f) Kabuki syndrome
g) Cornelia de Lange syndrome
h) Apert syndrome
i) Carpenter syndrome

VI. Atrioventricular septal abnormalities
A. AVSD, partial and complete
1. Autosomal trisomies
a) Down syndrome
(1) 60% of infants with AVSD have Down syndrome
b) Occurs also in trisomy 13 and 18
2. Other chromosome abnormalities
a) Deletions of 3p25, 8p2, 22q
b) Duplications of 10q, 11q, 22q
3. Isolated AVSD
a) Autosomal dominant AVSD
(1) Partial and complete
(2) Gene locus mapped to 1p21p31
4. Other syndromes
a) Holt-Oram syndrome (see above)
b) Noonan syndrome (see above)
c) Chondrodysplasias
d) Smith-Lemli-Opitz syndrome
e) Ellis-van Creveld syndrome (see above)
f) Hydrolethalus

VII. Patent ductus arteriosus
A. Familial patent ductus arteriosus
1. Char syndrome
a) Autosomal dominant
b) Noncardiac phenotypic features
(1) Characteristic facies
(2) Aplasia/hypoplasia of middle phalanges of fifth fingers
c) Variable expression
d) Mutations of *TFAP2B*

VIII. Conotruncal defects
A. Tetralogy of Fallot (51 entries in OMIM)
1. 22q11 deletion syndrome
a) Clinical features of DiGeorge/velocardiofacial/conotruncal anomaly face syndromes
b) Associated with a chromosome 22q11 deletion
c) Familial inheritance approximately 6% to 28%, autosomal dominant
d) Most are de novo deletions of 22q11
e) Highly variable clinical presentation
f) Most common noncardiac defects include
(1) Hypocalcemia
(2) Hypoplastic/aplastic thymus
(3) Immune deficiency
(4) Palate anomalies, including velopharyngeal insufficiency
(5) Feeding disorders
(6) Speech disabilities
(7) Learning disabilities
(8) Behavioral/psychiatric disorders
(9) Facial dysmorphia
g) Genetic testing available
(1) FISH for deletion 22q11
(2) Chromosome analysis for translocation or other 22q rearrangement
2. Alagille syndrome (see pulmonary artery branch stenosis)
3. Cat-eye syndrome
a) Associated with duplication of chromosomal region 22pter22q11
b) Most arise de novo
c) Highly variable clinical presentation
d) Most common noncardiac anomalies include
(1) Anal atresia
(2) Coloboma
(3) Microphthalmia
(4) Cleft palate
(5) Renal anomalies
(6) Facial dysmorphia, particularly misshapen ears
e) Genetic testing available
(1) FISH for extra marker 22 chromosome
4. Nearly 50 other syndromes in which tetralogy of Fallot is diagnosed (for details, search OMIM for tetralogy of Fallot)
a) Chromosomal abnormalities

Appendix 2. Continued

(1) Deletions of many chromosomes
(2) Duplications of many chromosomes
B. Truncus arteriosus/interruption of the aortic arch
1. 22q11 deletion syndrome (see above)
2. Trisomy 8
3. Deletion 10p
C. Transposition of the great arteries (D-TGA, L-TGA)
1. Chromosome abnormalities
a) Trisomy 18, 21
b) 22q11 deletion syndrome (very rarely)
c) Many other partial deletions of different chromosomes
D. Double-outlet right ventricle
1. Chromosome abnormalities
a) Autosomal trisomies 9, 13, 18
b) Duplication 2p, 12p
c) 22q11 deletion syndrome (very rarely)
IX. Tricuspid atresia
A. Most cases are sporadic
B. Familial occurrences reported but rare
1. In siblings
2. In association with a conotruncal malformation or annular hypoplasia in family members
C. Chromosome abnormalities reported but rare
1. Deletions: 22q11, 4p (Wolf-Hirsch3horn syndrome)
2. Duplications: partial duplication 22 (Cat-eye syndrome)
D. Targeted mutation of gene encoding Fog-2 in mice resulted in tricuspid atresia, thereby suggesting a genetic basis for the disease
X. Ebstein anomaly
A. Most cases are sporadic
B. Familial occurrences reported but rare
1. In siblings and other family members
2. In association with other mitral valve abnormalities in family members
3. In association with familial atrial standstill
C. Chromosome abnormalities reported but rare
1. Trisomy 21
2. Rearrangements of chromosome 11q in association with renal malformation and Pierre Robin sequence
D. Animal studies implicate several possible candidate genes on chromosome 17q
XI. Total anomalous pulmonary venous return
A. Most cases are sporadic
B. Familial occurrences reported
1. In siblings, twins, parents/children, first cousins
2. Chromosome 4p13-q12, autosomal dominant, variable expressivity, reduced penetrance in large Utah-Idaho family
3. Familial scimitar syndrome
C. Trisomy 8

LEOPARD syndrome indicates syndrome consisting of cardinal features of multiple lentigines, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, retardation of growth, and sensorineural deafness; AVSD, atrioventricular septal defect; ASD, atrial septal defect; OMIM, Online Mendelian Inheritance in Man; and TGA, transposition of the great atries.

Clinical testing is not yet available for many of the syndromes listed in this appendix.

American Medical Association ethical opinion

E-8.061 Gifts to Physicians from Industry

Many gifts given to physicians by companies in the pharmaceutical, device, and medical equipment industries serve an important and socially beneficial function. For example, companies have long provided funds for educational seminars and conferences. However, there has been growing concern about certain gifts from industry to physicians. Some gifts that reflect customary practices of industry may not be consistent with the Principles of Medical Ethics. To avoid the acceptance of inappropriate gifts, physicians should observe the following guidelines:

(1) Any gifts accepted by physicians individually should primarily entail a benefit to patients and should not be of substantial value. Accordingly, textbooks, modest meals, and other gifts are appropriate if they serve a genuine educational function. Cash payments should not be accepted. The use of drug samples for personal or family use is permissible as long as these practices do not interfere with patient access to drug samples. It would not be acceptable for non-retired physicians to request free pharmaceuticals for personal use or use by family members.

(2) Individual gifts of minimal value are permissible as long as the gifts are related to the physicianôs work (eg, pens and notepads).

(3) The Council on Ethical and Judicial Affairs defines a legitimate "conference" or "meeting" as any activity, held at an appropriate location, where (a) the gathering is primarily dedicated, in both time and effort, to promoting objective scientific and educational activities and discourse (one or more educational presentation(s) should be the highlight of the gathering), and (b) the main incentive for bringing attendees together is to further their knowledge on the topic(s) being presented. An appropriate disclosure of financial support or conflict of interest should be made.

(4) Subsidies to underwrite the costs of continuing medical education conferences or professional meetings can contribute to the improvement of patient care and therefore are permissible. Since the giving of a subsidy directly to a physician by a companyôs representative may create a relationship that could influence the use of the companyôs products, any subsidy should be accepted by the conferenceôs sponsor who in turn can use the money to reduce the conferenceôs registration fee. Payments to defray the costs of a conference should not be accepted directly from the company by the physicians attending the conference.

(5) Subsidies from industry should not be accepted directly or indirectly to pay for the costs of travel, lodging, or other personal expenses of physicians attending conferences or meetings, nor should subsidies be accepted to compensate for the physiciansô time. Subsidies for hospitality should not be accepted outside of modest meals or social events held as a part of a conference or meeting. It is appropriate for faculty at conferences or meetings to accept reasonable honoraria and to accept reimbursement for reasonable travel, lodging, and meal expenses. It is also

appropriate for consultants who provide genuine services to receive reasonable compensation and to accept reimbursement for reasonable travel, lodging, and meal expenses. Token consulting or advisory arrangements cannot be used to justify the compensation of physicians for their time or their travel, lodging, and other out-of-pocket expenses.

(6) Scholarship or other special funds to permit medical students, residents, and fellows to attend carefully selected educational conferences may be permissible as long as the selection of students, residents, or fellows who will receive the funds is made by the academic or training institution. Carefully selected educational conferences are generally defined as the major educational, scientific or policy-making meetings of national, regional, or specialty medical associations.

(7) No gifts should be accepted if there are strings attached. For example, physicians should not accept gifts if they are given in relation to the physicianôs prescribing practices. In addition, when companies underwrite medical conferences or lectures other than their own, responsibility for and control over the selection of content, faculty, educational methods, and materials should belong to the organizers of the conferences or lectures. (II)

Issued June 1992 based on the report "Gifts to Physicians from Industry," adopted December 1990 (JAMA. 1991; 265: 501); Updated June 1996 and June 1998.

Clarification of Opinion 8.061

Scope Opinion 8.061, ñGifts to Physicians from Industry,ò is intended to provide ethical guidance to physicians. Other parties involved in the health care sector, including the pharmaceutical, devices, and medical equipment industries and related entities or business partners, should view the guidelines as indicative of standards of conduct for the medical profession. Ultimately, it is the responsibility of individual physicians to minimize conflicts of interest that may be at odds with the best interest of patients and to access the necessary information to inform medical recommendations.

The guidelines apply to all forms of gifts, whether they are offered in person, through intermediaries, or through the Internet. Similarly, limitations on subsidies for educational activities should apply regardless of the setting in which, or the medium through which, the educational activity is offered.

General Questions (a) Do the guidelines apply only to pharmaceutical, device, and equipment manufacturers?

"Industry" includes all "proprietary health-related entities that might create a conflict of interest."

Guideline 1 Any gifts accepted by physicians individually should primarily entail a benefit to patients and should not be of substantial value. Accordingly, textbooks, modest meals, and other gifts are appropriate if they serve a genuine educational function. Cash payments should not be accepted. The use of drug samples for personal or family use is permissible as long as these practices do not interfere with patient access to drug samples. It would not be acceptable for non-retired physicians to request free pharmaceuticals for personal use or for use by family members.

(a) May physicians accept gram stain test kits, stethoscopes, or other diagnostic equipment?

Diagnostic equipment primarily benefits the patient. Hence, such gifts are permissible as long as they are not of substantial value. In considering the value of the gift, the relevant measure is not the cost to the company of providing the gift. Rather, the relevant measure is the cost to the physician if the physician purchased the gift on the open market.

(b) May companies invite physicians to a dinner with a speaker and donate $100 to a charity or medical school on behalf of the physician?

There are positive aspects to the proposal. The donations would be used for a worthy cause, and the physicians would receive important information about patient care. There is a direct personal benefit to the physician as well, however. An organization that is important to the physician-and one that the physician might have ordinarily felt obligated to make a contribution to-receives financial support as a result of the physicianôs decision to attend the meeting. On balance, physicians should make their own judgment about these inducements. If the charity is predetermined without the physicianôs input, there would seem to be little problem with the arrangement.

(c) May contributions to a professional societyôs general fund be accepted from industry?

The guidelines are designed to deal with gifts from industry which affect, or could appear to affect, the judgment of individual practicing physicians. In general, a professional society should make its own judgment about gifts from industry to the society itself.

(d) When companies invite physicians to a dinner with a speaker, what are the relevant guidelines?

First, the dinner must be a modest meal. Second, the guideline does allow gifts that primarily benefit patients and that are not of substantial value. Accordingly, textbooks and other gifts that primarily benefit patient care and that have a value to the physician in the general range of $100 are permissible. When educational meetings occur in conjunction with a social event such as a meal, the educational component must have independent value, such as a presentation by an authoritative speaker other than a sales representative of the company. Also, the meal should be a

modest one similar to what a physician routinely might have when dining at his or her own expense. In an office or hospital encounter with a company representative, it is permissible to accept a meal of nominal value, such as a sandwich or snack.

(e) May physicians accept vouchers that reimburse them for uncompensated care they have provided?

No. Such a voucher would result directly in increased income for the physician.

(f) May physicians accumulate "points" by attending several educational or promotional meetings and then choose a gift from a catalogue of education options?

This guideline permits gifts only if they are not of substantial value. If accumulation of points would result in physicians receiving a substantial gift by combining insubstantial gifts over a relatively short period of time, it would be inappropriate.

(g) May physicians accept gift certificates for educational materials when attending promotional or educational events?

The Council views gift certificates as a grey area which is not per se prohibited by the guidelines. Medical textbooks are explicitly approved as gifts under the guidelines. A gift certificate for educational materials, ie, for the selection by the physician from an exclusively medical textbook catalogue, would not seem to be materially different. The issue is whether the gift certificate gives the recipient such control as to make the certificate similar to cash. As with charitable donations, preselection by the sponsor removes any question. It is up to the individual physician to make the final judgment.

(h) May physicians accept drug samples or other free pharmaceuticals for personal use or use by family members?

The Councilôs guidelines permit personal or family use of free pharmaceuticals (i) in emergencies and other cases where the immediate use of a drug is indicated, (ii) on a trial basis to assess tolerance, and (iii) for the treatment of acute conditions requiring short courses of inexpensive therapy, as permitted by Opinion 8.19, "Self-Treatment or Treatment of Immediate Family Members." It would not be acceptable for physicians to accept free pharmaceuticals for the long-term treatment of chronic conditions.

(i) May companies invite physicians to a dinner with a speaker and offer them a large number of gifts from which to choose one?

In general, the greater the freedom of choice given to the physician, the more the offer seems like cash. A large number of gifts presented to physicians who attend a dinner would therefore be inappropriate.

There is no precise way of deciding an appropriate upper limit on the amount of choice that is acceptable. However, it is important that a specific limit be chosen to ensure clarity in the guidelines. A limit of eight has been chosen because it permits flexibility but prevents undue freedom of choice. Each of the choices must have a value to the physicians of no more than $100.

(j) May physicians charge for their time with industry representatives or otherwise receive material compensation for participation in a detail visit?

Guideline 1 states that gifts in the form of cash payments should not be accepted. Also, Guideline 6 makes clear that, in the context of the industry-physician relationship, only physicians who provide genuine services may receive reasonable compensation. When considering the time a physician spends with an industry representative, it is the representative who offers a service, namely the presentation of information. The physician is a beneficiary of the service. Overall, these guidelines do not view that physicians should be compensated for the time spent participating in educational activities, nor for time spent receiving detail information from an industry representative.

Guideline 2 Individual gifts of minimal value are permissible as long as the gifts are related to the physicianôs work (eg, pens and notepads).

(a) May physicians, individually or through their practice group, accept electronic equipment, such as hand held devices or computers, intended to facilitate their ability to receive detail information electronically?

Although Guideline 2 recognizes that gifts related to a physicianôs practice may be appropriate, it also makes clear that these gifts must remain of minimal value. It is not appropriate for physicians to accept expensive hardware or software equipment even though one purpose only may pertain to industry-related activities of a modest value.

Guideline 3 The Council on Ethical and Judicial Affairs defines a legitimate "conference" or "meeting" as any activity, held at an appropriate location, where (a) the gathering is primarily dedicated, in both time and effort, to promoting objective scientific and educational activities and discourse (one or more educational presentation(s) should be the highlight of the gathering), and (b) the main incentive for bringing attendees together is to further their knowledge on the topic(s) being presented. An appropriate disclosure of financial support or conflict of interest should be made.

Guideline 4 Subsidies to underwrite the costs of continuing medical education conferences or professional meetings can contribute to the improvement of patient care and therefore are permissible. Since the giving of a subsidy directly to a physician by a companyôs sales representative may create a relationship which could influence the use of the companyôs products, any subsidy should be accepted by the conferenceôs sponsor who in turn can use the money to reduce the conferenceôs registration fee. Payments to defray the costs of a conference should not be accepted directly from the company by the physicians attending the conference.

(a) Are conference subsidies from the educational division of a company covered by the guidelines?

Yes. When the Council says "any subsidy," it would not matter whether the subsidy comes from the sales division, the educational division, or some other section of the company.

(b) May a company or its intermediary send physicians a check or voucher to offset the registration fee at a specific conference or a conference of the physicianôs choice?

Physicians should not directly accept checks or certificates which would be used to offset registration fees. The gift of a reduced registration should be made across the board and through the accredited sponsor.

Guideline 5 Subsidies from industry should not be accepted directly or indirectly to pay for the costs of travel, lodging, or other personal expenses of physicians attending conferences or meetings, nor should subsidies be accepted to compensate for the physiciansô time. Subsidies for hospitality should not be accepted outside of modest meals or social events held as a part of a conference or meeting. It is appropriate for faculty at conferences or meetings to accept reasonable honoraria and to accept reimbursement for reasonable travel, lodging, and meal expenses. It is also appropriate for consultants who provide genuine services to receive reasonable compensation and to accept reimbursement for reasonable travel, lodging, and meal expenses. Token consulting or advisory arrangements cannot be used to justify the compensation of physicians for their time or their travel, lodging, and other out-of-pocket expenses.

(a) If a company invites physicians to visit its facilities for a tour or to become educated about one of its products, may the company pay travel expenses and honoraria?

This question has come up in the context of a rehabilitation facility that wants physicians to know of its existence so that they may refer their patients to the facility. It has also come up in the context of surgical device or equipment manufacturers who want physicians to become familiar with their products.

In general, travel expenses should not be reimbursed, nor should honoraria be paid for the visiting physicianôs time since the presentations are analogous to a pharmaceutical companyôs educational or promotional meetings. The Council recognizes that medical devices, equipment, and other technologies may require, in some circumstances, special evaluation or training in proper usage which can not practicably be provided except on site. Medical specialties are in a better position to advise physicians regarding the appropriateness of reimbursement with regard to these trips. In cases where the company insists on such visits as a means of protection from liability for improper usage, physicians and their specialties should make the judgment. In no case would honoraria be appropriate and any travel expenses should be only those strictly necessary.

(b) If the company invites physicians to visit its facilities for review and comment on a product, to discuss their independent research projects, or to explore the potential for collaborative research, may the company pay travel expenses and an honorarium?

If the physician is providing genuine services, reasonable compensation for time and travel expenses can be given. However, token advisory or consulting arrangements cannot be used to justify compensation.

(c) May a company hold a sweepstakes for physicians in which five entrants receive a trip to the Virgin Islands or airfare to the medical meeting of their choice?

No. The use of a sweepstakes or raffle to deliver a gift does not affect the permissibility of the gift. Since the sweepstakes is not open to the public, the guidelines apply in full force.

(d) If a company convenes a group of physicians to recruit clinical investigators or convenes a group of clinical investigators for a meeting to discuss their results, may the company pay for their travel expenses?

Expenses may be paid if the meetings serve a genuine research purpose. One guide to their propriety would be whether the National Institute of Health (NIH) conducts similar meetings when it sponsors multi-center clinical trials. When travel subsidies are acceptable, the guidelines emphasize that they be used to pay only for "reasonable" expenses. The reasonableness of expenses would depend on a number of considerations. For example, meetings are likely to be problematic if overseas locations are used for exclusively domestic investigators. It would be inappropriate to pay for recreation or entertainment beyond the kind of modest hospitality described in this guideline.

(e) How can a physician tell whether there is a "genuine research purpose?"

A number of factors can be considered. Signs that a genuine research purpose exists include the facts that there are (1) a valid study protocol, (2) recruitment of physicians with appropriate

qualifications or expertise, and (3) recruitment of an appropriate number of physicians in light of the number of study participants needed for statistical evaluation.

(f) May a company compensate physicians for their time and travel expenses when they participate in focus groups?

Yes. As long as the focus groups serve a genuine and exclusive research purpose and are not used for promotional purposes, physicians may be compensated for time and travel expenses. The number of physicians used in a particular focus group or in multiple focus groups should be an appropriate size to accomplish the research purpose, but no larger.

(g) Do the restrictions on travel, lodging, and meals apply to educational programs run by medical schools, professional societies, or other accredited organizations which are funded by industry, or do they apply only to programs developed and run by industry?

The restrictions apply to all conferences or meetings which are funded by industry. The Council drew no distinction on the basis of the organizer of the conference or meeting. The Council felt that the gift of travel expenses is too substantial even when the conference is run by a non-industry sponsor. (Industry includes all "proprietary health-related entities that might create a conflict of interest.")

(h) May company funds be used for travel expenses and honoraria for bona fide faculty at educational meetings?

This guideline draws a distinction between attendees and faculty. As was stated, "[i]t is appropriate for faculty at conferences or meetings to accept reasonable honoraria and to accept reimbursement for reasonable travel, lodging, and meal expenses."

Companies need to be mindful of the guidelines of the Accreditation Council on Continuing Medical Education. According to those guidelines, "[f]unds from a commercial source should be in the form of an educational grant made payable to the CME sponsor for the support of programming."

(i) May travel expenses be reimbursed for physicians presenting a poster or a "free paper" at a scientific conference?

Reimbursement may be accepted only by bona fide faculty. The presentation of a poster or a free paper does not by itself qualify a person as a member of the conference faculty for purposes of these guidelines.

(j) When a professional association schedules a long-range planning meeting, is it appropriate for industry to subsidize the travel expenses of the meeting participants?

The guidelines are designed to deal with gifts from industry which affect, or could appear to affect, the judgment of individual practicing physicians. In general, a professional society should make its own judgment about gifts from industry to the society itself.

(k) May continuing medical education conferences be held in the Bahamas, Europe, or South America?

There are no restrictions on the location of conferences as long as the attendees are paying their own travel expenses.

(l) May travel expenses be accepted by physicians who are being trained as speakers or faculty for educational conferences and meetings?

In general, no. If a physician is presenting as an independent expert at a CME event, both the training and its reimbursement raise questions about independence. In addition, the training is a gift because the physicianôs role is generally more analogous to that of an attendee than a participant. Speaker training sessions can be distinguished from meetings (See 5d) with leading researchers, sponsored by a company, designed primarily for an exchange of information about important developments or treatments, including the sponsorôs own research, for which reimbursement for travel may be appropriate.

(m) What kinds of social events during conferences and meetings may be subsidized by industry?

Social events should satisfy three criteria. First, the value of the event to the physician should be modest. Second, the event should facilitate discussion among attendees and/or discussion between attendees and faculty. Third, the educational part of the conference should account for a substantial majority of the total time accounted for by the educational activities and social events together. Events that would be viewed (as in the succeeding question) as lavish or expensive should be avoided. But modest social activities that are not elaborate or unusual are permissible, eg, inexpensive boat rides, barbecues, entertainment that draws on the local performers. In general, any such events which are a part of the conference program should be open to all registrants.

(n) May a company rent an expensive entertainment complex for a evening during a medical conference and invite the physicians attending the conference?

No. The guidelines permit only modest hospitality.

(o) If physicians attending a conference engage in interactive exchange, may their travel expenses be paid by industry?

No. Mere interactive exchange would not constitute genuine consulting services.

(p) If a company schedules a conference and provides meals for the attendees that fall within the guidelines, may the company also pay for the costs of the meals for spouses?

If a meal falls within the guidelines, then the physicianôs spouse may be included.

(q) May companies donate funds to sponsor a professional societyôs charity golf tournament?

Yes. But it is sensible if physicians who play in the tournament make some contribution themselves to the event.

(r) If a company invites a group of consultants to a meeting and a consultant brings a spouse, may the company pay the costs of lodging or meals of the spouse? Does it matter if the meal is part of the program for the consultants?

Since the costs of having a spouse share a hotel room or join a modest meal are nominal, it is permissible for the company to subsidize those costs. However, if the total subsidies become substantial, then they become unacceptable.

Guideline 6 Scholarship or other special funds to permit medical students, residents, and fellows to attend carefully selected educational conferences may be permissible as long as the selection of students, residents, or fellows who will receive the funds is made by the academic or training institution. Carefully selected educational conferences are generally defined as the major educational, scientific, or policy-making meetings of national, regional, or specialty medical associations.

(a) When a company subsidizes the travel expenses of residents to an appropriately selected conference, may the residents receive the subsidy directly from the company?

Funds for scholarships or other special funds should be given to the academic departments or the accredited sponsor of the conference. The disbursement of funds can then be made by the departments or the conference sponsor.

(b) What is meant by "carefully selected educational conferences?"

The intent of Guideline 6 is to ensure that financial hardship does not prevent students, residents, and fellows from attending major educational conferences. For example, we did not want to deny cardiology fellows the opportunity to attend the annual scientific meeting of the American College of Cardiology or orthopedic surgery residents the opportunity to attend the annual scientific meeting of the American Academy of Orthopedic Surgeons. However, it was not the

intent of the guideline to permit reimbursement of travel expenses in other circumstances, such as when conferences or symposia are designed specifically for students, residents, or fellows.

Funds are limited to travel and lodging expenses for attendance at major educational, scientific, or policy-making meetings of national, regional, or specialty medical associations.

Guideline 7 No gifts should be accepted if there are strings attached. For example, physicians should not accept gifts if they are given in relation to the physicianôs prescribing practices. In addition, when companies underwrite medical conferences or lectures other than their own, responsibility for and control over the selection of content, faculty, educational methods, and materials should belong to the organizers of the conferences or lectures.

(a) May companies send their top prescribers, purchasers, or referrers on cruises?

No. There can be no link between prescribing or referring patterns and gifts. In addition, travel expenses, including cruises, are not permissible.

(b) May the funding company itself develop the complete educational program that is sponsored by an accredited continuing medical education sponsor?

No. The funding company may finance the development of the program through its grant to the sponsor, but the accredited sponsor must have responsibility and control over the content and faculty of conferences, meetings, or lectures. Neither the funding company nor an independent consulting firm should develop the complete educational program for approval by the accredited sponsor.

(c) How much input may a funding company have in the development of a conference, meeting, or lectures?

The guidelines of the Accreditation Council on Continuing Medical Education on commercial support of continuing medical education address this question.

Issued 1992. Updated December 2000, June 2002, and June 2004 (Food and Drug Law Journal, 2001;56(1):27-40).

POLICY STATEMENT

Global Climate Change and Children's Health

Organizational Principles to Guide and Define the Child Health Care System and/or Improve the Health of All Children

Committee on Environmental Health

ABSTRACT

There is broad scientific consensus that Earth's climate is warming rapidly and at an accelerating rate. Human activities, primarily the burning of fossil fuels, are very likely (>90% probability) to be the main cause of this warming. Climate-sensitive changes in ecosystems are already being observed, and fundamental, potentially irreversible, ecological changes may occur in the coming decades. Conservative environmental estimates of the impact of climate changes that are already in process indicate that they will result in numerous health effects to children. The nature and extent of these changes will be greatly affected by actions taken or not taken now at the global level.

Physicians have written on the projected effects of climate change on public health, but little has been written specifically on anticipated effects of climate change on children's health. Children represent a particularly vulnerable group that is likely to suffer disproportionately from both direct and indirect adverse health effects of climate change. Pediatric health care professionals should understand these threats, anticipate their effects on children's health, and participate as children's advocates for strong mitigation and adaptation strategies now. Any solutions that address climate change must be developed within the context of overall sustainability (the use of resources by the current generation to meet current needs while ensuring that future generations will be able to meet their needs). Pediatric health care professionals can be leaders in a move away from a traditional focus on disease prevention to a broad, integrated focus on sustainability as synonymous with health.

This policy statement is supported by a technical report that examines in some depth the nature of the problem of climate change, likely effects on children's health as a result of climate change, and the critical importance of responding promptly and aggressively to reduce activities that are contributing to this change.

BACKGROUND

"Warming of the climate system is unequivocal."[1] According to the National Climatic Data Center, all records indicate that during the past century, global surface temperatures have increased at a rate near 0.6°C per century (1.1°F per century); this trend has been 3 times larger since 1976.[2] Human activity, particularly the burning of fossil fuels, has very likely (>90% probability) driven this rise by greatly increasing atmospheric concentrations of carbon dioxide (CO_2) and other greenhouse gases (GHGs).[1]

There is strong consensus among expert scientists that Earth is undergoing rapid, global climate change,[1,3] although there remains uncertainty about how rapidly and extensively the climate will change in the future. Overall scientific predictions agree, however, that temperatures and sea level will continue to rise

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

throughout the 21st century.[1,4] Even if GHG emissions were abruptly reduced to zero, the planet would continue to warm for decades until the energy stored in the system equilibrates.[5] The possibility of reaching a tipping point at which abrupt, large, and irreversible change could be superimposed on current trends adds both urgency and further ambiguity to the situation.[6] Current human activities are accelerating these changes, and future human activities will affect their trajectories; the window of opportunity for successful mitigation, therefore, may be very short.[7] Actions made in the coming decade will have a profound effect on global health and, in particular, on children's health.

DIRECT EFFECTS OF CLIMATE CHANGE ON CHILDREN'S HEALTH

Because of their physical, physiologic, and cognitive immaturity, children are often most vulnerable to adverse health effects from environmental hazards.[8] As the climate changes, environmental hazards may shift and possibly increase (Fig 1), and children are likely to suffer disproportionately from these changes.[9] Anticipated direct health consequences of climate change include injury and death from extreme weather events and natural disasters, increases in climate-sensitive infectious diseases, increases in air pollution–related illness, and more heat-related, potentially fatal, illness. Within all of these categories, children have increased vulnerability compared with other groups (see the accompanying technical report[10]).

INDIRECT EFFECTS OF CLIMATE CHANGE AND IMPLICATIONS FOR FUTURE GENERATIONS

Additional effects of climate change, with profound implications for the health and welfare of future generations of children, are anticipated. Food availability could be reduced as land and ocean food productivity patterns shift and species diversity declines.[11] Water availability will change and become too abundant in some regions (flooding) and much reduced in others (drought).[12] Coastal populations will be forced to move because of the rising sea level. Large-scale, forced migrations are conceivable, driven by abrupt climate change, natural disaster, or political instability over resource availability.[13]

The speed with which global GHG emissions can be reduced will have a significant effect on the rate and degree of warming, but even the most optimistic scenarios describe continued warming into the next century.[1,5] As climate change progresses, social and political institutions must respond with aggressive mitigation and flexible adaptation strategies to preserve and protect public health, particularly for children.

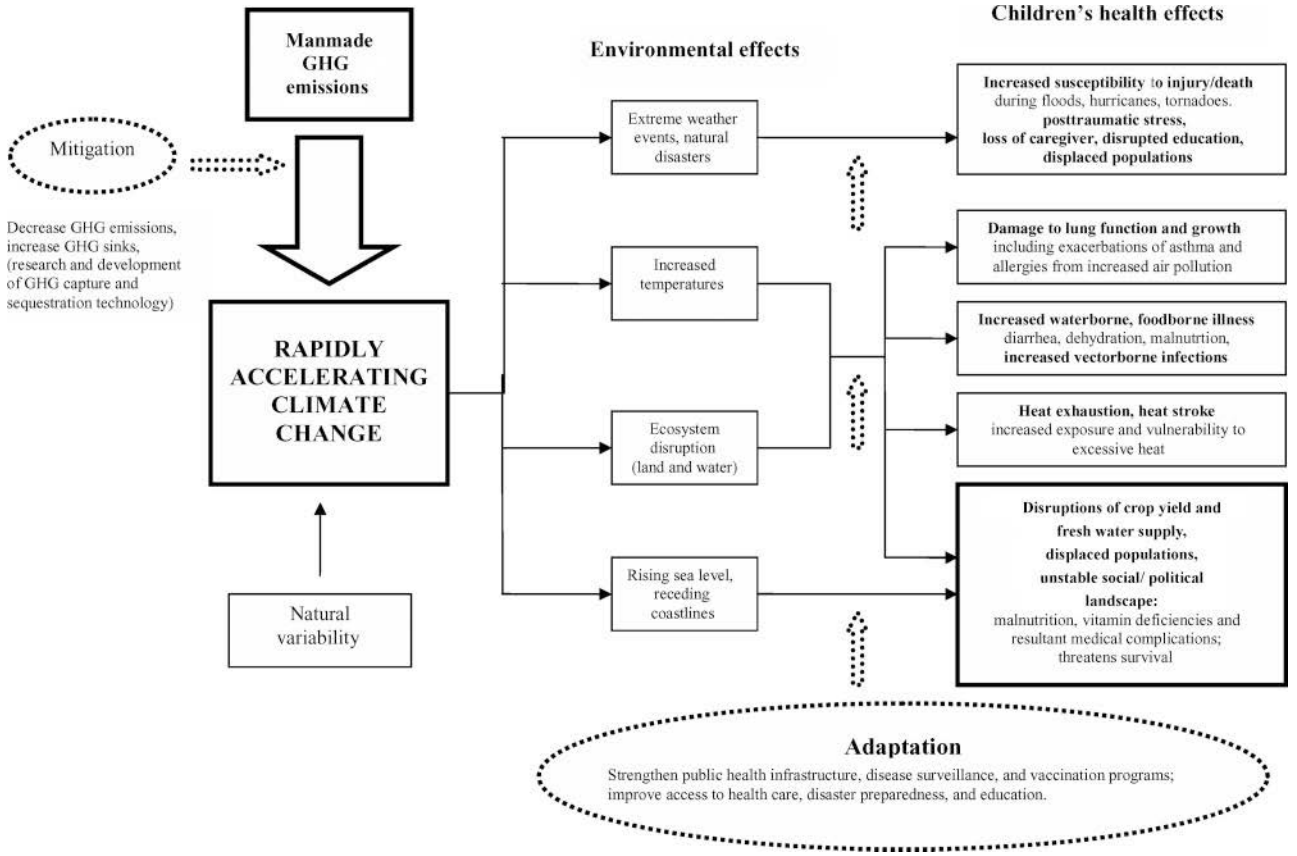

FIGURE 1
Potential effects of global climate change on child health. (Adapted from McMichael et al[18] and Haines and Patz[19].)

MITIGATION AND ADAPTATION STRATEGIES

Strategies to address the effects of climate change (mitigation and adaptation) are concepts that focus on both primary and secondary prevention strategies in pediatric health care (Fig 1). Mitigation (primary prevention) involves reducing GHG concentrations in the atmosphere with the goal of reducing climate change. Adaptation (secondary prevention) involves developing public health strategies to minimize and, in some cases, eliminate local and regional adverse health outcomes that are anticipated from climate change.

A wide variety of governmental and nongovernmental organizations have developed detailed lists of mitigation and adaptation strategies, from international conventions such as the Kyoto Protocol[14] to individual actions such as reducing automobile use.[15]

However, any solutions that address climate change must be developed within the context of overall sustainable development (the use of resources by the current generation to meet current needs while ensuring that future generations will be able to meet their needs). Given the health implications of climate change for current and future generations of children, the disease-prevention role for pediatric health care professionals includes advocating for environmental sustainability.

RECOMMENDATIONS TO PEDIATRICIANS

Pediatricians are dedicated to the promotion and protection of children's health. Climate change threatens the health, welfare, and future of current and subsequent generations of children. Pediatricians can incorporate considerations of the effects of climate change on health into their professional practice and personal lives in many ways, including patient education, lifestyle practices, and political advocacy. Some possible approaches might include the following.

1. Recognize and educate yourself about the links between child health and climate change. Existing anticipatory guidance already incorporates many issues that can help mitigate climate change. For example, encouraging families and children to walk or ride bicycles more may reduce automobile emissions.
2. Advocate for comprehensive local and national policies that address climate change to improve the health of children now and in the future. Educate elected officials on the health risks to children from climate change; write letters to the editor, attend public meetings, or provide expert testimony. Work with local schools, child care centers, community organizations, and businesses on projects that will help reduce GHGs. Support policies to expand parks and green spaces, strengthen public transport, improve sidewalks and bicycle lanes, and create local award systems for energy-efficient businesses, buildings, organizations, and households.
3. Serve as a role model for practices that promote environmental sustainability. Emphasize energy conservation in your workplace, encourage and model reduced dependency on automobile travel, and consider the environmental and energy costs when making major purchases for your practice or institution.
4. Help to build and support coalitions across disciplines and institutions to search for novel, comprehensive approaches to mitigate and adapt to climate change in your community and region. Work with local and state health departments to strengthen public health infrastructure, disease surveillance and reporting, and disaster preparedness.
5. Work to ensure that concepts related to the pediatric health implications of climate change are part of pediatric training and curricula.

RECOMMENDATIONS TO GOVERNMENT

Government at all levels, from the smallest municipalities to the national and international levels, should implement aggressive policies to halt man-made contributions to climate change and to mitigate its impact on children's health.

1. Develop aggressive, long-term policies to reduce the major contributing factors to global climate change.
2. Invest in prudent and vital preparations for our public health care systems, including immunization programs and disease surveillance, reporting, and tracking.
3. Give specific attention to the needs of children in emergency management and disaster response.[13,16]
4. Support education and public awareness of the threats from climate change and their implications for public and children's health now and in the future.
5. Fund interdisciplinary research to develop, implement, and measure outcomes of innovative strategies to both mitigate and adapt to climate change, particularly in areas with direct implications for children's health.

TECHNICAL REPORT

Global Climate Change and Children's Health

Katherine M. Shea, MD, MPH, and the Committee on Environmental Health

ABSTRACT

There is a broad scientific consensus that the global climate is warming, the process is accelerating, and that human activities are very likely (>90% probability) the main cause. This warming will have effects on ecosystems and human health, many of them adverse. Children will experience both the direct and indirect effects of climate change. Actions taken by individuals, communities, businesses, and governments will affect the magnitude and rate of global climate change and resultant health impacts. This technical report reviews the nature of the global problem and anticipated health effects on children and supports the recommendations in the accompanying policy statement on climate change and children's health.

INTRODUCTION

Scientists[1] and governments[2] concur that Earth is warming; rapid global climate change is underway, and human activities are very likely (>90% probability) the main cause. Adverse human health and ecosystem consequences are anticipated,[3] and some are already being measured. Physicians have written on the projected effects of climate change on public health,[4,5] but little has been written specifically about anticipated effects of climate change on children's health.[6]

Children represent a particularly vulnerable group that is likely to suffer disproportionately from both direct and indirect adverse health effects of climate change.[7] Pediatric health care professionals must understand the escalating nature of these threats, anticipate their effects on children's health, and participate as children's advocates for strong mitigation and adaptation strategies now and at all levels, from local to global.[8] This technical report examines both direct and indirect threats to children's health and futures related to climate change.*

NATURE OF THE GLOBAL PROBLEM

"Warming of the climate system is unequivocal, as is now evident from observations of increases in global average air and ocean temperature, widespread melting of snow and ice, and rising global mean sea level."[1] According to the National Climatic Data Center, all records indicate that during the past century, global surface temperatures have increased at a rate near 0.6°C per century (1.1°F per century), but the trend has been 3 times larger since 1976.[9] The results of this warming on regional climate are not uniform. In general, land-surface temperatures are increasing faster than sea-surface temperatures.[9] The climate in latitudes between 40°N and 70°N is warming more quickly than that in lower latitudes, and some areas (eg, the southeastern United States) are actually cooling. Changes in precipitation that occur with climate change

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

are also nonuniform.[10] Since 1900, precipitation has increased 5% globally, but it has increased 0.5% to 1% per decade in northern midlatitudes and decreased 0.3% per decade in subtropical latitudes.[11] In contrast, snowfall in the northern hemisphere has decreased by 10% since 1966.[11]

Examples of the effects of climate change have been widely reported.[11] Glaciers are in rapid retreat, and Arctic sea ice is melting.[12] As a result of thermal expansion, sea level has increased 1 to 2 mm/year over the past 100 years.[11] Oceans are acidifying as atmospheric carbon dioxide (CO_2) is absorbed by the marine buffer system.[13] Ecosystems and individual species are being affected in a variety of ways.[14] Changes in temperature affect the density and range of species; natural history traits such as migration, flowering, and egg laying; morphology such as body size and behavior; and genetic frequency shifts. In an analysis of 143 studies that span decades of observation,[15] more than 80% of 1468 species (mollusks to mammals and grasses to trees) are currently showing significant changes in temperature-sensitive species traits.

There is strong consensus among expert scientists that Earth is undergoing rapid, global climate change,[1,16] although there remains uncertainty about how rapidly and extensively the climate will change in the future. Given the range of possibilities, the Intergovernmental Panel on Climate Change has developed a suite of scenarios for different levels of mitigation and adaptation in response to anthropogenic (man-made) global climate change; all their cases predict that temperatures and sea level will continue to rise throughout the 21st century.[17] Recent analyses describe thermal inertia in Earth's climate system such that even if greenhouse gas (GHG) emissions were abruptly reduced to zero, the planet would continue to warm for decades until the energy stored in the system equilibrates.[18] The possibility of reaching a tipping point at which abrupt, large, and irreversible change could be superimposed on current trends adds both urgency and further ambiguity to the situation.[19] In this context, it is critical to understand that current human activities are accelerating climate change and that future human activities will affect their trajectories.[20]

ANTHROPOGENIC CAUSES OF THE CHANGE

The greenhouse effect is necessary to life on Earth as we know it (Fig 1). Without heat-trapping GHGs such as water vapor, CO_2, and other natural components of the atmosphere, Earth would be a lifeless, frozen planet (average temperature: −18°C) instead of the diverse biosphere we know today.[11] Since the onset of the industrial age, however, human activity has dramatically enhanced the greenhouse effect by rapidly adding large amounts of GHGs to the atmosphere (Table 1 [note that the United States leads total country and per-capita emissions]). Three GHGs, CO_2, methane, and nitrous oxide, are responsible for approximately 88% of the anthropogenic influences that enhance the greenhouse effect and have increased 35%, 155%, and 18%, respectively, since 1750 (the beginning of the industrial era).[21] Rates of increase in GHGs are accelerating, up 20% since 1990.

CO_2 is the most important GHG and is responsible for more than 60% of human-enhanced increases and more than 90% of rapid increase in the past decade.[21] Most CO_2 emissions are from the burning of fossil fuels such as coal, oil, and gas. Rising CO_2 is also related, to a lesser extent, to deforestation, which eliminates an important carbon sink (carbon sinks are reservoirs that absorb or take up released carbon from another part of the carbon cycle; the 4 major sinks on the planet are the atmo-

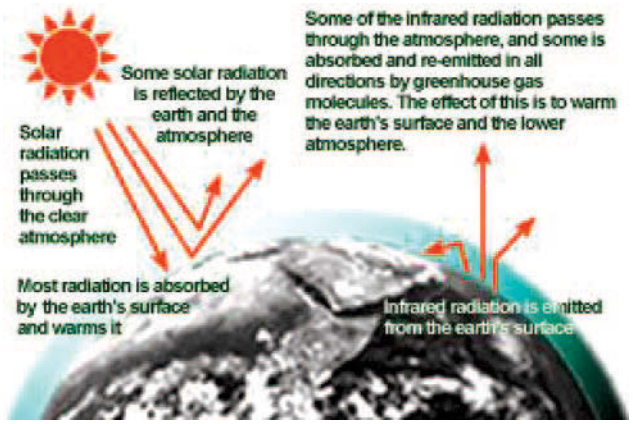

FIGURE 1
The greenhouse effect. Energy from the sun drives Earth's weather and climate and heats its surface; in turn, the earth radiates energy back into space. Atmospheric greenhouse gases (water vapor, CO_2, and other gases) trap some of the outgoing energy, retaining heat somewhat like the glass panels of a greenhouse. Without this natural "greenhouse effect," temperatures would be much lower than they are now, and life as known today would not be possible. Instead, thanks to GHGs, Earth's average temperature is a more hospitable 60°F. However, problems may arise when the atmospheric concentration of GHGs increases. (Source: US Environmental Protection Agency [http://yosemite.epa.gov/oar/globalwarming.nsf/content/climate.html].)

sphere, the terrestrial biosphere [eg, trees and freshwater systems], oceans, and sediments).[21] Currently, the atmosphere contains approximately 370 ppm of CO_2, which is the highest concentration in 420 000 years and perhaps as long as 2 million years.[11] Estimates of CO_2 concentrations at the end of the 21st century range from 490 to 1260 ppm, or a 75% to 350% increase above preindustrial concentrations.[11]

The importance of the magnitude of GHG emissions is linked to the rate of release. In the distant geologic past, similar concentrations of atmospheric CO_2 have occurred, but they accumulated over a 10 000-year period, allowing for the slow, global biogeochemical cycles to adjust to the increases. Current emissions are being added to the atmosphere at 300 times this rate.[11] This confluence of speed and quantity of emissions has created the current, unprecedented rapid climate change.

CLIMATE CHANGE–ASSOCIATED HEALTH EFFECTS ON CHILDREN

Human health is affected by the condition of the physical environment.[22] Because of their physical, physiologic, and cognitive immaturity, children are often most vulnerable to adverse health effects from environmental hazards.[23] As the climate changes, environmental hazards will change and often increase, and children are likely to suffer disproportionately from these changes.[8] Anticipated health threats from climate change include extreme weather events and weather disasters, increases in certain infectious diseases, air pollution, and thermal stress. Within all of these categories, children have increased vulnerability compared with other groups. These direct health threats are discussed in this section, with an emphasis on children in the United States.[24] Indirect threats are discussed briefly in "Long-term and Indirect Climate Change-Associated Health Threats to Children" below.

Extreme Weather Events and Weather Disasters

The Intergovernmental Panel on Climate Change predicts that it is "likely" or "extremely likely" that climate change will cause increased frequency and intensity of extreme weather events and weather disasters.[25] Often, these events are categorized as floods, storms, and droughts. Floods represented 43% of weather-related disasters between 1992 and 2001 and are the most frequent weather-related disaster. Although less prevalent, droughts and their associated famines are the most deadly weather-related disasters.[3] Developed countries such as the United States have systematically increased the risk to populations from flood events by developing coastlines and flood plains. In the United States, hurricanes and tornadoes may be the most dramatic and visible weather disasters. Evidence suggests that the frequency of category 4 and 5 hurricanes has increased over the past 30 years, but the observation period is still too short to attribute this change to increased sea-surface temperature and climate change with high confidence.[26]

The health consequences associated with extreme weather events include death, injury, increases in infectious diseases, and posttraumatic mental health and behavior problems.[27] Few studies have specifically examined such consequences in children. Globally, 66.5 million children annually were affected by disasters between 1990 and 2000.[28] Children everywhere are at risk of injury and death from storms and floods.[29] In the developed world, infectious disease outbreaks follow natural disasters when sanitation, sewage treatment, and water-purification plants become damaged or overwhelmed, refrigeration and cooking facilities are disrupted, and people are unusually crowded in temporary shelter. These outbreaks are usually mild and well controlled, which is in contrast to the aftermath of similar catastrophes in developing nations, where disease outbreaks can be deadly.[24] Mosquito-borne and other vector-borne illnesses may also be increased when storms or floods create large amounts of standing water suitable for breeding. Mental and emotional distress documented for children and adolescents after weather disasters include posttraumatic stress disorder and high rates of sleep disturbance, aggressive behavior, sadness, and substance use/abuse.[29] Some studies have suggested that children have more persistent symptoms than adults who experience the same disaster,[30] but more studies specific to children's experience are required.[31] Community support services[32] and early therapeutic intervention and postdisaster counseling[33,34] can significantly reduce the medium- and long-term mental health burden on children. Experiences with Hurricane Katrina demonstrated the difficulties with tracking children's whereabouts, keeping children and caregivers together, and special needs of hospitalized infants and children during and after major natural disasters.[35]

Infectious Diseases

Globally, infectious diarrhea is the second-leading cause of death in young children; water-borne gastroenteritis is projected to increase under conditions of global warming. Currently, the World Health Organization estimates that, approximately 1.62 million children younger than 5 years die of diarrhea annually, and most cases are attributable to contaminated water.[36] Although children in developed countries are unlikely to die of water-borne infections, they may suffer illness that is attributable indirectly to climate change. Events associated with El Nino serve as a model for global warming by altering weather for periods of several years in the direction of a hotter climate. During El Nino events, rates of hospitalizations of children for diarrhea increase.[37] (In 1 study, the rate of hospitalizations of children for diarrhea increased 8% per degree centigrade of temperature increase.[38]) Water-borne disease outbreaks in the United

States exhibit a positive correlation with excess precipitation events, which are likely to increase with climate change; over a 45-year period, 68% of water-borne illness outbreaks have been associated with precipitation above the 80th percentile.[39] Foodborne illness correlates positively with ambient temperature and is also likely to increase as the climate warms.[37,40,41]

Vector-borne infections are affected by climate change.[42] Both the hosts (eg, rodents, insects, snails) and the pathogens (eg, bacteria, viruses, parasites) can be sensitive to climatic variables such as temperature, humidity, and rainfall. The ability to predict disease rates related to climate change is complicated by a large number of additional variables such as topography, land use, urbanization, human population distribution, level of economic development, and public health infrastructure.[43] There is no easy formula that predicts climate change–related infection risk with confidence.

Malaria is a climate-sensitive vector-borne illness to which children are particularly vulnerable. According to the World Health Organization, malaria currently causes 350 million to 500 million illnesses annually and more than 1 million deaths.[44] Because they lack specific immunity, children experience disproportionately high levels of both morbidity and mortality from malaria; 75% of malaria deaths occur in children younger than 5 years. The young are also more susceptible to cerebral malaria, which can lead to lifelong neurologic damage in those who survive. In areas of sub-Saharan Africa, the death rate from malaria in children 0 to 4 years of age is 9.4 in 1000 vs 0.13 in 1000 in those older than 14 years.[45] More than 3 billion people live in malaria-prone areas today. Climate change is expanding the range of host mosquitoes to higher altitudes and higher latitudes, and warmer temperatures speed the development of the parasite within the host vector.[46] Small children will be most affected by the expansion of malaria zones and the success or failure of societal response to this change.

Three vector-borne diseases that affect the United States illustrate ways in which climate change can enhance disease burden: West Nile virus infection, Lyme disease, and hantavirus pulmonary syndrome.

West Nile virus infection was first reported in the United States in New York in 1999. Although it is still not known how it entered the United States, once introduced, it spread rapidly. A series of warm winters failed to kill the mosquito vectors. Warmer summers amplified the life cycle of the mosquitoes and increased the viral load. Drought and rain cycles, particularly as they affected urban landscapes, increased the contact of the bridging mosquito vectors with birds and humans.[46] Human populations with no herd immunity were highly susceptible to infection. In 1999, there were 62 human cases of West Nile virus infection, all reported from New York state. In 2003, there were 9862 human cases reported from 45 states and the District of Columbia.[47] Although this infection is primarily of concern for the elderly rather than children, the rapid spread illustrates the challenge of infection control in a warming climate.

The prevalence of Lyme disease has been increasing in the United States since it became a reportable disease in 1992.[48] The geographic distribution of *Ixodes* species ticks, the vectors for this bacterial infection, is expanding as well. Researchers in Sweden have documented a correlation between the expanding range for *Ixodes* ticks and climate change.[49] Children 5 to 14 years of age and adults 50 to 59 years of age are most likely to contract the illness. Lyme disease, although rarely fatal, occasionally causes long-term morbidity and represents another example of a disease that is likely to increase further as the climate warms.

Finally, the 1993 outbreak of hantavirus pulmonary syndrome in the southwest United States has been linked to the El Nino conditions of 1991–1992, with increased rainfall and pine nut production, which favored population growth among rodent vectors.[50] With a case fatality rate of 36%,[51] it is of concern that warmer climates may enhance vector populations further. As with most infectious diseases, human adaptations can reduce exposure risk and disease burden.[52]

Ambient Air Pollution

Air pollution is well established as a short-term contributor to hospital use[53] and premature death. Air pollutants such as fine particulates, nitrogen oxides, sulfur oxides, and ozone are likely to increase as countries adapt to hotter temperatures by using more energy to drive air conditioning and fans. The anticipated global population of 9 billion by 2050 will also be associated with increased energy demands, which, if met by burning more fossil fuels, will exacerbate both ambient air pollution and GHG emissions.[54] Children are especially vulnerable to both short-term illness and long-term damage from ambient air pollution, because their lungs are developing and growing, they breathe at a higher rate than adults, and they spend more time outdoors engaging in vigorous physical activity.[55] Air pollution (such as ozone and particulate matter) causes respiratory and asthma hospitalizations, school absences, increased respiratory symptoms, and decrements in lung function.[55] Formation of ozone, in particular, is known to increase with increasing temperature, even without increases in the precursor primary pollutants (volatile organic hydrocarbons and oxides of nitrogen).[56] Children who are active in outdoor sports in communities with high ozone are at increased risk of developing asthma.[57] In addition, high levels of particulate matter and other copollutants affect the ability of children's lungs to grow regardless of history of asthma.[58] Rates of preterm births, low birth weight, and infant mortality are increased in

communities with high levels of particulate air pollution.[55]

A second change that is being observed is the temperature-related increases in pollen production and other aeroallergens in some regions and some cities. Increased temperature causes increases in amounts of pollens produced by some plants[59] and can also affect spatial distribution and density of plants, fungi, and molds that produce aeroallergens.[60] To the extent that exposure to aeroallergens contributes to the incidence, prevalence, and severity of asthma, atopy, and other respiratory disease, climate change will affect the pattern of disease in children. Some investigators have argued that part of the current global increase in childhood asthma can be explained by increased exposure to aeroallergens driven by climate change.[61]

Thermal Stress

For all organisms, there exists a range of ideal temperature above and below which mortality increases. Humans are no exception, although temperature-mortality relationships vary significantly by latitude, climatic zone, and level of socioeconomic development.[3] As ambient temperatures increase, the frequency of heat waves will increase. It is expected that there will be fewer cold-related deaths in a warmer world,[62] but whether this will offset the expected increase in heat-related deaths is unknown. Populations that live in temperate climates, such as in the United States and Europe, are likely to be hard hit initially, because global warming is most dramatic in these latitudes and there has been little time for populations to acclimatize to changes in temperature. Observations on heat and mortality have been reported for decades[63] and have gained recent attention with the heat waves of 2003 in Europe[64] and of 2006 in Europe and North America.[63,65] Heat-related deaths and hospitalizations are most common in the elderly, especially if they are ill.[66,67] One study has found that infants and young children may represent a second, albeit smaller, higher-risk group,[68] but effects on children have not been studied adequately. In addition, children spend more time outside, especially playing sports in the heat of the afternoon, which puts them at increased risk of heat stroke and heat exhaustion.[69] Increased outdoor time during hot weather may also put children at increased risk of UV radiation–related skin damage, including basal cell carcinoma and malignant melanoma.[70] Some data indicate that heat-related mortality in the United States has decreased in recent years, in part associated with increasing percentage of homes with air conditioners.[71] It is currently unknown how effective adaptation and acclimatization will be in preventing excess heat-related deaths and illness.[72,73]

LONG-TERM AND INDIRECT CLIMATE CHANGE-ASSOCIATED HEALTH THREATS TO CHILDREN

Long-term and indirect effects on children's health from climate change will depend on how the climate continues to change over the next decades and what sorts of mitigation and adaptation strategies are adopted now.[17] How quickly and comprehensively GHG emissions can be stabilized and then reduced will have a significant effect on the rate and degree of warming, but even the most optimistic scenarios describe continued warming through the end of this century.[17] Food availability may be affected as land and ocean food-productivity patterns shift.[74] Water availability may change and become much reduced in some regions, including during summer in the snow run-off–dependent American west coast.[75] Coastal populations will be forced to move because of rises in sea level, and massive forced migrations, driven by abrupt climate change, natural disaster, or political instability over resource availability, are conceivable.[24] In addition, world population is expected to grow by 50% to 9 billion by 2050, which would place additional stress on ecosystem services and increase the demand for energy, fresh water, and food.[54] As these changes evolve, social and political institutions will need to respond with aggressive mitigation strategies and flexible adaptation strategies to preserve and protect public health, particularly for children.

MITIGATION AND ADAPTATION STRATEGIES

Strategies to address the effects of climate change, known as mitigation and adaptation, are concepts that parallel the focus on both primary and secondary prevention strategies in pediatric health care. These strategies are discussed briefly here. The prevention or minimization of the effects of climate change on children's health is beyond the control of an individual pediatrician. Yet, pediatricians can play important public roles as advocates by individual example and through community participation, political involvement, or collective advocacy at the local, state, and national levels.[76,77]

Broadly, mitigation policies (Table 2) for reduction of atmospheric GHG include reducing emissions through energy efficiency and use of renewable energy sources, increasing carbon sinks by forest preservation and reforestation, and development of GHG-capture and -sequestration technologies (carbon sequestration is the fixation of atmospheric CO_2 in a carbon sink through an active process). Adaptation involves developing public health strategies to minimize adverse health outcomes that are anticipated from climate change. These strategies include improved disease surveillance and reporting, improved weather forecasting and early warning systems, advanced emergency management and disaster-preparedness programs, development and dissemination of appropriate vaccines and medicines, and public health education and preparedness. Category-specific examples

TABLE 2 **Some Examples of Mitigation Strategies**

	International	National and State	Community	Business, Nonprofits, Professional Societies	Individuals
Reduce emissions and increase use of renewable energy sources	Impose carbon-emissions caps by treaty	Create GHG inventory	LEED certification of public buildings	Energy audit of office and work toward LEED certification[a]	Drive less, use public transport, carpool
	Support clean, renewable technologies in developing countries	Impose carbon-emissions caps at national and/or state level	Energy audits and renovations for all public buildings	Reward carpoolers or employees who use public transport or walk/bike to work	Use vehicles that get the highest gas mileage
	Support research, development, and use of clean, renewable fuels	Increase solar, wind, energy-efficient biofuels, and other renewable energy sources	Efficient lighting in public spaces	Promote energy conservation	Perform energy audit of home or business and make associated changes
	Promote energy conservation	Invest in research, development, and use of clean, renewable fuels	Reward businesses and home owners for energy efficiency	Buy Energy Star office equipment	Buy Energy Star appliances
		Raise corporate average fuel efficiency standards for vehicles	Maximize public transport, ticket idling cars, tax individual parking spaces, create bike lanes, and enforce high-occupancy vehicle lanes	Support telecommuting and flexible hours	Buy local foods
		Promote energy conservation	Develop sustainability awards	Video and teleconference meetings	Engage in energy-conservation efforts
		Augment public transportation options	Promote energy conservation	Consider buying carbon offsets for travel to meetings[b]	Switch to compact fluorescent bulbs
Increase (protect) sinks	Arrest deforestation	Identify, protect, and restore carbon sinks	Plant trees	Increase green space	Plant trees and shrubs
	Restore forests and wilderness	Protect national forests and wilderness areas	Reward construction of green roofs	Add plants and trees in parking areas	Support parks and greenways
			Build parks and green space		
Carbon trapping and sequestration	Support research and development	Support research and development	Support research and development	Support research and development	Support through personal investments

This information here is not exhaustive. Many strategies have been proposed and overlap among sectors. Additional information can be found at www.grida.no/climate/ipcc_tar/wg3/index.htm, http://epa.gov/climatechange/wycd/index.html, and www.princeton.edu/~cmi.

LEED indicates Leadership in Energy and Environmental Design.

[a] The LEED Green Building Rating System is a nationally accepted benchmark for the design, construction, and operation of high-performance green buildings. LEED gives building owners and operators the tools they need to have an immediate and measurable impact on their building's performance. LEED promotes a whole-building approach to sustainability by recognizing performance in 5 key areas of human and environmental health: sustainable site development, water savings, energy efficiency, materials selection, and indoor environmental quality.

[b] Reduction of individual GHG production can be accomplished by buying carbon offsets whereby, in this principle, an individual or business can pay someone to reduce or remove GHG production in that company's name. For example, if a company agrees to buy 10 tons of carbon offsets, the seller guarantees that 10 fewer tons of GHG will enter the atmosphere.

can be found at www.grida.no/climate/ipcc_tar/wg2/646.htm#tab18-2. These adaptation strategies include policy and legislative actions, engineering responses, and personal behavior change.

Effective implementation of mitigation and adaptation strategies must involve actions from the global to local levels by governments, corporations, communities, and individuals. Furthermore, climate change is part of generalized global change, which includes population growth, land use, economic change, and evolving technology; all have effects on individual human and public health (Fig 2). Any solutions that address climate change must be developed within the context of overall sustainable development (the use of resources by the current generation to meet current needs while ensuring that future generations will be able to meet their needs). Protecting the health of current and future generations requires a fundamental shift in thinking for health professionals[78]; pediatricians, as advocates for children's health, can be leaders in a move away from a traditional focus on disease prevention to a broader, more integrated focus that encompasses sustainability as synonymous with health. Given the health implications for current and future generations of children, the disease-prevention role for pediatric health care professionals includes advocating for environmental sustainability.

SUMMARY

This technical report describes the broad scientific consensus that man-made climate change has begun

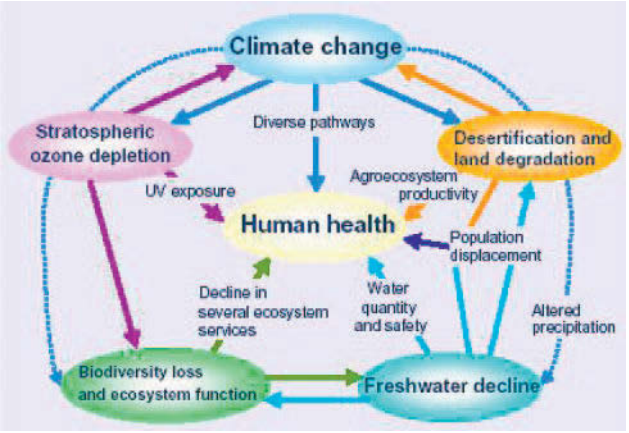

FIGURE 2
Global drivers that affect human health. Large-scale and global environmental hazards to human health include climate change, stratospheric ozone depletion, loss of biodiversity, changes in hydrological systems and the supplies of fresh water, land degradation, and stresses on food-producing systems. (Source: World Health Organization [www.who.int/globalchange/en/index.html].)

and is accelerating. The major cause of this change is the rapid release of CO_2 from burning of fossil fuel. All predictions indicate that climate change will continue for at least a century, but the trajectory of that change depends on human responses. There are anticipated effects on human health from extreme weather events, infectious diseases, air pollution, and heat stress. Although little research thus far has concentrated on the pediatric age group, it is likely that children will suffer disproportionately from climate change.[6] Furthermore, the state of the world of future children is uncertain and depends on actions taken to mitigate and adapt to climate change and other global-scale trends. Pediatric health care professionals are in an ideal position to advocate for action, not only to address climate change but also, more broadly, to ensure sustainability. Specific recommendations for pediatricians and governments are enumerated in the American Academy of Pediatrics policy statement[79] on climate change and children's health, which accompanies this technical report.

FEDERATION OF PEDIATRIC ORGANIZATIONS

Graduate Medical Education and Pediatric Workforce Issues and Principles

Task Force on Graduate Medical Education Reform

The following principles were crafted by a special Task Force on GME convened by the American Academy of Pediatrics to develop policies and principles concerning GME and pediatric workforce issues. The Task Force met in the Washington office of the Academy on September 4, 1993. These principles have been reviewed at a meeting on September 9, 1993, revised and approved by the Federation of Pediatric Organizations. The Federation component organizations include: the Ambulatory Pediatric Association; American Academy of Pediatrics; American Board of Pediatrics; American Pediatric Society; Association of Medical School Pediatric Department Chairmen; Association of Pediatric Program Directors; and Society for Pediatric Research. These principles represent the consensus opinion of the American pediatric community comprising both academic and practicing physicians and residents.

OVERVIEW

The United States is presently poised to enact a universal health care program that could include the coverage of an additional 12 million children and adolescents. The passage of such a proposal might eliminate financial barriers to needed health care for many children and generate an increase in demand for primary care physicians. These children and adolescents will need quality health care, the provision of which is very complex. Pediatricians are the most appropriate providers of primary care for infants, children and adolescents. Today, nearly two-thirds of office (physician) visits made by children aged 5 years and younger are to pediatricians.

There is presently a national shortage and geographic maldistribution of pediatricians the effects of which could be acutely aggravated by health care reform. The federated pediatric community agrees that there is a need for increased support for primary care specialties as a whole, and pediatrics in particular. In contrast to adult medicine and surgery, the overwhelming majority of pediatricians practice primary care medicine; less than 20 percent of certified pediatricians are certified in subspecialties and even fewer are practicing subspecialties exclusively. Currently, and for the past decade, over 60 percent of graduating pediatric residents still choose to enter primary care.

It is important to recognize the need for training of pediatric generalists and pediatric subspecialists to meet the unique clinical, research and educational needs of child and adolescent populations in the next century. There will be an increased demand for subspecialists (in the face of existing shortages) due to the complex illnesses faced by children and adolescents—congenital anomalies, pediatric AIDS, derivatives of substance abuse, etc. Some pediatric fellowship training—such as general academic pediatrics, adolescent medicine, behavioral pediatrics, developmental pediatrics—is often undertaken to enhance the pediatrician's ability to provide optimal primary care services and many graduates of such programs actually practice primary care.

Population and incidence of disease limit the numbers of pediatric subspecialty patients and, because of this, the number and distribution of subspecialists the country needs. There is currently an acute shortage of certain pediatric subspecialties (i.e., pediatric gastroenterologists, pediatric hematologist/oncologists and pediatric endocrinologists). In contrast to adult specialists, pediatric subspecialists are not usually found in private practice.

NATIONAL HEALTH CARE WORKFORCE COMMISSION

The federated pediatric community recommends that an independent National Health Care Workforce Commission be established, insulated from the political process and with broad representation from the primary care community, including pediatrics. This National Health Care Workforce Commission would be responsible for:

- projecting the aggregate need of the medical care workforce for the health care delivery system;
- determining the necessary number of residency positions on a national basis (including the number of International Medical Graduates (IMGs)) and maintaining the appropriate number of generalists and subspecialists;
- allocating residency positions by specialty and subspecialty with regard to medical personnel and population needs;
- implementing appropriate incentives to reinforce the selection of primary care;
- conducting on-going research that will ensure the availability of appropriate data on which to base workforce decisions;
- evaluating and monitoring the efficacy of all recommendations and their implementation; ensuring that the process allows for flexibility, particularly during the transition period; and reevaluating recommendations as appropriate.

The federated pediatric community recommends that this independent and autonomous National Health Care Workforce Commission have features of both the Federal Reserve Board and the Defense Base Closure and Alignment Commission. The statute creating this National Workforce Commission would require that its recommendations be sent to the President for approval or disapproval, and then require the Congress to take an "up" or "down" vote on its package of recommendations without amendment. Its decisions, if accepted in this manner, are binding as statute.

The composition of the National Commission should be balanced and should reflect the entire primary care community as well as include representation from non-primary care disciplines. Its membership should include practicing physicians, medical educators, allied health professionals, i.e., nurse practitioners and physicians assistants, hospital administrators and consumers.

The federated pediatric community believes that training and service needs should be disconnected. Therefore, distribution of residency training positions should be based on the quality of the training program. However, until there is appropriate distribution of training positions based on quality and primary care/specialty needs, we recognize that some service issues must still be considered.

The federated pediatric community believes that the ACGME and the RRC should maintain their current function and focus on quality, and should not be involved in the allocation of residency training positions.

ALLOCATION OF GME SLOTS

The principal goal of the federated pediatric community is to increase the number of primary care pediatricians. We support the need to prepare more generalists. Accordingly, whatever mechanism for allocating residency positions is selected must assure that there are at least as many residency positions in pediatrics as currently exists. We recognize the need to decrease the total number of GME training slots overall, while simultaneously increasing the number of primary care slots. However, reliable data for projecting future physician need are not available, particularly the need for pediatric generalists and subspecialists.

While the goal of limiting the number of filled first year resident positions to 110 percent of the number of US medical school graduates may be a reasonable initial target, the federated pediatric community believes that the National Health Care Workforce Commission should ultimately establish the total number of residency positions, including IMGs.

The federated pediatric community supports the limitation of residency positions only if it is implemented subsequent to the allocation of slots across specialties and pursuant to the recommendations of the National Health Care Workforce Commission. The pediatric community is deeply concerned that, in some parts of the country, IMGs currently provide a significant portion of pediatric care especially in urban hospitals in under-served communities. In these communities, ImGs may provide more than 50 percent of care. The health of children in these communities must not be compromised by the reduction of residency positions while awaiting alternative health care providers.

The federated pediatric community believes the phasing in period, accompanied by transition funding, is vitally important to hospitals that lose a larger percentage of their residency positions through the allocation process or with the assignment of residents to ambulatory care sites.

PAYMENT FOR GME

The federated pediatric community concurs with the Physician Payment Review Commission's (PPRC) 1993 Annual Report to Congress in its support of the concept that "all payers should share the costs of graduate medical education."

Within the limits of the national goals established by the National Commission, the pediatric community is in favor of maintaining as much flexibility of choice by resident applicants as possible. Operating under the allocation of residency slots established by the National Health Care Workforce Commission, the federated pediatric community supports a continuation of the current matching system.

One option to assist in assuring a distribution of residency specialties that will meet the future health needs of the nation is to explore the use of a voucher/certificate system given to medical students in conjunction with the National Resident Matching Program as suggested in a 1985 Report by the Task Force on Academic Health Centers of The Commonwealth Fund. Alternatively, funds could be allocated directly to programs or to regional or local consortia as proposed by the PPRC and the Council on Graduate Medical Education. Any one of these proposals would help assure that monies for medical education are used for that purpose.

Whatever the mechanism, it is preferable that the funds are allocated in a manner that facilitates the training of primary care physicians, including expanding the training venues outside of the hospital setting.

INCENTIVES, INCLUDING WEIGHTING OF PRIMARY CARE POSITIONS

The federated pediatric community believes that primary care residents should receive total compensation that is equal to or greater than other residency positions in the institution.

The federated pediatric community believes that the use of differential weights in calculating payments for primary care residency positions could provide an incentive for teaching institutions to increase the number of primary care residency positions. However, these weights must be large enough to encourage the development of additional primary care positions and education sites outside of the teaching hospital. Funding must be specifically designated for this purpose.

This short term strategy must be accompanied by long term incentives for medical students, residents, and physicians (especially under-represented minor-

ity groups) to choose primary care. A full array of support for primary care should be considered including: expansion of the National Health Services Corp; continuation and expansion of primary care training programs, such as Title VII; loan forgiveness in return for practicing in identified under-served areas; loan repayment based on a percentage of earnings; forbearance and deferment of low interest loans for entering primary care; development and implementation by all payers of a pediatric RBRVS and increased payment for pediatric services; increased funding for primary care research and other system-wide supports for pediatric and other primary care specialties including the reduction in administrative burden to primary care physicians.

RETRAINING

Unlike adult medicine and surgery, retraining for pediatricians is not a significant issue because all pediatricians are initially trained as generalists and some take additional training in a subspecialty. Renewal of subspecialty certification in pediatrics also requires recertification in general pediatrics. However, the federated pediatric community strongly believes that the setting of standards for retraining other specialists in fields which include the care of children must involve the federated pediatric community. This is to ensure that the same quality of care is provided to all children and adolescents.

CONCLUSION

The Federation of Pediatric Organizations supports designing a program to ensure quality health care to all children by developing appropriate guidelines and funding for GME.

FEDERATION OF PEDIATRIC ORGANIZATIONS

The Ambulatory Pediatric Association (APA) is an organization of individuals dedicated to research, education and service in general pediatrics addressing the needs of children and their families.

The **American Academy of Pediatrics** (AAP) is an organization of 47,000 physicians dedicated to health, safety and well-being of infants, children, adolescents and young adults.

The **American Board of Pediatrics'** (ABP) purpose, through the certification process, is to provide assurance to the public and to the medical profession that a certified pediatrician has successfully completed an accredited education program, an evaluation, including an examination, and possess the knowledge, skills, and experience requisite to the provision of high-quality care in pediatrics.

The **American Pediatric Society** (APS) is an organization bringing together academic pediatricians for the advancement of the study of child health and illness, for the promotion of health and the prevention of illness, and for the advancement of pediatric education and research, and for the recognition of those who by their contributions to pediatrics, have aided in its advancement.

The **Association of Pediatric Program Directors** (APPD) is an organization of individuals responsible for residency training programs in pediatrics. The mission of the Association is to advance and enhance the graduate medical education of pediatricians.

The **Association of Medical School Pediatric Department Chairmen** (AMSPDC) is an organization of chairs of medical school pediatric departments who are responsible for the conduct of teaching, patient care, research and service within American medical schools and their clinical services.

The **Society for Pediatric Research** (SPR) is an international society for scientists whose purpose is to encourage investigation of a broad range of areas involving the health and well being of children.

DEDICATED TO THE HEALTH OF ALL CHILDREN™

Organizational Principles to Guide and Define the Child Health Care System and/or Improve the Health of all Children

Policy Statement—Guidance for the Administration of Medication in School

abstract

Many children who take medications require them during the school day. This policy statement is designed to guide prescribing health care professionals, school physicians, and school health councils on the administration of medications to children at school. All districts and schools need to have policies and plans in place for safe, effective, and efficient administration of medications at school. Having full-time licensed registered nurses administering all routine and emergency medications in schools is the best situation. When a licensed registered nurse is not available, a licensed practical nurse may administer medications. When a nurse cannot administer medication in school, the American Academy of Pediatrics supports appropriate delegation of nursing services in the school setting. Delegation is a tool that may be used by the licensed registered school nurse to allow unlicensed assistive personnel to provide standardized, routine health services under the supervision of the nurse and on the basis of physician guidance and school nursing assessment of the unique needs of the individual child and the suitability of delegation of specific nursing tasks. Any delegation of nursing duties must be consistent with the requirements of state nurse practice acts, state regulations, and guidelines provided by professional nursing organizations. Long-term, emergency, and short-term medications; over-the-counter medications; alternative medications; and experimental drugs that are administered as part of a clinical trial are discussed in this statement. This statement has been endorsed by the American School Health Association. *Pediatrics* 2009;124:1244–1251

PEDIATRICS (ISSN Numbers: Print, 0031-4005; Online, 1098-4275).

INTRODUCTION

School boards and districts are responsible for policies and procedures for administration of medications to students who require them during the school day. The health circumstances that require medication are diverse. Medical advances have enabled many students with special health care needs or chronic health conditions to be included in classes with their peers.[1] Some schools struggle to balance the need for health care services for increasing numbers of children with special health care needs with the current resources available to provide those services.[2–12]

The presence in schools of a full-time licensed registered school nurse is strongly endorsed.[13] Registered nurses (RNs) have the knowledge and skills required for the delivery of medication, the clinical knowledge of the student's health, and the responsibility to protect the health

and safety of all students. The use of untrained school staff to administer medications to children with special health care needs creates risks, not only of medical liability for the school and the licensed registered school nurse but also of medication error for the student.[14–16] To ensure the health and safety of students, all schools should have a full-time licensed RN who has the knowledge and skills required for the delivery of medication and the assessment of student health.[17,18]

This policy statement has been endorsed by the American School Health Association.

TRAINED UNLICENSED ASSISTIVE PERSONNEL

When a school nurse is not available at all times, the American Academy of Pediatrics (AAP), the National Association of School Nurses, and the American Nurses Association recommend trained and supervised unlicensed assistive personnel (UAP) who have the required knowledge, skills, and composure to deliver specific school health services under the guidance of a licensed RN. UAP duties are delegated by a licensed RN.[19,20] Training and supervision of UAP are necessary for providing safe, accurate, and timely administration of medication. Delegation is a tool that may be used by the licensed registered school nurse to allow UAP to provide standardized routine health services under the supervision of the nurse and on the basis of physician guidance and school nursing assessment of the unique needs of the individual child and the suitability of delegation of specific nursing tasks. Any delegation of nursing duties must be consistent with the requirements of state nurse practice acts, state regulations, and guidelines provided by professional nursing organizations. Delegation of nursing duties is the responsibility of the certified licensed school nurse or licensed RN. The nurse determines which nursing services can be delegated and then selects, trains, and evaluates the performance of UAP; audits school medication records and documents; and conducts refresher classes throughout the school year.[21–23] The training, certification, and supervision of UAP should be determined by national and state nursing organizations and state nurse practice laws. Delegation is an ongoing process and a management tool, not a once-a-year event.

UAP training is typically limited and specific for medication-administration tasks and cannot replace a nursing assessment. In most circumstances, a medication UAP should be an ancillary health office staff member (health assistant/aide) who is also trained in basic first aid and district health office procedures. On rare occasions when a member of the health office staff (RN, licensed practice nurse, or UAP health assistant/aide) is not available, other willing volunteer school staff may be trained by the licensed RN to assume specific limited tasks such as single-dose medication delivery or life-saving emergency medication administration. In those instances, it is important for school districts to identify and satisfactorily address medical liability issues for the school district, the nurse, and the voluntary nonmedical staff member who is serving temporarily as UAP.

SCHOOL POLICY AND PROCEDURES

Section 504 of the Rehabilitation Act and the Individuals With Disabilities Education Act (IDEA) provide protection for students with disabilities by requiring schools to make reasonable accommodations and to allow for safe inclusion of these students in school programs.[24–27] These federal laws apply only to schools that receive federal funds, do not cover all students who require medications during the school day (eg, short-term needs), and are not specific about how administration of medications should be conducted in school. The AAP supports state laws, regulations, or standards that establish more specific policies for administration of medications that apply to all of the state's school districts. State standards can limit discrepancies among school districts within the state and reduce confusion for parents and prescribing health care professionals. School boards and school superintendents are responsible for establishing policies and detailed procedures for the safe administration of medication in the school setting. When state standards are insufficient, school health professionals, consulting physicians, and school health councils can work with AAP chapters to promote improved state standards and assist with local policies and procedures. Individual school districts also might wish to seek legal advice as they assume the responsibility for giving medication during school hours and during activities at school before or after school hours. Liability coverage should be provided for the staff, including nurses, teachers, athletic staff, principals, superintendents, and members of the school board.[15] Any student who must take medication during regular school hours should do so in compliance with all federal and state laws and school district policies.

Guidance for pediatricians, school physicians, and school health consultants is consistent with policy declarations of the National Association of School Nurses[28] and the American Nurses Association.[20] The following are recommendations for school districts in implementing medication-administration policies and procedures.[29]

- Protect student safety and prevent medication errors. Nursing services

at school, whether emergent, urgent, or routine, require the creation of a confidential, timely, and accurate record of the service provided.

- Identify the licensed health professional (certified or registered school nurse or school physician) on the school staff who supervises and is responsible for the safe keeping and accessibility and administration of medications, including documentation and a system of accountability for students who carry and self-administer their medications.
- Use a systematic review of documentation of medication-administration records for quality improvement, especially to reduce medication errors and to verify controlled substance counts.
- Create an ongoing training and certification program for UAP who perform specific nursing services when delegated and supervised by the licensed school RN or school physician.
- Establish and follow effective communication systems that support the school's nursing plan (individualized health plans, etc) and promote accurate implementation of the prescriber's instructions for the medical management of a designated student's health needs.
- Require a written medication form, signed by the authorized prescriber and parent, with the name of the student, the drug, the dose, approximate time it is to be taken, and the diagnosis or reason the medication is needed. This requirement applies for all prescription medications.
- Require written parental approval if over-the-counter (OTC) medications are permitted. Limit the duration that an OTC medication is administered at school.[30] Use of OTC medications over an extended time period warrants an authorized prescriber's oversight and authorization.
- Protect student health information confidentiality as outlined in the Family Education Rights and Privacy Act[31,32] and the Health Insurance Portability and Accountability Act.[33]
- Train, delegate, and supervise appropriate UAP who have the knowledge and skills to administer or assist in the administration of medication to students when assessed to be appropriate by the supervising and delegating licensed registered school nurse or school physician in compliance with applicable state laws and regulations.
- Permit responsible students to carry and self-administer emergency medications for those conditions authorized by school policies and regulations, which also describe students'/parents' rights and responsibilities.[34,35]
- Provide and encourage parents to provide spare life-saving medications in the health office for students who carry and self-administer emergency medications in the event that the life-saving medication cannot be located when a student is in need of the medicine.
- Make provisions for secured and immediate access to emergency medications at school at all times, including before and after school hours and during students' off-campus school-sponsored activities.[35–39]

ADMINISTRATION OF LONG-TERM MEDICATIONS

Long-term medications are those needed to manage a student's symptoms or promote health over an extended period of time. Many students who require long-term medications are children with special health care needs whose school attendance and participation in school activities depend on the administration of the prescribed treatment. Asthma, attention-deficit/hyperactivity disorder, seizures, heart conditions, cerebral palsy, and diabetes mellitus are among the common conditions that require medication at school.[40–42] Although not common, students infected with HIV may require multiple medications during the school day. In most cases, school nurses will develop individualized health plans for children with special health care needs.[43]

School nurses should review all school medication orders, establish liaisons with the student's health care professionals, administer medication, and/or provide effective training and supervision of UAP who are delegated to administer medication.[13,44] Requests to administer nonstandard medications (eg, doses in excess of manufacturer guidelines; alternative, homeopathic, or experimental medications; nutritional supplements) do not have to be honored by a school nurse. However, a school nurse has a professional obligation to promptly record the request and resolve the conflict with the parent, the prescriber, and/or, when needed, the school physician.[45]

EMERGENCY AND URGENT MEDICATIONS

Emergency and urgent medications are often given by nonoral routes and are administered to initiate treatment or amelioration of a disease or condition that may be life-threatening or cause grave morbidity. The complexity and urgency of this intervention is the focus of the AAP policy statement "Medical Emergencies Occurring at School,"[36] which describes prevention and mitigation of emergent events and stresses the role of the school nurse in providing this nursing service at school. The school nurse is the professional most likely to train school staff, to create a liaison with com-

munity emergency response teams and other health care professionals, and to assist, in coordination with the school physician, the school administration in development of policies and administrative regulations concerning medical emergencies.[17,34,36,37,46–48] State laws or regulations designate the roles and responsibilities of school staff in this situation. They may specifically limit or expand the role of UAP in emergency care settings. Some states have legislated authority to create protocols and procedures through which school staff are identified, trained, and certified to initiate medical care in a medically urgent or emergent situation and to address concerns of liability for nursing services provided under such conditions.[49–51]

Immediate access to emergency medications (eg, autoinjectable epinephrine, albuterol, rectal diazepam, and glucagon) is a high priority and is crucial to the effectiveness of these lifesaving interventions. To maintain medication security and safety and provide for timely treatment, local procedures must specify where medications will be stored, who is responsible for the medication, who will regularly review and replace outdated medication, and who will carry the medication for field trips. In addition to unlicensed health office staff, other school staff may be trained, designated, and supervised as emergency UAP to be "first responders" to a student who experiences a medical emergency.

Schools also need an adequate supply of emergency medications in the event of a school lock-down or evacuation. Parent-supplied extra medication and/or school-supplied stock medications (including but not limited to autoinjectable epinephrine and albuterol inhalers) are among the emergency or urgent care medications that need to be available in these circumstances.[37,38,52]

SECURITY AND STORAGE OF MEDICATIONS

All prescription medications brought to school should be in original containers appropriately labeled by the pharmacist or physician. Except for self-carry medications, they should be stored securely in accordance with manufacturer directions. Controlled substances must be double-locked.[53] The school nurse, licensed practice nurse, or delegated, trained UAP must be available and have access to the medications at all times during the school day. All medications should be returned to the parents at the end of the school year or disposed of in accordance with existing laws, regulations, or standards. Care should be taken not to flush any drugs into the water system unnecessarily.

STUDENT SELF-CARRYING AND SELF-ADMINISTRATION OF PRESCRIBED MEDICATIONS

A responsible student should be permitted to carry medication for urgent or emergency need when it does not require refrigeration or security, according to policies determined by the school in accordance with laws, regulations, and standards.[34,54] Controlled substances and those at risk of drug abuse or sale to others are not appropriate for self-carrying. The student's personal health care professional, the parents, and the school nurse and school physician should collaboratively determine the ability of a student to appropriately self-administer the prescribed medication in a responsible and secure manner. School personnel must also permit the student to possess and take the medication once a determination has been made that the student is mature enough to carry and self-administer the medication. Some schools use self-administration agreements or have given a "medication pass" to students, verifying school permission for the student to carry and take medication. The student's ability to appropriately self-administer the prescribed medication must be evaluated by the school nurse at regular intervals to ensure safety and correctness of administration. For elementary school–aged children, the self-administration of a dose of medication should be reported to school personnel as soon as the self-administered dose is given for documentation and assessment of need for additional assistance. Medications carried by students should be either on the person of the student, as in a dedicated "fanny pack," or in possession of a supervising adult who will return the medication pack to the student as needed or when the student moves on to a new location. Medications should not be left unattended.

OTC MEDICATIONS

School administrators and health personnel should consider whether the benefits of administration of OTC medications outweigh the risks. Some states and school districts apply the same standards for OTC as for prescription medications. Others permit parent-recommended OTC medications or dietary supplements to be administered without a physician order. Either approach can be problematic. Providing parent-approved short-term medications, such as pain relievers, antiinflammatory medications, and antihistamines, for example, may provide symptomatic improvement for the student, which enables attendance for learning and causes less classroom disruption. However, this practice can result in liability for a school district, because nonprescribed medications have potential to cause harm or adverse effects that may impede learning. There are also issues of school safety and security of drug use (eg, sharing of medication between classmates when OTC medications are not stored in the school health office). On the other hand, the social realities of parents who work, often in jobs that do

not allow for medical leave to attend to their children's illnesses, may require that they send their children to school with mild illnesses. It can be difficult to obtain physician authorization for OTC medications. Because of these realities, it may be necessary to consider allowing the administration of nonprescribed, parent-recommended medications for students during the school day on a short-term basis. The relative value of OTC medications for the specific population should guide policies. Cold and cough OTC medicines have not been shown to be effective in children younger than 6 years and are not appropriate for use at school without a physician order.[55] When OTC medications are permitted, school physicians and school nurses should develop standing protocols or standing orders that support 1-time verbal parental permission for specific OTC medications (eg, acetaminophen and ibuprofen).[28,30,56]

ADDITIONAL CIRCUMSTANCES

Alternative medications, such as herbal or homeopathic medications, are not tested by the US Food and Drug Administration for safety or effectiveness. Lack of safety information for these medications limits their appropriate use at school.[57] State and district medication policies should be used for alternative medications. These medications should never be administered without a written physician order. State and district policies should also address experimental medications and medications administered at doses in excess of manufacturer guidelines.[58]

RECOMMENDATIONS

Recommendations for Pediatricians and Other Child Health Professionals

The AAP recommends that pediatricians and other prescribing pediatric health care professionals take the following actions when writing prescriptions for students:

1. Prescribe medications for administration at school only when necessary. Many short-term and long-term medications can be given before and after school.
2. Learn about local school nursing services, medication policies and forms, and self-administration procedures.
3. Write specific, clear, and detailed instructions on dated, standardized school medication forms. Consider that the "need to treat" may be delegated to UAP.
4. Carefully assess and declare in writing your recommendation concerning students' self-carrying/self-administration on the basis of your patient demonstrating the appropriate developmental, physical, and intellectual capacity to self-carry and/or self-administer an emergency medication at school (see National Asthma Education and Prevention Program guidance[34]).
5. Collaborate with school physicians and school nurses and encourage parental collaboration.
6. Promote student health by advocating for coordinated school health programs.
7. Advocate for improved communication systems among schools, families, and pediatricians that support medication-administration services for students at school.
8. Advocate for improved school medication data collection and reporting by schools and school nurses.
9. Participate on your district's school health council. School health councils offer an opportunity for the development of collaborative liaisons among school administrators, licensed school health staff, and community health professionals.

Recommendations for Public Advocacy

The AAP recommends that pediatricians and other child health professionals and their state professional organizations take the following actions:

1. Participate on or support the creation of a district school health council to promote student health and improved communications in a coordinated school health program;
2. Work with state departments of health and/or education, state and local school boards, and school districts to ensure the development and funding of adequate school health program staffing and sound school medication policies and procedures as outlined in this statement; and
3. Support state laws, regulations, or standards that establish specific policies for the safe and effective administration of medications in schools that apply to all state school districts.

AMERICAN ACADEMY OF PEDIATRICS

Committee on Psychosocial Aspects of Child and Family Health

Guidance for Effective Discipline

ABSTRACT. When advising families about discipline strategies, pediatricians should use a comprehensive approach that includes consideration of the parent–child relationship, reinforcement of desired behaviors, and consequences for negative behaviors. Corporal punishment is of limited effectiveness and has potentially deleterious side effects. The American Academy of Pediatrics recommends that parents be encouraged and assisted in the development of methods other than spanking for managing undesired behavior.

Parents often ask pediatricians for advice about the provision of appropriate and effective discipline. In fact, 90% of pediatricians report that they include advice about discipline when providing anticipatory guidance to families.[1] The American Academy of Pediatrics held a consensus conference on corporal punishment, the report of which was published in *Pediatrics* and serves as one major source of information for this statement.[2]

The word discipline, which comes from the root word disciplinare—to teach or instruct—refers to the system of teaching and nurturing that prepares children to achieve competence, self-control, self-direction, and caring for others.[3] An effective discipline system must contain three vital elements: 1) a learning environment characterized by positive, supportive parent–child relationships; 2) a strategy for systematic teaching and strengthening of desired behaviors (proactive); and 3) a strategy for decreasing or eliminating undesired or ineffective behaviors (reactive). Each of these components needs to be functioning adequately for discipline to result in improved child behavior.

DEVELOPMENTAL APPROACH TO DISCIPLINE

The earliest discipline strategy is passive and occurs as infants and their caregivers gradually develop a mutually satisfactory schedule of feeding, sleeping, and awakening. Biologic rhythms tend to become more regular and adapt to family routines. Signals of discomfort, such as crying and thrashing, are modified as infants acquire memories of how their distress has been relieved and learn new strategies to focus attention on their emerging needs.[4]

The main parental discipline for infants is to provide generally structured daily routines but also to learn to recognize and respond flexibly to the infant's needs. As infants become more mobile and initiate more contact with the environment, parents must impose limitations and structure to create safe spaces for them to explore and play. Equally important, parents must protect them from potential hazards (eg, by installing safety covers on electric outlets and by removing dangerous objects from their reach) and introduce activities that distract their children from potential hazards. Such proactive behaviors are central to discipline for toddlers. Communicating verbally (a firm no) helps prepare the infant for later use of reasoning, but parents should not expect reasoning, verbal commands, or reprimands to manage the behavior of infants or toddlers.

As children grow older and interact with wider, more complex physical and social environments, the adults who care for them must develop increasingly creative strategies to protect them and teach them orderly and desirable patterns of behavior. As a result of consistent structure and teaching (discipline), children integrate the attitudes and expectations of their caregivers into their behavior. Preschoolers begin to develop an understanding of rules, and their behavior is guided by these rules and by the consequences associated with them. As children become school age, these rules become internalized and are accompanied by an increasing sense of responsibility and self-control. Responsibility for behavior is transferred gradually from the caregiving adult to the child, and is especially noticeable during the transition to adolescence. Thus, parents must be prepared to modify their discipline approach over time, using different strategies as the child develops greater independence and capacity for self-regulation and responsibility. The process can be more challenging with children who have developmental disabilities and may require additional or more intense strategies to manage their behavior.

STRATEGIES FOR EFFECTIVE DISCIPLINE

Effective discipline requires three essential components: 1) a positive, supportive, loving relationship between the parent(s) and child, 2) use of positive reinforcement strategies to increase desired behaviors, and 3) removing reinforcement or applying punishment to reduce or eliminate undesired behaviors. All components must be functioning well for discipline to be successful.

Promoting Optimal Parent–Child Relationships and Reinforcing Positive Behaviors

For discipline techniques to be most effective, they must occur in the context of a relationship in which children feel loved and secure. In this context, parents' responses to children's behavior, whether approving or disapproving, are likely to have the greatest effect because the parents' approval is important to the children. Parental responses within the context of loving and secure relationships also provide chil-

dren with a sense that their environment is stable and that a competent adult is taking care of them, which leads to the development of a sense of personal worth. As children respond to the positive nature of the relationship and consistent discipline, the need for frequent negative interactions decreases, and the quality of the relationship improves further for both parents and children. To this end, the best educators of children are people who are good role models and about whom children care enough to want to imitate and please. Certain conditions in the parent–child relationship have been found to be especially important in promoting positive child behavior, including:

- maintaining a positive emotional tone in the home through play and parental warmth and affection for the child[5];
- providing attention to the child to increase positive behavior (conversely ignoring, removing, or withholding parent attention to decrease the frequency or intensity of undesirable behaviors).[6] For older children, attention includes being aware of and interested in their school and other activities;
- providing consistency in the form of regular times and patterns for daily activities and interactions to reduce resistance, convey respect for the child, and make negative experiences less stressful[7];
- responding consistently to similar behavioral situations to promote more harmonious parent–child relationships and more positive child outcomes[8]; and
- being flexible, particularly with older children and adolescents, through listening and negotiation to reduce fewer episodes of child noncompliance with parental expectations.[8] Involving the child in decision-making has been associated with long-term enhancement in moral judgment.[9]

These factors are important in developing a positive, growth-enhancing relationship between parent and child. Even in the best relationships, however, parents will need to provide behavioral limits that their children will not like, and children will behave in ways that are unacceptable to parents. Disagreement and emotional discord occur in all families, but in families with reinforcing positive parent–child relationships and clear expectations and goals for behavior, these episodes are less frequent and less disruptive.

Rewarding Desirable or Effective Behaviors

The word discipline usually connotes strategies to reduce or eliminate undesirable behaviors. However, more successful child-rearing systems use procedures to both increase desirable behaviors and decrease undesirable behaviors. Eliminating undesirable behavior without having a strategy to stimulate more desirable behavior generally is not effective. The most critical part of discipline involves helping children learn behaviors that meet parental expectations, are effective in promoting positive social relationships, and help them develop a sense of self-discipline that leads to positive self-esteem. Behaviors that the parents value and want to encourage need to be identified by the parents and understood by their children.

Many desirable behavioral patterns emerge as part of the child's normal development, and the role of adults is to notice these behaviors and provide positive attention to strengthen and refine them. Other desirable behaviors are not part of a child's natural repertoire and need to be taught, such as sharing, good manners, empathy, study habits, and behaving according to principles despite the fact that immediate rewards for other behaviors (eg, lying or stealing) may be present. These behaviors must be taught to children through modeling by parents and shaping skills through parental attention and encouragement. It is much easier to stop undesired behaviors than to develop new, effective behaviors. Therefore, parents must identify the positive behaviors and skills that they want for their children and make a concerted effort to teach and strengthen these behaviors.

Strategies for parents and other caregivers that help children learn positive behaviors include:

- providing regular positive attention, sometimes called special time (opportunities to communicate positively are important for children of all ages);
- listening carefully to children and helping them learn to use words to express their feelings;
- providing children with opportunities to make choices whenever appropriate options exist and then helping them learn to evaluate the potential consequences of their choice;
- reinforcing emerging desirable behaviors with frequent praise and ignoring trivial misdeeds; and
- modeling orderly, predictable behavior, respectful communication, and collaborative conflict resolution strategies.[10]

Such strategies have several potential benefits: the desired behavior is more likely to become internalized, the newly learned behavior will be a foundation for other desirable behaviors, and the emotional environment in the family will be more positive, pleasant, and supportive.

Reducing and Eliminating Undesirable Behavior

When undesirable behavior occurs, discipline strategies to reduce or eliminate such behavior are needed.[11] Undesirable behavior includes behavior that places the child or others in danger, is noncompliant with the reasonable expectations and demands of the parents or other appropriate adults (eg, teachers), and interferes with positive social interactions and self-discipline. Some of these behaviors require an immediate response because of danger or risk to the child. Other undesirable behaviors require a consistent consequence to prevent generalization of the behavior to other situations. Some problems, particularly those that involve intense emotional exchanges, may be handled best by taking a break from the situation and discussing it later when emotions have subsided, developing alternative ways to handle the situation (removing attention), or, in many cases, avoiding these situations altogether.

Extinction including time-out and removal of privileges, and punishment are two common discipline approaches that have been associated with reducing undesired behavior. These different strategies, sometimes both confusingly called punishment, are effective if applied appropriately to specific behaviors. Although they both reduce undesired behavior, they work in very different ways and have very different short- and long-term effects. For both strategies, the following factors may increase the effectiveness:

- clarity on the part of the parent and child about what the problem behavior is and what consequence the child can expect when this behavior occurs;
- providing a strong and immediate initial consequence when the targeted behavior first occurs;
- consistently providing an appropriate consequence each time a targeted problematic behavior occurs;
- delivering instruction and correction calmly and with empathy; and
- providing a reason for a consequence for a specific behavior, which helps children beyond toddler age to learn the appropriate behavior[12] and improves their overall compliance with requests from adults.[13]

Occasionally, the consequence for an undesired behavior is immediate, without parental involvement (eg, breaking one's own toy), and may be effective in teaching children to change their behavior. When this consequence is combined with parental reprimand, there is an increase in the likelihood that the child's behavior will be affected for future similar situations.

Time-Out or Removal of Privileges

Time-out and removal of privileges are approaches that involve removing positive reinforcement for unacceptable behavior. For young children, time-out usually involves removing parental attention and praise (ignoring) or being placed in a chair for a specified time with no adult interaction. For older children and adolescents, this strategy usually involves removing privileges or denying participation in activities (eg, grounding for an evening with no TV or loss of driving privileges). To be effective, this strategy requires that a valued privilege or reinforcer is removed. In preschool children, time-out (removal of positive parental attention) has been shown to increase compliance with parental expectations from ~25% to 80%,[12] and similar effectiveness is seen when used appropriately with older children.[14] To be effective, however, time-out must be used consistently, for an appropriate duration, not excessively, and with strategies for managing escape behavior in place before the time-out is imposed. To be successful, time-out requires effort and practice on the part of the parents and, in some cases, requires specific education with a professional.

Several aspects of time-out must be considered to ensure effectiveness. When time-out is first implemented, it usually will result in increased negative behavior by the child, who will test the new limit with a display of emotional behavior, sometimes approaching a temper tantrum. The parent who accepts this normal reaction and does not respond to the child's behavior will find that outbursts become less frequent and that the targeted undesirable behavior also diminishes or disappears. When time-out is used appropriately, the child's feelings are neither persistent nor damaging to self-esteem, despite the intensity of the reaction. However, if the parent engages in verbal or physical interaction with the child during this disruptive behavior, the emotional outburst, as well as the behavior originally targeted, not only will persist, but may worsen. Second, time-out often is not effective immediately, although it is highly effective as a long-term strategy. Third, it is often difficult emotionally for a parent to ignore the child during periods of increased negative behaviors or when the child begins pleading and bargaining for time-out to end. The inability of parents to deal with their own distress during a time-out is one of the most common reasons for its failure.

PUNISHMENT

Punishment is defined as the application of a negative stimulus to reduce or eliminate a behavior. There are two types typically used with children: punishment involving verbal reprimands and disapproval and punishment involving physical pain, as in corporal punishment.

Verbal Reprimands

Many parents use disapproving verbal statements as a form of punishment to alter undesired behavior. When used infrequently and targeted toward specific behaviors, such reprimands may be transiently effective in immediately halting or reducing undesirable behaviors. However, if used frequently and indiscriminately, verbal reprimands lose their effectiveness and become reinforcers of undesired behavior because they provide attention to the child. Verbal reprimands given by parents during time-out are a major cause of reduced effectiveness of this form of discipline. Verbal reprimands should refer to the undesirable behavior and not slander the child's character.

Corporal Punishment

Corporal punishment involves the application of some form of physical pain in response to undesirable behavior. Corporal punishment ranges from slapping the hand of a child about to touch a hot stove to identifiable child abuse, such as beatings, scaldings, and burnings. Because of this range in the form and severity of punishment, its use as a discipline strategy is controversial. Although significant concerns have been raised about the negative effects of physical punishment and its potential escalation into abuse, a form of physical punishment—spanking—remains one of the strategies used most commonly to reduce undesired behaviors, with >90% of American families reporting having used spanking as a means of discipline at some time.[15] Spanking, as discussed here, refers to striking a child with an open

hand on the buttocks or extremities with the intention of modifying behavior without causing physical injury. Other forms of physical punishment, such as striking a child with an object, striking a child on parts of the body other than the buttocks or extremities, striking a child with such intensity that marks lasting more than a few minutes occur, pulling a child's hair, jerking a child by the arm, shaking a child, and physical punishment delivered in anger with intent to cause pain, are unacceptable and may be dangerous to the health and well-being of the child. These types of physical punishment should never be used.

Despite its common acceptance, and even advocacy for its use,[16] spanking is a less effective strategy than time-out or removal of privileges for reducing undesired behavior in children. Although spanking may immediately reduce or stop an undesired behavior, its effectiveness decreases with subsequent use. The only way to maintain the initial effect of spanking is to systematically increase the intensity with which it is delivered, which can quickly escalate into abuse. Thus, at best, spanking is only effective when used in selective infrequent situations.

The following consequences of spanking lessen its desirability as a strategy to eliminate undesired behavior.

- Spanking children <18 months of age increases the chance of physical injury, and the child is unlikely to understand the connection between the behavior and the punishment.
- Although spanking may result in a reaction of shock by the child and cessation of the undesired behavior, repeated spanking may cause agitated, aggressive behavior in the child that may lead to physical altercation between parent and child.
- Spanking models aggressive behavior as a solution to conflict and has been associated with increased aggression in preschool and school children.[17]
- Spanking and threats of spanking lead to altered parent–child relationships, making discipline substantially more difficult when physical punishment is no longer an option, such as with adolescents.
- Spanking is no more effective as a long-term strategy than other approaches,[18] and reliance on spanking as a discipline approach makes other discipline strategies less effective to use.[19] Time-out and positive reinforcement of other behaviors are more difficult to implement and take longer to become effective when spanking has previously been a primary method of discipline.
- A pattern of spanking may be sustained or increased. Because spanking may provide the parent some relief from anger, the likelihood that the parent will spank the child in the future is increased.[20]

Parents who spank their children are more likely to use other unacceptable forms of corporal punishment.[21] The more children are spanked, the more anger they report as adults, the more likely they are to spank their own children, the more likely they are to approve of hitting a spouse, and the more marital conflict they experience as adults.[20] Spanking has been associated with higher rates of physical aggression, more substance abuse, and increased risk of crime and violence[22] when used with older children and adolescents.

RECOMMENDATIONS

Because of the negative consequences of spanking and because it has been demonstrated to be no more effective than other approaches for managing undesired behavior in children, the American Academy of Pediatrics recommends that parents be encouraged and assisted in developing methods other than spanking in response to undesired behavior.

The Pediatrician's Role

Encouraging alternative methods may evoke strong responses from some parents and pediatricians because 90% of parents in the United States spank their children, and most adults were spanked when they were children. A survey indicated that ≤59% of pediatricians support the use of corporal punishment, at least in certain situations.[1] Support for spanking is higher in response to a child who runs into the street than it is as a punishment for hitting another child, even though the adult reaction of fear is the most effective deterrent in the former. As with other adults, pediatricians have learned much of their parenting skills from their own parents, who likely used spanking, and find their parents' practices more acceptable than other methods.[23] Changing discipline methods in the United States is likely to take time and to occur gradually, but it should be a goal of pediatricians and parents.

Discussing discipline with parents can be difficult and emotionally charged because opinions about these practices are formed in childhood. This learning occurred under emotional circumstances and is affected by parents' needs to justify their own parents' practices. Also, some religious groups take strong positions on this issue, often in favor of corporal punishment. In addition, discipline practices are under public scrutiny because of the increasing recognition of child abuse, which pediatricians are required to report. As a result, parents may be cautious about discussing their discipline practices. One effective way to start a discussion is by making an observation about the child's behavior during a health care visit and asking about the child's behavior at home. If parents comment negatively about their child's behavior, the severity of the problem should be determined. Eliciting specific examples of disciplinary encounters and responding nonjudgmentally to them are key to understanding the degree of behavioral disturbance[24] and the appropriateness of parental response. Asking about the parents' childhood experiences with discipline, their decision about how they would discipline as parents, and what other key people in their lives say about how they should discipline their children can be beneficial to understanding the parents' philosophy about discipline. It is important to obtain information about all

three aspects of the system of discipline (parent–child relationship, shaping and teaching desired behavior, and reducing undesired behavior) to determine which aspects may require intervention.[3] Generally, a visit with all the key caregiving adults is most effective when there is a problem, although this may not be necessary in cases involving minor discipline problems.[25] Parenting is difficult; parents deserve information, encouragement, and support over time.

Specific Physician Activities

When counseling families about discipline, physicians need to[26]:

1. be clear about what constitutes acceptable discipline;
2. avoid displaying strong emotions during the visit;
3. work to understand the parents' justification of their current practices and address their reasoning when presenting alternatives (offer privacy from children during this discussion);
4. demonstrate interest and expertise in child development and behavior during general visits to develop credibility for future discussions about discipline;
5. use good interviewing skills to show empathy;
6. let the family lead in individualizing a plan and choosing among techniques presented that are acceptable to them. Address the views of other influential family members;
7. look for examples of the parents' effective discipline approach; help them gain strength and generalize from those to other situations. Suggest ways to modify the family's techniques to make them more effective and appropriate;
8. follow up on the discipline discussion in subsequent conversations, by phone or in person;
9. discuss discipline during well-child visits when the child is young to help parents establish reasonable behavioral control. It is preferable to work toward preventing problems, because established negative behaviors often are extremely difficult to change;
10. identify parenting programs and individual counselors who are available in your community for parents with more difficult parenting problems; and
11. participate in public education and advocacy to change cultural attitudes about discipline.

The aspects of the system of discipline presented herein are effective when used at home, in out-of-home child care, at school, and in laboratory settings. Parents can be taught the use of appropriate discipline effectively through reading[27]; at-home family review of videotapes presenting behavioral situations[28]; individual instruction by a nurse in a health care setting[29]; individual or family counseling with a competent professional; group didactic teaching; or group instruction with modeling, role-playing, videotapes, or direct feedback about their parent–child interactions.[30] The intensity and duration of intervention needed to produce a change in family interaction depend on the severity of the child's behavior problems and on other stresses in the family, rather than on income level or social class. Studies have shown generalization from laboratory settings to the home, school,[28] and untreated sibling behavior, and across time. Pediatricians must be creative, persistent, and hopeful to generate change in the gradual manner in which it is likely to occur. A broader view of discipline needs to include the entire social structure. For example, cultures with children with relatively few behavior problems have been characterized by clear role definitions, clear expectations for the child's active work role in the family, very stable family constellations, and involvement of other community members in child care and supervision.[31] Advocacy by pediatricians for other supports within communities also is desirable.

SUPPLEMENTARY INFORMATION

1. Parents are more likely to use aversive techniques of discipline when they are angry or irritable, depressed, fatigued, and stressed. In 44% of those surveyed, corporal punishment was used ≥50% of the time because the parent had lost it. Approximately 85% expressed moderate to high anger, remorse, and agitation while punishing their children.[21] These findings challenge most the notion that parents can spank in a calm, planned manner. It is best not to administer any punishments while in a state of anger.
2. Spanking of young children is highly correlated with continued spanking of school and adolescent children.[20] More than half of 13- and 14-year-olds are still being hit an average eight times per year.[17] Parents who have relied on spanking do not seem to shift strategies when the risks of detrimental effects increase with developmental age, as has been argued.
3. Spanking of preschool boys by fathers with whom the child identified only moderately or little resulted in increased aggressive behavior by those children.[17]
4. Corporal punishment in two-parent, middle class families occurred weekly in 25%, was associated with the use of an object occasionally in 35% and half of the time in 17%, caused considerable pain at times in 12%, and inflicted lasting marks at times in 5%.[21] Thus, striking children in the abusive range is neither rare nor confined to families of lower socioeconomic class, as has been asserted.
5. Although children may view spanking as justified and symbolic of parental concern for them, they rate spanking as causing some or much pain in more than half of cases and generally experience anger at the adult as a result. Despite this, children come to accept spanking as a parent's right at an early age, making changes in adult acceptance of spanking more difficult.[21]
6. The more children are hit, the more anger they report as adults, the more they hit their own children when they are parents, the more likely they are to approve of hitting and to actually hit

their spouses, and the greater their marital conflict.[20]

7. Although 93% of parents justify spanking, 85% say that they would rather not if they had an alternative in which they believed.[21] One study found that 54% of mothers said that spanking was the wrong thing to have done in at least half of the times they used it.[20] This ambivalence likely results in inconsistent use, which limits further its effectiveness as a teaching tool.
8. Although spanking has been shown to be effective as a back-up to enforce a time-out location, it was not more effective than use of a barrier as an alternative.[32]
9. Even controlling for baseline antisocial behavior, the more 3- to 6-year-old children were hit, the worse their behavior when assessed 2 years later.[20]
10. Actions causing pain such as spanking can acquire a positive value rather than the intended adversive value.[31] Children who expect pain may actually seek it through escalating misbehaviors.
11. Parents who spank are more likely to use other forms of corporal punishment and a greater variety of verbal and other punitive methods.[22] When punishment fails, parents who rely on it tend to increase the intensity of its use rather than to change strategies.

Guideline for the Evaluation of Cholestatic Jaundice in Infants: Recommendations of the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition

Abstract

For the primary care provider, cholestatic jaundice in infancy, defined as jaundice caused by an elevated conjugated bilirubin, is an uncommon but potentially serious problem that indicates hepatobiliary dysfunction. Early detection of cholestatic jaundice by the primary care physician and timely, accurate diagnosis by the pediatric gastroenterologist are important for successful treatment and a favorable prognosis. The Cholestasis Guideline Committee of the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition has formulated a clinical practice guideline for the diagnostic evaluation of cholestatic jaundice in the infant. The Cholestasis Guideline Committee, consisting of a primary care pediatrician, a clinical epidemiologist (who also practices primary care pediatrics), and five pediatric gastroenterologists, based its recommendations on a comprehensive and systematic review of the medical literature integrated with expert opinion. Consensus was achieved through the Nominal Group Technique, a structured quantitative method.

The Committee examined the value of diagnostic tests commonly used for the evaluation of cholestatic jaundice and how those interventions can be applied to clinical situations in the infant. The guideline provides recommendations for management by the primary care provider, indications for consultation by a pediatric gastroenterologist, and recommendations for management by the pediatric gastroenterologist.

The Cholestasis Guideline Committee recommends that any infant noted to be jaundiced at 2 weeks of age be evaluated for cholestasis with measurement of total and direct serum bilirubin. However, breast-fed infants who can be reliably monitored and who have an otherwise normal history (no dark urine or light stools) and physical examination may be asked to return at 3 weeks of age and, if jaundice persists, have measurement of total and direct serum bilirubin at that time.

This document represents the official recommendations of the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition on the evaluation of cholestatic jaundice in infants. The American Academy of Pediatrics has also endorsed these recommendations. These recommendations are a general guideline and are not intended as a substitute for clinical judgment or as a protocol for the care of all patients with this problem.

BACKGROUND

Cholestatic jaundice, characterized by elevation of serum *conjugated* bilirubin, is an uncommon but potentially serious condition that indicates hepatobiliary dysfunction. Early detection of cholestatic jaundice by the primary care provider and timely, accurate diagnosis by the pediatric gastroenterologist are important for successful treatment and a favorable prognosis. In contrast, *physiologic jaundice* and *breast milk jaundice*, common causes of jaundice in the first weeks of life, are caused by an elevation of serum *unconjugated* bilirubin. Both are self-limited maturational disorders observed in many infants in the first weeks of life.

Cholestatic jaundice affects approximately 1 in every 2,500 infants (1,2), and is thus infrequently seen by most providers of medical care to infants. However, distinguishing jaundice caused by cholestasis from noncholestatic conditions is critical because cholestatic jaundice is much more likely to have a serious etiology that needs prompt diagnosis and therapy. The most common causes of cholestatic jaundice in the first months of life are biliary atresia and neonatal hepatitis, which account for most cases. Neonatal hepatitis has referred to a histologic appearance of widespread giant cell transformation. Although giant cell transformation is recognized to be nonspecific and may be associated with infectious, metabolic, and syndromic disorders, this term is used to be consistent with the older literature reviewed for this guideline. Alpha-1 antitrypsin deficiency causes another 5% to 15% of cases (1,2). The remaining cases are caused by a variety of other disorders, including extrahepatic obstruction from common duct gallstone or choledochal cyst; metabolic disorders such as tyrosinemia, galactosemia, and hypothyroidism; inborn errors of bile acid metabolism; Alagille syndrome; infection; and other rare disorders (Table 1).

Infants with cholestatic jaundice caused by bacterial sepsis, galactosemia, hypopituitarism, or gallstone often appear acutely ill. These disorders require early diagnosis and urgent treatment. However, many infants with cholestatic jaundice appear otherwise healthy and grow normally. The benign appearance of such an infant may lull the parents or physician into believing that the jaundice is physiologic or caused by breast-feeding, when in fact it may be caused by biliary atresia. Biliary atresia occurs in 1 in 10,000 to 19,000 infants (3ï 6) (Elliott EJ, Australian Pediatric Surveillance Unit, Extra-hepatic Biliary Atresia Study Group, personal communication,

2001). Substantial observational evidence suggests that earlier diagnosis and surgical repair lead to better outcomes for this disorder (7). The Kasai portoenterostomy appears to have the greatest likelihood of re-establishment of bile flow and the longest term survival of the infantôs native liver when performed before the age of 45 to 60 days (7ï 10). Early diagnosis of many of the other conditions that cause cholestasis may also lead to better outcomes because better support of the infant may avoid complications of liver disease (11).

Despite these data showing that early diagnosis is potentially life saving, referral for evaluation of cholestatic jaundice frequently occurs after 45 to 60 days of age (12). In recognition of this, and noting that no evidence-based guideline for its evaluation currently exists, the Cholestasis Guideline Committee was formed by the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (NASPGHAN) to develop a clinical practice guideline for the diagnostic evaluation of cholestasis in infants.

METHODS

The Cholestasis Guideline Committee consisted of a general pediatrician, a clinical epidemiologist who also practices general pediatrics, and five pediatric gastroenterologists. The team addressed the problem of jaundice caused by conjugated hyperbilirubinemia in the 2- to 8-week-old infant. The guideline is intended to assist primary care pediatricians, neonatologists, family practitioners, nurse practitioners, physicianôs assistants, pediatric gastroenterologists, and pediatric surgeons with the process of diagnosis of infants with cholestatic jaundice, and is specifically intended to decrease the time from initial presentation to diagnosis because of the importance of early diagnosis and treatment of biliary atresia. The targeted settings include primary care outpatient settings, as well as specialty referral facilities. This guideline is not intended for the care of the ill premature infant in the intensive care setting.

Cholestasis was defined as reduced bile formation or flow resulting in the retention of substances normally excreted into bile. Conjugated hyperbilirubinemia is the most common marker; issues regarding the specifics of bilirubin measurement are detailed below. A desirable outcome was defined as optimal treatment of the underlying conditions. Optimal treatment requires timely diagnosis of the cause of the jaundice, minimizing unnecessary diagnostic testing and consultation, and minimizing delay in diagnosis of time-sensitive conditions, such as biliary atresia.

The guideline development process was intended to incorporate the best available evidence from the medical literature, in combination with expert consensus when available evidence was limited. Using expert opinion, an initial diagnostic algorithm was developed, including a set of potentially useful diagnostic tests for infants with cholestatic jaundice. To develop evidence-based estimates of the sensitivity, specificity, and accuracy of the diagnostic tests under consideration, Medline (1966ï 2002) was searched without language restriction using the terms listed in Table 2. Unpublished literature was not sought.

Abstracts for articles found in each search were reviewed for relevance. After editorials, letters, and review articles were eliminated, original studies that appeared to address the accuracy and reliability of the tests in question for the diagnosis of biliary atresia were retrieved in full and independently reviewed by two committee members, using previously published criteria for the validity of studies of diagnostic tests (13) (Table 3). The key criteria include an independent, blind comparison of the diagnostic test to a criterion standard, performed in nonselected, consecutive patients at risk for the condition of

TABLE 2. *Search strategies*

Biopsy: biliary atresia/ti,ab,sh and (biopsy or biopsy, needle)
GGT: biliary atresia/ti,ab,sh and gamma glutamyl transferase
Radionuclide scan: biliary atresia/RI
ERCP: biliary atresia/ti,ab,sh and explode cholangiopancreatography, endoscopic retrograde
Lipoprotein X: biliary atresia/ti,ab,sh and lipoprotein X
Ultrasound: biliary atresia/ti,ab,sh and (ultrasound or sonography or ultrasonography)
Duodenal aspirate: biliary atresia/ti,ab,sh and (intestinal secretions/sh or intubation, gastrointestinal)

TABLE 3. *Validity criteria for studies of diagnostic tests*

1. Was the diagnostic standard adequate?
2. Was the test compared independently and blindly to the diagnostic (ñcriterionò) standard?
3. Were the referral pattern and patient population described?
4. Was there an adequate spectrum of disease in tested patients?
5. Was the test clearly described?
6. Was observer variation in test results addressed?

interest. Studies were considered to meet minimum criteria for validity if the test was performed in consecutive patients and did not appear to influence the determination of the final diagnosis. Each article was assigned a score based on these criteria, and the quality of evidence underlying each of the recommendations made by the Cholestasis Guideline Committee was determined according to the scheme shown in Table 4.

The final algorithm (Fig. 1) is based on the evidence found for each test, combined with expert opinion and consensus when the published evidence was insufficient. Recommendations are summarized in Table 5. Consensus was achieved through the nominal group technique (14).

The guidelines were then reviewed by primary care physicians in community and academic practices. In addition, the guidelines were distributed to the NASPGHAN membership for review and comment and were officially endorsed by the NASPGHAN Executive Council. This document represents the official recommendations of NASPHGAN on the evaluation of cholestatic jaundice of the infant. The American Academy of Pediatrics has also endorsed these recommendations. This review and recommendations are a general guideline and are not intended as a substitute for clinical judgment or as a protocol for the care of all patients with this problem.

TABLE 4. *Coding scheme for quality of evidence*

Level of evidence	Criterion for this level
Level A	Recommendation based on 2 or more studies that compared the test to a criterion standard in an independent, blind manner in an unselected population of infants similar to those addressed in the guideline.
Level B	Recommendation based on a single study that compared the test to a criterion standard in an independent, blind manner in an unselected population of infants similar to those addressed in the guideline.
Level C	Recommendation based on lower quality studies or studies for which inadequate information is provided to assess quality, together with expert opinion and consensus of the committee.
Level D	No studies available; recommendation based on expert opinion and consensus of the committee.

Table 5. *Recommendations*

Recommendation	Level of evidence
It is recommended that any infant noted to be jaundiced at 2 weeks of age be clinically evaluated for cholestasis with measurement of total and direct serum bilirubin. However, breast-fed infants who can be reliably monitored and who have an otherwise normal history (no dark urine or light stools) and physical examination may be asked to return at 3 weeks of age and, if jaundice persists, have measurement of total and direct serum bilirubin at that time.	C
Retest any infant with an acute condition or other explanation for jaundice whose jaundice does not resolve with appropriate management of the diagnosed condition.	D
Ultrasound is recommended for infants with cholestasis of unknown etiology.	A
Liver biopsy is recommended for most infants with cholestasis of unknown etiology.	A
GGTP and lipoprotein X are not routinely recommended in the evaluation of cholestasis in young infants.	C
Scintigraphy and duodenal aspirate are not routinely recommended but may be useful in situations in which other tests are not readily available.	A
MRCP and ERCP are not routinely recommended, although ERCP may be useful in experienced hands.	C

INITIAL EVALUATION OF THE JAUNDICED INFANT

The initial recognition and evaluation of any infant with possible cholestasis depends upon physicians and other providers of medical care to infants. The age limits of 2 weeks to 8 weeks of age used in this guideline were selected because they represent times when primary care providers typically examine healthy infants. As the evaluation proceeds, the tests to accurately diagnose cholestasis fall increasingly in the province of the referral center and pediatric gastroenterologist. Different care models or differing relationships between primary physicians and referral centers may alter the point at which the responsibility for the evaluation shifts from primary care to specialist. The goal remains the early detection and efficient diagnostic evaluation of cholestasis in infants.

No screening test can predict which infant will experience cholestasis (15). Thus, the detection of cholestasis rests on the clinical recognition of jaundice, pale stools, and/or dark urine by the parent or primary care provider. Each of these findings is an imperfect method of detecting cholestasis. Jaundice at 2 weeks of age is a relatively common finding, observed in 2.4% to 15% of newborns (16,17). Most such infants have unconjugated hyperbilirubinemia because of breast milk jaundice, a benign condition, although a recent report documents occasional kernicterus in otherwise healthy-appearing infants (18). In one study, jaundice was found in 9% of breast-fed infants at 4 weeks of age, but in fewer than 1 in 1,000

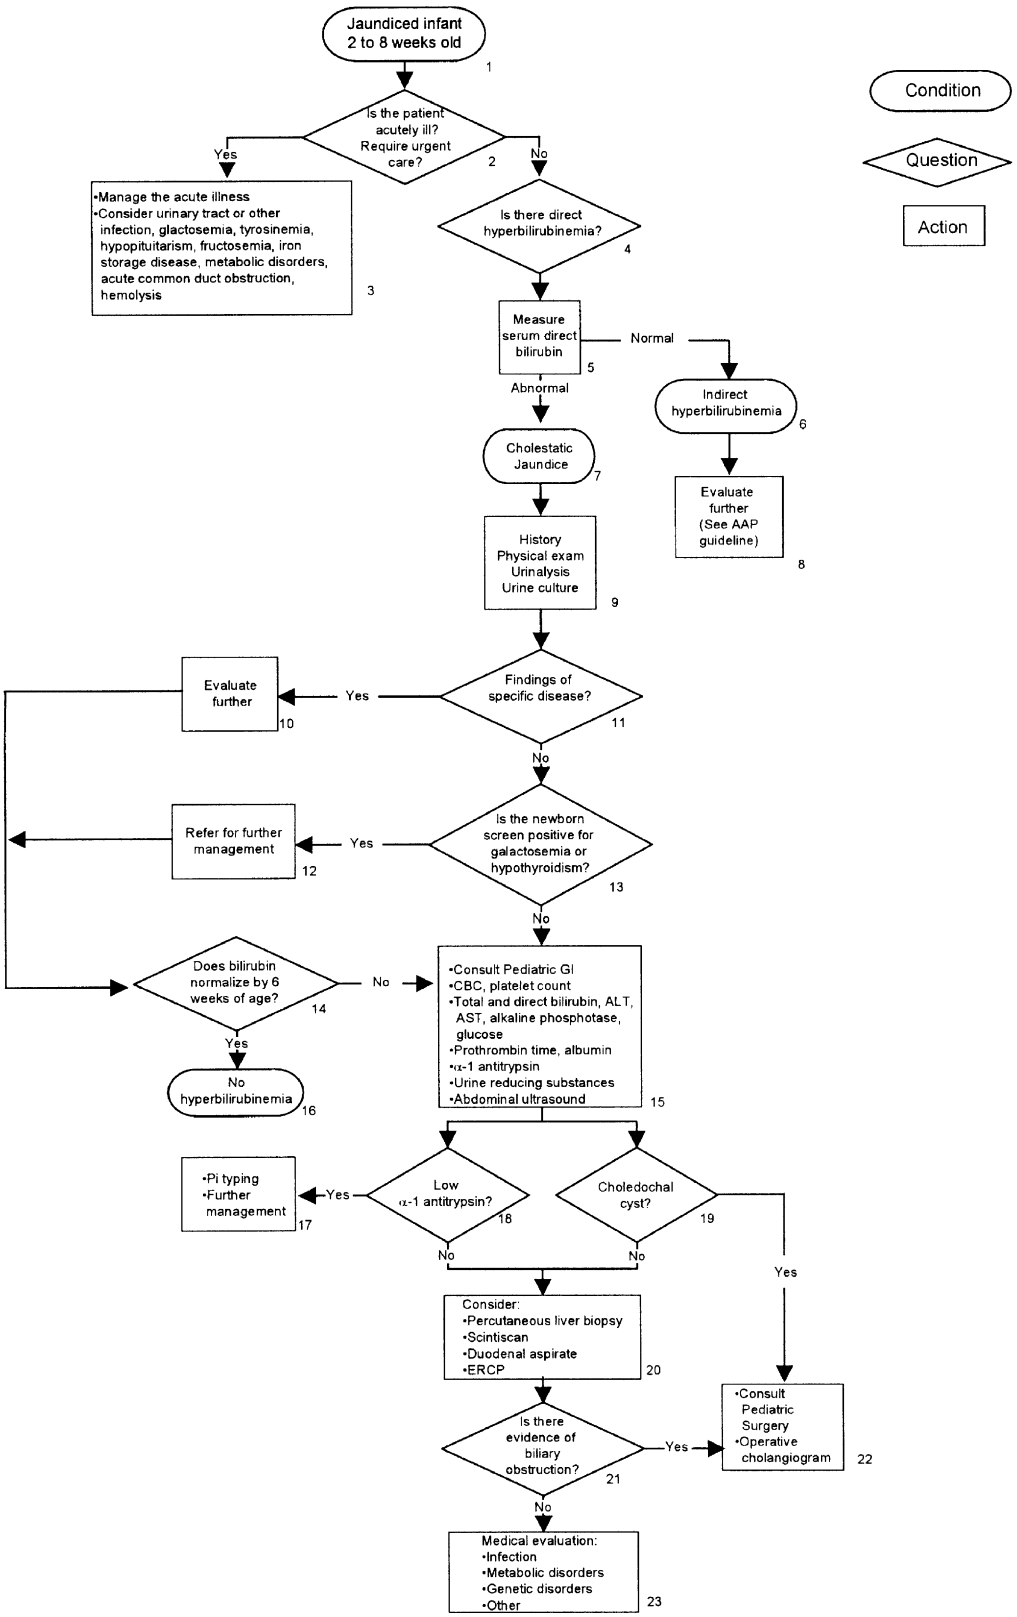

FIG. 1. Cholestasis clinical practice guideline. Algorithm for a 2- to 8-week-old infant. (North American Society for Pediatric Gastroenterology, Hepatology & Nutrition Cholestasis Guideline Committee.)

bottle-fed infants (19). Testing of all jaundiced newborns at the 2-week visit will detect cholestasis in relatively few infants (for every 60 to 375 infants with visible jaundice, 1 will have cholestasis). However, the next scheduled health maintenance visit generally does not occur until 2 months of age, beyond the optimal time for intervention in biliary atresia.

The report of pale stools by the parent or observation of clay colored stool by the physician raises the suspicion of cholestasis. In one study of 3,629 infants, 4 passed pale stools during the first 4 weeks of life, none more than three times. None of these infants had liver disease. The high specificity of persistent pale stools means that this finding almost certainly indicates disease when it is present. However, infants with biliary atresia have been noted to have pigmented stools at presentation, and stool color is variable in other conditions causing cholestasis (20). Parents do not appear to be reliable observers of stool color: even when the specific question ñWhat color is your babyôs stool?ò was added to a booklet received by all parents for well care, the average age for definitive care for infants with biliary atresia was not improved (4). A scoring card displaying color photographs of normal and abnormal stools modestly improved case finding in a subsequent program (21).

Dark urine is also a nonspecific indicator of increased conjugated bilirubin. No studies could be found that addressed the utility of this sign for case finding. Literature review did not identify any studies that defined specificity or sensitivity for the findings of jaundice, pale stools, or dark urine in combination. Thus, the clinician must continue to test for cholestasis when these findings are present, despite the low yield. The American Academy of Pediatrics practice parameter on the management of hyperbilirubinemia in the healthy term newborn recommends testing for conjugated hyperbilirubinemia if jaundice is accompanied by dark urine or light stool or if it persists beyond 3 weeks (22).

The Cholestasis Guideline Committee recommends that any infant noted to be jaundiced at 2 weeks of age be evaluated for cholestasis with measurement of total and direct serum bilirubin. However, breast-fed infants who can be reliably monitored and who have an otherwise normal history (no dark urine or light stools) and physical examination (Table 6) may be asked to return at 3 weeks of age and, if jaundice persists, have measurement of total and direct serum bilirubin at that time.

Bacterial infections, including urinary tract infection, are a well known cause of concomitant conjugated hyperbilirubinemia, probably because of the effect of bacterial endotoxin on bile formation (23,24). Otherwise asymptomatic jaundiced infants may have urinary tract infection, particularly if the onset of jaundice occurs after 8 days of age (25). Jaundice caused by an acute infection resolves when the acute illness has been addressed. Because jaundice is more likely to be related to the underlying illness, rather than primary liver disease, in the acutely ill infant, management is oriented to the underlying acute illness.

Because either conjugated or unconjugated hyperbilirubinemia may be present in a jaundiced infant who does not appear acutely ill, measurement of serum bilirubin that includes both total and direct (conjugated) bilirubin is recommended. The most commonly used laboratory determination (the diazo or van den Bergh method) does not specifically measure conjugated bilirubin but reports direct bilirubin. For methodological reasons, the higher the total bilirubin (even if it is all unconjugated), the higher the reported direct bilirubin (26ï 28). Measurements of direct bilirubin may vary significantly both within and between laboratories (29ï 32). The methods used may also influence the measurement of conjugated bilirubin (33ï 35). A specific measurement of conjugated bilirubin, such as that obtained with the Ektachem system, is optimal. Because canalicular excretion of bilirubin can be rate limiting to overall clearance, infants with high nonconjugated bilirubin may retain some conjugated bilirubin. Therefore, in the presence of elevated total bilirubin, conjugated bilirubin levels are considered abnormal when values greater than 1.0 mg/dL are reported (36). Practitioners whose laboratories use the Ektachem system could use a value of conjugated bilirubin greater than 1.0 to define cholestasis, regardless of total bilirubin. For this guideline, we defined an abnormal direct bilirubin as a value greater than 1.0 mg/dL if the total bilirubin is less than 5 mg/dL, or a value of direct bilirubin that represents more than 20% of the total bilirubin if the total bilirubin is greater than 5 mg/dL. It is important to be aware of the potential for error in these measurements and consult with the laboratory if the measurements are inconsistent with the appearance of the patient. Urine testing has also been used to diagnose cholestasis: assay of sulfated bile acids in urine was found in a single study to distinguish control infants from those with cholestasis, but this test is not generally available (37).

INITIAL EVALUATION OF THE INFANT WITH CONJUGATED HYPERBILIRUBINEMIA

For infants with only unconjugated hyperbilirubinemia, practitioners can refer to the previously published guideline on management of unconjugated hyperbilirubinemia from the American Academy of Pediatrics (22). If the conjugated serum bilirubin is elevated, cholestasis is present. The further evaluation of an infant with cholestasis is a matter of some urgency. Because biliary atresia is one of the possible causes of cholestasis, the goal of management is to complete the diagnostic evaluation, or at least to exclude biliary atresia, by 45 to 60 days of age. History and physical examination can help guide the diagnostic process for the infant with cholestasis. Some findings on history or physical examination

TABLE 6. *History and physical findings to consider for the differential diagnosis of infants with conjugated hyperbilirubinemia (see Box 9 of Figure 1)*

Topic	Specific question	Implication
History	Similar problem with parents or among siblings	Occurrence in other family members implies autosomal dominant inheritance, and occurrence in sibs implies genetic disease or nongenetic recurrence pattern: e.g., α-1AT deficiency, progressive familial intrahepatic cholestasis (PFIC), Alagilleôs, cystic fibrosis
	Consanguinity	Risk for autosomal recessive inheritance
	Maternal infection that can affect baby	TORCH infections, occasionally HBV, others
	Cholestasis of pregnancy	May be seen in PFIC
	Fetal ultrasound (yes/no; findings)	Choledochal cyst and bowel anomalies (e.g., duplication cysts) that can cause jaundice
	Past ABO or Rh disease, or Rh negative	Hemolysis
	Birth weight	SGA implies fetal involvement and weighs against biliary atresia
	Neonatal infection, including UTI, sepsis and viral infection	Often associated with conjugated hyperbilirubinemia
	Feeding history and history of weight gain	Neonatal hepatitis can cause FTT; metabolic disease (e.g., galactosemia and hereditary fructose intolerance) can cause anorexia, FTT, and jaundice. Panhypopituitarism
	Bowel historyð vomiting, stooling	Vomitingð metabolic disease, pyloric stenosis, bowel obstruction (atresia, annular pancreas); delayed stoolingð CF, hypothyroidism; diarrheað infection, metabolic disease, PFIC1, CF; clay colored stoolð biliary obstruction
	Source of nutrition	Breast or formula; composition of formula: galactose containingð galactosemia, fructose or sucrose containingð hereditary fructose intolerance
	Disposition	Irritable: may be associated with some metabolic disorders; ñgreat baby, sleeps all the time, never awake,ò lethargicð hypothyroidism or panhypopituitarism
	Urine colorð preferably directly observed	Dark urineð conjugated hyperbilirubinemia
	Stool color (useful to have reference such as yellow paint strip from paint dealer); preferably directly observed	Pale or clay colored; cholestasis, rule out obstruction
	Excessive bleeding	Coagulopathy; vitamin K deficiency
Physical findings	Vital signs; weight, length, OFC; weight for length	
	Global assessment of general health	
	Global assessment of nutritional status	Acute illness
	HEENT	Dysmorphic findingsð Alagilleôs syndrome, scleral icterus (qualitatively different in cholestasis versus nonconjugated jaundice), fundoscopic (intrauterine infection)
		Slit-lamp findings (Alagille syndrome, cataracts) snuffles
	Chest/heart	Evidence of pneumoniað neonatal infection
		Evidence of heart failureð Congestive hepatopathy
		Murmurs or other evidence of congenital heart diseaseð biliary atresia, Alagilleôs syndrome
	Abdomen	Distention
		Ascites
		Abdominal wall vasculature
		Liver size (exactly measured)
		Liver consistency
		Spleen size (below costal margin)
		Spleen consistency
		Masses
		Umbilical hernia
	Diaper exam	Dark urineð conjugated hyperbilirubinemia
		Pale or clay colored stoolð cholestasis, rule out obstruction
	Skinð bruising, petechiae, rashes	
	Neurologicð general assessment of vigor, tone, and symmetry	

will lead the clinician to other diagnostic possibilities. For example, 3% of infants with severe ABO hemolytic disease have conjugated hyperbilirubinemia that may persist until 2 weeks of age; thus, further observation may suffice for these infants (38). Table 6 describes abnormalities that may be present on history and physical examination and their potential significance. Abnormalities suggestive of a particular disease entity would lead

to more focused diagnostic evaluation, rather than further investigation of cholestasis. It is important to evaluate or repeat the newborn screen for galactosemia and hypothyroidism because these conditions can present with conjugated hyperbilirubinemia and require urgent management to prevent serious sequelae (39ï 42). Keeping in mind that the diagnosis of one disease does not preclude the presence of another, additional evaluation is necessary if the jaundice does not resolve with treatment of these specific conditions.

Consultation with a pediatric gastroenterologist is essential for infants with conjugated hyperbilirubinemia of unknown cause. The nature of this consultation may vary among practice settings. A telephone consultation may be particularly useful for practitioners at some distance from specialty care. Of the tests listed in Box 15 of the algorithm (Fig. 1), which should be ordered and where they should be performed is likely to vary, depending on which of the tests are readily available to the referring physician, and on whether examination of the patient by the specialist will be delayed. If the level of serum alpha-1 antitrypsin is found to be low, Pi typing is indicated. If an obvious extrinsic obstruction (such as choledochal cyst) is present, referral for surgery is warranted. Of the tests listed at this decision point, the ultrasound is the most operator dependent, and thus may be most appropriately performed at the referral center by more experienced personnel. In many practice settings, all of the listed tests would be best obtained by immediate referral of the patient for evaluation by the pediatric gastroenterologist. In the evaluation for infants with possible biliary atresia, it is optimal for an experienced pediatric surgeon to also be involved.

Ultrasonography is useful to identify anatomic abnormalities such as choledochal cyst. The finding of a small or absent gallbladder may suggest extrahepatic biliary atresia, but reported sensitivities as low as 73% indicate that ultrasound cannot be used to rule out this diagnosis. Several reports of high sensitivity and specificity of the ñtriangular cordò sign on ultrasound suggest that this test may be useful in the diagnosis of extrahepatic biliary atresia.(43ï 45) Again, this appears to be operator dependent. Despite these limitations, we recommend ultrasonography for the evaluation of the infant with cholestasis of unknown etiology.

Gamma glutamyl transpeptidase (GGT) has been used in the past to distinguish biliary atresia from neonatal hepatitis, but wide variability in levels makes interpretation of test results difficult. Especially in the older infant with cholestasis, a very low GGT level may be useful to exclude obstruction and, in conjunction with an elevated alkaline phosphatase level, suggests genetic and metabolic causes of intracellular cholestasis. The degree of elevation of GGT is not useful in discriminating the etiology of the cholestasis. The evidence supporting the use of ultrasound and GGT is summarized in Table 7.

FURTHER EVALUATION OF THE INFANT WITH CHOLESTASIS

Once it is established that cholestasis is present, the principal diagnostic concern is the differentiation of hepatocellular from obstructive cholestasis, of disorders of physiology from disorders of anatomy, and of disease that is managed medically from disease that is managed surgically. The tests that have been used to make this differentiation and about which we were able to find at least some evidence regarding their value were percutaneous liver biopsy, hepatobiliary radionuclide scan, and duodenal aspirate. Evidence and citations for the use of these tests are summarized in Table 7.

Percutaneous Liver Biopsy

Most studies of percutaneous liver biopsy are retrospective analyses using as a gold standard the clinical course or surgical or autopsy results. Biopsy interpretation is pathologist dependent, and requires experience that many general pathologists lack. Review of all of the studies of biopsy revealed that 50% to 99% of patients with biliary atresia are correctly identified with biopsy. Biliary atresia is incorrectly suspected from the biopsy in 0% to 46%.

In 1974, Brough and Bernstein (46) demonstrated the diagnostic usefulness of the percutaneous liver biopsy and established the diagnostic criteria that are in current use. They compared the original pathologic diagnosis in 181 consecutive patients to the ultimate diagnosis based on surgical findings and long-term follow-up. The original diagnosis was correct in 148 patients (93.7%), a high level of accuracy. More importantly, the type of error seen in the 10 patients with incorrect diagnoses would not lead to missed diagnosis of biliary atresia. In only one patient with biliary atresia was the original biopsy interpreted as hepatitis, which would lead to delay in the diagnosis and loss of important time before surgical correction. The remaining nine were suspected of having biliary atresia but actually had hepatitis. In this report, liver biopsy had a very high sensitivity (99%) and specificity (92%) for the diagnosis of biliary atresia, with somewhat less specificity for the diagnosis of neonatal hepatitis. Unfortunately, 23 patients were lost to follow-up, which reduces the value of this study. The highest quality subsequent studies performed using the Brough and Bernstein criteria demonstrate very good sensitivity and specificity for biliary atresia.

The interpretation of a single liver biopsy in a child with neonatal cholestasis is also limited by the dynamics of disease. Many cholestatic conditions express themselves differently with time. Liver biopsy specimens obtained early in the course of biliary atresia may be indistinguishable from hepatitis (47). In addition to being able to visualize the hepatocanalicular cholestasis and injury,

TABLE 7. *Diagnostic tests to distinguish EHBA from other causes of cholestasis (Box 21 of Figure 1)*

Procedure	Quality of evidence	Sensitivity* for obstruction	Specificity* for obstruction	Likelihood ratio* for obstruction	Likelihood ratio* for nonobstructive cholestasis	Time delay	Risk	Commentsð other diagnoses, issues relevant to this test
Ultrasound 44ï 46, 51ï 71	A	73%ï 100% for small or absent GB 83%ï 100% for ñtriangular cordò sign	67%ï 100% for small or absent GB 98%ï 100% for ñtriangular cordò sign	2.2ï infinite 41.5ï infinite	2.5ï infinite 5.8ï infinite	Minimal	Minimal	Procedure is operator dependent; primarily useful to rule out anatomic abnormalities such as choledochal cyst, rather than make a diagnosis of EHBA.
GGTP 47, 56, 72ï 81	C	78%ï 86%	67%ï 100%	2.4ï infinite	3.0ï 7.1	Minimal	Minimal	Variety of cut-off values used, no study with clearly independent comparison; most studies show considerable overlap.
Percutaneous biopsy 47, 56, 62, 69, 74, 82ï 89	A	89%ï 99%	82.5%ï 98%	5.2ï 49.5	7.5ï 98	1ï 3 days	Very low	Paucity of intrahepatic bile ducts, giant cell transformation, metabolic and storage diseases, PFIC, infection, neonatal sclerosing cholangitis can be diagnosed with this test. Most patients will require this test; should be interpreted by a pathologist experienced with pediatric liver disease. Sensitivity may be higher in expert hands.
Radionuclide scanning 53, 54, 56, 62, 65, 69, 74, 82, 86, 89ï 109	A	83%ï 100%	33%ï 100%	1.3ï infinite	2ï infinite	3ï 5 days for phenobarbital priming	Minimal	Most studies with sensitivity of 100%, so obstruction extremely unlikely if excretion found. Disadvantage of test is time delay and cost.
Duodenal aspirate 62, 82, 88, 97, 110ï 114	A	91%ï 100%	43%ï 100%	1.6ï infinite	4.8ï infinite	none	Minimal	Obstruction extremely unlikely if bile found in duodenal fluid. May require fluoroscopy for tube placement; test is invasive.
MRCP 71, 115ï 119	C	100% 2 studies	60% 1 study	2.5 (imprecise)	Infinite (imprecise)		Minimal	Requires deep sedation or general anesthesia; very few adequate studies.
ERCP 88, 120ï 127	C	100% 1 study	100% 1 study	Infinite	Infinite	?	Unknown	Requires sophisticated instrumentation and expertise not currently widely available; numbers based on a single study with a single endoscopist.
Lipoprotein X 79, 128ï 136	Not discussed	30%ï 88%	81%ï 100%	1.5ï infinite	2.7ï 8.3		Minimal	Test no longer available, most studies very small with poor description of methods.

Sensitivity, range of values from highest quality studies.

Specificity, range of values from highest quality studies.

LR, the ratio of the likelihood of a test result in patients who have a disease compared with the likelihood of the same test result in those without the disease; can be calculated as sensitivity (1-specificity). See Jaeschke et al[14] for details. In this table, the range is based on the sensitivity and specificity from highest quality studies.

the liver biopsy also can provide disease-specific findings. Examples include PAS-positive granules in alpha-1 antitrypsin deficiency, ductal paucity in Alagille syndrome, necroinflammatory duct lesions in sclerosing cholangitis, and other findings that are relatively specific for metabolic and storage diseases.

The evidence indicates that liver biopsy can be performed safely and expeditiously in young infants and is useful in establishing specific diagnoses (48). The Cholestasis Guideline Committee recommends that a liver biopsy be performed in most infants with undiagnosed cholestasis, to be interpreted by a pathologist with expertise in pediatric liver disease. A percutaneous liver biopsy is recommended before performing a surgical procedure to diagnose biliary atresia. If the biopsy is done early in the course of the disease (before 6 weeks of age), the biopsy may have to be repeated if the results are equivocal.

Scintigraphy

Injected radioactive material is normally excreted into the intestine within a predictable period of time. Nonvisualization of radioactivity within the intestine (in the scanning field comprising the intestines) 24 hours after injection is considered to be an abnormal result, indicating biliary obstruction or hepatocellular dysfunction. In the studies reviewed, a variety of radiolabeled scintigraphic agents were used, the diagnostic criteria varied greatly, and no blinded comparisons were found between scintigraphy and a gold standard for diagnosis. Although it is thought that the precision of the test can be improved by administering phenobarbital for several days before imaging, no studies are available to confirm or refute this hypothesis. In the available studies, the sensitivity of scintigraphy for the diagnosis of biliary atresia is high; virtually all patients with complete biliary obstruction showed no excretion on scintiscan. A few patients with a negative test (tracer evident in the intestine) later experienced biliary atresia, presumably because of disease evolving from incomplete to complete obstruction. Specificity of scintigraphy for biliary atresia or other obstructive processes is low; many patients without anatomic obstruction will not excrete tracer. Although the high sensitivity for biliary atresia makes this a fairly good single test for detecting disease, it is time consuming and expensive and does have significant false-positive and false-negative results. The Cholestasis Guideline Committee concludes that hepatobiliary scintigraphy generally adds little to the routine evaluation of the cholestatic infant but may be of value if other means for excluding biliary obstruction are not available.

Duodenal Aspirate

Limited data indicate that duodenal aspirate analysis for bilirubin concentration can identify patients with biliary obstruction with a sensitivity similar to that of scintiscan. In this test, fluid is obtained from the duodenum, either by placing a tube or a string in the duodenum, and analyzed for bilirubin concentration. A positive test for obstruction is one in which the bilirubin concentration of the aspirate is no greater than serum concentration. This would appear to be a low-tech, inexpensive alternative to scintiscan, yet it is not commonly used, probably because it is time and labor intensive, invasive, and inconvenient. The Cholestasis Guideline Committee concludes that the duodenal aspirate test may be useful in situations in which other tests to detect biliary obstruction are not available.

Magnetic Resonance Cholangiopancreatography

The few reports available to date have studied a very small number of patients, and although the results are encouraging, firm conclusions are not possible. Magnetic resonance cholangiopancreatography (MRCP) requires deep sedation or general anesthesia. Additional technical advancement and clinical experience are necessary before MRCP can be used in the evaluation of cholestatic infants. The Cholestasis Guideline Committee concludes that this test cannot be routinely recommended based on the currently available data.

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is an evolving technology that has been increasingly used in some tertiary referral centers to diagnose the cause of cholestasis in young infants. ERCP involves endoscopic intubation of the biliary (and pancreatic) ducts via the ampulla of Vater with a small tapered catheter and injection of contrast material to facilitate radiologic visualization of the ductal systems. A small pediatric side-viewing duodenoscope has enhanced the capability to perform this procedure in young infants. Most endoscopists prefer to perform this procedure with the patient under general anesthesia.

The data supporting the use of ERCP for the evaluation of the cholestatic infant are sparse. Many of the reports simply document the use of the prototype smaller side-viewing instrument for these patients. Operators report mixed success with the procedure to distinguish biliary atresia from neonatal hepatitis and other forms of nonoperative cholestasis. Most tertiary centers use ERCP to sort as surgical or nonsurgical cases that remain equivocal after liver biopsy. No controlled studies have been conducted to compare endoscopic techniques. In larger studies, sensitivity and specificity are excellent, but failed cannulation and/or visualization are reported in more than 10%. Patient populations vary from young infants to older infants (before or after 60 to 90 days of age). No controlled study has been done to demonstrate

that ERCP will alter the final diagnosis. A cost-benefit analysis of ERCP has not been performed, but it is possible that the procedure could obviate the need for surgical exploration in some infants. ERCP in pediatric patients has been recommended only at facilities with appropriate support staff and specialists with expertise in this procedure in young infants (49).

The Cholestasis Guideline Committee concludes that ERCP is not frequently used because of the cost of instrumentation and the need for technical expertise. The usefulness of ERCP appears to be center and operator dependent. Clinicians with the appropriate expertise and instrumentation will find the test a useful adjunct in the evaluation of the difficult-to-diagnose cause of cholestasis in an infant in whom laparotomy is being contemplated. The Committee recommends that a liver biopsy be obtained before subjecting an infant to ERCP. Under selected circumstances, ERCP can clarify the cause of neonatal cholestasis and obviate the need for laparotomy. ERCP can be recommended in selected cases at facilities with appropriate support staff and specialists with expertise in this procedure in young infants.

Lipoprotein X

This test is no longer widely available; the few studies on this subject are of poor quality and suggest poor sensitivity and specificity for differentiating biliary atresia from neonatal hepatitis. The Cholestasis Guideline Committee recommends that this test not be performed.

CONCLUSION

The rapid and effective diagnosis of the cause of cholestasis in an infant is challenging. The initial detection of these infants remains in the domain of the primary care provider and depends on the recognition of jaundice past the age of 2 weeks or recognition of abnormal stool or urine color. Laboratory testing for cholestasis should include direct (conjugated) bilirubin. A direct bilirubin value greater than 1.0 mg/dL if the total bilirubin is less than 5 mg/dL or a direct bilirubin more than 20% of the total bilirubin if the total bilirubin is greater than 5 mg/dL is considered abnormal. The relative rarity of cholestatic jaundice in contrast to unconjugated hyperbilirubinemia in this age range dictates that many jaundiced infants will be tested to find a few with elevated direct bilirubin. It is recommended that primary care providers continue to screen for cholestasis, despite its rarity, because of the gravity of the consequences of missed diagnosis.

The Cholestasis Guideline Committee recommends that any infant noted to be jaundiced at 2 weeks of age be evaluated for cholestasis with measurement of total and direct serum bilirubin. However, breast-fed infants who can be reliably monitored and who have an otherwise normal history (no dark urine or light stools) and physical examination may be asked to return at 3 weeks of age and, if jaundice persists, have measurement of total and direct serum bilirubin at that time.

Identification of cholestasis warrants a prompt effort to accurately diagnose the cause. In an ill appearing infant, the primary cause of the acute problem should be sought and treated. Cholestasis that does not resolve with resolution of the acute problem requires thorough evaluation. In a well appearing infant, cholestasis should be evaluated without delay because this condition has etiologies that are both serious and treatable. Patients with extrahepatic biliary atresia often appear well at initial presentation, and in these patients there is evidence that early diagnosis and surgical bile drainage is associated with longer survival of the native liver.

Most of the diagnostic tests that are used to determine the etiology of cholestasis in infants are operator dependent and variable in utility, and most are not commonly performed outside of referral centers. Although specific circumstances may support the performance of diagnostic testing at a referring hospital, most practitioners will need to use the diagnostic expertise of a referral center. Diagnostic workup by referring hospitals may be most useful to quickly exclude some of the many causes of cholestasis.

For all diagnostic tests reviewed, the sensitivity and specificity varied widely. Percutaneous liver biopsy had the greatest diagnostic accuracy in published studies. However, because of the dynamic and progressive nature of extrahepatic biliary atresia, even this test can be misleading. Scintigraphy appears to be primarily useful in excluding extrahepatic obstruction, consistent with the diagnosis of extrahepatic biliary atresia. Sonographic evaluation is currently useful for excluding anatomic abnormalities but may have a greater value in the future if descriptions of new findings (such as the ñtriangular cordò sign) are corroborated. ERCP may have a role in centers with pediatric gastroenterologists experienced in its use. Too little experience with MRCP has been reported to analyze its utility. Duodenal aspirate or string test may be useful in remote sites or if other testing is not readily available.

In summary, the diagnosis of neonatal cholestasis is an urgent matter. This guideline and algorithm have been developed to assist in this process. No single pathway appears to be clearly superior for the diagnosis of conditions leading to cholestasis. A guide is provided here for clinicians who are challenged with the prospect of detecting and evaluating the rare infant with cholestasis. Vigilance is crucial in detecting these patients, selecting appropriate and timely diagnostic testing based on the resources available in their own institutions, and referring the infant to a pediatric gastroenterologist who can provide the essential diagnostic and treatment modalities for optimal outcome. The scarcity and relatively low

quality of research found in this area indicate that further research is needed.

Financial Disclosure: Dr Cheung is on the speakers' bureau of Eli Lilly; Dr Jensen has received several unrestricted educational grants from Eli Lilly, McNeil, and Janssen-Ortho, is a consultant for Shire-Richwood, UCB Pharma, McNeil, and Janssen-Ortho, and is on the speakers' bureau for UCB Pharma, McNeil, and Janssen-Ortho. The other authors have indicated they have no financial relationships relevant to this article to disclose.

Endorsements: The Canadian Paediatric Society, the Society for Adolescent Medicine, the Canadian Association for Adolescent Health, the National Association for Pediatric Nurse Practitioners, the Society for Developmental and Behavioral Pediatrics, the American Academy of Child and Adolescent Psychiatry, the Canadian Academy of Child Psychiatry, the Canadian Psychiatric Association, the College of Family Medicine of Canada, the National Alliance on Mental Illness, the Mental Health Association of New York City, the National Mental Health Association (now known as Mental Health America), the Depression and Bipolar Support Alliance, and the Federation of Families for Children's Mental Health have endorsed these guidelines. Endorsements from the American Academy of Pediatrics and the Canadian Psychological Association are pending. The American Academy of Family Physicians, the American Medical Association, and the American Psychological Association have been involved in the development of the guidelines but do not endorse external guidelines.

ABSTRACT

OBJECTIVES. To develop clinical practice guidelines to assist primary care clinicians in the management of adolescent depression. This first part of the guidelines addresses identification, assessment, and initial management of adolescent depression in primary care settings.

METHODS. By using a combination of evidence- and consensus-based methodologies, guidelines were developed by an expert steering committee in 5 phases, as informed by (1) current scientific evidence (published and unpublished), (2) a series of focus groups, (3) a formal survey, (4) an expert consensus workshop, and (5) draft revision and iteration among members of the steering committee.

RESULTS. Guidelines were developed for youth aged 10 to 21 years and correspond to initial phases of adolescent depression management in primary care, including identification of at-risk youth, assessment and diagnosis, and initial management. The strength of each recommendation and its evidence base are summarized. The identification, assessment, and initial management section of the guidelines includes recommendations for (1) identification of depression in youth at high risk, (2) systematic assessment procedures using reliable depression scales, patient and caregiver interviews, and *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* criteria, (3) patient and family psychoeducation, (4) establishing relevant links in the community, and (5) the establishment of a safety plan.

CONCLUSIONS. This part of the guidelines is intended to assist primary care clinicians in the identification and initial management of depressed adolescents in an era of great clinical need and a shortage of mental health specialists but cannot replace clinical judgment; these guidelines are not meant to be the sole source of guidance for adolescent depression management. Additional research that addresses the identification and initial management of depressed youth in primary care is needed, including empirical testing of these guidelines.

MAJOR DEPRESSION IN adolescents is recognized as a serious psychiatric illness with extensive acute and chronic morbidity and mortality.[1,2] Research shows that only 50% of adolescents with depression are diagnosed before they reach adulthood.[3] In primary care (PC), as many as 2 in 3 depressed youth are not identified by their PC clinicians and do not receive any kind of care.[4,5] Even when diagnosed by PC physicians, only half of these patients are treated appropriately.[3] Furthermore, rates of completion of specialty mental health referral for youth with a recognized emotional disorder from general medical settings are quite low (J. V. Campo, MD, written communication, 2006).

In view of the shortage of mental health clinicians and barriers to children having access to mental health professionals, the well-documented need for PC clinicians to learn how to manage this condition, the increasing evidence base available to guide clinical practice, increased selective serotonin reuptake inhibitor–prescribing rates in pediatric PC,[6,7] and new evidence that a multifaceted approach with mental health consultation may improve the management of depression in PC settings,[8–11] guidelines may be a necessary first step in the identification and management of depression in adolescents in PC. Unfortunately, no depression-management guidelines have been developed for use in the PC setting in the United States or Canada.

Although additional randomized, controlled, clinical trial (RCT) information is urgently needed to guide PC clinicians in optimal management approaches, such studies often take years to complete, and many critical PC adolescent depression-management questions have not been, and will likely never be, addressed in completed or ongoing studies. To address this gap and meet the needs of PC clinicians and families who are on the "front lines" with few mental health resources available, this report and its companion article[12] constitute the first-ever evidence- and expert consensus–derived guidelines to guide PC clinicians' management of adolescent depression. These guidelines are also accompanied by a toolkit (available at no cost for download at www.glad-pc.org; see Appendix).

Over the last 3 years, the Center for the Advancement of Children's Mental Health at Columbia University and the Sunnybrook Health Sciences Center at the University of Toronto joined forces with the New York Forum for Child Health, New York District II and New York Chapters 1 through 3 of the American Academy of Pediatrics and, more recently, the REACH Institute, along with leading experts across the United States and Canada, to address the need for a synthesis of knowledge in this area. The result of this initiative was the development of the Guidelines for the Management of Adolescent Depression in Primary Care (GLAD-PC). These guidelines are based on available research and consensus of experts in depression and in PC.

In this article, we present the summary result of literature reviews of the available data and the recommendations on the identification and assessment of depression in PC settings; in our accompanying report,[12] we present the results of the reviews and recommendations on treatment (psychotherapy, psychopharmacology, and pediatric counseling) and ongoing management. Although very few studies have addressed adolescent depression identification and management in PC settings, many PC clinicians are already attempting to change their clinical practices; thus, a great need exists to develop and disseminate methods and tools for assisting PC clinicians in managing adolescent depression.

Major depressive disorder (MDD) is a specific diagnosis described in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV),[13] which includes symptoms of low mood, anhedonia, and other neurovegetative symptoms (ie, insomnia, decreased concentration, low energy, etc). Other types of depression exist, including dysthymia, subthreshold forms, or those that occur as part of bipolar disorder or other mental illness. Although the evidence for the psychopharmacology recommendations in the accompanying article[12] focus exclusively on MDD, the recommendations around identification, assessment, and initial management can be applied to other forms of depression as well.

Our guidelines also distinguish between mild, moderate, and severe forms of MDD. The DSM-IV depression criteria include 9 specific symptoms that have been shown to cluster together, run in families, and have a genetic basis,[14–18] and a large body of evidence accumulated over time now supports the internal consistency of depressive symptoms and the validity of the major depression construct, based on the validational criteria for all psychiatric diagnoses.[14] According to the DSM-IV, severity of depressive disorders can be based on symptom count. This commonly used method to define depression severity has been used in large population-based studies[19] and may be particularly relevant in PC settings in which less-severe clinical presentations of depression may be more common. Thus, mild depression may be characterized on the basis of lower scores in standardized depression scales with shorter duration of symptoms or meeting minimal criteria for depression. Following the DSM-IV, mild depression might be defined as 5 to 6 symptoms that are mild in severity. Furthermore, the patient might experience only mild impairment in functioning.

In contrast, depression might be deemed to be severe if a patient experiences all of the depressive symptoms listed in the DSM-IV. Depression might also be considered severe if the patient experiences severe impairment in functioning. Moderate depression falls between these 2 categories. In general, however, even if not all 9 DSM-IV–defined symptoms of depression are present, for the purposes of these guidelines, an adolescent who meets at

least 5 criteria for the diagnosis of MDD should be considered to be in the severe category if he or she presents with a specific suicide plan, clear intent, or recent attempt; psychotic symptoms; or severe impairment in functioning (such as being unable to leave home).

These guidelines were developed for PC clinicians who are in a position to identify and assist depressed youth in their practice settings. Although the age range of 10 to 21 years may encompass preteens, adolescents, and young adults in specific instances, this age range was chosen to include those who might be developmentally "adolescent." Research that supports adult depression guidelines includes adults 18 years and older. Much of the adolescent depression research focuses on children 18 years and younger. However, because adolescent medicine clinicians and school health clinicians often see patients until they are 21 years old, we have included the older adolescents. However, a primary caregiver faced with an adolescent between the ages of 18 and 21 can choose to use either adult or adolescent depression guidelines on the basis of the developmental status of the adolescent and their own comfort and familiarity with each set of guidelines.

METHODS

The following recommendations were developed on the basis of a synthesis of expert consensus- and evidence-based research-review methodologies. We compiled the necessary information to develop these recommendations in 5 phases.

1. To understand the problems and obstacles faced by PC clinicians regarding the management of adolescent depression, we first conducted focus groups with PC clinicians and youth patients and their family members to review issues pertinent to the PC management of depression.
2. Systematic literature reviews were conducted in each of 5 key areas in which recommendations were subsequently developed. Whenever possible, these reviews focused on identifying empirical evidence that was developed within child/adolescent PC settings. When PC studies were unavailable, research from specialty mental health care was reviewed. In all 5 review instances, the GLAD-PC Steering Group first determined the existence of all high-quality, previously published, systematic evidence-based reviews that met the following criteria: (*a*) clear definition of search terms from Medline, including words and word roots; (*b*) explicit delineation of years searched; (*c*) exclusion of non–English-language studies; (*d*) physical review and reading of search-identified titles and abstracts; and (*e*) selection, review, and reading of possibly relevant articles before determination of final inclusion. When more than 1 systematic evidence-based review was identified for a given area, all reviews were drawn on to identify relevant articles for potential inclusion. More than 1 systematic evidence-based review was available for the areas of efficacy of psychotherapeutic interventions for youth MDD and efficacy of pharmacologic treatments for youth MDD. For all reviews, when appropriate, we updated the review for any ensuing years transpired since the latest review by using these same 5 methods. When systematic reviews were not available for a given area, the GLAD-PC team conducted a systematic review by using Medline (from inception to 2004/2005) and the criteria described above. Reviews were guided by members of the GLAD-PC Steering Committee, which comprised leading experts in each of these areas.

   To address the first key area regarding the identification and assessment of adolescent depression in PC, a systematic evidence review was conducted to identify all available evidence about adolescent depression identification in PC, as well as information regarding current practices. This review has since been published.[20] Because of limited information about depression assessment and screening measures in PC specifically, we also reviewed adolescent-screening instruments/tools previously used in psychiatric or community populations. Beginning from 2 previous systematic evidence reviews,[21,22] the GLAD-PC team performed an additional systematic review from 1998 to 2004.

   To address the second key area regarding the initial management of adolescent depression in PC, a systematic evidence review was conducted to identify all available evidence about interventions for adolescent depression in PC and has since been published as well.[23] Other evidence for the initial management of adolescent depression in PC came from systematic evidence reviews that addressed the chronic illness model, systems of care, and safety planning for suicidal patients.
3. On the basis of the questions and issues identified during the focus groups and the literature reviews, we developed a survey to answer questions regarding critical issues in PC management of adolescent depression that have not been answered in the empirical literature. The survey questions were developed and reviewed by clinical and research experts in the area of mental health and PC. Using this survey, research and clinical experts were surveyed on their depression assessment and management recommendations. Depression clinical/research experts ($N = 81$) from Canada and the United States were asked to complete the 34-item study survey. Of these items, 3 questions dealt with the identification and diagnosis of depression. Subjects were chosen by using 1 of 4 criteria: (*a*) membership in child and adolescent psychiatric organizations in Canada and the United States including their academies of child and adoles-

cent psychiatry; (*b*) recipient of federal grants for related research; (*c*) lead author of at least 2 articles on clinical research in the area from 1999 to 2004 on the basis of Medline citations; or (*d*) key PC clinical and research leader with expertise in the area of guideline development and/or emotional and behavioral disorders that present in PC settings. Complete survey results ($n = 76$) will be presented in a subsequent peer-reviewed article and are available from the authors on request.[24]

4. An expert consensus workshop was held in July 2004 with 81 North American experts on depression, clinical pediatrics, quality improvement, mental health policy, and health economics. Published data from the literature review, unpublished high-quality research currently in process of publication, and the results of the survey were presented to guide the initial discussion and consensus process.
5. Guidelines were developed on the basis of multiple iterations shared among a small group of core writers, guidance of the larger steering committee, and ultimate input of all consensus-conference attendees to obtain full ownership of the final product. The results of this process are presented below.

On the basis of the 5-step method, 2 guidelines were developed to address different areas of adolescent depression management in PC settings: (1) identification, assessment, and initial management and (2) treatment and ongoing management. This part of the guidelines focuses on identification, assessment, and initial management. Each section of both guidelines is composed of individual recommendations followed by a brief rationale that refers to available empirical findings and experts' consensus opinion on which the recommendations were based. Each recommendation is graded on the basis of the Oxford Centre for Evidence-Based Medicine grade of evidence (A–D) system (see www.cebm.net/levels_of_evidence.asp). In addition, the strength of each recommendation, in terms of the extent to which experts agreed that the recommendation is highly appropriate and a "first-line" practice, was reached for each recommendation. Recommendation strength was rated in 4 categories: very strong (>90% agreement), strong (>70% agreement), fair (>50% agreement), and weak (<50% agreement). The recommendations in the guidelines were developed only in areas of management that had at least "strong agreement" among experts.

RESULTS

Literature Reviews: Identification and Assessment

Twenty-five articles were located that discussed specific identification methods for adolescent depression in pediatric PC. Only 10 of these articles presented psychometric data of any kind, such as sensitivity, specificity, positive predictive value, negative predictive value, and area under the curve (a full table is available in the published review[20]). One of the 25, plus an additional 5 survey articles, dealt with current identification practices by PC physicians. According to those data, most PC clinicians rely on the use of presenting complaints and family concerns to identify depressed youth.[25] Likewise, other surveys confirmed that very few pediatric providers have instituted a systematic assessment or case-finding tool to identify adolescent depression.[26,27]

Despite clinicians' principal reliance on adolescent and parental chief complaints and physician interview in current practice, the authors of the review found that the use of these methods alone underidentify adolescent depression.[20] Even physicians who are trained in the use of mnemonics to guide interviews underidentify adolescent depression.[28] Instead, only by asking patients directly about depression and suicide (versus relying on them to volunteer the information) does one reliably improve case finding and the psychometric quality of diagnostic data.[29–32] Using systematic assessment methods with depression-specific questions seems to provide the best identification results.[27–29,33]

Many steps are involved in implementing systematic depression-identification procedures within a busy practice setting (eg, training office staff in the use of procedures, adjusting other paperwork demands to fit the depression-identification procedures, ensuring that providers review the information, teaching providers how to use the information, and determining whether the procedures actually benefit youth). Although no study has documented the feasibility and outcomes of taking all of these steps within a single study, evidence from the review cited above as well as a recently published pilot study,[34] suggests that each of these steps can be implemented in real-world settings (ie, training office staff[27,28,30,33–37], ensuring PC providers review any results[27,28,32–34,37], and establishing that appropriate counseling and/or needed mental health referrals are made[33,39]). Finally, and perhaps most importantly, although no study compared outcomes between screened and not-screened groups, 1 study did demonstrate that an identification program in PC when combined with high-quality depression treatment actually yields better outcomes than treatment-as-usual conditions[8] (when no high-quality depression treatment is available).

Because of limited information about depression assessment and screening measures in PC specifically, we also reviewed adolescent-screening instruments/tools previously used in psychiatric or community populations. Beginning from 2 previous systematic evidence reviews,[21,22] the GLAD-PC team performed an additional systematic review for the years 1998–2004 and found 15 studies with psychometric performance data on depression instruments in English-speaking adolescents. A table that presents these 15 studies, the gold-standard

diagnostic assessment used, sensitivity, specificity, positive predictive value, negative predictive value, prevalence, and study population is available on request. Commonly used adolescent-screening instruments included the Beck Depression Inventory,[40] the Reynolds Adolescent Depression Screen,[41] and the Mood and Feelings Questionnaire.[42] Sensitivities of these more common instruments ranged from .70 to .90, and specificities ranged from .39 to .90. In addition, the Kutcher Adolescent Depression Scale, a newer 6- item instrument, had sensitivity and specificity of .81 and .86, respectively, in a school population with a positive predictive value of .39 and a negative predictive value of .98 given a 10% prevalence.[43]

In summary, no perfect depression screening/assessment tool exists, but a number of adolescent depression assessment instruments do possess adequate psychometric properties to commend their use in depression detection and assessment. Thus, it is reasonable to expect that depression detection in PC can be improved by the use of self- or parent-report checklists. Reliance on adolescent self-report depression checklists alone will lead to substantial numbers of false-positive and false-negative cases. Instead, optimal diagnostic procedures should combine the use of depression-specific screening tools as diagnostic aids buttressed by follow-up clinical interviews in which one obtains information from other informants (eg, parents) and reconciles discrepant information to arrive at an accurate diagnosis and impairment assessment before treatment. For more information about rating scales and cutoff scores, please refer to the GLAD-PC toolkit (available at www.glad-pc.org; see Appendix).

Initial Management of Adolescent Depression

A GLAD-PC review of adolescent depression interventions performed in PC[23] found 4 articles that directly discussed interventions for adolescent depression in PC, only 1 of which reported an intervention by a PC staff member as opposed to a mental health worker.[44] This identified RCT[44] evaluated the effectiveness of a PC-delivered consultation intervention that invited teens from 8 general practices in Britain to discuss their health concerns with a PC nurse who provided individual consultations. In addition to discussing adolescents' general health concerns, the PC nurses offered mental health referrals when they deemed it appropriate. Posthoc analyses indicated that among teens with high Center for Epidemiological Studies Depression Scale for Children (CES-DC) scores, those who were randomly assigned to the PC nurse consultation had lower CES-DC scores on follow-up than adolescents with high CES-DC scores who were not randomly assigned to the consultation, which suggests that a PC-delivered intervention may be useful in addressing depression symptoms and/or similar emotional issues (because these patients were not diagnosed with a depressive disorder per se), perhaps by the consultation itself or by the resulting referral to mental health.

Although the study discussed above was the only one that dealt with an intervention by a PC provider for adolescent depression, the large multisite trial conducted by Asarnow et al[8] showed that improving links between PC and mental health will result in better outcomes for depressed adolescents who present in PC.

In addition, on behalf of the GLAD-PC team, Stein et al[23] reviewed the literature on psychosocial interventions for anticipatory guidance. No RCTs or evidence-based reviews were found.[23] Citing earlier literature reviews in the area of injury prevention[45] and anticipatory guidance[46]; Stein et al[23] found some limited evidence that anticipatory guidance strategies such as education and counseling in the PC setting can be effective.

Another area reviewed by Stein et al[23] involved psychosocial interventions for improved adherence. An evidence review by Lemanek et al[47] on asthma adherence suggested that some educational and behavioral strategies are "probably efficacious" in creating change. In addition, a study that used cognitive behavioral strategies suggested that diabetic adherence can also be improved.[47]

In addition, our team searched the Cochrane database for systematic reviews of all types of interventions implemented in the adherence arena. These reviews[48–50] suggested that only complex, multifaceted approaches that included convenient care, patient education, reminders, reinforcement, counseling, and additional supervision by a member of the care team were effective in improving adherence in different chronic medical conditions including asthma, hypertension, diabetes, and adult depression. These complex models have also moved beyond the somewhat paternalistic traditional model to a model of shared decision-making between the provider and patient.[51] However, improvements in treatment outcomes remain small even with these complex and resource-intensive interventions.[49] In the pediatric literature, research regarding adherence commonly involved interventions that targeted both patients and their families.[52] Several key components have been identified that may improve compliance/adherence, including patient self-management/monitoring, patient/family education/support, and the setting and documentation of achievement of management goals.[53,54] The identification and periodic review of short- and long-term goals provides an individualized plan that both the provider and the patient and family can follow over time.[53,54] However, current research evidence suggests that more complex interventions that include shared decision-making between provider and patient are likely to have the greatest impact on both adherence and treatment outcomes. This kind of coordinated care has been designated the PC medical home and is discussed further in this section.[55]

Factors that pertain to the linkages between/among organizations have been studied as well. For example, the concept of "system of care" was first described in 1986 in a monograph by Stroul and Friedman[56] and used to support the Children and Adolescent Service System Program; their monograph outlined the ideal model for an integrated system of care for children and youth with severe emotional disturbances. Over the last 2 decades, numerous examples of comprehensive, coordinated, community-based systems of care have been implemented and evaluated.[57–60] Most of them showed no improvement in patient outcomes but significant improvement in other areas such as patient/family satisfaction, decreased wait time, and more appropriate care.[57–60]

In the chronic care medical literature, PC professionals have been encouraged to provide a medical home for their patients with chronic conditions. In effect, professionals are expected to remain accessible to patients and families through periods of quiescence and medical crises, coordinate care with other health care professionals, advocate with third-party payers, and provide continuity of care to prevent long-term consequences of chronic illnesses.[61–63] A review of the evidence for the medical home was conducted by Cooley,[55] who found that although no studies of the outcomes of the broad application of the medical home exist, some evidence exists for positive outcomes for different aspects of the concept. Again, no RCTs exist that we could find. In 1 study, children without a medical home were twice as likely to delay or forego needed care and to have unmet health care service needs.[64] Two other reviews focused on the impact of coordination of care and continuity of care.[65,66] As a recent vaccination study demonstrated, just having a medical home available to a patient does not necessarily mean that the patient will make full use of the available services.[67] Thus, as outlined in a recent American Academy of Pediatrics policy statement,[68] the medical home must provide care coordination and help patients to make use of available resources.

Although the "system of care" focuses on the overall coordination of care involving many agencies that are involved in the care of youth (child welfare services, schools, etc), a crucial link in that system and for adolescent depression is that between mental health and PC. Currently, no specific literature addresses the issue of referral to specialty care of adolescent patients with depression (such as which subgroups of patients would benefit from referral to mental health professionals). Studies have been conducted with adults with depression that demonstrate that increased collaborative care between mental health and PC professionals is needed to improve the care of patients with depression in PC.[11,69–71] The adult literature shows the importance of a close working relationship between mental health specialists and PC clinicians in the PC setting.[11,69] Different models of collaboration have been shown to be effective in the adult depression literature, including the use of case managers in PC practices and consultation by on-site mental health clinicians. Other models include shared care and telephone consultation on an ad hoc basis. Although these models suggest improved outcomes for both clinicians and patients, there are significant barriers to the successful implementation of these collaborative models, including funding deficiencies and shortage of mental health providers. Financial and other incentives for both PC and mental health clinicians to develop these models and obtain the training needed to function within these models are essential. Increased development of skills needed for collaborative care and training in mental health may also be addressed at earlier stages of training such as during residency for both PC and mental health clinicians.

Safety Planning

Safety planning with depressed suicidal or potentially suicidal adolescent patients usually consists of instructing the family to remove lethal means, instructing the family to monitor for risk factors for suicide, engaging the potentially suicidal adolescent in his or her treatment, providing adolescents with mutually agreeable and available emergency contacts should they find themselves with increasing suicidality, and establishing clear follow-up. Our review of the literature found no trials that have studied the impact of or how to conduct any of these aspects of safety planning with depressed adolescents. No studies have examined the benefits or risks of a safety contract. Some studies have suggested that limiting access to firearms or other lethal means can decrease suicide by those methods,[72–75] but the evidence is still unclear as to whether, on a broader population level, restricting access to certain lethal methods results in an overall decrease of suicide rates. In addition, a study by Brent et al[76] found that families of depressed adolescents are frequently noncompliant with recommendations to remove firearms from the house. Yet, a small prospective follow-up of patients seen in an emergency department for mental health concerns found that the majority of families removed or secured lethal means (firearms, alcohol, prescription medications, and over-the-counter medications) after injury-prevention education in the emergency department, whereas no families who did not receive injury-prevention education did so.[76] Some limited evidence suggests that quick and consistent follow-up with a team approach will be most helpful in increasing compliance and engagement among suicidal patients.[78,79]

GUIDELINES

Identification

Recommendation 1: Patients with depression risk factors (such as history of previous episodes, family history, other psychiatric

disorders, substance abuse, trauma, psychosocial adversity, etc) should be identified (grade of evidence: C; strength of recommendation: very strong) and systematically monitored over time for the development of a depressive disorder (grade of evidence: C; strength of recommendation: very strong).

Although most PC clinicians believe it is their responsibility to identify depression in their adolescent patients, evidence suggests that only a fraction of these youth are identified when they present in PC settings, and only 50% of depressed adolescents are diagnosed before reaching adulthood.[3,25] As part of overall health care, PC clinicians should routinely monitor the psychosocial functioning of all youth, because problems in psychosocial functioning may be an early indication of a variety of problems, including depression. For those at known increased risk for depression, PC clinicians should use systematic, effective identification strategies. Risk factors that clinicians may use to identify those who are at high risk for depression include a personal history and/or family history of (1) depression, (2) bipolar disorder, (3) suicide-related behaviors, (4) substance abuse, and (5) other psychiatric illness, or (6) significant psychosocial stressors such as family crises, physical and sexual abuse and neglect, and other trauma history. Research evidence shows that patients who present with such risk factors are likely to experience future depressive episodes.[17,80–86] Patients who have been treated for depression or suicidality in the past should continue to be monitored. PC clinicians should systematically evaluate adolescents at high risk for depression during health care visits (ie, well-child visits, urgent care visits). This systematic assessment should take place at least once a year, but frequent somatizers may need to be assessed more often.

Identification methods of youth at high risk may involve tools such as standardized written instruments, either generalized (eg, Guidelines for Adolescent Preventive Services and Strength and Difficulties Questionnaire) or specific emotional symptom checklists (eg, Beck Depression Inventory, Kutcher Adolescent Depression Scale). Although mnemonic-based interviews (eg, HEADSS: home, education/employment, activities, drugs, sexuality, suicide/depression) may also be used routinely during visits to guide the direct interview, systematic and scheduled use of psychometrically reliable and practical methods such as brief symptom checklists or validated depression scales are a preferred adjunct.

Assessment/Diagnosis

Recommendation 1: PC clinicians should evaluate for depression in adolescents at high risk as well as those who present with emotional problems as the chief complaint (grade of evidence: B; strength of recommendation: very strong). Clinicians should assess for depressive symptoms on the basis of diagnostic criteria established in the DSM-IV or International Classification of Diseases, 10th Revision *(grade of evidence: B; strength of recommendation: very strong) and should use standardized depression tools to aid in the assessment (grade of evidence: A; strength of recommendation: very strong).*

PC clinicians should probe for the presence of any of several depressive disorders, including MDD, dysthymia, and depression not otherwise specified by using systematic, rigorous assessment methods. Standardized instruments should be used to help with diagnosis but should not replace direct interview by the clinician.[87–89] Because adolescents with depression may not be able to clearly identify depressed mood as their presenting complaint, providers need to be aware of common presenting symptoms that may signal MDD. These symptoms may include insomnia, weight loss, decline in academic functioning, family conflict, and other symptoms of depressive disorders.[90] The *Diagnostic and Statistical Manual for Primary Care*[91] can help PC clinicians distinguish between transient depressive responses and depressive disorders.

Recommendation 2: Assessment for depression should include direct interviews with the patients and families/caregivers (grade of evidence: B; strength of recommendation: very strong) and should include the assessment of functional impairment in different domains (grade of evidence: B; strength of recommendation: very strong) and other existing psychiatric conditions (grade of evidence: B; strength of recommendation: very strong).

Evidence of the core symptoms of depression and functional impairment should be obtained from the youth and from families/caregivers separately.[92–94] The involvement of the family is critical in all phases of management and should be included in the assessment for depressive disorders. Family relationships also may affect the presentation of depression in adolescents. Cultural background of the patients and their families also must be considered during the assessment, because it can affect the presentation of core symptoms.[95] Collateral information from other sources (such as teachers) may also be obtained to aid in the assessment. Given the high rates of comorbidities, clinicians should assess for the existence of comorbid conditions that may affect the diagnosis and treatment of the depressive disorder.[2,17,96,97] These comorbidities may include 1 or more of the following conditions: substance abuse, anxiety disorder, attention-deficit/hyperactivity disorder, bipolar disorder, physical abuse, sexual abuse, and trauma. Instruments that assess for a range of common comorbid mental health conditions should be considered also. Clinicians should also assess for impairment in key areas of functioning including school, home, and peer settings.[98] Subjective distress should be assessed also. Regardless of the diagnostic impression or any additional treatment plans, a safety assessment must be completed by the clinician (see recommendation 4 in "Initial Management of Depression").

Initial Management of Depression

Recommendation 1: Clinicians should educate and counsel families and patients about depression and options for the management of the disorder (grade of evidence: C; strength of recommendation: very strong). Clinicians should also discuss limits of confidentiality with the adolescent and family (grade of evidence: D; strength of recommendation: very strong).

Management should be based on a plan developed with the understanding that depression is often a recurring condition. As seen in studies of depression interventions, families and patients need to be educated about the causes and symptoms of depression, impairments associated with it, and the expected outcomes of treatment.[23,99–101] Information should be provided at a developmentally appropriate level, in a way that the patient and family can understand the nature of the condition and the management plan. Communication that is developmentally appropriate should facilitate the ability of parents and patients to work with the clinician to develop an effective and achievable treatment plan. To establish a strong therapeutic alliance, the clinician should also take into account cultural factors that may affect the diagnosis and management of this disorder.[95] Clinicians should also be aware of the negative reactions of family members to a possible diagnosis of depression in the teen (ie, sadness, anger, denial). Sample materials are available in the GLAD-PC toolkit and include resources for patients and parents. Because the symptoms of depression can also affect many areas of an adolescent's life, other ongoing partnerships may need to be established with personnel in schools and other settings (extracurricular activities). Confidentiality must also be discussed with the adolescent and his or her family. Adolescents and their families should be aware of the limits of confidentiality, including the need to involve parents or legal authorities when the risk of harm to the adolescent or others may be imminent. Clinicians should be aware of state laws regarding confidentiality (eg, see www.advocatesforyouth.org/publications/iag/confhlth.htm for additional information).

Recommendation 2: Clinicians should develop a treatment plan with patients and families (grade of evidence: C; strength of recommendation: very strong) and set specific treatment goals in key areas of functioning, including home, peer, and school settings (grade of evidence: D; strength of recommendation: very strong).

From studies of chronic disorders in youth, it is suggested that better adherence to treatment is associated with the identification and tracking of specific treatment goals and outcomes. Written action plans in asthma management have produced evidence for improved outcomes.[102] If a patient presents with moderate-to-severe depression or has persistent depressive symptoms, treatment goals and outcomes should be identified and agreed upon, based on close collaboration with the patient and family at the time of treatment initiation. Treatment goals may include the establishment of a regular exercise routine, adequate nutrition, and regular meetings to resolve issues at home. In the adult depression literature, monitoring seems most effective when implemented through designated case managers who monitor patients' clinical status and treatment-plan adherence.[9] The benefits of such programs may be enhanced through the use of electronic medical charts and the development of patient registries.

Recommendation 3: The PC clinician should establish relevant links/collaboration with mental health resources in the community (grade of evidence: B; strength of recommendation: very strong), which may include patients and families who have dealt with adolescent depression and are willing to serve as resources to other affected adolescents and their family members (grade of evidence: D; strength of recommendation: very strong).

A major gap in the management of chronic disorders in young people is the lack of linkages between relevant services that make up the system of care for an individual youth.[103] Furthermore, family-based interventions have been shown to help youth with mental illness.[104] Therefore, establishing relevant links/collaboration with mental health resources in the local community, including peer support groups, advocacy groups, and traditional community- or hospital-based mental health services whenever these services are available, is essential to ensure timely and effective access to needed services.[8,105] Such linkages may include prearranged agreement regarding referral, exchange of clinical information, points of contact, etc. Where appropriate (eg, rural areas), clinicians should also establish links with paraprofessionals who may provide the bulk of counseling and supportive services in underserved areas.

Recommendation 4: All management must include the establishment of a safety plan, which includes restricting lethal means, engaging a concerned third party, and developing an emergency communication mechanism should the patient deteriorate, become actively suicidal or dangerous to others, or experience an acute crisis associated with psychosocial stressors, especially during the period of initial treatment when safety concerns are highest (grade of evidence: C; strength of recommendation: very strong).

Suicidality, including ideation, behaviors, or attempts, is common among adolescents with depression. In studies of completed suicide, more than 50% of the victims had a diagnosis of depression.[106] Therefore, clinicians who manage this disorder must develop an emergency communication mechanism for handling increased suicidality or acute crises. After assessing a suicidal patient for suicidality, the clinician must obtain information from a third party, assess that adequate adult supervision and support are available, have an adult agree to help remove lethal medications and firearms from the premises, warn the patient of the disin-

hibiting effects of drugs and alcohol, put contingency planning in place, and establish follow-up within a reasonable period of time.[72,107] This plan should be developed with adolescents (and with their families/caregivers if possible) and should include a list of persons/services for the adolescent to contact in case of acute crisis or increased suicidality. The establishment of this plan is especially important during the period of diagnosis and initial treatment when safety concerns are highest. Clinicians may also work with schools to develop an emergency plan for all students who may experience an acute suicidal crisis. This global approach may prevent, in some instances, having to label a specific child suicidal when providers are merely trying to ensure that safety measures are in place in case the child decompensates. Components of a safety plan may also include a list of persons who are aware of the adolescents' issues and will be able to assist if contacted during an acute crisis.

DISCUSSION

Although not definitive and subject to modification on the basis of ongoing accumulation of additional evidence, this part of the guidelines is intended to address the lack of recommendations regarding the screening, diagnosis, and initial management of depression in adolescents aged 10 to 21 years in PC settings in the United States and Canada. As such, these guidelines are intended to assist clinicians in family medicine, pediatrics, nursing, and internal medicine who may be the first (and sometimes only) clinicians to identify, manage, and possibly treat adolescent depression. These guidelines may also be helpful to allied health professionals who care for adolescents.

Although not all the steps involved in identifying, diagnosing, and initially managing the care for adolescent depression in PC have been (or even can be) subject to rigorous RCTs, there is sound reason to believe that existing tools and management protocols for adolescent depression can be applied in the PC setting. Although more research is needed, our review suggests that these components of the identification and initial management of adolescent depression in PC can be done. The recommendations were developed on the basis of areas that had at least "strong agreement" among experts. However, there were other controversial areas that were not addressed in these recommendations, such as universal screening. New emerging evidence may affect the inclusion of such areas in future iterations of these guidelines and the accompanying toolkit.

Should These Guidelines Be Universally Deployed?

One might question whether PC clinicians should identify and diagnose the problem of adolescent depression if the lack of psychiatric services prevents them from referring these youth.[108] This caution notwithstanding, the increasingly prevailing recommendation is that as a minimum, PC clinicians should be provided the necessary guidance to support their initial management of adolescent depression.[109,110] Nonetheless, because practitioners and their clinical practice settings vary widely in their degree of "readiness" in identifying and managing adolescent depression, it is likely that a good deal of time and flexibility will be required before these guidelines are adopted systematically or as a universal requirement. It is conceivable that integrated health care systems with electronic medical charts, tracking systems, and access to specialty mental health back-up and consultation will be most "ready" and able to fully implement the guidelines. The second part of the guidelines, the companion article,[12] addresses the treatment of this disorder. Practices that do identify adolescent depression and have nowhere to refer the patients may benefit from the guidance offered in the next set of recommendations.

Preparatory Steps

Because the management of adolescent depression may constitute a new or major challenge for some PC practices, a number of important considerations should be kept in mind when preparing to implement the guidelines, given the findings from studies in the adult literature, input from our focus groups with clinicians, families and patients, and the experience of members of the GLAD-PC Steering Committee. Specifically, PC clinicians who manage adolescent depression should pursue (1) additional education regarding issues such as advances in screening, diagnosis, treatment, and follow-up, liability, consent, confidentiality, and billing, (2) practice and systems changes such as office staff training and "buy-in," electronic medical charts, and automated tracking systems, whenever available, and (3) establishing linkages with mental health services.

Linkages with community mental health resources are necessary to both meet the learning needs of the PC clinician and facilitate consultation/referral of difficult cases. Practice and systems changes are useful in increasing clinicians' capacity to ensure monitoring and follow-up of patients with depression. For example, staff training may help prioritize calls from adolescent patients who may not state the nature of their call. Specific tools and/or templates have been developed that offer examples of how to efficiently identify, monitor, track, and refer teens with depression. These materials are available in the GLAD-PC toolkit (available at www.glad-pc.org). The toolkit addresses how each of the recommendations might be accomplished without each practice necessarily having to "reinvent the wheel."

CONCLUSIONS

Review of the evidence suggests that PC clinicians who have appropriate training and are attempting to deliver comprehensive health care should be able to identify and initiate management of adolescent depression. This

will likely require real changes in existing systems of care. As health care models such as the medical home indicate, comprehensive health care must include assessment and coordination of care for both physical and behavioral health. This first part of the guidelines for adolescent depression in PC may enable providers to pull together the current best evidence and attempt to initiate the best available high-quality care, even in instances in which they are not in a position to treat such youth. Mounting evidence suggests that pediatric providers can and should identify and coordinate depression care for their adolescent population.

APPENDIX: PART I TOOLKIT ITEMS

- Screening/assessment instruments (ie, Columbia Depression Scale)
- Information sheet on the developmental considerations in the diagnosis of depression
- Assessment algorithm/flow sheet (Fig 1)
- Fact sheet/family educational materials
- Educational materials on suicide prevention/safety planning

Financial Disclosure: Dr Cheung is on the speakers' bureau of Eli Lilly; Dr Jensen has received several unrestricted educational grants from Eli Lilly, McNeil, and Janssen-Ortho, is a consultant for Shire-Richwood, UCB Pharma, McNeil, and Janssen-Ortho, and is on the speakers' bureau for UCB Pharma, McNeil, and Janssen-Ortho. The other authors have indicated they have no financial relationships relevant to this article to disclose.

Endorsements: The Canadian Paediatric Society, the Society for Adolescent Medicine, the Canadian Association for Adolescent Health, the National Association for Pediatric Nurse Practitioners, the Society for Developmental and Behavioral Pediatrics, the American Academy of Child and Adolescent Psychiatry, the Canadian Academy of Child Psychiatry, the Canadian Psychiatric Association, the College of Family Medicine of Canada, the National Alliance on Mental Illness, the Mental Health Association of New York City, the National Mental Health Association (now known as Mental Health America), the Depression and Bipolar Support Alliance, and the Federation of Families for Children's Mental Health have endorsed these guidelines. Endorsements from the American Academy of Pediatrics and the Canadian Psychological Association are pending. The American Academy of Family Physicians, the American Medical Association, and the American Psychological Association have been involved in the development of the guidelines but do not endorse external guidelines.

ABSTRACT

OBJECTIVES. To develop clinical practice guidelines to assist primary care clinicians in the management of adolescent depression. This second part of the guidelines addresses treatment and ongoing management of adolescent depression in the primary care setting.

METHODS. Using a combination of evidence- and consensus-based methodologies, guidelines were developed in 5 phases as informed by (1) current scientific evidence (published and unpublished), (2) a series of focus groups, (3) a formal survey, (4) an expert consensus workshop, and (5) revision and iteration among members of the steering committee.

RESULTS. These guidelines are targeted for youth aged 10 to 21 years and offer recommendations for the management of adolescent depression in primary care, including (1) active monitoring of mildly depressed youth, (2) details for the specific application of evidence-based medication and psychotherapeutic approaches in cases of moderate-to-severe depression, (3) careful monitoring of adverse effects, (4) consultation and coordination of care with mental health specialists, (5) ongoing tracking of outcomes, and (6) specific steps to be taken in instances of partial or no improvement after an initial treatment has begun. The strength of each recommendation and its evidence base are summarized.

CONCLUSIONS. These guidelines cannot replace clinical judgment, and they should not be the sole source of guidance for adolescent depression management. Nonetheless, the guidelines may assist primary care clinicians in the management of depressed adolescents in an era of great clinical need and a shortage of mental health specialists. Additional research concerning the management of youth with depression in primary care is needed, including the usability, feasibility, and sustainability of guidelines and determination of the extent to which the guidelines actually improve outcomes of youth with depression.

doi:10.1542/peds.2006-1395

Key Words
adolescents, depression, primary care, guidelines

Abbreviations
PC—primary care
MDD—major depressive disorder
AACAP—American Academy of Child and Adolescent Psychiatry
PCP—primary care provider
GLAD-PC—Guidelines for Adolescent Depression in Primary Care
FDA—Food and Drug Administration
RCT—randomized, controlled trial
CES-DC—Center for Epidemiological Studies Depression Scale for Children
MAOI—monoamine oxidase inhibitor
CBT—cognitive behavioral therapy
SSRI—selective serotonin reuptake inhibitor
IPT—interpersonal psychotherapy
CI—confidence interval

Accepted for publication Apr 16, 2007

STUDIES HAVE SHOWN that up to 9% of teenagers meet criteria for depression at any one time, with as many as 1 in 5 teens having a history of depression at some point during adolescence.[1–5] In primary care (PC) settings, point prevalence rates are likely higher, with rates up to 28%.[6–10] Taken together, epidemiologic and PC-specific studies have suggested that despite relatively high rates, major depressive disorder (MDD) in youth is underidentified and undertreated in PC settings.[11]

Because of barriers to adolescents receiving specialty mental health services, only a small percentage of depressed adolescents are treated by mental health professionals.[12] As a result, PC settings have become the de facto mental health clinics for this population, although most PC clinicians feel inadequately trained, supported, or reimbursed for the management of this disorder.[13–18] Although MDD management guidelines have been developed for specialty care settings (eg, see the American Academy of Child and Adolescent Psychiatry [AACAP] practice parameters[19]) or for related problems such as suicidal ideation or attempts,[20] it is clear that significant practice and clinician differences exist between the primary and specialty care settings that do not allow a simple transfer of guidelines from one setting to another.

Recognizing this gap in clinical guidance for PC providers (PCPs), a group of researchers from the United States and Canada established the Guidelines for Adolescent Depression in Primary Care (GLAD-PC), a North American collaborative, to develop guidelines for the management of adolescent depression in the PC setting. The development process of GLAD-PC is described in detail in our companion report.[21] This article describes the recommendations regarding treatment, ongoing management, and follow-up along with the supporting empirical evidence for those recommendations. Our companion article provides the corresponding evidence and resulting recommendations for depression identification, assessment and diagnosis, and initial management before the formal onset of specific treatments.[21]

METHODS

A full description of the methodology used for the development of GLAD-PC is included in our companion article.[21] In brief, the expert collaborative used a mix of qualitative (focus groups, expert consensus) and quantitative (survey, literature reviews) methods to inform the development of GLAD-PC. In view of space limitations, only the results of the literature reviews regarding available evidence pertaining to treatment, ongoing management, and follow-up procedures are presented in this article.

Literature Reviews

The literature-review approach used for all of the reviews was as follows. First, the GLAD-PC team identified the existence of high-quality, previously published, systematic evidence-based reviews that met the following criteria: (1) explicit definition of search terms and years covered; (2) exhaustive search of Medline; (3) reading of abstracts to determine relevance, followed by review of entire articles from relevant abstracts; (4) restriction to English-language journals only; (5) restriction to empirical articles; and (6) identification of any otherwise omitted citations from the reference sections from key reviews. In areas where there were no carefully executed and well-described systematic literature reviews had been recently conducted (ie, Food and Drug Administration [FDA], Cochrane), the GLAD-PC team conducted a systematic review for primary studies for each area by using Medline (from inception to 2004/2005 based on the 5 criteria described above.

Three literature reviews were conducted for the GLAD-PC recommendations presented in this article: (1) nonspecific psychosocial interventions in pediatric PC,[22] (2) antidepressant treatment,[23] and (3) the use of psychotherapy. For the first review, Stein et al[22] searched the literature (Medline, PsycINFO, and the Cochrane database) for articles that examined evidence for psychosocial interventions delivered in the PC setting. The reference lists of all relevant articles were searched for additional studies. In addition, experts in the field were consulted to identify additional studies. Given the paucity of randomized, controlled trials (RCTs) identified earlier in a review by Bower et al[24] in 2001, studies with simple before-and-after comparisons were also included.

In the second review, we examined the efficacy and safety of antidepressant medications in the pediatric population (aged 7–18). The studies were identified in 2 stages. Given the thorough reanalyses of safety data on both published and unpublished clinical trials completed by the FDA, all RCTs included in the FDA safety report were reviewed.[25] Second, to ensure that additional studies not reported to the FDA were not missed, Medline and PsycINFO were searched. For a full description of the review, please refer to the published review.[23]

In the final review, we searched the literature for depression trials that examined the efficacy of psychotherapy. The search included all forms of psychotherapy including both individual and group-based therapies. We not only identified individual studies but also high-quality systematic reviews given the extensive empirical literature in this area. Additional details on each of these searches, including search terms, number of abstracts selected, etc, are available from the authors on request.

Expert Consensus

Expert consensus was reached through 2 stages. First, expert participants completed a survey regarding adolescent depression management. Subsequently, the expert participants then met in a 2-day workshop to review the survey results to reach consensus on key issues regard-

ing identification and treatment of adolescent depression in PC. Overall, the guidelines only included recommendations that the experts agreed are highly appropriate and "first-line" practices.

RESULTS: LITERATURE REVIEWS

Psychosocial Interventions in PC

On behalf of the GLAD-PC team, Stein et al[22] reviewed the evidence for the efficacy of PC-delivered psychosocial interventions. The studies identified were divided into 2 categories of evidence: direct and indirect. Direct evidence included data from studies that evaluated interventions specific for adolescent depression, and indirect evidence included data from studies that examined PC interventions for adults with depression and PC interventions for other psychosocial problems in the pediatric population. Additional details about the review can be found in the Stein et al report.[22]

The literature review identified 4 articles that focused on depression interventions in the PC setting for adolescents,[26–29] all of which showed positive outcomes for the PC-delivered interventions. Walker et al conducted an RCT to evaluate the effectiveness of a PC-delivered consultation intervention that involved teens from 8 general practices in Britain. Teens were invited to discuss their health concerns with PC nurses who provided individual consultations.[22,26] The PC nurses also offered mental health referrals when appropriate. In those with high Center for Epidemiological Studies Depression Scale for Children (CES-DC) scores, those who were randomly assigned to PC nurse consultation had lower CES-DC scores on follow-up than adolescents with high CES-DC scores who were not randomly assigned to the consultation. The results suggest that PC-delivered intervention may be helpful in reducing depressive symptomology as measured by the CES-DC.

Stein et al[22] also identified 6 additional studies that focused on PC counseling, 4 that focused on improved patient outcomes for adult depression, and 2 that focused on improved parent-child relationships in postpartum depression. The adult depression in PC literature has shown that psychosocial support by a physician, nurse, or other staff, in the context of 15-minute problem-solving therapy, improves outcomes in depressed adults.[30–32]

With the pediatric PC literature, findings revealed that authors of previous studies have attempted to train pediatricians in various types of counseling such as anticipatory guidance or preventive counseling in a number of disorder areas. Before the Stein et al review,[22] the most recently published systematic review on the impact of psychosocial interventions in pediatric PC was conducted by Bower et al.[24] These investigators reviewed 25 studies in pediatric PC that demonstrated tremendous variability in the problems treated, clinician interventions, and outcomes studied.[24] As noted by Stein et al,[22] most studies did not compare the intervention group to a control group, and those that were RCTs did not provide enough information to judge the design. Thus, one must be cautious in stating that the "innovative" PC interventions were superior to usual care, although some positive effects were found. However, as shown in a review by Bass et al,[33] 18 studies have demonstrated positive effects of injury-prevention counseling in pediatric PC, and Stein et al[22] reviewed additional studies that suggested that modest educational counseling performed by pediatric PC staff can be useful.

Antidepressant Treatment

The treatment review for antidepressant safety and efficacy included RCTs of antidepressants in youth under the age of 19 with depression. This review has also been published elsewhere.[23] This GLAD-PC–initiated review identified 8 peer-reviewed articles in this area, including 4 trials with fluoxetine,[34–37] 1 with sertraline,[38] 1 with citalopram,[38] 1 with paroxetine,[39] and 1 with venlafaxine.[40] Older antidepressants (ie, monoamine oxidase inhibitors [MAOIs], tricyclic antidepressants) were not included in our review because the current controversy and the recent FDA review only involved newer classes of antidepressants and because of the known lack of efficacy (ie, tricyclic antidepressants) and clinical trials data (ie, MAOIs) for other classes of older antidepressants.[40] Finally, because of the continuing controversy around the disclosure of unpublished clinical research data, unpublished studies included in the FDA review were also reviewed. There were no completed yet unpublished studies identified that were excluded in the FDA analyses. For additional details regarding this review, see the Cheung et al report.[23]

Overall, both individual clinical trial evidence and evidence from systematic reviews support the use of antidepressants in adolescents with MDD. Bridge et al[41] conducted a meta-analysis of the clinical trials data and calculated the numbers needed to treated and numbers needed to harm. They concluded that 6 times more teens would benefit from treatment with antidepressants than would be harmed.[41] In reviewing the individual studies, the percentage of subjects who responded to antidepressants ranged from 47% to 69% and 33% to 57% for those on placebo (see Table 1). The majority of these studies found a significant difference between those on medication versus those on placebo. Overall, fluoxetine has had the largest number of studies with positive results, whereas paroxetine has had the largest number of studies with negative results.[34–37,39,42,43] However, methodologic differences may have played a role in these differing results.[23] The largest study, the Treatment for Adolescent Depression Study, involved subjects who were randomly assigned to receive placebo, cognitive behavioral therapy (CBT) alone, fluoxetine alone, or

TABLE 1 **Response Rates in RCTs of Antidepressants Based on Clinical Global Impression**

Medication	Drug, %	Placebo, %	*P*
Fluoxetine (March et al[36] [2004])[a]	56	33	.02
Fluoxetine (Emslie et al[89] [1997])	52	36.8	.03
Fluoxetine (Emslie et al[62] [2002])	61	35	.001
Paroxetine (Keller et al[39] [2001])[b]	66	48	.02
Paroxetine[c]	69	57.3	NS
Paroxetine[c]	65	46	.005
Citalopram (Wagner et al[38] [2004])	47	45	NS
Sertraline (Wagner et al[90] [2003])	63	53	.05
Escitalopram (Wagner et al[91] [2007])	63	52	NS

NS indicates not significant.

CBT with fluoxetine.[36] Subjects assigned to receive CBT with fluoxetine or fluoxetine alone showed significantly greater improvement in their depressive symptoms compared with those who received placebo or were treated with CBT alone (also see "Cognitive Behavioral Therapy").

Finally, available evidence from several large RCTs[23] suggests that adverse effects do emerge in depressed youth who are treated with antidepressants. Adverse effects (ie, nausea, headaches, behavioral activation, etc) occur in up to 93% of the subjects treated with these medications and in up to 75% of those treated with placebo when subjects are asked about specific adverse effects. Therefore, routine monitoring of the development of adverse events is critical for depressed youth who are treated with antidepressants.

Authors of several recent studies have used population data to evaluate the risks versus benefits of prescribing antidepressants. Olfson et al[44] focused specifically on youth aged 10 to 19 years; their study revealed decreased suicide rates in geographic areas where the rates of newer antidepressant prescriptions are increasing. Gibbons et al[45] reported similar findings when they conducted a study of children aged 5 to 14. Several other studies have focused on general populations that included significant numbers of children and adolescents.[46–49] Although one Australian study did identify a link between increased prescription rates of newer antidepressants and increased suicide rates in adolescents and young adults aged 15 to 24,[46] other American and international studies have indicated an inverse relationship between rates of selective serotonin reuptake inhibitor (SSRI) prescriptions and rates of suicide in adolescent populations.[48,49]

Still other studies have used large databases to carry out naturalistic studies of possible associations between antidepressant use and suicidality.[50–53] In the only 1 of these studies that focused exclusively on youth, Valuck et al[50] conducted a propensity-adjusted retrospective cohort study to examine links between antidepressant treatment and suicide attempts in depressed adolescents (aged 12–18) by using a community sample of managed care enrollees. They found no increase in suicide rates with treatment with SSRIs, other antidepressants, or multiple antidepressants after a diagnosis of MDD, finding instead that treatment for at least 6 months reduced the likelihood of suicide attempts compared with treatment for less than 8 weeks.

Psychotherapy

The final review conducted examined the efficacy of psychotherapy such as CBT, interpersonal psychotherapy (IPT), and nonspecific interventions such as counseling and support. Through our search, we were able to identify both individual studies and several high-quality meta-analyses/reviews that were recently conducted to examine the efficacy of psychotherapy in adolescent depression. A full description of the review is available from the authors on request.

Cognitive Behavioral Therapy

In 1998, Reinecke et al[54] and Harrington et al[55] conducted reviews of CBT trials and found improved outcomes. In addition to the above-mentioned meta-analytical studies, several systematic narrative reviews of CBT studies have been conducted. The most recent and comprehensive of these reviews was conducted by Compton et al[56] and included 12 studies published between 1990 and 2002. Although some of these studies showed negative results, Compton et al conclude that, in sum, they provided solid evidence of the effectiveness of CBT conducted by trained therapists for mild-to-moderate depression.

The effectiveness of CBT for adolescents with moderate to moderately severe depression was evaluated recently in the multicenter Treatment for Adolescents With Depression Study, which randomly assigned 439 depressed 12- to 17-year-olds to treatment with CBT, fluoxetine, CBT plus fluoxetine, or placebo.[36] According to Clinical Global Impressions severity scores, the post-treatment response rate to 15 sessions of CBT over 12 weeks (43.2% [95% confidence interval [CI]: 34–52]) was not significantly different ($P = .40$) from placebo (34.8% [95% CI: 26–44]). The authors attributed this relatively low response rate, in part, to the fact that the study population suffered from more severe and chronic depression than participants in previous studies and to a high rate of psychiatric comorbidity in their study participants.[36] Along with the fairly robust placebo-response rate, it is also possible that the nonspecific therapeutic aspects of this medication management could have successfully competed with the specific effects of the CBT intervention. As a consequence, one cannot and should not conclude that CBT was ineffective.

Although the Compton et al[56] review of studies pro-

vided evidence for the efficacy of CBT in specialty mental health clinics for adolescents with mild-to-moderate depression, more recent studies have helped determine the effectiveness of CBT in "real-world" situations. In 2003, Puskar et al[57] evaluated whether a group CBT intervention conducted in a high school by a masters-level nurse could improve depressive symptoms among 89 rural students with Reynold's Adolescent Depression Screen scores of ≥60. The 46 students who completed 10 weekly CBT group sessions had significantly better mean depressive scores immediately after treatment and at 6 months than those (n = 43) who were randomly assigned to receive usual care. In contrast, Kerfoot et al[58] studied the impact of training social workers in CBT methods (versus treatment as usual) on 52 depressed youth. The study showed no differences in depression scores across the 2 interventions, which was partially attributed to high drop-out rates.[58]

In yet another study with more difficult adolescents, Rohde et al[59] recently assessed the effectiveness of CBT in treating adolescents with comorbid MDD and conduct disorder by recruiting 13- to 17-year-olds (N = 93). After randomly assigning them to a CBT-based "Coping With Depression" course or a life skills tutoring control condition, 39% of the adolescents who "completed" the CBT course recovered compared with only 19% of the adolescents who participated in the life skills tutoring control group (odds ratio: 2.66; 95% CI: 1.03–6.85).

Finally, in the Youth Partners-in-Care study, Asarnow et al[27] evaluated the effectiveness of a quality improvement intervention that involved increasing access of PC clinicians and depressed youth to CBT and antidepressant medication. Participants (N = 418) were randomly assigned to usual care "enhanced" by an education intervention or the quality improvement intervention.[27] At the study's 6-month end point, subjects in the intervention group were significantly improved according to the study's 2 primary outcome variables as measured by the Center for Epidemiological Study Depression Scale. The intervention group had lower Center for Epidemiological Study Depression Scale scores and fewer youth scored in the severe range at the end of the study. Given the fact that the intervention and usual-care groups differed significantly only in their use of CBT (53% vs 36%, respectively; OR: 2.2; 95% CI: 1.3–3.9; P = .007), much of the intervention groups' improvement can be attributed to the availability of this treatment modality for patients screened and identified in PC settings.

Interpersonal Therapy

In terms of IPT, only a handful of studies have been conducted. First, Mufson et al[28] assigned 48 depressed adolescents to IPT for adolescents (IPT-A) or clinical monitoring. Those who received IPT-A reported fewer depressive symptoms and improved overall functioning. In the Rossello and Bernal[60] study, 71 depressed Puerto Rican adolescents were randomly assigned to receive IPT, CBT, or be placed on a waiting list. After 12 weeks, both IPT- and CBT-treated adolescents reported significantly fewer depressive symptoms. In the most recent study, 63 depressed adolescents (any depressive disorder) were randomly assigned to receive either 16 weeks of IPT-A or a treatment-as-usual condition (supportive counseling).[61] Subjects who were treated with IPT-A showed significantly greater symptom reduction and improved overall functioning.

GUIDELINES

Each of the recommendations listed below was graded on the basis of the level of supporting research evidence from the literature and the extent to which experts agreed that it is highly appropriate in PC. The level of supporting evidence for each recommendation is based on the Oxford Centre for Evidence-Based Medicine grades of evidence (A–D) system (see www.cebm.net/levels_of_evidence.asp).

Recommendation strength based on expert consensus was rated in 4 categories: very strong (>90% agreement), strong (>70% agreement), fair (>50% agreement), and weak (<50% agreement). The recommendations in the guidelines were developed only in areas of management that had at least "strong agreement" among experts (see Fig 1 for the treatment algorithm).

Treatment

Recommendation 1: After initial diagnosis, in cases of mild depression, clinicians should consider a period of active support and monitoring before starting other evidence-based treatment (grade of evidence: B; strength of recommendation: very strong).

After a preliminary diagnostic assessment, in cases of mild depression, clinicians should consider a period of active support and monitoring before recommending treatment (from 6 to 8 weeks of weekly or biweekly visits for active monitoring). Evidence from RCTs of antidepressants and CBT show that a sizable percentage of patients respond to nondirective supportive therapy and regular symptom monitoring.[34–40,62–65] However, if symptoms persist, treatment with antidepressants or psychotherapy should be offered. Active support and monitoring is also essential for cases in which depressed patients and/or their families/caregivers refuse other treatments. Active support and counseling for adolescents by pediatric PC clinicians have been evaluated for several different disorders including substance abuse and sleep disorders.[22]

Furthermore, expert opinion based on extensive clinical experience and qualitative research with families, patients, and clinicians indicate that these strategies are a crucial component of management by PC clinicians. For additional guidance on how to provide active sup-

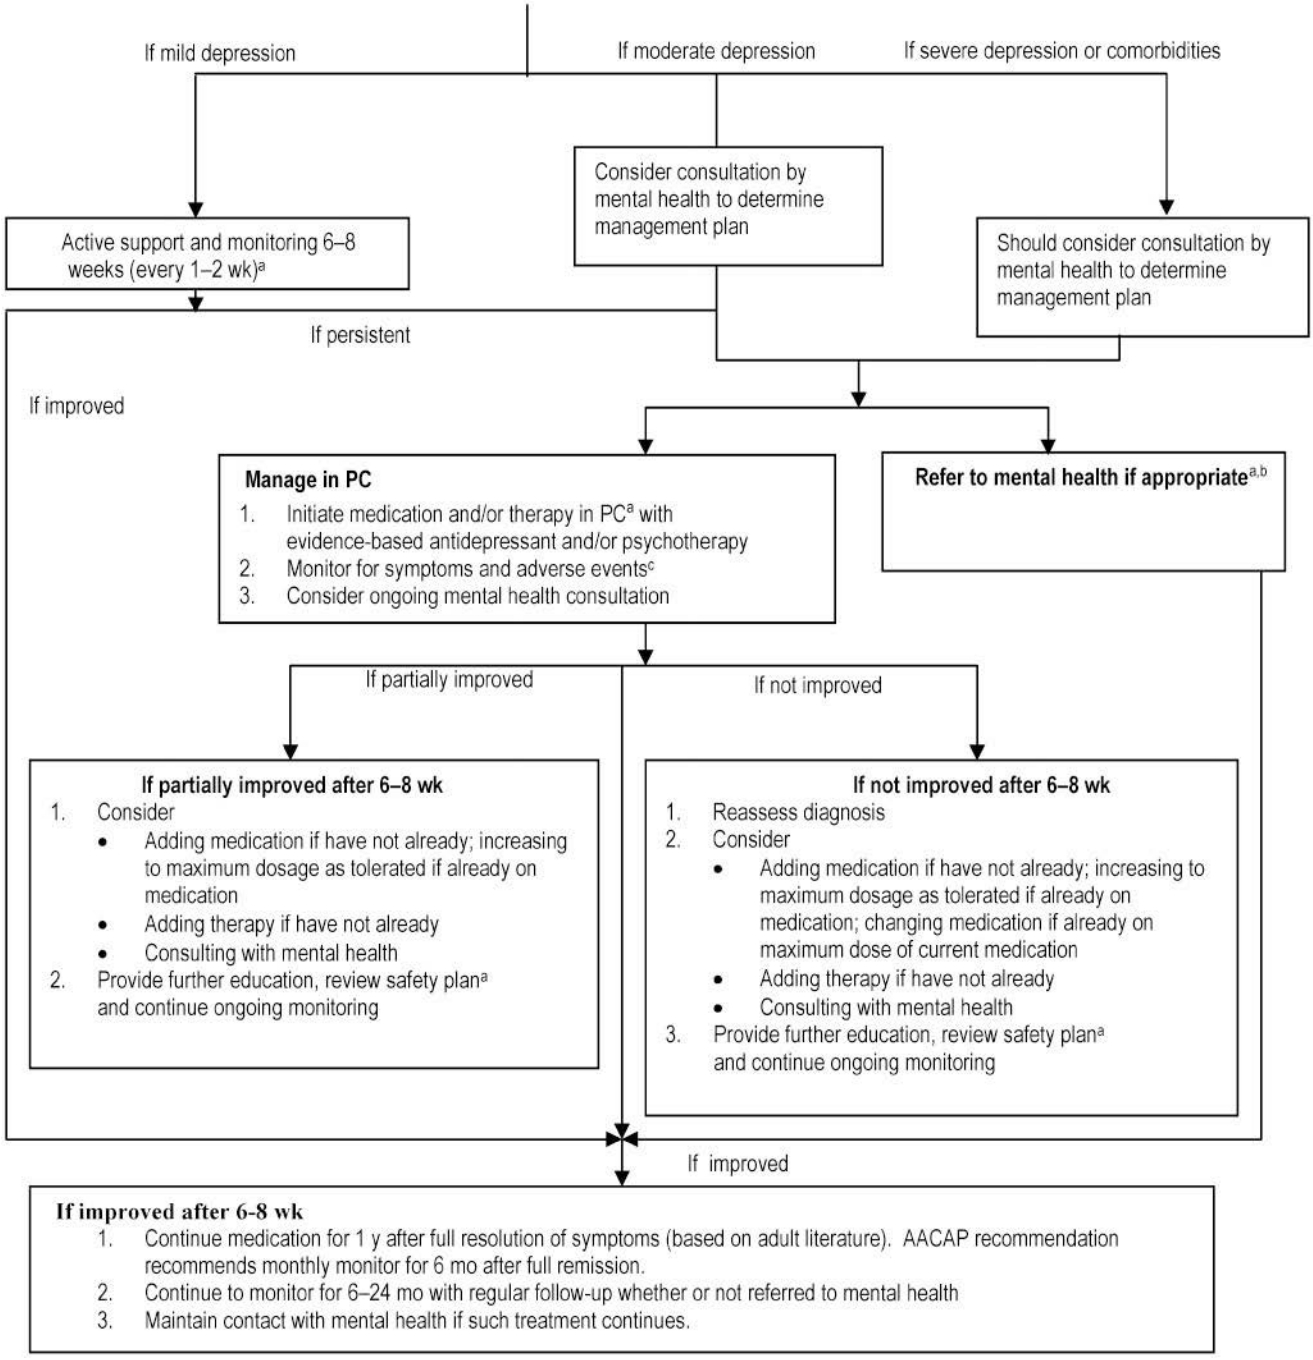

FIGURE 1

Clinical management flowchart. [a] Provide psychoeducation, provide supportive counseling, facilitate parental and patient self-management, refer for peer support, and regularly monitor for depressive symptoms and suicidality. [b] Negotiate roles/responsibilities between PC and mental health and designate case coordination responsibilities; continue to monitor in PC after referral; and maintain contact with mental health. [c] Clinicians should monitor for changes in symptoms and emergence of adverse events such as increased suicidal ideation, agitation, or induction of mania. For monitoring guidelines, refer to the GLAD-PC toolkit.

port, please refer to the GLAD-PC toolkit (available at www.glad-pc.org).

For moderate or severe cases, the clinician should recommend treatment, crisis intervention (as indicated), and mental health consultation immediately without a period of active monitoring.

Recommendation 2: If a PC clinician identifies an adolescent with moderate or severe depression or complicating factors/conditions such as coexisting substance abuse or psychosis, consultation with a mental health specialist should be considered (grade of evidence: C; strength of recommendation: strong). Appropriate roles and responsibilities for ongoing management by the PC and mental health clinicians should be communicated and agreed upon (grade of evidence: C; strength of rec-

ommendation: strong). The patient and family should be consulted and approve the roles of the PC and mental health professionals (grade of evidence: D; strength of recommendation: strong).

In adolescents with severe depression or comorbidities such as substance abuse, clinicians should consider consultation with mental health professionals and refer to such professionals when deemed necessary. In cases of moderate depression with or without comorbid anxiety, clinicians should consider consultation by mental health and/or treatment in the PC setting. Although the access barriers to mental health services need to be addressed by policy makers to make necessary mental health consultations more feasible, available, and affordable in underserviced areas, clinical judgment must prevail in the meantime; thus, the need for consultation should be based on the clinician's judgment. PC clinicians must also take into consideration the treatment preferences of patients/families, the severity and urgency of the case presentation, and the physician's level of training and experience.

Active support and treatment should also be started in cases in which there is a lengthy waiting list for mental health services. Once a referral is made, the PC clinician must remain involved in the follow-up. In particular, roles and responsibilities should be agreed upon between the PC clinician and mental health clinician(s), including the designation of case coordination responsibilities.[66–72]

Recommendation 3: PC clinicians should recommend scientifically tested and proven treatments (ie, psychotherapies such as CBT or IPT and/or antidepressant treatment such as SSRIs) whenever possible and appropriate to achieve the goals of the treatment plan (grade of evidence: A; strength of recommendation: very strong).

After providing education and support to the patient and family, the range of effective treatment including medications, psychotherapies, and family support options should be considered. The patient and family should be assisted to arrive at a treatment plan that is both acceptable and implementable while taking into account their preferences and availability of treatment services. The treatment plan should be customized according to the severity of disease, risk of suicide, and the existence of comorbid conditions. The GLAD-PC toolkit will provide more detailed guidance around the factors that may influence a treatment choice (ie, a patient with psychomotor retardation may not be able to actively engage in psychotherapy). The management of depression in youth is an emerging field, and new treatments may become available. However, common-sense approaches such as the prescription of physical exercise and adequate nutrition should also be used in the management of these patients.

As an aside, the majority of CBT and IPT studies that included patients with MDD also included patients with depression not otherwise specified, subthreshold depressive symptoms, or dysthymic disorder. In contrast, medication RCTs for depression in adolescents generally only included subjects with MDD. Thus, although these guidelines address the treatment of depression generally, medication-specific guidelines apply only to fully expressed MDD.

Psychotherapies

Both CBT and IPT have been adapted to address depression in adolescents and have been shown to be effective in treating adolescents with MDD in tertiary care and in community settings.[28,61,73] CBT has been used in the PC setting with positive preliminary results.[27,29] However, the results of a recent RCT demonstrated superior efficacy of combination therapy (medication and CBT) versus CBT alone.[36] For a brief description of the 2 therapies, see Table 2.

Antidepressant Treatment

Previous research has shown that up to 25% of pediatric PC clinicians and 42% of family physicians in the United States had recently prescribed SSRIs for more than 1 adolescent under the age of 18.[13] When indicated by clinical presentation (clear diagnosis of MDD with no comorbid conditions) and patient/family preference, an SSRI should be used. The selection of the specific SSRI should be based on the optimum combination of safety and efficacy data. The patient and family should be informed about the possible adverse effects (clinicians may use a checklist) including possible switch to mania or the development of behavioral activation or suicidal-behavior. Once the antidepressant is started, and if tolerated, the clinician should ensure an adequate trial up to the maximum dose and duration.

Table 3 lists recommended antidepressants and dos-

TABLE 2 Components of CBT and IPT for Adolescents

Therapy	Key Components
CBT	Thoughts influence behaviors and feelings, and vice versa. Treatment targets a patient's thoughts and behaviors to improve his or her mood.
	Essential elements of CBT include increasing pleasurable activities (behavioral activation), reducing negative thoughts (cognitive restructuring), and improving assertiveness and problem-solving skills to reduce feelings of hopelessness. CBT for adolescents may include sessions with parents/caregivers to review progress and increase compliance with CBT-related tasks.
IPT-A	Interpersonal problems may cause or exacerbate depression, and that depression, in turn, may exacerbate interpersonal problems. Treatment targets a patient's interpersonal problems to improve both interpersonal functioning and his or her mood.
	Essential elements of IPT include identifying an interpersonal problem area, improving interpersonal problem-solving skills, and modifying communication patterns.
	Parents/caregivers are involved in sessions during specific phases of the therapy.

TABLE 3 **SSRI Titration Schedule**

Medication	Starting Dose, mg/d	Increments, mg	Effective Dose, mg	Maximum Dose, mg	Contraindication
Citalopram	10	10	20	60	MAOIs
Fluoxetine	10	10–20	20	60	MAOIs
Fluvoxamine	50	50	150	300	MAOIs
Paroxetine	10	10	20	60	MAOIs
Sertraline	25	12.5–25	50	200	MAOIs
Escitalopram	5	5	10	20	MAOIs

ages for use in youth with depression. These recommendations are based on the expert survey results and were also reviewed by our expert consensus panel. Generally, the effective dosages for antidepressants in adolescents are lower than would be found in adult guidelines. Note that only fluoxetine has been approved by the FDA for use in children and adolescents with depression. Clinicians should know the potential drug interactions with SSRIs. Further information on the use of antidepressants are described in the GLAD-PC toolkit. In addition, all SSRIs, with the exception of fluoxetine, should be slowly tapered when discontinued because of the risk of withdrawal effects. Details regarding the initial selection of a specific SSRI and possible reasons for initial drug choice can be found in the GLAD-PC toolkit.

Contact (either in person or by telephone with either the clinician or member of the clinical staff) should take place after the initiation of treatment to review the patient's and family's understanding of and adherence to the treatment plan. Issues such as the current status of the patient and the patient's/family's access to educational materials regarding depression should be discussed during follow-up conversations. For relevant educational resources for patients and/or families, refer to the GLAD-PC toolkit.

Recommendation 4: PC clinicians should monitor for the emergence of adverse events during antidepressant treatment (SSRIs) (grade of evidence: B; strength of recommendation: very strong).

Recent reanalyses of safety data from clinical trials of antidepressants have led to a black-box warning from the FDA regarding the use of these medications in children and adolescents and a recommendation for close monitoring. The exact wording of the FDA recommendation is, "all pediatric patients being treated with antidepressants for any indication should be observed closely for clinical worsening, suicidality, and unusual changes in behavior, especially during the initial few months of a course of drug therapy, or at times of dose changes, either increases or decreases."

Although the frequency of monitoring has been controversial, the FDA further suggested that, "*Ideally, such observation would include at least weekly face-to-face contact with patients or their family members or caregivers during the first 4 weeks, then at biweekly visits for the next 4 weeks, then at 12 weeks, and as clinically indicated beyond 12 weeks. Additional contact by telephone may be appropriate between face-to-face visits.*" It should be noted, however, that there is no empirical evidence to support the requirement of weekly face-to-face meetings per se for the first 4 weeks after initiating antidepressant treatment. In fact, evidence from large population-based surveys show high reliability of telephone interviews with adolescent subjects for the diagnosis of depression.[74,75] Although obtaining a diagnosis is not the same as the elicitation of adverse events while in treatment, this evidence suggests that telephone contact may be just as effective in monitoring for adverse events. A regular and frequent monitoring schedule should be developed, and care should be taken to obtain input from the adolescents and families to ensure compliance with the monitoring strategy.[76,77] Recommendations endorsed by the AACAP have also highlighted the lack of research evidence to support weekly face-to-face visits. However, the AACAP does recommend that providers attempt to follow the FDA guidelines until other research findings become available.

ONGOING MANAGEMENT

Recommendation 1: Systematic and regular tracking of goals and outcomes from treatment should be performed, including assessment of depressive symptoms and functioning in several key domains: home, school, and peer settings (grade of evidence: D; strength of recommendation: very strong).

Goals should include both improvement in functioning status and resolution of depressive symptoms. Tracking of goals and outcomes from treatment should include function in several important domains (ie, home, school, peers). Evidence from large RCTs demonstrates that depressive symptoms and functional impairments may not improve at the same rate with treatment.[23,36] Therefore, symptoms and functioning should be tracked regularly during the course of treatment with information gathered from both the patients and their families when possible.

According to expert consensus, patients should be seen within 1 week of the initiation of treatment. At every visit, clinicians should inquire about ongoing depressive symptoms, risk of suicide, possible adverse effects from treatment (including the use of specific ad-

verse-effect scales), adherence to treatment, and new or ongoing environmental stressors.

Recently, Emslie et al[63] examined medication maintenance after response. The researchers randomly assigned those pediatric patients who had responded to fluoxetine by 19 weeks to placebo or to medication continuation for an additional 32 weeks. Of the 20 subjects who were randomly assigned to the 32-week medication relapse-prevention arm, 10 were exposed to fluoxetine for 51 weeks. Significantly fewer relapses occurred in the group of subjects who were randomly assigned to medication maintenance, which suggests that longer medication-continuation periods, possibly 1 year, may be necessary for relapse prevention. In addition, Emslie et al[63] found the greatest risk of relapse to be in the first 8 to 12 weeks after discontinuing medication, which suggests that after stopping an antidepressant, close follow-up should be encouraged for at least 2 to 3 months.

With the limited evidence in children and adolescents and the emerging evidence in the adult literature that suggests antidepressant medication should be continued for 1 year, the GLAD-PC and AACAP experts concluded that medication should be maintained for 6 to 12 months after the full resolution of depressive symptoms.[19,78]

However, regardless of the length of treatment, all patients should be monitored on a monthly basis for 6 to 12 months after the full resolution of symptoms.[19] If the depressive episode is a recurrence, clinicians are encouraged to monitor patients for up to 2 years given the high rates of recurrence as demonstrated in the adult literature, in which maintenance treatment in those with recurrent depression continue for up to 2 years after the full resolution of symptoms. Clinicians should obtain consultation from mental health if a teen develops psychosis, suicidal or homicidal ideation, or new or worsening of comorbid conditions.

Recommendation 2: Diagnosis and initial treatment should be reassessed if no improvement is noted after 6 to 8 weeks of treatment (grade of evidence: B; strength of recommendation: very strong). Mental health consultation should be considered (grade of evidence: D; strength of recommendation: very strong).

If improvement is not seen within 6 to 8 weeks of treatment, mental health consultation should be considered. Evidence of improvement may include reduction in the number of depressive symptoms, improved functioning in social or school settings, or improvement spontaneously reported by the adolescent and/or parent/caregiver. The clinician should also reassess the initial diagnosis, choice and adequacy of initial treatment, adherence to treatment plan, presence of comorbid conditions (eg, substance abuse) or bipolar symptoms that may influence treatment effectiveness, and new external stressors. If a patient has no response to maximum therapeutic dose of an antidepressant medication, the clinician should consider changing the medication. Alternatively, if the patient's condition fails to improve on antidepressant medication or therapy alone, the addition of, or switch to, the other modality should be considered.

Recommendation 3: For patients who achieve only partial improvement after PC diagnostic and therapeutic approaches have been exhausted (including exploration of poor adherence, comorbid disorders, and ongoing conflicts or abuse), a mental health consultation should be considered (grade of evidence: D; strength of recommendation: very strong).

If a patient only partially improves with treatment, mental health consultation should be considered. The clinician should also review the diagnosis and explore possible causes of partial response such as poor adherence to treatment, comorbid disorders, or ongoing conflicts and/or abuse. These causes may need to be managed first before changes to the treatment plan are made.

If a patient has been treated with an SSRI (maximum tolerated dosage) and has shown only partial improvement, the addition of an evidence-based psychotherapy should be considered if it has not previously been conducted. Other considerations may include the addition of another medication, an increase of the dosage above FDA-approved ranges, or a switch to another medication, preferably in consultation with a mental health professional. Likewise, if a patient's condition fails to improve after a trial of either CBT or IPT and has not yet begun medication, the clinician should consider a trial of SSRI antidepressant treatment. Strong consideration should also be given to a referral to mental health services.

Recommendation 4: PC clinicians should actively support depressed adolescents who are referred to mental health to ensure adequate management (grade of evidence: D; strength of recommendation: very strong). PC clinicians may also consider sharing care with mental health agencies/professionals when possible (grade of evidence: B; strength of recommendation: very strong). Appropriate roles and responsibilities regarding the provision and coordination of care should be communicated and agreed upon by the PC clinician and the mental health specialist (grade of evidence: D; strength of recommendation: very strong).

PC clinicians should continue follow-up with adolescents with depression who have been referred to mental health services for assessment and/or management. When possible, PC clinicians may consider sharing management of depressed adolescents with mental health agencies/professionals. There is emerging evidence from the adult literature about the greater effectiveness of "shared-care" models for the management of depression in the PC setting.[67–72,79–81] Similar evidence from case reports in the pediatric literature is emerging.[82]

DISCUSSION

The recommendations regarding treatment and ongoing management highlight the need for PC professionals to become familiar with the use of empirically tested treatments for adolescent depression including both antidepressants and psychotherapy. In particular, antidepressant treatments can be useful in certain clinical situations in the PC setting. However, in many of these clinical scenarios, PCPs need to ensure that there is systematic and regular follow-up and adequate mental health support if needed. The need for systematic follow-up, whether by the PCP or by a mental health provider, is especially important in light of the recent FDA warnings regarding the emergence of adverse events with antidepressant treatment.

Psychotherapy is also recommended as first-line treatment for depressed adolescents in the PC setting. Although the provision of psychotherapy may be less feasible and practical within the constraints (ie, time, availability of trained staff) of PC settings, there is some evidence that quality improvement projects that involve psychotherapy can improve the care of depressed adolescents.[27]

Another critical recommendation of the guidelines is the need for PCPs to establish connections to available mental health resources in the community, because PCPs will undoubtedly encounter complex cases in which mental health consultation or shared care may be required. Furthermore, increased coordination of care involving different providers are linked to improved outcomes for youth with both general medical and mental health disorders.[35,83–86] However, to increase linkages between PCPs and mental health specialists, changes in many existing health care systems need to occur (eg, mental health specialists to set aside time and be reimbursed for brief telephone consultations to PCPs).

The GLAD-PC was developed on the basis of the needs of PC clinicians who are faced with the challenge of caring for depressed adolescents and encounter many barriers including the shortage of mental health resources in most community settings. Although it is clear that more evidence and research in this area are needed, these guidelines represent a necessary step toward improving the care of depressed adolescents in the PC setting. Similar guidelines have also been produced for other health care contexts such as in the United Kingdom (www.nice.org.uk/pdf/CG028NICEguideline.pdf). The GLAD-PC and the toolkit reflects the coming together of available evidence and the consensus of a large number of experts representing a broad spectrum of specialties and advocacy organizations within the North American health care context. However, no improvements in care will be achieved if changes do not occur in the health care systems that would allow for increased training in mental health for PC clinicians and in collaborative models for both PC and specialty care clinicians. Therefore, it is critical that training programs for PCPs increase their focus on mental health issues and that trainees in both PC and specialty care areas be helped to hone their skills in working in collaborative care models. For providers who are currently practicing, continuing education for primary and specialty care professionals must strengthen skills in collaborative work, and specifically, for PCPs, increase skills and knowledge in the management of depression.

Limitations

Although these guidelines cover a range of issues regarding the management of adolescent depression in the PC setting, there were other controversial areas that were not addressed in these recommendations. These included such issues as universal screening, using a second antidepressant when patients' conditions fail to respond to an initial antidepressant, and the treatment of subthreshold symptoms. New emerging evidence may impact on the inclusion of such areas in future iterations of the guidelines and the accompanying toolkit. Many of these recommendations are made in the face of absence of evidence or lower levels of evidence.

Future Directions

Ample evidence exists to indicate that guidelines alone are insufficient in closing the gaps between recommended versus actual practices.[87,88] Thus, it will be necessary to identify effective methods for disseminating information and to provide assistance in changing practice to PC clinicians. Future studies of these guidelines must build on this work by piloting and evaluating methods, tools, and strategies to facilitate the adoption of these guidelines for the management of adolescent depression in PC settings. These studies must also explore optimal methods for helping clinicians and their organizations/practices address the range of obstacles that may interfere with adoption of necessary practices to yield sustainable management of adolescent depression in PC settings. Also, of course, such studies must show not only changes in PC clinicians' adolescent depression management but also improvements in outcomes of youth with depression.

Many jurisdictions have recognized the need to increase collaborative care to address the care of adolescents with mental illness. In Canada and the United States, models of care that involve mental health and PC are being implemented. However, the empirical support for these models is modest; therefore, additional research is urgently needed. Work has already begun in Massachusetts to implement GLAD-PC in pediatric practices with funding from AACAP. The findings from this and other studies will build the empirical base for new models of care in the pediatric setting.

APPENDIX: PART II TOOLKIT ITEMS

- Algorithm/flow sheet (Fig 1)
- Treatment choices: active support guide, psychotherapy guide, and medication guide and dosage charts
- Referral information
- Authorization to disclose protected health information between PCP and mental health professional
- Follow-up scripts for management
- Fact sheet/family education materials
- Self-management tools

ACKNOWLEDGMENTS

We thank the Center for Substance Abuse Treatment (Substance Abuse and Mental Health Services Administration), the Josiah Macy, Jr Foundation, the New York State Office of Mental Health, the Lowenstein Foundation, the Center for the Advancement of Children's Mental Health (Columbia University), Sunnybrook Health Sciences Centre (University of Toronto), the American Academy of Pediatrics (District II, New York chapters 1, 2 and 3), the New York Council on Child and Adolescent Psychiatry, the Children' Health Forum (New York Academy of Medicine), the Kellogg Foundation, and the Civic Research Institute, Inc for financial support of the GLAD-PC project.

The GLAD-PC Steering Group consists of members of the GLAD-PC project team, steering committee, and official organizational liaisons. The GLAD-PC project team members are Peter S. Jensen, MD (project director, REACH Institute), Amy Cheung, MD (project coordinator, University of Toronto/Columbia University), Rachel A. Zuckerbrot, MD (project coordinator, Columbia University), Kareem Ghalib, MD (Columbia University), and Anthony Levitt, MD (project consultant, University of Toronto). The steering committee members are (listed alphabetically) Boris Birmaher, MD (Western Psychiatric Institute & Clinic, University of Pittsburgh), John Campo, MD (Ohio State University and Nationwide Children's Hospital), Greg Clarke, PhD (Center for Health Research, Kaiser Permanente), Dave Davis, MD (University of Toronto), Angela Diaz, MD (Mount Sinai School of Medicine), Allen Dietrich, MD (Dartmouth Hitchcock Medical Center), Graham Emslie, MD (University of Texas Southwestern Medical School), Bernard Ewigman, MD (Department of Family Medicine, University of Chicago), Eric Fombonne, MD (McGill University), Sherry Glied, PhD (Columbia University), Kimberly Eaton Hoagwood, PhD (Office of Mental Health, New York State/Columbia University), Charles Homer, MD (National Initiative for Children's Healthcare Quality), Danielle Laraque, MD (AAP New York Chapter 3, District II/Mount Sinai School of Medicine), Miriam Kaufman, MD (Hospital for Sick Children, University of Toronto), Kelly J. Kelleher, MD (Ohio State University), Stanley Kutcher, MD (Dalhousie Medical School), Michael Malus, MD (Department of Family Medicine, McGill University), James Perrin, MD (Massachusetts Medical School/Harvard Medical School), Harold Pincus, MD (Columbia University/New York State Psychiatric Institute), Brenda Reiss-Brennan, APRN (Intermountain Health), Diane Sacks, MD (Canadian Paediatric Society), Ruth E. K. Stein, MD (Forum for Child Health, New York Academy of Medicine, Albert Einstein College of Medicine), and Bruce Waslick, MD, Baystate Health Systems, MA). The organizational liaisons are Angela Diaz, MD (American Academy of Pediatrics), Kelly Kelleher, MD (American Academy of Pediatrics), James Perrin, MD (American Academy of Pediatrics), Diane Sacks, MD (American Academy of Pediatrics/Canadian Paediatric Society), Bruce Waslick, MD (American Medical Association), David Fassler, MD (AACAP), Eric Fombonne, MD (Canadian Academy of Child Psychiatry and Canadian Psychiatric Association), James McIntyre, MD (American Psychiatric Association), Judy Garber, PhD (American Psychological Association), Vicky Wolfe, PhD (Canadian Psychological Association), Michael Malus, MD (College of Family Medicine of Canada), Johanne Renaud, MD (Canadian Association for Adolescent Health), Debbie Ebner, PhD (Society for Adolescent Medicine), Stanford Friedman, MD (Society for Developmental and Behavioral Pediatrics), Terry Stancin, PhD (Society for Developmental and Behavioral Pediatrics), Kathryn Salisbury, PhD (Mental Health Association of New York City), Michael Faenza, MSSW (National Mental Health Association), Susan Bergeson (Depression and Bipolar Support Alliance), Darcy Gruttadaro (National Alliance on Mental Illness), Sandra Spencer (Federation of Families for Children's Mental Health), and Elizabeth Hawkins-Walsh, DNSc, CPNP (National Association for Pediatric Nurse Practitioners).

In addition to members of the GLAD-PC Steering Group, we also acknowledge the GLAD-PC conference attendees: Perry Adler, PhD; Joan Asarnow, PhD; Loretta Young Au, MD, FAAP; Abraham Bartell, MD; Tamar Bauer; Rachel Bergeson, MD; Blanche Benenson, MD; Linda Theil Cahill, MD; Wayne Cannon, MD; Marie Barone Casalino, MD; Sonia Chehil, MD; Joseph Cramer, MD; Cathryn Cunningham, MD; Wendy Davis, MD; Carolyn Dewa, PhD; Benard P. abstract

Children who require emergency care have unique needs, especially when emergencies are serious or life-threatening. The majority of ill and injured children are brought to community hospital emergency departments (EDs) by virtue of their geography within communities. Similarly, emergency medical services (EMS) agencies provide the bulk of out-of-hospital emergency care to children. It is imperative, therefore, that all hospital EDs have the appropriate resources (medications, equipment, policies, and education) and staff to provide effective emergency care for children. This statement outlines resources necessary to ensure that hospital EDs stand ready to care for children of all ages, from neonates to adolescents. These guidelines are consistent with the recommendations of the Institute of Medicine's report on the future of emergency care in the United States health system. Although resources within emergency and trauma care systems vary locally, regionally, and nationally, it is essential that hospital ED staff and administrators and EMS systems' administrators and medical directors seek to meet or exceed these guidelines in efforts to optimize the emergency care of children they serve. This statement has been endorsed by the Academic Pediatric Association, American Academy of Family Physicians, American Academy of Physician Assistants, American College of Osteopathic Emergency Physicians, American College of Surgeons, American Heart Association, American Medical Association, American Pediatric Surgical Association, Brain Injury Association of America, Child Health Corporation of America, Children's National Medical Center, Family Voices, National Association of Children's Hospitals and Related Institutions, National Association of EMS Physicians, National Association of Emergency Medical Technicians, National Association of State EMS Officials, National Committee for Quality Assurance, National PTA, Safe Kids USA, Society of Trauma Nurses, Society for Academic Emergency Medicine, and The Joint Commission. *Pediatrics* 2009;124:1233–1243

INTRODUCTION

This policy statement delineates guidelines and the resources necessary to prepare hospital emergency departments (EDs) to serve pediatric patients. Adoption of these guidelines should facilitate the delivery of emergency care for children of all ages and, when appropriate, timely transfer to a facility with specialized pediatric services. This policy is an update of previously published guidelines.[1,2]

This statement has been endorsed by the Academic Pediatric Association, American Academy of Family Physicians, American Academy of Physician Assistants, American College of Osteopathic Emergency Phy-

sicians, American College of Surgeons, American Heart Association, American Medical Association, American Pediatric Surgical Association, Brain Injury Association of America, Child Health Corporation of America, Children's National Medical Center, Family Voices, National Association of Children's Hospitals and Related Institutions, National Association of EMS Physicians, National Association of Emergency Medical Technicians, National Association of State EMS Officials, National Committee for Quality Assurance, National PTA, Safe Kids USA, Society of Trauma Nurses, Society for Academic Emergency Medicine, and The Joint Commission.

BACKGROUND

The National Hospital Ambulatory Medical Care Survey reported that in 2006, there were approximately 3833 EDs in the United States. Most of these EDs routinely care for patients of all ages.[3–6] Of the 119 million ED visits in the United States in 2006, almost 20% were for children.[5,6]

In 1993, after nearly a decade of efforts to integrate the needs of children into emergency medical services (EMS) systems, the Institute of Medicine was asked to provide an independent review of emergency medical services for children (EMSC) and report to the nation on the state of the continuum of care for children within the EMS system.[7] Summary recommendations of that report concluded that all agencies with jurisdiction over hospitals "require that hospital emergency departments . . . have available and maintain equipment and supplies appropriate for the emergency care of children" and that they "address the issues of categorization and regionalization in overseeing and development of EMSC and its integration into state and regional EMS systems."

Published data have suggested that compliance with national guidelines is low and that many EDs in the United States and Canada still do not have some of the basic equipment and supplies needed to care for children of all ages.[8–10] Middleton and Burt,[6] in the emergency pediatric services and equipment supplement of the 2002–2003 National Hospital Ambulatory Medical Care Survey, reported that only 6% of US EDs have all of the recommended pediatric supplies and equipment as outlined in previously published national guidelines. Gausche-Hill et al[10] reported similar results in a nationwide survey of EDs in the United States and cited reasons for the lack of equipment availability in many EDs (including lack of awareness, with only 59% of ED managers being aware of the published guidelines) and relative lack of pediatric experience among the workforce, with limited exposure to critically ill or injured pediatric patients at many US hospitals. In fact, 50% of EDs care for fewer than 10 pediatric patients per day; therefore, pediatric planning by these facilities is crucial.[10]

Access to optimal emergency care for children is affected by the lack of availability of equipment, appropriately trained staff to care for children, and policies and procedures that ensure timely transfer to definitive care.[11] Although advances have been made that promote access to emergency care for children, improved awareness of the pediatric resources available to hospitals, in addition to the development of regionalized and coordinated emergency and trauma care systems, may optimize access and outcomes for many acutely ill and injured children.[12,13]

The Institute of Medicine, in a comprehensive report on the state of emergency care in the United States in 2006, made a strong recommendation for regionalized systems of care and further recommended that hospitals and EMS systems appoint qualified coordinators for pediatric emergency care.[12] Only 18% of EDs in the United States currently appoint a physician coordinator, and 12% appoint a nursing coordinator for pediatric emergency care. EDs that do appoint these positions tend to be more prepared as measured by compliance with guidelines on the care of children in the ED published by the American College of Emergency Physicians and American Academy of Pediatrics.[10]

The Health Resources and Services Administration-EMSC program has also advocated for such regionalized systems, and in response to the need to document outcomes of the program's activities, performance measures for states and territories were outlined in 2009.[14] These performance measures call for the existence of a statewide, territorial, or regional standardized system that recognizes hospitals that are able to stabilize and/or manage pediatric medical emergencies and trauma. Target dates have been set for states to comply with these performance measures. Clearly, much work is left to be done to promote and measure pediatric preparedness in all EDs in the United States and for emergency and trauma care systems to be ready to meet the needs of children in disasters.

The following guidelines are intended for all hospital EDs that provide emergency care 24 hours a day, 7 days a week that are continuously staffed by a physician. Children may be cared for in other emergency settings, such as freestanding EDs or urgent care centers, critical access hospitals[15] or stand-by emergency facilities, retail-based clinics, and primary care office practices. These care settings are not addressed in this document, but administrators, physicians, nurses, and other health care providers who staff

these settings should ensure that these facilities maintain the necessary equipment, medications, and supplies and are staffed appropriately to care for pediatric patients. Pediatric emergency-preparedness guidelines have been created for urgent care centers as well as for offices of primary care providers.[16,17]

These guidelines provide current information on equipment, medications, supplies, and personnel considered essential for managing pediatric emergencies in EDs. This statement also offers guidelines for the administration and coordination of pediatric care in the ED; pediatric emergency care quality improvement (QI), performance improvement (PI), and patient safety activities; policies, procedures, and protocols for pediatric care; and key ED support services. It is expected that all EDs in the United States that are staffed by a physician 24 hours a day, 7 days a week can meet or exceed these guidelines and that some hospitals, such as pediatric critical care centers or children's hospitals with greater resources, will develop and implement even more comprehensive guidelines and share their expertise with their local and regional communities. New technology and research will require that such emergency drug, equipment, and supply lists be kept current and that updated recommendations be readily available to hospitals that provide emergency care to children.

I. GUIDELINES FOR ADMINISTRATION AND COORDINATION OF THE ED FOR THE CARE OF CHILDREN

A. A physician coordinator for pediatric emergency medicine is appointed by the ED medical director.
   1. The physician coordinator has the following qualifications:
      a. Meets the qualifications for credentialing by the hospital as a specialist in emergency medicine or pediatric emergency medicine. It is recognized that physicians in these specialties may not always be available in some communities; in these areas, the physician coordinator must meet the qualifications for credentialing by the hospital as a specialist in pediatrics or family medicine and demonstrate, through experience or continuing education, competence in the care of children in emergency settings, including resuscitation.
      b. Has special interest, knowledge, and skill in emergency medical care of children as demonstrated by training, clinical experience, or focused continuing medical education.
      c. Maintains competency in pediatric emergency care (see "III. GUIDELINES FOR QI/PI IN THE ED").
      d. May be a staff physician who is currently assigned other roles in the ED or may be shared through formal consultation agreements with professional resources from a hospital that is capable of providing definitive pediatric care.
   2. The physician coordinator is responsible for the following:
      a. Promoting and verifying adequate skill and knowledge of ED staff physicians and other ED health care providers (ie, physician assistants and advanced practice nurses) in the emergency care and resuscitation of infants and children.
      b. Overseeing ED pediatric QI, PI, patient safety, injury and illness prevention, and clinical care activities.
      c. Assisting with development and periodic review of ED policies and procedures and standards for medications, equipment, and supplies to ensure adequate resources for children of all ages.
      d. Serving as liaison/coordinator to appropriate in-hospital and out-of-hospital pediatric care committees in the community (if they exist).
      e. Serving as liaison/coordinator to a definitive care hospital (such as a regional pediatric referral hospital and trauma center), EMS agencies, primary care providers, health insurers, and any other medical resources needed to integrate services for the continuum of care of the pediatric patient.
      f. Facilitating pediatric emergency education for ED health care providers and out-of-hospital providers affiliated with the ED.
      g. Ensuring that competency evaluations completed by the staff are pertinent to children of all ages.
      h. Ensuring that pediatric needs are addressed in hospital disaster/emergency-preparedness plans.
      i. Collaborating with the nursing coordinator to ensure adequate staffing, medications, equipment, supplies, and other resources for children in the ED.

B. A nursing coordinator for pediatric emergency care is appointed by the ED nursing director.

1. The nursing coordinator has the following qualifications:
   a. Is a registered nurse (RN) who possesses special interest, knowledge, and skill in the emergency medical care of children as demonstrated by training, clinical experience, or focused continuing nursing education.
   b. Maintains competency in pediatric emergency care (see "III. GUIDELINES FOR QI/PI IN THE ED").
   c. Is credentialed and has competency verification per the hospital policies and guidelines to provide care to children of all ages.
   d. May be a staff nurse who is currently assigned other roles in the ED, such as clinical nurse specialist, or may be shared through formal consultation agreements with professional resources from a hospital that is capable of providing definitive pediatric care.
2. The nursing coordinator is responsible for the following:
   a. Facilitating ED pediatric QI/PI activities.
   b. Serving as liaison to appropriate in-hospital and out-of-hospital pediatric care committees.
   c. Serving as liaison to inpatient nursing as well as to a definitive care hospital, a regional pediatric referral hospital and trauma center, EMS agencies, primary care providers, health insurers, and any other medical resources needed to integrate services for the continuum of care of the pediatric patient.
   d. Facilitating, along with hospital-based educational activities, ED nursing continuing education in pediatrics and ensuring that pediatric-specific elements are included in orientation for new staff members.
   e. Ensuring that initial and annual competency evaluations completed by the ED nursing staff are pertinent to children of all ages.
   f. Promoting pediatric disaster preparedness for the ED and participating in hospital disaster-preparedness activities.
   g. Promoting patient and family education in illness and injury prevention.
   h. Providing assistance and support for pediatric education of out-of-hospital providers who are affiliated with the ED.
   i. Working with clinical leadership to ensure the availability of pediatric equipment, medications, staffing, and other resources through the development and periodic review of ED standards, policies, and procedures.
   j. Collaborating with the physician coordinator to ensure that the ED is prepared to care for children of all ages, including children with special health care needs.

II. PHYSICIANS, NURSES, AND OTHER HEALTH CARE PROVIDERS WHO STAFF THE ED

A. Physicians who staff the ED have the necessary skill, knowledge, and training in the emergency evaluation and treatment of children of all ages who may be brought to the ED, consistent with the services provided by the hospital.
B. Nurses and other ED health care providers have the necessary skill, knowledge, and training in providing emergency care to children of all ages who may be brought to the ED, consistent with the services offered by the hospital.
C. Baseline and periodic competency evaluations completed for all ED clinical staff, including physicians, are age specific and include evaluation of skills related to neonates, infants, children, adolescents, and children with special health care needs. Competencies are determined by each institution's medical staff privileges policy.

III. GUIDELINES FOR QI/PI IN THE ED

A pediatric patient care-review process is integrated into the QI/PI plan of the ED according to the following guidelines:

A. Components of the process interface with out-of-hospital, ED, trauma, inpatient pediatric, pediatric critical care, and hospital-wide QI or PI activities.
B. The QI/PI plan of the ED shall include pediatric-specific indicators. Minimum components of the QI/PI process should include collecting and analyzing data to discover variances, defining a plan for improvement, and evaluating the success of the QI/PI plan with measures that are outcome based.
C. Pediatric clinical-competency evaluations should be developed as a part of the local credentialing process for all licensed ED staff (eg, sedation and analgesia, airway management [Appendix 1]). Competencies should be age specific and include those for neonates, infants, children, adolescents, and children with special health care needs.

D. Mechanisms should be in place to monitor professional performance, credentialing, continuing education, and clinical competencies, including integration of findings from QI audits and case reviews.

IV. GUIDELINES FOR IMPROVING PEDIATRIC PATIENT SAFETY IN THE ED

The delivery of pediatric care should reflect an awareness of unique pediatric patient safety concerns[18,19] and should include the following policies or practices:

A. Children should be weighed in kilograms, with the exception of children who require emergent stabilization, and the weight should be recorded in a prominent place on the medical record, such as with the vital signs.
   1. For children who require resuscitation or emergency stabilization, a standard method for estimating weight in kilograms should be used (eg, length-based system).

B. Infants and children should have a full set of vital signs recorded to include temperature, heart rate, and respiratory rate. Blood pressure and pulse oximetry monitoring should be available for children of all ages on the basis of illness and injury severity.

C. A process should be in place for identifying abnormal vital signs according to the age of the patient and for notifying the physician of abnormal values obtained.

D. Processes for safe medication storage, prescribing, and delivery should be established[20,21] and should include the use of precalculated dosing guidelines for children of all ages.

E. Infection-control practices, including hand hygiene and use of personal protective equipment, should be implemented and monitored.

F. Pediatric emergency services should be culturally and linguistically appropriate,[22] and the ED should provide an environment that is safe for children and supports patient- and family-centered care.[23]

G. Patient-identification policies, consistent with the Joint Commission national patient safety goals, should be implemented and monitored.[24]

H. Policies for the timely reporting and evaluation of patient safety events and for the disclosure of medical errors or unanticipated outcomes should be implemented and monitored, and education and training in disclosure should be available to care providers who are assigned this responsibility.[18,19]

V. GUIDELINES FOR POLICIES, PROCEDURES, AND PROTOCOLS FOR THE ED

A. Policies, procedures, and protocols for the emergency care of children are developed and implemented; staff should be educated accordingly; and they should be monitored for compliance and periodically updated. These resources should include, but are not limited to, the following:
   1. Illness and injury triage.
   2. Pediatric patient assessment and reassessment.
   3. Documentation of pediatric vital signs, abnormal vital signs, and actions to be taken for abnormal vital signs.
   4. Immunization assessment and management of the underimmunized patient.[25]
   5. Sedation and analgesia for procedures, including medical imaging.[26,27]
   6. Consent (including situations in which a parent is not immediately available).[28]
   7. Social and mental health issues.
   8. Physical or chemical restraint of patients.
   9. Child maltreatment (physical and sexual abuse, sexual assault, and neglect) and domestic violence mandated reporting criteria, requirements, and processes.
   10. Death of the child in the ED.[29,30]
   11. Do-not-resuscitate orders.
   12. Family-centered care,[31–35] including:
      a. Involving families in patient care decision-making and in medication safety processes.
      b. Family presence during all aspects of emergency care, including resuscitation.[35,36]
      c. Education of the patient, family, and regular caregivers.
      d. Discharge planning and instruction.
      e. Bereavement counseling.
   13. Communication with the patient's medical home or primary health care provider.[37]
   14. Medical imaging policies that address age- or weight-appropriate dosing for children receiving studies that impart ionizing radiation, consistent with as-low-as-reasonably-achievable (ALARA) principles.[38]
   15. All-hazard disaster-preparedness plan that addresses the following pediatric issues[12,39–41]:
      a. Availability of medications, vaccines, equipment, and appropriately trained providers for children in disasters.
      b. Pediatric surge capacity for both injured and noninjured children.
      c. Decontamination, isolation, and

quarantine of families and children of all ages.

d. A plan that minimizes parent-child separation and includes system tracking of pediatric patients, allowing for the timely reunification of separated children with their families.

e. Access to specific medical and mental health therapies, as well as social services, for children in the event of a disaster.

f. Disaster drills, which should include a pediatric mass-casualty incident at least every 2 years.

g. Care of children with special health care needs.

h. A plan that includes evacuation of pediatric units and pediatric specialty units.

B. Hospitals should have written pediatric interfacility transfer procedures that include the following pediatric components of transfer[42]:

1. Defined process for initiation of transfer, including the roles and responsibilities of the referring facility and referral center (including responsibilities for requesting transfer and communication).

2. Transport plan for delivering children safely and in a timely manner to the appropriate facility that is capable of providing definitive care.

3. Process for selecting the appropriate care facility for pediatric specialty services not available at the hospital. These specialty services may include:

a. Medical subspecialty and surgical specialty care.

b. Critical care.

c. Reimplantation (replacement of severed digits or limbs).

d. Trauma and burn care.

e. Psychiatric emergencies.

f. Obstetric and perinatal emergencies.

g. Child maltreatment (physical and sexual abuse and assault).

h. Rehabilitation for recovery from critical medical or traumatic conditions.

4. Process for selecting the appropriately staffed transport service to match the patient's acuity level (eg, level of care required by patient, equipment needed in transport) and appropriate for children with special health care needs.

5. Process for patient transfer (including obtaining informed consent).

6. Plan for transfer of patient information (eg, medical record and copy of signed transport consent), personal belongings of the patient, and provision of directions and referral institution information to family.

7. Process for return transfer of the pediatric patient to the referring facility as appropriate.

VI. GUIDELINES FOR ED SUPPORT SERVICES

A. The radiology department should have the skills and capability to provide imaging studies of children and have the equipment necessary to do so and must have guidelines for reducing radiation exposure that are age and size specific.[38]

1. The radiology capability of hospitals may vary from 1 institution to another; however, the radiology capability of a hospital must meet the needs of the children in the community it serves.

2. A process should be established for the referral of children to appropriate facilities for radiologic procedures that exceed the capability of the hospital.

3. A process should be in place for the timely review, interpretation, and reporting by a qualified radiologist for medical imaging studies.

B. The laboratory should have the skills and capability to perform laboratory tests for children of all ages, including obtaining samples, and should have the availability of microtechnique for small or limited sample size.

1. The clinical laboratory capability must meet the needs of the children in the community it serves.

2. There should be a clear understanding of what the laboratory capability is for any given community and definitive plans for referring children to the appropriate facility for laboratory studies should be in place.

VII. GUIDELINES FOR EQUIPMENT, SUPPLIES, AND MEDICATIONS FOR THE CARE OF PEDIATRIC PATIENTS IN THE ED

A. Pediatric equipment, supplies, and medications should be appropriate for children of all ages and sizes and shall be easily accessible, clearly labeled, and safely and logically organized.

B. Resuscitation equipment and supplies shall be located in the ED; trays and other items may be housed in other departments (such as the newborn nursery or central supply) as long as the items are immediately accessible to the ED staff. A mobile pedi-

TABLE 1 Guidelines for Medications for Use in Pediatric Patients in EDs

Resuscitation Medications	Other Drug Groups
Atropine	Activated charcoal
Adenosine	Topical, oral, and parenteral analgesics
Amiodarone	Antimicrobial agents (parenteral and oral)
Antiemetic agents	Anticonvulsant medications
Calcium chloride	Antidotes (common antidotes should be accessible to the ED)[a]
Dextrose (D10W, D50W)	Antipyretic drugs
Epinephrine (1:1000; 1:10 000 solutions)	Bronchodilators
Lidocaine	Corticosteroids
Magnesium sulfate	Inotropic agents
Naloxone hydrochloride	Neuromuscular blockers
Procainamide	Sedatives
Sodium bicarbonate (4.2%, 8.4%)	Vaccines
	Vasopressor agents

For a more complete list of medications used in a pediatric ED, see ref.[44] D10W indicates dextrose 10% in water; D50W, dextrose 50% in water.

[a] For less frequently used antidotes, a procedure for obtaining them should be in place.

atric crash cart is strongly recommended.

C. ED staff shall be appropriately educated on the location of all items.

D. Each ED shall have a method of daily verification of proper location and function of equipment and supplies.

E. Medication chart, length-based tape, medical software, or other systems shall be readily available to ED staff to ensure proper sizing of resuscitation equipment and proper dosing of medications.

F. Table 1 and Appendix 2 outline medications, equipment, and supplies that are necessary for the care of children in the ED.

SUMMARY

The 2006 Institute of Medicine report *Emergency Care for Children: Growing Pains* uses the word "uneven" to describe the current status of pediatric emergency care in the United States.[12] Although programs such as EMSC have led toward improvement in the level of pediatric emergency readiness in many communities,[43] there remains a significant opportunity for further progress nationwide. The updated guidelines offered in this policy statement are intended to serve as a resource for clinical and administrative leadership of hospital EDs as they endeavor to improve their readiness for children of all ages. An important first step in ensuring readiness is the identification of both a physician and a nurse coordinator for pediatric emergency care.

All hospital EDs must be continually prepared to receive, accurately assess, and, at a minimum, stabilize and safely transfer acutely ill or injured children, which is necessary even for hospitals located in communities with readily accessible pediatric tertiary care centers and regionalized systems for pediatric trauma and critical care. The vast majority of children who require emergency services in the United States receive this care in a non–children's hospital ED, with 50% of EDs providing care for fewer than 10 children per day.[10] This relatively infrequent exposure of hospital-based emergency care professionals to seriously ill or injured children represents a substantial barrier to the maintenance of essential skills and clinical competency. Recognition of the unique needs of the ill and/or injured children served by a hospital, including children with special health care needs; the commitment to better meeting those needs through adoption of these guidelines; and the ongoing commitment to evaluating care quality and safety and maintaining pediatric emergency care competencies should provide a strong foundation for pediatric emergency and all-hazard disaster readiness.

APPENDIX 1: CLINICAL AND PROFESSIONAL COMPETENCY

Demonstration and maintenance of pediatric clinical competency may be achieved through a number of continuing education mechanisms including participation in local educational programs, professional organization conferences, and national life-support programs (ie, Pediatric Advanced Life Support [PALS], Advanced Pediatric Life Support [APLS]: The Pediatric Emergency Medicine Course, Emergency Nursing Pediatric Course [ENPC]) or through scheduled mock codes or patient simulation, team training exercises, or experiences in other clinical settings such as the operating room (ie, airway management).

Potential areas for the development of pediatric competency and professional performance evaluations may include but should not be limited to:

1. Triage
2. Illness and injury assessment and management
3. Pain assessment and treatment, including sedation and analgesia
4. Airway management
5. Vascular access
6. Critical care monitoring
7. Neonatal and pediatric resuscitation
8. Trauma care
9. Burn care
10. Mass-casualty events
11. Patient- and family-centered care

12. Medication delivery and device/equipment safety
13. Team training and effective communication

APPENDIX 2: GUIDELINES FOR EQUIPMENT AND SUPPLIES FOR USE IN PEDIATRIC PATIENTS IN THE ED

General Equipment

- Patient warming device
- Intravenous blood/fluid warmer
- Restraint device
- Weight scale, in kilograms only (not pounds), for infants and children
- Tool or chart that incorporates both weight (in kilograms) and length to assist physicians and nurses in determining equipment size and correct drug dosing (by weight and total volume), such as a length-based resuscitation tape
- Pain-scale–assessment tools appropriate for age

Monitoring Equipment

- Blood pressure cuffs (neonatal, infant, child, adult-arm and thigh)
- Doppler ultrasonography devices
- Electrocardiography monitor/defibrillator with pediatric and adult capabilities including pediatric-sized pads/paddles
- Hypothermia thermometer
- Pulse oximeter with pediatric and adult probes
- Continuous end-tidal CO_2 monitoring device*

*End-tidal CO_2 monitoring is considered the optimal method of assessing for and monitoring of endotracheal tube placement in the trachea; however, for low-volume hospitals, adult and pediatric CO_2 colorimetric detector devices could be substituted. Clinical assessment alone is not appropriate.

Respiratory Equipment and Supplies

- Endotracheal tubes
  - Uncuffed: 2.5 and 3.0 mm
  - Cuffed or uncuffed: 3.5, 4.0, 4.5, 5.0, and 5.5 mm
  - Cuffed: 6.0, 6.5, 7.0, 7.5, and 8.0 mm
- Feeding tubes (5F and 8F)
- Laryngoscope blades (curved: 2 and 3; straight: 0, 1, 2, and 3)
- Laryngoscope handle
- Magill forceps (pediatric and adult)
- Nasopharyngeal airways (infant, child, and adult)
- Oropharyngeal airways (sizes 0–5)
- Stylets for endotracheal tubes (pediatric and adult)
- Suction catheters (infant, child, and adult)
- Tracheostomy tubes (sizes 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 5.5 mm)
- Yankauer suction tip
- Bag-mask device (manual resuscitator), self-inflating (infant size: 450 mL; adult size: 1000 mL)
- Clear oxygen masks (standard and nonrebreathing) for an infant, child, and adult
- Masks to fit bag-mask device adaptor (neonatal, infant, child, and adult sizes)
- Nasal cannulas (infant, child, and adult)
- Nasogastric tubes (sump tubes): infant (8F), child (10F), and adult (14F–18F)
- Laryngeal mask airway† (sizes 1, 1.5, 2, 2.5, 3, 4, and 5)

†Laryngeal mask airways could be shared with anesthesia but must be immediately accessible to the ED.

Vascular Access Supplies and Equipment

- Arm boards (infant, child, and adult sizes)
- Catheter-over-the-needle device (14–24 gauge)
- Intraosseous needles or device (pediatric and adult sizes)
- Intravenous catheter–administration sets with calibrated chambers and extension tubing and/or infusion devices with ability to regulate rate and volume of infusate
- Umbilical vein catheters (3.5F and 5.0F)‡
- Central venous catheters (4.0F–7.0F)
- Intravenous solutions to include: normal saline; dextrose 5% in normal saline; and dextrose 10% in water

Fracture-Management Devices

- Extremity splints, including femur splints (pediatric and adult sizes)
- Spine-stabilization method/devices appropriate for children of all ages§

Specialized Pediatric Trays or Kits

- Lumbar-puncture tray including infant (22-gauge), pediatric (22-gauge), and adult (18- to 21-gauge) lumbar-puncture needles
- Supplies/kit for patients with difficult airway conditions (to include but not limited to supraglottic airways of all sizes, such as the laryngeal mask airway,[2] needle cricothyrotomy supplies, surgical cricothyrotomy kit)
- Tube thoracostomy tray

‡Feeding tubes (size 5F) may be used as umbilical venous catheters but are not ideal. A method for securing the umbilical catheter, such as an umbilical tie, should also be available.

§A spinal stabilization device should be a device that can also stabilize the neck of an infant, child, or adolescent in a neutral position.

- Chest tubes to include infant, child, and adult sizes (infant: 10F–12F; child, 16F–24F; adult, 28F–40F)
- Newborn delivery kit (including equipment for initial resuscitation of a newborn infant: umbilical clamp, scissors, bulb syringe, and towel)
- Urinary catheterization kits and urinary (indwelling) catheters (6F–22F)

ACKNOWLEDGMENTS

Development of this statement was supported by the US Department of Health and Human Services, Health Resources and Services Administration's Maternal and Child Health Bureau, Partnership for Information and Communication Project (U93MC00184) and the Emergency Medical Services for Children National Resource Center at Children's National Medical Center (U07MC09174). The statement is also consistent with recommendations of the Institute of Medicine's report on the future of emergency care in the US health system.

Clinical Report—Guidelines for the Determination of Brain Death in Infants and Children: An Update of the 1987 Task Force Recommendations

abstract

FREE

OBJECTIVE: To review and revise the 1987 pediatric brain death guidelines.

METHODS: Relevant literature was reviewed. Recommendations were developed using the GRADE system.

CONCLUSIONS AND RECOMMENDATIONS: (1) Determination of brain death in term newborns, infants and children is a clinical diagnosis based on the absence of neurologic function with a known irreversible cause of coma. Because of insufficient data in the literature, recommendations for preterm infants less than 37 weeks gestational age are not included in this guideline.

(2) Hypotension, hypothermia, and metabolic disturbances should be treated and corrected and medications that can interfere with the neurologic examination and apnea testing should be discontinued allowing for adequate clearance before proceeding with these evaluations.

(3) Two examinations including apnea testing with each examination separated by an observation period are required. Examinations should be performed by different attending physicians. Apnea testing may be performed by the same physician. An observation period of 24 hours for term newborns (37 weeks gestational age) to 30 days of age, and 12 hours for infants and chi (> 30 days to 18 years) is recommended. The first examination determines the child has met the accepted neurologic examination criteria for brain death. The second examination confirms brain death based on an unchanged and irreversible condition. Assessment of neurologic function following cardiopulmonary resuscitation or other severe acute brain injuries should be deferred for 24 hours or longer if there are concerns or inconsistencies in the examination.

(4) Apnea testing to support the diagnosis of brain death must be performed safely and requires documentation of an arterial $Paco_2$ 20 mm Hg above the baseline and ≥ 60 mm Hg with no respiratory effort during the testing period. If the apnea test cannot be safely completed, an ancillary study should be performed.

(5) Ancillary studies (electroencephalogram and radionuclide cerebral blood flow) are not required to establish brain death and are not a substitute for the neurologic examination. Ancillary studies may be us d to assist the clinician in making the diagnosis of brain death (i) when components of the examination or apnea testing cannot be completed safely due to the underlying medical condition of the patient; (ii) if there is uncertainty about the results of the neurologic examination; (iii) if a medication effect may be present; or (iv) to reduce the inter-examination observation period. When ancillary studies are used, a second clinical examination and apnea test should be performed and components that can be completed must remain consistent with brain death. In this instance the observation interval may be shortened and the second neurologic examination and apnea test (or all components that are able to be completed safely) can be performed at any time thereafter.

(6) Death is declared when the above criteria are fulfilled. *Pediatrics* 2011;128: e720–e740

INTRODUCTION

In 1987, guidelines for the determination of brain death in children were published by a multi-society task force.[1,2] These consensus based guidelines were developed because existing guidelines from the President's Commission failed to adequately address criteria to determine brain death in pediatric patients. They emphasized the importance of the history and clinical examination in determining the etiology of coma so that correctable or reversible conditions were eliminated. Additionally, age-related observation periods and the need for specific neurodiagnostic tests were recommended for children younger than 1 year of age. In children older than 1 year, it was recommended that the diagnosis of brain death could be made solely on a clinical basis and laboratory studies were optional. Little guidance was provided to determine brain death in neonates less than 7 days of age because of limited clinical experience and lack of sufficient data.

These guidelines generally have been accepted and used to guide clinical practice; however they have not been reviewed nor revised since originally published. Several inherent weaknesses have been recognized including: (1) limited clinical information at the time of publication; (2) uncertainty concerning the sensitivity and specificity of ancillary testing; (3) biological rationale for the use of age-based criteria; and (4) little direction as to whether, when and how the diagnosis of brain death could be made in neonates. Despite national and legal acceptance of the concept of brain death, these limitations have resulted in the lack of a standardized approach to determining brain death in children.[3–9] These issues are not unique to infants and children[10] nor limited to the United States. The American Academy of Neurology published guidelines to determine brain death in adults in 1995 which have been revised in 2010.[11,12] Additionally, guidelines to determine brain death in adults and children have been published in Canada.[13]

The Society of Critical Care Medicine (SCCM) and the Section on Critical Care and Section on Neurology of the American Academy of Pediatrics (AAP), in conjunction with the Child Neurology Society (CNS), formed a multidisciplinary committee of medical and surgical subspecialists under the auspices of the American College of Critical Care Medicine (ACCM) to review and revise the 1987 guidelines. Its purpose was to review the neonatal and pediatric literature from 1987, including any prior relevant literature, and update recommendations regarding appropriate examination criteria and use of ancillary testing to diagnose brain death in neonates, infants and children. The committee was also charged with developing a checklist to provide guidance and standardization to document brain death. Uniformity in the determination of brain death should allow physicians to pronounce brain death in pediatric patients in a more precise and orderly manner and ensure that all components of the examination are performed and appropriately documented.

Tables 1–3 of this publication contain the committee's updated recommendations, the GRADE classification system, and clinical and neurologic examination criteria for brain death. Appendices 1–7 provide additional information concerning the diagnosis of brain death in children. Appendix 1 (check list) and Appendix 2 (pharmacological data for the time interval to testing after medication discontinuation) provide additional resources to aid the clinician in diagnosing brain death. Appendix 3 summarizes data regarding apnea testing. Appendices 4–6 provide data on the diagnostic yield of ancillary testing, specifically electroencephalography (EEG), and radionuclide cerebral blood flow (CBF) studies. Appendix 7 compares the 1987 guideline's criteria to the revised recommendations. Appendix 8 provides an algorithm for the determination of brain death in infants and children.

This update affirms the definition of death as stated in the 1987 pediatric guidelines. This definition had been established by multiple organizations including the American Medical Association, the American Bar Association, the National Conference of Commissioners on Uniform State Laws, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research and the American Academy of Neurology as follows: "An individual who has sustained either (1) irreversible cessation of circulatory and respiratory functions, or (2) irreversible cessation of all functions of the entire brain, including the brainstem, is dead. A determination of death must be made in accordance with accepted medical standards."[1]

METHODS

A multidisciplinary committee composed of physicians and nurses with expertise in pediatrics, pediatric critical care, neonatology, pediatric neurology and neurosurgery, nuclear medicine, and neuroradiology was formed by the SCCM and the AAP to update the guidelines for the diagnosis of pediatric brain death. The committee was divided into three working groups, each charged with reviewing the literature on brain death in neonates, infants and children for the following specific areas: (1) examination criteria and observation periods; (2) ancillary testing; and (3) declaration of death by medical personnel including legal and ethical implications.

A Medline search of relevant literature published from January 1987 to June

TABLE 1 Summary Recommendations for the Diagnosis of Brain Death in Neonates, Infants, and Children

Recommendation	Evidence Score	Recommendation Score
1. Determination of brain death in neonates, infants and children relies on a clinical diagnosis that is based on the absence of neurologic function with a known irreversible cause of coma. Coma and apnea must coexist to diagnose brain death. This diagnosis should be made by physicians who have evaluated the history and completed the neurologic examinations.	High	Strong
2. Prerequisites for initiating a brain death evaluation		
a. Hypotension, hypothermia, and metabolic disturbances that could affect the neurological examination must be corrected prior to examination for brain death.	High	Strong
b. Sedatives, analgesics, neuromuscular blockers, and anticonvulsant agents should be discontinued for a reasonable time period based on elimination half-life of the pharmacologic agent to ensure they do not affect the neurologic examination. Knowledge of the total amount of each agent (mg/kg) administered since hospital admission may provide useful information concerning the risk of continued medication effects. Blood or plasma levels to confirm high or supratherapeutic levels of anticonvulsants with sedative effects that are not present should be obtained (if available) and repeated as needed or until the levels are in the low to mid therapeutic range.	Moderate	Strong
c. The diagnosis of brain death based on neurologic examination alone should not be made if supratherapeutic or high therapeutic levels of sedative agents are present. When levels are in the low or in the mid-therapeutic range, medication effects sufficient to affect the results of the neurologic examination are unlikely. If uncertainty remains, an ancillary study should be performed.	Moderate	Strong
d. Assessment of neurologic function may be unreliable immediately following cardiopulmonary resuscitation or other severe acute brain injuries and evaluation for brain death should be deferred for 24 to 48 hours or longer if there are concerns or inconsistencies in the examination.	Moderate	Strong
3. Number of examinations, examiners and observation periods		
a. Two examinations including apnea testing with each examination separated by an observation period are required.	Moderate	Strong
b. The examinations should be performed by different attending physicians involved in the care of the child. The apnea test may be performed by the same physician, preferably the attending physician who is managing ventilator care of the child.	Low	Strong
c. Recommended observation periods:		
(1) 24 hours for neonates (37 weeks gestation to term infants 30 days of age)	Moderate	Strong
(2) 12 hours for infants and children ($>$ 30 days to 18 years).		
d. The first examination determines the child has met neurologic examination criteria for brain death. The second examination, performed by a different attending physician, confirms that the child has fulfilled criteria for brain death.	Moderate	Strong
e. Assessment of neurologic function may be unreliable immediately following cardiopulmonary resuscitation or other severe acute brain injuries and evaluation for brain death should be deferred for 24 to 48 hours or longer if there are concerns or inconsistencies in the examination.	Moderate	Strong
4. Apnea testing		
a. Apnea testing must be performed safely and requires documentation of an arterial $Paco_2$ 20 mm Hg above the baseline $Paco_2$ and $\geq$ 60 mm Hg with no respiratory effort during the testing period to support the diagnosis of brain death. Some infants and children with chronic respiratory disease or insufficiency may only be responsive to supranormal $Paco_2$ levels. In this instance, the $Paco_2$ level should increase to $\geq$ 20 mm Hg above the baseline $Paco_2$ level.	Moderate	Strong
b. If the apnea test cannot be performed due to a medical contraindication or cannot be completed because of hemodynamic instability, desaturation to $<$ 85%, or an inability to reach a $Paco_2$ of 60 mm Hg or greater, an ancillary study should be performed.	Moderate	Strong
5. Ancillary studies		
a. Ancillary studies (EEG and radionuclide CBF) are not required to establish brain death unless the clinical examination or apnea test cannot be completed	Moderate	Strong
b. Ancillary studies are not a substitute for the neurologic examination.	Moderate	Strong
c. For all age groups, ancillary studies can be used to assist the clinician in making the diagnosis of brain death to reduce the observation period or when (i) components of the examination or apnea testing cannot be completed safely due to the underlying medical condition of the patient; (ii) if there is uncertainty about the results of the neurologic examination; or (iii) if a medication effect may interfere with evaluation of the patient. If the ancillary study supports the diagnosis, the second examination and apnea testing can then be performed. When an ancillary study is used to reduce the observation period, all aspects of the examination and apnea testing should be completed and documented.	Moderate	Strong
d. When an ancillary study is used because there are inherent examination limitations (ie, i to iii), then components of the examination done initially should be completed and documented.	High	Strong
e. If the ancillary study is equivocal or if there is concern about the validity of the ancillary study, the patient cannot be pronounced dead. The patient should continue to be observed until brain death can be declared on clinical examination criteria and apnea testing, or a follow-up ancillary study can be performed to assist with the determination of brain death. A waiting period of 24 hours is recommended before further clinical reevaluation or repeat ancillary study is performed. Supportive patient care should continue during this time period.	Moderate	Strong
6. Declaration of death		
a. Death is declared after confirmation and completion of the second clinical examination and apnea test.	High	Strong
b. When ancillary studies are used, documentation of components from the second clinical examination that can be completed must remain consistent with brain death. All aspects of the clinical examination, including the apnea test, or ancillary studies must be appropriately documented.	High	Strong
c. The clinical examination should be carried out by experienced clinicians who are familiar with infants and children, and have specific training in neurocritical care.	High	Strong

The "evaluation score" is based on the strength of the evidence available at the time of publication.
The "recommendation score" is the strength of the recommendations based on available evidence at the time of publication. Scoring guidelines are listed in Table 2.

TABLE 2 Grading of Recommendations Assessment, Development and Evaluation (GRADE) System[14-18]

1. Classification of evidence	
Grade	
A. High	Further research is very unlikely to change our confidence in the estimate of effect
B. Moderate	Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate
C. Low	Further research is very likely to have an important impact on confidence in the estimate of effect and is likely to change the estimate
D. Very low	Any estimate of effect is very uncertain
2. Recommendations: The strength of a recommendation reflects the extent to which we can be confident that desirable effects of an intervention outweigh undesirable effects.	
Strong	When the desirable effects of an intervention clearly outweigh the undesirable effects, or clearly do not. (a) For patients—most people in your situation would want the recommended course of action and only a small proportion would not (b) For clinicians—most patients should receive the recommended course of action (c) For policy makers—the recommendation can be adopted as a policy in most situations
Weak	Evidence suggests that desirable and undesirable effects are closely balanced or the quality of evidence is low. (a) For patients—most people in your situation would want the recommended course of action, but many would not (b) For clinicians—you should recognize that different choices will be appropriate for different patients and you must help each patient to arrive at a management decision consistent with his or her values and preferences. (c) For policy makers—policy making will require substantial debate and involvement of many stakeholders
No specific recommendations	The advantages and disadvantages of the recommendations are equivalent or where there is insufficient evidence on which to formulate a recommendation

2008 was conducted. Key words included: brain death, neurologic death, neonatal, pediatric, cerebral blood flow, electroencephalography, apnea test, and irreversible coma with the subheading, "children." Additional articles cited in the post 1987 literature that were published prior to 1987 were also reviewed if they contained data relevant to this guideline. Abstracts and articles were independently reviewed and summarized by at least two individuals on each committee. Data were summarized into five categories: clinical examination, apnea testing, observation periods, ancillary tests, and other considerations.

Methodological issues regarding analysis of evidence warrant further discussion as they directly affected the decision of how information and recommendations about brain death are presented. No randomized control trials examining different strategies regarding the diagnosis of brain death exist. Standard evidence-based approaches for guidelines used by many organizations attempting to link the "strength of the evidence" to the "strength of the recommendations" therefore cannot be used in this instance. There is, however, considerable experiential consensus within observational studies in the pediatric population. Grading of Recommendations Assessment, Development and Evaluation (GRADE), a recently developed standardized methodological consensus-based approach, allows panels to evaluate the evidence and opinions and make recommendations.[14–17] GRADE uses 5 domains to judge the balance between the desirable and undesirable effect of an intervention. *Strong recommendations* are made when there is confidence that the desirable effects of adherence to a recommendation outweigh the undesirable effects. *Weak recommendations* indicate that the desirable effects of adherence to a recommendation probably outweigh the undesirable effects, but the panel is less confident. *No specific recommendations* are made when the advantages and disadvantages of alternative courses of action are equivalent or where there is insufficient evidence on which to formulate a recommendation.[15,18] Table 2 outlines the GRADE methodology used in formulating recommendations for this guideline. Each committee member assigned a GRADE score for (i) the strength of evidence linked to a specific recommendation and (ii) indicated (*a*) "yes," (*b*) "no" or (*c*) "uncertain" for each of the six recommendations listed at the end of this report. By a priori consensus, the committee decided that a "strong" recommendation could only be made if greater than 80% of the committee members voted "yes"

TABLE 3 Neurologic Examination Components to Assess for Brain Death in Neonates, Infants and Children* Including Apnea Testing

Reversible conditions or conditions that can interfere with the neurologic examination must be excluded prior to brain death testing.
See text for discussion

1. **Coma. The patient must exhibit complete loss of consciousness, vocalization and volitional activity.**
   - Patients must lack all evidence of responsiveness. Eye opening or eye movement to noxious stimuli is absent.
   - Noxious stimuli should not produce a motor response other than spinally mediated reflexes. The clinical differentiation of spinal responses from retained motor responses associated with brain activity requires expertise.
2. **Loss of all brain stem reflexes including:**

Midposition or fully dilated pupils which do not respond to light.
Absence of pupillary response to a bright light is documented in both eyes. Usually the pupils are fixed in a midsize or dilated position (4–9 mm). When uncertainty exists, a magnifying glass should be used.

Absence of movement of bulbar musculature including facial and oropharyngeal muscles.
Deep pressure on the condyles at the level of the temporomandibular joints and deep pressure at the supraorbital ridge should produce no grimacing or facial muscle movement.

Absent gag, cough, sucking, and rooting reflex
The pharyngeal or gag reflex is tested after stimulation of the posterior pharynx with a tongue blade or suction device. The tracheal reflex is most reliably tested by examining the cough response to tracheal suctioning. The catheter should be inserted into the trachea and advanced to the level of the carina followed by 1 or 2 suctioning passes.

Absent corneal reflexes
Absent corneal reflex is demonstrated by touching the cornea with a piece of tissue paper, a cotton swab, or squirts of water. No eyelid movement should be seen. Care should be taken not to damage the cornea during testing.

Absent oculovestibular reflexes
The oculovestibular reflex is tested by irrigating each ear with ice water (caloric testing) after the patency of the external auditory canal is confirmed. The head is elevated to 30 degrees. Each external auditory canal is irrigated (1 ear at a time) with ~10 to 50 mL of ice water. Movement of the eyes should be absent during 1 minute of observation. Both sides are tested, with an interval of several minutes.

3. **Apnea. The patient must have the complete absence of documented respiratory effort (if feasible) by formal apnea testing demonstrating a $Paco_2$ ≥ 60 mm Hg and ≥ 20 mm Hg increase above baseline.**
   - Normalization of the pH and $Paco_2$, measured by arterial blood gas analysis, maintenance of core temperature > 35°C, normalization of blood pressure appropriate for the age of the child, and correcting for factors that could affect respiratory effort are a prerequisite to testing.
   - The patient should be preoxygenated using 100% oxygen for 5–10 minutes prior to initiating this test.
   - Intermittent mandatory mechanical ventilation should be discontinued once the patient is well oxygenated and a normal $Paco_2$ has been achieved.
   - The patient's heart rate, blood pressure, and oxygen saturation should be continuously monitored while observing for spontaneous respiratory effort throughout the entire procedure.
   - Follow up blood gases should be obtained to monitor the rise in $Paco_2$ while the patient remains disconnected from mechanical ventilation.
   - If no respiratory effort is observed from the initiation of the apnea test to the time the measured $Paco_2$ ≥ 60 mm Hg and ≥ 20 mm Hg above the baseline level, the apnea test is consistent with brain death.
   - The patient should be placed back on mechanical ventilator support and medical management should continue until the second neurologic examination and apnea test confirming brain death is completed.
   - If oxygen saturations fall below 85%, hemodynamic instability limits completion of apnea testing, or a $Paco_2$ level of ≥ 60 mm Hg cannot be achieved, the infant or child should be placed back on ventilator support with appropriate treatment to restore normal oxygen saturations, normocarbia, and hemodynamic parameters. Another attempt to test for apnea may be performed at a later time or an ancillary study may be pursued to assist with determination of brain death.
   - Evidence of any respiratory effort is inconsistent with brain death and the apnea test should be terminated.
4. **Flaccid tone and absence of spontaneous or induced movements, excluding spinal cord events such as reflex withdrawal or spinal myoclonus.**
   - The patient's extremities should be examined to evaluate tone by passive range of motion assuming that there are no limitations to performing such an examination (eg, previous trauma, etc) and the patient observed for any spontaneous or induced movements.
   - If abnormal movements are present, clinical assessment to determine whether or not these are spinal cord reflexes should be done.

* Criteria adapted from 2010 American Academy of Neurology criteria for brain death determination in adults (Wijdicks et al, 2010).

for a recommendation and that a "weak" recommendation was made if greater than 60% but less than 80% voted "yes." "No recommendation" was made if less than 60% of the committee voted "yes" for a specific recommendation. Table 1 summarizes GRADE recommendations and evidence scores.

The committee believes these revised diagnostic guidelines, summarized in Table 1 and a standardized checklist form (Appendix 1), will assist physicians in determining and documenting brain death in children. This should ensure broader acceptance and utilization of such uniform criteria. The committee recognizes that medical judgment of involved pediatric specialists will direct the appropriate course for the medical evaluation and diagnosis of brain death. The committee also recognizes that no national brain death law exists. State statutes and policy may restrict determination of brain death in certain circumstances. Physicians should become familiar with laws and policies in their respective institution. The committee also recognizes that variability exists for the age designation of pediatric trauma patients. In some states, the age of the pediatric trauma patient is defined as less than 14 years of age.

Trauma and intensive care practitioners are encouraged to follow state/local regulations governing the specified age of pediatric trauma patients. The committee believes these guidelines to be an important step in protecting the health and safety of all infants and children. These revised guidelines and accompanying checklist are intended to provide a framework to promote standardization of the neurologic examination and use of ancillary studies based on the evidence available to the committee at the time of publication.

TERM NEWBORNS (37 WEEKS GESTATIONAL AGE) TO CHILDREN 18 YEARS OF AGE

Definition of Brain Death and Components of the Clinical Examination (*Recommendation 1, Table 1 and Table 3*)

Brain death is a clinical diagnosis based on the absence of neurologic function with a known diagnosis that has resulted in irreversible coma. Coma and apnea must coexist to diagnose brain death. A complete neurologic examination that includes the elements outlined in Table 3 is mandatory to determine brain death with all components appropriately documented.

Prerequisites for Initiating a Clinical Brain Death Evaluation (*Recommendations 2a–d, Table 1*)

Determination of brain death by neurologic examination should be performed in the setting of normal age-appropriate physiologic parameters. Factors potentially influencing the neurologic examination that must be corrected before examination and apnea testing include: (1) shock or persistent hypotension based on normal systolic or mean arterial blood pressure values for the patient's age. Systolic blood pressure or MAP should be in an acceptable range (systolic BP not less than 2 standard deviations below age appropriate norm) based on age; (2) hypothermia; (3) severe metabolic disturbances capable of causing a potentially reversible coma including electrolyte/glucose abnormalities; (4) recent administration of neuromuscular blocking agents; and (5) drug intoxications including but not limited to barbiturates, opioids, sedative and anesthetic agents, antiepileptic agents, and alcohols. Placement of an indwelling arterial catheter is recommended to ensure that blood pressure remains within a normal range during the process of diagnosing brain death and to accurately measure $Paco_2$ levels during apnea testing.

Hypothermia is used with increasing frequency as an adjunctive therapy for individuals with acute brain injury.[19–22] Hypothermia has also been used following cardiac arrest to protect the brain because it reduces cerebral metabolic activity.[23–26] The clinician caring for critically ill infants and children should be aware of the potential impact of therapeutic modalities such as hypothermia on the diagnosis of brain death. Hypothermia is known to depress central nervous system function[27–29] and may lead to a false diagnosis of brain death. Hypothermia may alter metabolism and clearance of medications that can interfere with brain death testing. Efforts to adequately rewarm before performing any neurologic examination and maintain temperature during the observation period are essential. The 1987 guidelines stated that the patient must not be significantly hypothermic however no definition was provided.[1] It is reasonable that the core body temperature at the time of brain death examination be as close to normal to reproduce normal physiologic conditions. A core body temperature of $>35°C$ (95°F) should be achieved and maintained during examination and testing to determine death. This temperature is consistent with current adult guidelines and is relatively easy to achieve and maintain in children.[11,13]

Severe metabolic disturbances can cause reversible coma and interfere with the clinical evaluation to determine brain death. Reversible conditions such as severe electrolyte imbalances, hyper or hyponatremia, hyper or hypoglycemia, severe pH disturbances, severe hepatic or renal dysfunction or inborn errors of metabolism may cause coma in a neonate or child.[28,29] These conditions should be identified and treated before evaluation for brain death, especially in situations where the clinical history does not provide a reasonable explanation for the neurologic status of the child.

Drug intoxications including barbiturates, opioids, sedatives, intravenous and inhalation anesthetics, antiepileptic agents, and alcohols can cause severe central nervous system depression and may alter the clinical examination to the point where they can mimic brain death.[28,29] Testing for these drugs should be performed if there is concern regarding recent ingestion or administration. When available, specific serum levels of medications with sedative properties or side effects should be obtained and documented to be in a low to mid therapeutic range before neurologic examination for brain death testing. Longer acting or continuous infusion of sedative agents can also interfere with the neurologic evaluation. These medications should be discontinued. Adequate clearance (based on the age of the child, presence of organ dysfunction, total amount of medication administered, elimination half-life of the drug and any active metabolites) should be allowed before the neurologic examination. In some instances this may require waiting several half-

lives and rechecking serum levels of the medication before conducting the brain death examination. If neuromuscular blocking agents have been used, they should be stopped and adequate clearance of these agents confirmed by use of a nerve stimulator with documentation of neuromuscular junction activity and twitch response. Other unusual causes of coma such as neurotoxins, and chemical exposure (ie, organophosphates, and carbamates) should be considered in rare cases where an etiology for coma has not been established. Recommendations of time intervals before brain death evaluation for many of the commonly used medications administered to critically ill neonates and children are listed in Appendix 2.

Clinical criteria for determining brain death may not be present on admission and may evolve during hospitalization. Assessment of neurologic function may be unreliable immediately following resuscitation after cardiopulmonary arrest[30–33] or other acute brain injuries and serial neurologic examinations are necessary to establish or refute the diagnosis of brain death. Additionally, initial stabilization may take several hours during which time correcting metabolic disturbances and identifying and treating reversible conditions that may imitate brain death can be accomplished. It is reasonable to defer neurologic examination to determine brain death for 24 hours or longer if dictated by clinical judgment of the treating physician in such circumstances. If there are concerns about the validity of the examination (eg, flaccid tone or absent movements in a patient with high spinal cord injury or severe neuromuscular disease) or if specific examination components cannot be performed due to medical contraindications (eg, apnea testing in patients with significant lung injury, hemodynamic instability, or high spinal cord injury), or if examination findings are inconsistent, continued observation and postponing further neurologic examinations until these issues are resolved is warranted to avoid improperly diagnosing brain death. An ancillary study can be pursued to assist with the diagnosis of brain death in situations where certain examination components cannot be completed.

Neuroimaging with either computed tomography (CT) or magnetic resonance imaging (MRI) should demonstrate evidence of an acute central nervous system injury consistent with the profound loss of brain function. It is recognized that early after acute brain injury, imaging findings may not demonstrate significant injury. In such situations, repeat studies are helpful in documenting that an acute severe brain injury has occurred. CT and MRI are not considered ancillary studies and should not be relied on to make the determination of brain death.

Number of Examinations, Examiners and Observation Periods (*Recommendations 3a–e, Table 1*)

Number of Examinations and Examiners

The 1987 guidelines recommended observation periods between brain death examinations based on age and the results of neurodiagnostic testing.[1] Two examinations and EEG's separated by at least 48 hours were recommended for infants 7 days to 2 months. Two examinations and EEG's separated by at least 24 hours were recommended for children 2 months to 1 year. A repeat EEG was not necessary if a cerebral radionuclide scan or cerebral angiography demonstrated no flow or visualization of the cerebral arteries. For children older than 1 year, an observation period of 12 hours was recommended and ancillary testing was not required when an irreversible cause existed. The observation period in this age group could be decreased if there was documentation of electrocerebral silence (ECS) or absent cerebral blood flow (CBF).[1] The general consensus was the younger the child, the longer the waiting period unless ancillary studies supported the clinical diagnosis of brain death and if so, the observation period could be shortened.

The current committee supports the 1987 guideline recommending performance of two examinations separated by an observation period. The committee recommends that these examinations be performed by different attending physicians involved in the care of the child. Children being evaluated for brain death may be cared for and evaluated by multiple medical and surgical specialists. The committee recommends that the best interests of the child and family are served if at least two different attending physicians participate in diagnosing brain death to ensure that (i) the diagnosis is based on currently established criteria, (ii) there are no conflicts of interest in establishing the diagnosis and (iii) there is consensus by at least two physicians involved in the care of the child that brain death criteria are met. The committee also believes that because the apnea test is an objective test, it may be performed by the same physician, preferably the attending physician who is managing ventilator care of the child.

Duration of Observation Periods

A literature review of 171 children diagnosed as brain dead found that 47% had ventilator support withdrawn an average of 1.7 days after the diagnosis of brain death was made.[34] Seventy-nine children (46%) in whom support was continued after declaration of brain death suffered a cardiac arrest an average of 22.7 days later. The re-

maining children died by an unknown mechanism (5%), or made an incomplete (1%) or complete recovery (0.5%). Review of the children who survived indicates they did not fulfill brain death criteria by accepted medical standards. The age range of the children in this study included preterm and term neonates and older infants and children up to 18 years of age. These data and the reports of more recent studies[35,36] suggest that there is likely no biological justification for using different durations of observation to diagnose brain death in infants greater than one month of age. In fact, there are no reports of children recovering neurologic function after meeting adult brain death criteria based on neurologic examination findings.[37] Although some authors have reported apparent reversibility of brain death, further review of these cases reveals these children would not have fulfilled brain death criteria by currently accepted US medical standards.[38]

Based on the above data, currently available literature and clinical experience, the committee recommends the observation period between examinations should be 24 hours for neonates (37 weeks up to 30 days), and 12 hours for infants and children (> 30 days to 18 years). The first examination determines the child has met neurologic examination criteria for brain death. The second examination confirms brain death based on an unchanged and irreversible condition. Timing of the first clinical brain death examination, reduction of the observation period, and use of ancillary studies are discussed in separate sections of this guideline.

Apnea Testing (*Recommendations 4a,b, Table 1*)

Apnea testing should be performed with each neurologic examination to determine brain death in all patients unless a medical contraindication exists. Contraindications may include conditions that invalidate the apnea test (such as high cervical spine injury) or raise safety concerns for the patient (high oxygen requirement or ventilator settings). If apnea testing cannot be completed safely, an ancillary study should be performed to assist with the determination of brain death.

The normal physiologic threshold for apnea (minimum carbon dioxide tension at which respiration begins) in children has been assumed to be the same as in adults with reports demonstrating that $Paco_2$ levels in the normal range (24–38 mm Hg) may be adequate to stimulate ventilatory effort in children with residual brainstem function.[39] Although expert opinion has suggested a range of $Paco_2$ levels from 44 to 60 mm Hg for apnea testing in adults, the general consensus in infants and children has been to use 60 mm Hg as a threshold.[40–42] Appendix 3 summarizes data from 4 studies (3 being prospective) on 106 apnea tests in 76 children 2 months old to 17 years with suspected brain death.[39–42] 73 of 76 children had no spontaneous ventilatory effort. In 3 of these studies mean $Paco_2$ values were 59.5 ± 10.2, 68.1 ± 17.7, and 63.9 ± 21.5 mm Hg; in the fourth study, mean $Paco_2$ values were not reported, only the range (ie, 60–116 mm Hg).[39–42] Three children exhibited spontaneous respiratory effort with measured $Paco_2$ levels < 40 mm Hg.[39,42] Serial measurements of $Paco_2$ were done in most studies and 15 minutes was the usual end point of testing although patients may have had apnea for longer periods. The maximum rate of $Paco_2$ increase usually occurred within 5 minutes. Sixty five children had no ventilatory effort during the apnea test. After completion of apnea testing, support was withdrawn in all of these patients. Patient outcome was not reported for one study although these 9 children all had absent brainstem reflexes for a period of > 72 hours.[41] In one study 4/9 patients had phenobarbital levels that were interpreted as not affecting the results of apnea testing.[41]

There are three case reports discussing irregular breaths or minimal respiratory effort with a Pco_2 > 60 mm Hg in children who otherwise met criteria for brain death.[43–45] Two children died, one after meeting all criteria for brain death including a second apnea test. The remaining child survived and was supported in a chronic care facility with a tracheostomy, chronic mechanical ventilation and a gastrostomy tube. One other report describes a 3-month-old who met all criteria for brain death including 2 apnea tests with serial Pco_2's of 69.3 mm Hg and 62.1 mm Hg respectively. This infant was declared dead on hospital day 5. This infant developed irregular spontaneous respirations at a rate of two to three breaths per minute 38 days later which continued while receiving mechanical ventilator support until death on day 71.[46] Review of this case and others remind us to be cautious in applying brain death criteria in young infants. However, these cases should not be considered to represent reversible deficits or failure of current brain death criteria.[47]

Technique for Apnea Testing

Apnea testing in term newborns, infants, and children is conducted similar to adults. Normalization of the pH and $Paco_2$, measured by arterial blood gas analysis, maintenance of core temperature > 35°C, normalization of blood pressure appropriate for the age of the child, and correcting for factors that could affect respiratory effort are a prerequisite to testing. The patient must be preoxygenated using 100% oxygen for 5–10 minutes before initiating this test. Intermittent manda-

tory mechanical ventilation should be discontinued once the patient is well oxygenated and a normal $Paco_2$ has been achieved. The patient can then be changed to a T piece attached to the endotracheal tube (ETT), or a self-inflating bag valve system such as a Mapleson circuit connected to the ETT. Tracheal insufflation of oxygen using a catheter inserted through the ETT has also been used, however caution is warranted to ensure adequate gas excursion and to prevent barotrauma. High gas flow rates with tracheal insufflation may also promote CO_2 washout preventing adequate $Paco_2$ rise during apnea testing. Continuous positive airway pressure (CPAP) ventilation has been used during apnea testing. Many current ventilators automatically change from a CPAP mode to mandatory ventilation and deliver a breath when apnea is detected. It is also important to note that spontaneous ventilation has been falsely reported to occur while patients were maintained on CPAP despite having the trigger sensitivity of the mechanical ventilator reduced to minimum levels.[48] Physician(s) performing apnea testing should continuously monitor the patient's heart rate, blood pressure, and oxygen saturation while observing for spontaneous respiratory effort throughout the entire procedure. $Paco_2$, measured by blood gas analysis, should be allowed to rise to $\geq$ 20 mm Hg above the baseline $Paco_2$ level and $\geq$ 60 mm Hg. If no respiratory effort is observed from the initiation of the apnea test to the time the measured $Paco_2 \geq 60$ mm Hg and ≥ 20 mm Hg above the baseline level, the apnea test is consistent with brain death. The patient should be placed back on mechanical ventilator support and medical management should continue until the second neurologic examination and apnea test confirming brain death is completed. If oxygen saturations fall below 85%, hemodynamic instability limits completion of apnea testing, or a $Paco_2$ level of $\geq$ 60 mm Hg cannot be achieved, the infant or child should be placed back on ventilator support with appropriate treatment to restore normal oxygen saturations, normocarbia, and hemodynamic parameters. In this instance, another attempt to test for apnea may be performed at a later time or an ancillary study may be pursued to assist with determination of brain death. Evidence of any respiratory effort that is inconsistent with brain death and the apnea test should be terminated and the patient placed back on ventilatory support.

Ancillary Studies (*Recommendations 5a–e, Table 1*)

The committee recommends that ancillary studies are not required to establish brain death and should not be viewed as a substitute for the neurologic examination. Ancillary studies may be used to assist the clinician in making the diagnosis of brain death (i) when components of the examination or apnea testing cannot be completed safely due to the underlying medical condition of the patient; (ii) if there is uncertainty about the results of the neurologic examination; (iii) if a medication effect may be present; or (iv) to reduce the inter-examination observation period. The term "ancillary study" is preferred to "confirmatory study" since these tests assist the clinician in making the clinical diagnosis of brain death. Ancillary studies may also be helpful for social reasons allowing family members to better comprehend the diagnosis of brain death.

Four-vessel cerebral angiography is the gold standard for determining absence of CBF. This test can be difficult to perform in infants and small children, may not be readily available at all institutions, and requires moving the patient to the angiography suite potentially increasing risk of exacerbating hemodynamic and respiratory instability during transport of a critically ill child outside of the intensive care unit. Electroencephalographic documentation of electrocerebral silence (ECS) and use of radionuclide CBF determinations to document the absence of CBF remain the most widely used methods to support the clinical diagnosis of brain death in infants and children. Radionuclide CBF testing must be performed in accordance with guidelines established by the Society of Nuclear Medicine and the American College of Radiology.[49,50] EEG testing must be performed in accordance with standards established by the American Electroencephalographic Society.[51] Interpretation of ancillary studies requires the expertise of appropriately trained and qualified individuals who understand the limitations of these studies to avoid any potential misinterpretation.

Similar to the neurologic examination, hemodynamic and temperature parameters should be normalized before obtaining EEG or CBF studies. Pharmacologic agents that could affect the results of testing should be discontinued (Appendix 2) and levels determined as clinically indicated. Low to mid therapeutic levels of barbiturates should not preclude the use of EEG testing.[48] Evidence suggests that radionuclide CBF study can be used in patients with high dose barbiturate therapy to demonstrate absence of CBF.[52,53]

Diagnostic Yield of the EEG in Suspected Brain Dead Children

Appendix 4 summarizes EEG data from 12 studies in 485 suspected brain dead children in all age groups.[34,54–65] The data show that 76% of all children who were evaluated with EEG for brain death on the first EEG had ECS. Multiple EEGs increased the yield to 89%. For those children who had ECS on their

first EEG, 64/66 patients (97%) had ECS on a follow-up EEG. The first exception was a neonate who had a phenobarbital level of 30 μg/mL when the first EEG was performed.[65] The second exception was a 5 year old head trauma patient who was receiving pentobarbital and pancuronium at the time of the initial EEG.[62] This patient also had a CBF study performed demonstrating flow. In retrospect, these two patients would not have met currently accepted standards for brain death based on pharmacologic interference with EEG testing. Additionally, of those patients with EEG activity on the first EEG, 55% had a subsequent EEG that showed ECS. The remaining 45% either had persistent EEG activity or additional EEGs were not performed. All died (spontaneously or by withdrawal of support). Only one patient survived from this entire group of 485 patients, a neonate with an elevated phenobarbital level whose first EEG showed photic response and survived severely neurologically impaired.

Diagnostic Yield of Radionuclide CBF Studies in Suspected Brain Dead Children

Appendix 5 summarizes CBF data from 12 studies in 681 suspected brain dead children in all age groups.[36,54,55,57,59,60,63,64–68] Different but well standardized and conventional radionuclide cerebral angiography methods were used. Absent CBF was found in 86% of children who were clinically brain dead and the yield did not significantly change if more than one CBF study was done (89%). Appendix 5 also summarizes follow-up data on children whose subsequent CBF study showed no flow. 24/26 patients (92%) had no flow on follow-up CBF studies when the first study showed absent flow. The two exceptions where flow developed later were newborns. The first newborn had minimal flow on the second study and ventilator support was discontinued. The other newborn developed flow on the second study and had some spontaneous respirations and activity. A phenobarbital level two days after the second CBF study with minimal flow was 8 μg/mL.[65]

In those patients with preserved CBF on the first CBF study, 26% (9/34) had a second CBF study that showed no flow. The remaining 74% either had preserved flow or no further CBF studies were done and all but one patient died (either spontaneously or by withdrawal of support). Only one patient survived with severe neurologic impairment from this entire group of patients—the same neonate as noted previously with no CBF on the first study but presence of CBF on the second study.

Diagnostic Yield of the Initial EEG Versus Radionuclide CBF Studies in Brain Dead Children

Appendix 6 summarizes the comparative diagnostic yield of EEG versus CBF determinations in children who had both studies done as part of the initial brain death evaluation. Data from the 12 studies cited in Appendices 4 and 5 were stratified by 3 age groups: (i) all children ($n = 149$); (ii) newborns (< 1 month of age, $n = 30$); and (iii) children age > 1 month to 18 years ($n = 119$).[36,54–56,58–68]

The data in Appendices 4 and 5 show that the yield from the initial CBF studies was higher (86%) than from the initial EEG (76%) but no differences were present for any CBF study (89%) vs any EEG study (89%). In contrast the data in Appendix 6 for all children show that when both studies are initially performed, the diagnostic yield is the same (70% had ECS; and 70% showed absent CBF). The diagnostic yield for children greater than 1 month of age was similar for both tests (EEG with ECS, 78%; no CBF, 71%). For newborns, EEG with ECS was less sensitive (40%) than absence of CBF (63%) when confirming the diagnosis of brain death but even in the CBF group the yield was low.

In summary, both of these ancillary studies remain accepted tests to assist with determination of brain death in infants and children. The data suggest that EEG and CBF studies are of similar confirmatory value. Radionuclide CBF techniques are increasingly being used in many institutions replacing EEG as an ancillary study to assist with the determination of brain death in infants and children.[5,69] Other ancillary studies such as the Transcranial Doppler study and newer tests such as CT angiography, CT perfusion using arterial spin labeling, nasopharyngeal somatosensory evoked potential studies, MRI-MR angiography, and perfusion MRI imaging have not been studied sufficiently nor validated in infants and children and cannot be recommended as ancillary studies to assist with the determination of brain death in children at this time.

Repeating Ancillary Studies

If the EEG study shows electrical activity or the CBF study shows evidence of flow or cellular uptake, the patient cannot be pronounced dead at that time. The patient should continue to be observed and medically treated until brain death can be declared solely on clinical examination criteria and apnea testing based on recommended observation periods, or a follow-up ancillary study can be performed to assist and is consistent with the determination of brain death, or withdrawal of life-sustaining medical therapies is made irrespective of meeting criteria for brain death. A waiting period of 24 hours is recommended before further ancillary testing, using a radionuclide CBF study, is performed allowing adequate clearance of Tc-99m.[49,50] While no evidence exists for a recommended

waiting period between EEG studies, a waiting period of 24 hours is reasonable and recommended before repeating this ancillary study.

Shortening the Observation Period

If an ancillary study, used in conjunction with the first neurologic examination, supports the diagnosis of brain death, the inter-examination observation interval can be shortened and the second neurologic examination and apnea test (or all components that can be completed safely) can be performed and documented at any time thereafter for children of all ages.

SPECIAL CONSIDERATIONS FOR TERM NEWBORNS (37 WEEKS GESTATION) TO 30 DAYS OF AGE (*RECOMMENDATIONS 1–5, TABLE 1*)

Preterm and term neonates younger than 7 days of age were excluded from the 1987 Task Force guidelines. The ability to diagnose brain death in newborns is still viewed with some uncertainty primarily due to the small number of brain-dead neonates reported in the literature[54,65,70] and whether there are intrinsic biological differences in neonatal brain metabolism, blood flow and response to injury. The newborn has patent sutures and an open fontanelle resulting in less dramatic increases in intracranial pressure (ICP) after acute brain injury when compared with older patients. The cascade of events associated with increased ICP and reduced cerebral perfusion ultimately leading to herniation are less likely to occur in the neonate.

Clinical Examination

Limited data are available regarding the clinical examination for brain death in preterm and term infants.[70] It has been recognized that examination of the preterm infant less than 37 weeks gestation to determine if they meet brain death criteria may be difficult because of the possibility that some of the brainstem reflexes may not be completely developed and that it is also difficult to assess the level of consciousness in a critically ill, sedated and intubated neonate. Because of insufficient data in the literature, recommendations for preterm infants less than 37 weeks gestational age were not included in this guideline. However, as discussed in the following section on observation periods, the available data suggest that recovery of neurologic function is unlikely when a term newborn is diagnosed with brain death. Based on review of the literature, the task force supports that brain death can be diagnosed in term newborns (37 weeks gestation) and older, provided the physician is aware of the limitations of the clinical examination and ancillary studies in this age group. It is important to carefully and repeatedly examine term newborns, with particular attention to examination of brainstem reflexes and apnea testing. As with older children, assessment of neurologic function in the term newborn may be unreliable immediately following an acute catastrophic neurologic injury or cardiopulmonary arrest. A period of 24 hours or longer is recommended before evaluating the term newborn for brain death.

Apnea Testing

Neonatal studies reviewing $Paco_2$ thresholds for apnea are limited. However, data from 35 neonates who were ultimately determined to be brain dead revealed a mean $Paco_2$ of 65 mm Hg suggesting that the threshold of 60 mm Hg is also valid in the newborn.[35] Apnea testing in the term newborn may be complicated by the following: (1) Treatment with 100% oxygen may inhibit the potential recovery of respiratory effort.[71,72] (2) Profound bradycardia may precede hypercarbia and limit this test in neonates. A thorough neurologic examination must be performed in conjunction with the apnea test to make the determination of death in any patient. If the apnea test cannot be completed as previously described, the examination and apnea test can be attempted at a later time, or an ancillary study may be performed to assist with determination of death. Ancillary studies in newborns are less sensitive than in older children. There are no reported cases of any neonate who developed respiratory effort after meeting brain death criteria.

Observation Periods in Term Newborns

There is some experience concerning the duration of observation periods in neonates being evaluated for brain death. A review of 87 newborns revealed that the duration of coma from insult to brain death was 37 hours and the duration of time from the initial neurologic examination being indicative of brain death to final confirmation was 75 hours. The overall average duration of brain death in these neonates was about 95 hours or almost 4 days.[37] 53 neonates less than 7 days of age donating organs for transplantation had a total duration of brain death including time to transplantation that averaged 2.8 days; for neonates 1–3 weeks of age, the duration of brain death was approximately 5.2 days.[37] None of these patients recovered any neurologic function. These data suggest that once the diagnosis of brain death is made in newborns, recovery is unlikely. Based on data extracted from available literature and clinical experience the committee recommends the observation period between examinations should be 24 hours for term newborns (37 weeks) to 30 days of age.

Ancillary Studies

Ancillary studies performed in the newborn $<$ 30 days of age are limited.[70] As summarized in Appendix 6, ancillary studies in this age group are less sensitive in detecting the pres-

ence/absence of brain electrical activity or cerebral blood flow than in older children. Of the two studies, detecting absence of CBF (63%) was more sensitive than demonstration of ECS (40%) in confirming the diagnosis of brain death, however even in the CBF study group the sensitivity was low.[70]

EEG activity is of low voltage in newborns raising concerns about a greater chance of having reversible ECS in this age group. In a retrospective review of 40 newborns with ECS, 9/10 with ECS on the initial EEG showed ECS on repeated studies.[70] The remaining patient had a phenobarbital level of 30 μg/mL at the time of the initial EEG, probably accounting for the initial ECS. Several other cases have been reported with initial ECS but careful review found that the patients were not clinically brain dead. Based on available data it is likely that if the initial EEG shows ECS (assuming an absence of correctable conditions) in a newborn who meets all clinical criteria for brain death, then it is an accurate and reliable predictor of brain death and repeat EEG studies are not indicated.

CBF in viable newborns can be extremely low because of the decreased level of brain metabolic activity.[50] However earlier studies using stable xenon computed tomography measurements of CBF have shown that the level of CBF in brain dead children is much lower than that seen in viable newborns.[73,74]

The available data suggest that ancillary studies in newborns are less sensitive than in older children. This can pose an important clinical dilemma in this age group where clinicians may have a greater level of uncertainty about performing a valid neurologic examination. There is a greater need to have more reliable and accurate ancillary studies in this age group. Awareness of this limitation would suggest that longer periods of observation and repeated neurologic examinations are needed before making the diagnosis of brain death and also that as in older infants and children, the diagnosis should be made clinically and based on repeated examinations rather than relying exclusively on ancillary studies.

DECLARATION OF DEATH (FOR ALL AGE GROUPS) (*RECOMMENDATIONS 6a–c, TABLE 1 AND APPENDIX 8 ALGORITHM*)

Death is declared after the second neurologic examination and apnea test confirms an unchanged and irreversible condition. An algorithm (Appendix 8) provides recommendations for the process of diagnosing brain death in children. When ancillary studies are used, documentation of components from the second clinical examination that can be completed, including a second apnea test, must remain consistent with brain death. All aspects of the clinical examination, including the apnea test, or ancillary studies must be appropriately documented. A checklist outlining essential examination and testing components is provided in Appendix 1. This checklist also provides standardized documentation to determine brain death.

ADDITIONAL CONSIDERATIONS (FOR ALL AGE GROUPS)

In today's modern pediatric and neonatal intensive care units, critical care practitioners and other physicians with expertise in neurologic injury are routinely called on to declare death in infants and children. Because the implications of diagnosing brain death are of great consequence, examination should be conducted by experienced clinicians who are familiar with neonates, infants and children and have specific training in neurocritical care. These physicians must be competent to perform the clinical examination and interpret results from ancillary studies. Qualified clinicians include: pediatric intensivists and neonatologists, pediatric neurologists and neurosurgeons, pediatric trauma surgeons, and pediatric anesthesiologists with critical care training. Adult specialists should have appropriate neurologic and critical care training to diagnose brain death when caring for the pediatric patient from birth to 18 years of age. Residents and fellows should be encouraged to learn how to properly perform brain death testing by observing and participating in the clinical examination and testing process performed by experienced attending physicians. It is recommended that both neurologic examinations be performed and documented by an attending physician who is qualified and competent to perform the brain death examination.

These revised pediatric brain death diagnostic guidelines are intended to provide an updated framework in an effort to promote standardization of the neurologic examination and use of ancillary studies. A standardized checklist (Appendix 1) will help to ensure that all components of the examination, and ancillary studies if needed, are completed and documented appropriately. Pediatric specialists should be invited to participate in the development of institutional guidelines to ensure that the brain death examination is conducted consistently each time the diagnosis is being considered. A comparison of the 1987 pediatric brain death guidelines and 2011 update for neonatal and pediatric brain death guidelines are listed in Appendix 7.

Diagnosing brain death must never be rushed or take priority over the needs of the patient or the family. Physicians are obligated to provide support and guidance for families as they face difficult end-of-life decisions and attempt to understand what has happened to their child. It is the responsibility of the physician to guide and direct families during the treatment of their child. Communication with families must be clear and concise using simple termi-

nology so that parents and family members understand that their child has died. Permitting families to be present during the brain death examination, apnea testing and performance of ancillary studies can assist families in understanding that their child has died. The family must understand that once brain death has been declared, their child meets legal criteria for death. Families may otherwise become confused or angry if discussions regarding withdrawal of support or medical therapies are entertained after declaration of death. It should be made clear that once death has occurred, continuation of medical therapies, including ventilator support, is no longer an option unless organ donation is planned. Appropriate emotional support for the family should be provided including adequate time to grieve with their child after death has occurred. Consultation or referral to the medical examiner or coroner may be required by state law in certain situations when death occurs.

FUTURE DIRECTIONS

Development of a national database to track infants and children who are diagnosed as brain dead should be strongly considered. Information compiled from this database would increase our knowledge about brain death, especially in neonates.

1. Studies comparing traditional ancillary studies to newer methods to assess CBF and neurophysiologic function should be pursued. Further information about ancillary studies, waiting periods, and research regarding validity of newer ancillary studies is needed for future recommendations to assist with determination of brain death in children.
2. Cerebral protective therapies such as hypothermia may alter the natural progression of brain death and their impact should be reviewed as more information becomes available. The clinician caring for critically ill infants and children should be aware of the potential impact of new therapeutic modalities on the diagnosis of brain death.
3. While each institution and state may have specific guidelines for the determination of brain death in infants and children, we should work with national medical societies to achieve a uniform approach to declaring death that can be incorporated in all hospital policies.[75] This will help eliminate confusion among medical personnel thereby fostering further trust from the community of patients and families that we serve.
4. Additional information or studies are required to determine if a single neurologic examination is sufficient for neonates, infants, and children to determine brain death as currently recommended for adults over 18 years of age.[12,76]

ENDORSEMENTS AND APPROVALS

APPENDIX 1 Check List for Documentation of Brain Death

Brain Death Examination for Infants and Children

Two physicians must perform independent examinations separated by specified intervals.

Age of Patient	Timing of first exam	Inter-exam. interval
Term newborn 37 weeks gestational age and up to 30 days old	☐ First exam may be performed 24 hours after birth OR following cardiopulmonary resuscitation or other severe brain injury	☐ At least 24 hours ☐ Interval shortened because ancillary study (section 4) is consistent with brain death
31 days to 18 years old	☐ First exam may be performed 24 hours following cardiopulmonary resuscitation or other severe brain injury	☐ At least 12 hours OR ☐ Interval shortened because ancillary study (section 4) is consistent with brain death

Section 1. PREREQUISITES for brain death examination and apnea test

A. IRREVERSIBLE AND IDENTIFIABLE Cause of Coma (Please check)

☐ Traumatic brain injury ☐ Anoxic brain injury ☐ Known metabolic disorder ☐ Other (Specify) _____

B. Correction of contributing factors that can interfere with the neurologic examination	Examination One		Examination Two	
a. Core Body Temp is over 95° F (35° C)	☐ Yes	☐ No	☐ Yes	☐ No
b. Systolic blood pressure or MAP in acceptable range (Systolic BP not less than 2 standard deviations below age appropriate norm) based on age	☐ Yes	☐ No	☐ Yes	☐ No
c. Sedative/analgesic drug effect excluded as a contributing factor	☐ Yes	☐ No	☐ Yes	☐ No
d. Metabolic intoxication excluded as a contributing factor	☐ Yes	☐ No	☐ Yes	☐ No
e. Neuromuscular blockade excluded as a contributing factor	☐ Yes	☐ No	☐ Yes	☐ No

If ALL prerequisites are marked YES, then proceed to section 2. OR

_____ confounding variable was present. Ancillary study was therefore performed to document brain death. (Section 4).

Section 2. Physical Examination (Please check) NOTE: SPINAL CORD REFLEXES ARE ACCEPTABLE	Examination One Date/ time: _____		Examination Two Date/ Time: _____	
a. Flaccid tone, patient unresponsive to deep painful stimuli	☐ Yes	☐ No	☐ Yes	☐ No
b. Pupils are midposition or fully dilated and light reflexes are absent	☐ Yes	☐ No	☐ Yes	☐ No
c. Corneal, cough, gag reflexes are absent	☐ Yes	☐ No	☐ Yes	☐ No
Sucking and rooting reflexes are absent (in neonates and infants)	☐ Yes	☐ No	☐ Yes	☐ No
d. Oculovestibular reflexes are absent	☐ Yes	☐ No	☐ Yes	☐ No
e. Spontaneous respiratory effort while on mechanical ventilation is absent	☐ Yes	☐ No	☐ Yes	☐ No

The _____ (specify) element of the exam could not be performed because _____

Ancillary study (EEG or radionuclide CBF) was therefore performed to document brain death. (Section 4).

Section 3. APNEA Test	Examination One Date/ Time_____	Examination Two Date/ Time_____
No spontaneous respiratory efforts were observed despite final $PaCO_2 \geq 60$ mm Hg and a ≥ 20 mm Hg increase above baseline. (Examination One) No spontaneous respiratory efforts were observed despite final $PaCO_2 \geq 60$ mm Hg and a ≥ 20 mm Hg increase above baseline. (Examination Two)	Pretest $PaCO_2$: _____ Apnea duration: _____min Posttest $PaCO_2$: _____	Pretest $PaCO_2$: _____ Apnea duration: _____min Posttest $PaCO_2$: _____

Apnea test is contraindicated or could not be performed to completion because _____

Ancillary study (EEG or radionuclide CBF) was therefore performed to document brain death. (Section 4).

Section 4. ANCILLARY testing is required when (1) any components of the examination or apnea testing cannot be completed; (2) if there is uncertainty about the results of the neurologic examination; or (3) if a medication effect may be present. Ancillary testing can be performed to reduce the inter-examination period however a second neurologic examination is required. Components of the neurologic examination that can be performed safely should be completed in close proximity to the ancillary test	Date/Time: _____
☐ Electroencephalogram (EEG) report documents electrocerebral silence OR	☐ Yes ☐ No
☐ Cerebral Blood Flow(CBF) study report documents no cerebral perfusion	☐ Yes ☐ No

Section 5. Signatures

Examiner One

I certify that my examination is consistent with cessation of function of the brain and brainstem. Confirmatory exam to follow.

_____ _____

(Printed Name) (Signature)

_____ _____ _____ _____

(Specialty) (Pager #/License #) (Date mm/dd/yyyy) (Time)

Examiner Two

☐ I certify that my examination ☐ and/or ancillary test report ☐ confirms unchanged and irreversible cessation of function of the brain and brainstem. The patient is declared brain dead at this time.

Date/Time of death: _____

_____ _____

(Printed Name) (Signature)

_____ _____ _____ _____

(Specialty) (Pager #/License #) (Date mm/dd/yyyy) (Time)

APPENDIX 2 Medications Administered to Critically Ill Pediatric Patients and Recommendations for Time Interval to Testing After Discontinuation

Medication	Infants/Children Elimination ½ life	Neonates Elimination ½ life
Intravenous induction, anesthetic, and sedative agents		
Thiopental	Adults: 3–11.5 hours (shorter ½ life in children)	
Ketamine	2.5 hours	
Etomidate	2.6–3.5 hours	
Midazolam	2.9–4.5 hours	4–12 hours[77–80]
Propofol	2–8 minutes, Terminal ½ life 200 minutes (range 300–700 minutes)	
Dexmedetomidine	Terminal ½ life 83–159 minutes[79–81]	Infants have faster clearance[81–83]
Antiepileptic drugs		
Phenobarbital	Infants: 20–133 hours* Children: 37–73 hours*	45–500 hours*[79,84,85]
Pentobarbital	25 hours*	
Phenytoin	11–55 hours*	63–88 hours*
Diazepam	1 month–2 years: 40–50 hours 2 years–12 years: 15–21 hours 12–16 years: 18–20 hours	50–95 hours[79,86,87]
Lorazepam	Infants: 40.2 hours (range 18–73 hours) Children: 10.5 hours (range 6–17 hours)	40 hours[86]
Clonazepam	22–33 hours	
Valproic Acid	Children > 2 months: 7–13 hours* Children 2–14 years: Mean 9 hours; range 3.5–20 hours	10–67 hours*
Levetiracetam	Children 4–12 years: 5 hours	
Intravenous narcotics		
Morphine sulfate	Infants 1–3 months: 6.2 hours (5–10 hours) 6 months–2.5 years: 2.9 hours (1.4–7.8 hours) Children: 1–2 hours	7.6 hours (range 4.5–13.3 hours)[79,89–91]
Meperidine	Infants < 3 months: 8.2–10.7 hours (range 4.9–31.7 hours) Infants 3–18 months: 2.3 hours Children 5–8 years: 3 hours	23 hours (range 12–39 hours)
Fentanyl	5 months–4.5 years: 2.4 hours (mean) 0.5–14 years: 21 hours (range 11–36 hours for long term infusions)	1–15 hours
Sufentanil	Children 2–8 years: 97 ± 42 minutes	382–1162 minutes
Muscle relaxants		
Succinylcholine	5–10 minutes Prolonged duration of action in patients with pseudocholinesterase deficiency or mutation	
Pancuronium	110 minutes	
Vecuronium	41 minutes	65 minutes
Atracurium	17 minutes	20 minutes
Rocuronium	3–12 months: 1.3 ± 0.5 hours 1 to < 3 years: 1.1 ± 0.7 hours 3 to < 8 years: 0.8 ± 0.3 hours Adults: 1.4–2.4 hours	

Modified from Ashwal and Schneider.[57]

Metabolism of pharmacologic agents may be affected by organ dysfunction and hypothermia.

Physicians should be aware of total amounts of administered medication that can affect drug metabolism and levels.

* Elimination ½ life does not guarantee therapeutic drug levels for longer acting medications or medications with active metabolites. Drug levels should be obtained to ensure that levels are in a low to mid therapeutic range prior to neurologic examination to determine brain death. In some instances this may require waiting several half-lives and rechecking serum levels of the medication before conducting the brain death examination.

APPENDIX 3 Apnea Testing in Pediatric Brain Death

Author	*n*	Age Range	$Paco_2$	Comments
Rowland (1984)[41]	9 children, 16 apnea tests performed	4 months–13 years	Range: 60–116 mm Hg after 15 minutes of apnea	No spontaneous respiratory effort noted in any patient during testing. Phenobarbital levels of 10,11.6,18,25 mg/dL were measured in 4 patients,
Outwater & Rockoff (1984)[40]	10 children	10 months–13 years	Mean 59.5 ± 10.2 mm Hg after 5 minutes of apnea	No spontaneous respiratory effort noted in any patient during testing or after support was withdrawn
Riviello (1988)[39]	19 children	2 months–15 years	Mean 63.9 ± 21.5 mm Hg	2 children with Pco_2 levels of 24 mm Hg and 38 mm Hg had spontaneous respirations during the apnea test. All other children had no spontaneous respiratory effort noted after support was withdrawn.
Paret (1995)[42]	38 children, 61 apnea tests performed	2 months–17 years	Mean 68.07 ± 17.66 after 5 minutes Mean 81.8 ± 20.2 after 10 minutes Mean 86.88 ± 25.6 after 15 minutes	1 child had spontaneous respiratory effort with a $Paco_2$ of 49 mm Hg. This patient was retested 24 hours later and had no respiratory effort.

APPENDIX 7 Comparison of 1987 Pediatric Brain Death Guidelines and the Updated Guideline for Determination of Brain Death in Infants and Children

	1987	Updated Guidelines
Waiting period before initial brain death examination	Not specified	24 hours following cardiopulmonary resuscitation or severe acute brain injury is suggested if there are concerns about the neurologic examination or if dictated by clinical judgment
Clinical examination	Required	Required
Core body temperature	Not specified	> 35°C (95°F)
Number of examinations	Two exams 2nd examination not necessary in 2 months–1 year age group if initial examination, EEG and concomitant CBF consistent with brain death	Two exams, irrespective of ancillary study results (if ancillary testing is being done in lieu of initial examination elements that cannot be safely performed, the components of the second examination that can be done must be completed)
Number of examiners	Not specified	Two (Different attending physicians must perform the first and second exam)
Observation interval between neurologic examinations	Age dependent ● 7 days–2 months: 48 hours ● 2 months–1 year: 24 hours ● >1 year: 12 hours (24 hrs if HIE)	Age Dependent ● Term newborn (37 weeks gestation) to 30 days of age: 24 hours ● 31 days–18 years: 12 hours
Reduction of observation period between exams	Permitted only for > 1 year age group if EEG or CBF consistent with brain death	Permitted for both age groups if EEG or CBF consistent with brain death
Apnea testing	Required, number of tests ambiguous	Two apnea tests required unless clinically contraindicated
Final Pco_2 threshold for apnea testing	Not specified	≥60 mm Hg and ≥20 mm Hg above the baseline $Paco_2$
Ancillary study recommended	● Age dependent 7 days–2 months: 2 EEGs separated by 48 hrs ● 2 months–1 year: 2 EEG's separated by 24 hours. CBF can replace the need for 2nd EEG ● >1 year: No testing required	Not required except in cases where the clinical examination and apnea test cannot be completed ● Term newborn (37 weeks gestation) to 30 days of age: EEG or CBF are less sensitive in this age group. CBF may be preferred. ● >30 days–18 years: EEG and CBF have equal sensitivity
Time of death	Not specified	Time of the second examination and apnea test (or completion of ancillary study and the components of the second examination that can be safely completed)

EEG Electroencephalogram.
CBF Cerebral blood flow.
HIE Hypoxic ischemic encephalopathy.

SOCIETY OF CRITICAL CARE MEDICINE

Pediatric Section Admission Criteria Task Force

Guidelines for Developing Admission and Discharge Policies for the Pediatric Intensive Care Unit

ABSTRACT. These guidelines were developed to provide a reference for preparing policies on admission to and discharge from pediatric intensive care units. They represent a consensus opinion of physicians, nurses, and allied health care professionals. By using this document as a framework for developing multidisciplinary admission and discharge policies, use of pediatric intensive care units can be optimized and patients can receive the level of care appropriate for their condition.

ABBREVIATION. PICU, pediatric intensive care unit.

It should be understood that critically ill pediatric patients should be admitted to designated pediatric critical care beds.[1] The following are recommended as guidelines for admission and discharge for pediatric intensive care units (PICUs). The purpose of these guidelines is to provide a reference for admitting and subsequently discharging critically ill pediatric patients. Because of continuing developments in pediatric critical care, periodic review of these criteria is necessary.

These guidelines must be adapted and modified to each institution's policies and procedures regarding the nature and scope of the critical illnesses seen in that institution[1] and the interhospital transfer arrangements of each institution.

Physiologic parameters should be added to these guidelines by each institution so that patients may be triaged appropriately in and out of the intensive care unit.

PREPARING GUIDELINES FOR INDIVIDUAL UNITS

The following listing is not meant to be inclusive, nor is it necessary for every PICU to admit all patients with every condition listed. However, the following has been prepared for the multiprofessional team developing such criteria to consider when developing admission and discharge policies.

In addition, accrediting agencies have recommended that physiologic limits be placed wherever possible in preparing admission and discharge policies. For example, a "potassium of 6.0 mEq/L" may be selected to indicate admission to the intensive care unit rather than simply "hyperkalemia."

ADMISSION CRITERIA

Respiratory System

Patients with severe or potentially life-threatening pulmonary or airway disease. Conditions include, but are not limited to:

1. Endotracheal intubation or potential need for emergency endotracheal intubation and mechanical ventilation, regardless of etiology;
2. Rapidly progressive pulmonary, lower or upper airway, disease of high severity with risk of progression to respiratory failure and/or total obstruction;
3. High supplemental oxygen requirement ($F_{IO_2} \geq 0.5$), regardless of etiology;
4. Newly placed tracheostomy with or without the need for mechanical ventilation;
5. Acute barotrauma compromising the upper or lower airway;
6. Requirement for more frequent or continuous inhaled or nebulized medications than can be administered safely on the general pediatric patient care unit (according to institution guidelines).

Cardiovascular System

Patients with severe, life-threatening, or unstable cardiovascular disease. Conditions include, but are not limited to:

1. Shock;
2. Postcardiopulmonary resuscitation;
3. Life-threatening dysrhythmias;
4. Unstable congestive heart failure, with or without need for mechanical ventilation;
5. Congenital heart disease with unstable cardiorespiratory status;
6. After high-risk cardiovascular and intrathoracic procedures;
7. Need for monitoring of arterial, central venous, or pulmonary artery pressures;
8. Need for temporary cardiac pacing;

Neurologic

Patients with actual or potential life-threatening or unstable neurologic disease. Conditions include, but are not limited to:

The recommendations in this statement do not indicate an exclusive course of treatment or serve as a standard of medical care. Variations, taking into account individual circumstances, may be appropriate.

1. Seizures, unresponsive to therapy or requiring continuous infusion of anticonvulsive agents;
2. Acutely and severely altered sensorium where neurologic deterioration or depression is likely or unpredictable, or coma with the potential for airway compromise;
3. After neurosurgical procedures requiring invasive monitoring or close observation;
4. Acute inflammation or infections of the spinal cord, meninges, or brain with neurologic depression, metabolic and hormonal abnormalities, and respiratory or hemodynamic compromise or the possibility of increased intracranial pressure;
5. Head trauma with increased intracranial pressure;
6. Preoperative neurosurgical conditions with neurologic deterioration;
7. Progressive neuromuscular dysfunction with or without altered sensorium requiring cardiovascular monitoring and/or respiratory support;
8. Spinal cord compression or impending compression;
9. Placement of external ventricular drainage device.

Hematology/Oncology

Patients with life-threatening or unstable hematologic or oncologic disease or active life-threatening bleeding. Conditions include, but are not limited to:

1. Exchange transfusions;
2. Plasmapheresis or leukopheresis with unstable clinical condition;
3. Severe coagulopathy;
4. Severe anemia resulting in hemodynamic and/or respiratory compromise;
5. Severe complications of sickle cell crisis, such as neurologic changes, acute chest syndrome, or aplastic anemia with hemodynamic instability;
6. Initiation of chemotherapy with anticipated tumor lysis syndrome;
7. Tumors or masses compressing or threatening to compress vital vessels, organs, or airway.

Endocrine/Metabolic

Patients with life-threatening or unstable endocrine or metabolic disease. Conditions include, but are not limited to:

1. Severe diabetic ketoacidosis requiring therapy exceeding institutional patient care unit guidelines. (If hemodynamic or neurologic compromise, see specific section);
2. Other severe electrolyte abnormalities, such as:
   - Hyperkalemia, requiring cardiac monitoring and acute therapeutic intervention
   - Severe hypo- or hypernatremia
   - Hypo- or hypercalcemia
   - Hypo- or hyperglycemia requiring intensive monitoring
   - Severe metabolic acidosis requiring bicarbonate infusion, intensive monitoring, or complex intervention
   - Complex intervention required to maintain fluid balance
3. Inborn errors of metabolism with acute deterioration requiring respiratory support, acute dialysis, hemoperfusion, management of intracranial hypertension, or inotropic support.

Gastrointestinal

Patients with life-threatening or unstable gastrointestinal disease. Conditions include, but are not limited to:

1. Severe acute gastrointestinal bleeding leading to hemodynamic or respiratory instability;
2. After emergency endoscopy for removal of foreign bodies;
3. Acute hepatic failure leading to coma, hemodynamic, or respiratory instability.

Surgical

Postoperative patients requiring frequent monitoring and potentially requiring intensive intervention. Conditions include, but are not limited to:

1. Cardiovascular surgery;
2. Thoracic surgery;
3. Neurosurgical procedures;
4. Otolaryngologic surgery;
5. Craniofacial surgery;
6. Orthopedic and spine surgery;
7. General surgery with hemodynamic or respiratory instability;
8. Organ transplantation;
9. Multiple trauma with or without cardiovascular instability;
10. Major blood loss, either during surgery or during the postoperative period.

Renal System

Patients with life-threatening or unstable renal disease. Conditions include, but are not limited to:

1. Renal failure;
2. Requirement for acute hemodialysis, peritoneal dialysis, or other continuous renal replacement therapies in the unstable patient;
3. Acute rhabdomyolysis with renal insufficiency.

Multisystem and Other

Patients with life-threatening or unstable multisystem disease. Conditions include, but are not limited to:

1. Toxic ingestions and drug overdose with potential acute decompensation of major organ systems;
2. Multiple organ dysfunction syndrome;
3. Suspected or documented malignant hyperthermia;
4. Electrical or other household or environmental (eg, lightning) injuries;
5. Burns covering >10% of body surface (institutions with burn units only; institutions without such units will have transfer policy to cover such patients).

Special Intensive Technologic Needs

Conditions that necessitate the application of special technologic needs, monitoring, complex intervention, or treatment including medications associated with the disease that exceed individual patient care unit policy limitations.

DISCHARGE/TRANSFER CRITERIA

Patients in the PICU will be evaluated and considered for discharge based on the reversal of the disease process or resolution of the unstable physiologic condition that prompted admission to the unit, and it is determined that the need for complex intervention exceeding general patient care unit capabilities is no longer needed.

Transfer/discharge will be based on the following criteria:

1. Stable hemodynamic parameters;
2. Stable respiratory status (patient extubated with stable arterial blood gases) and airway patency;
3. Minimal oxygen requirements that do not exceed patient care unit guidelines;
4. Intravenous inotropic support, vasodilators, and antiarrhythmic drugs are no longer required or, when applicable, low doses of these medications can be administered safely in otherwise stable patients in a designated patient care unit;
5. Cardiac dysrhythmias are controlled;
6. Intracranial pressure monitoring equipment has been removed;
7. Neurologic stability with control of seizures;
8. Removal of all hemodynamic monitoring catheters;
9. Chronically mechanically ventilated patients whose critical illness has been reversed or resolved and who are otherwise stable may be discharged to a designated patient care unit that routinely manages chronically ventilated patients, when applicable, or to home;
10. Routine peritoneal or hemodialysis with resolution of critical illness not exceeding general patient care unit guidelines;
11. Patients with mature artificial airways (tracheostomies) who no longer require excessive suctioning;
12. The health care team and the patient's family, after careful assessment, determine that there is no benefit in keeping the child in the PICU or that the course of treatment is medically futile.[2]

Clinical Report—Guidelines for the Ethical Conduct of Studies to Evaluate Drugs in Pediatric Populations

abstract

The proper ethical conduct of studies to evaluate drugs in children is of paramount importance to all those involved in these types of studies. This report is an updated revision to the previously published guidelines from the American Academy of Pediatrics in 1995. Since the previous publication, there have been great strides made in the science and ethics of studying drugs in children. There have also been numerous legislative and regulatory advancements that have promoted the study of drugs in children while simultaneously allowing for the protection of this particularly vulnerable group. This report summarizes these changes and advances and provides a framework from which to guide and monitor the ethical conduct of studies to evaluate drugs in children. *Pediatrics* 2010;125:850–860

THE NEED TO STUDY DRUGS IN CHILDREN

The performance of research studies to evaluate drugs in children is critical for determining the safety and efficacy of medications in children. Without this type of research, medication use in children will be limited to extrapolation from adult studies or off-label use for indications that have not been studied in children, thereby putting children at increased risk of adverse effects. Growth and maturation can alter the kinetics, end-organ responses, and toxicities of drugs used in infants, children, and adolescents compared with adults. Without proper drug studies in children, children may not benefit from and may even be harmed by drugs that are available to adults. Also, certain disorders affect children primarily, necessitating drug testing on appropriately aged subjects. It is morally imperative, therefore, to formally study drugs in children so that they can enjoy appropriate access to existing and new therapeutic agents.

Since enactment of the exclusivity program in the US Food and Drug Administration (FDA) Modernization Act in 1997 (Pub L No. 105–115), drug studies in children have greatly increased in number. The reauthorization of this exclusivity program as the Best Pharmaceuticals for Children Act in 2002 (Pub L No. 107–109) and again in 2007 (Pub L No 10–85) and the enactment of the Pediatric Research Equity Act (Pub L No. 108–155) have allowed for increased motivation for pharmaceutical companies and other sponsors to partner with investigators to carry out drug trials in children.[1] Increased interest in pediatric drug research has been accompanied by increased numbers of pediatric drug-research studies and increased variability of the studies. Achieving proper balance between the overall good that comes from perform-

ing these studies and the need to protect children as research subjects is a challenge. This report provides a framework from which to guide and monitor the ethical conduct of studies to evaluate drugs in children.

THE NEED FOR ETHICAL GUIDELINES

Historically, ethical guidelines to protect human subjects of scientific investigation were developed in recognition of past exploitation of human subjects and the acknowledged need to protect individual human rights. Federal regulations governing the protection of human subjects were published in 1974 and revised in 2005.[2] The American Academy of Pediatrics (AAP) first published "Guidelines for the Ethical Conduct of Studies to Evaluate Drugs in Pediatric Populations" in 1977[3] and revised the document in 1995.[4] Federal regulations that specifically addressed research in children were published in 1978,[5] 1983,[6] 2001,[7] and 2005.[8]

In the landmark Belmont report of 1978,[9] 3 basic ethical principles for the protection of all human subjects were outlined:

1. Respect for persons
   - Individuals should be treated as autonomous agents.
   - Persons with diminished autonomy are entitled to protection.
2. Beneficence
   - Human subjects should not be harmed.
   - Research should maximize possible benefits and minimize possible harms.
3. Justice
   - The benefits and risks of research must be distributed fairly.

The conduct of research in children carries with it all the ethical obligations of research in adults as well as additional obligations and protections. Children are an especially vulnerable population, and respect for children is a critical guide for research in this population. This situation imposes special considerations when inviting participation in studies, assessing risks and benefits, and ensuring equitable participation in and benefits of clinical research.

RESEARCH-PROPOSAL DESIGN

Proposals for clinical investigation of drugs in children must include measures to protect the interests of children and must:

1. Be scientifically sound and significant, with value to children in general and, in most cases, to the individual child subject. Outcomes should be meaningful and measurable, with adequate control or normative data for comparison and there should be appropriate power analysis to ensure enrollment of an adequate number of subjects to answer the research question and strategies for dealing with potential problems with recruitment and retention.
2. Be directed by investigators who operate in a state of scientific uncertainty; that is, the investigators should have true uncertainty about which of the treatments being compared in the research study is superior.
3. Include a robust plan to monitor safety during the study.
4. Take into consideration the unique physiology, anatomy, psychology, pharmacology, social situation, and special needs of children and their families.
5. Minimize risk while maximizing benefit.
6. Take into account the racial, ethnic, gender, and socioeconomic characteristics of children and their parents and, when appropriate, include input from the community or appropriate advocacy representatives.
7. Conform to all local, regional, and national regulatory guidelines and laws.

Timing of Pediatric Studies

The timing of the initiation of pediatric studies should be governed by a risk/benefit analysis that incorporates all relevant information on the drug under study as well as considerations related to the disease that is targeted for treatment and the availability of alternative therapies. Because the large majority of compounds that enter phase 1 trials in adults never receive regulatory approval because of safety concerns and/or inadequate proof of efficacy, the risk/benefit ratio is high at that stage of development (Table 1). In general, drugs should be tested for safety, pharmacokinetics, and at least initial indications of efficacy in adults before being tested in children. It may often be appropriate to defer pediatric testing until adult testing has reached phase 3 or beyond, when substantial data are available on the safety and efficacy of a drug in adults.

The severity of a disease and the availability of alternative therapies may influence the risk/benefit analysis and, thereby, support the earlier initiation of pediatric studies. For example, for a disease that is severe or life-threatening in children and for which no alternative, proven therapy exists, it may be reasonable to initiate pediatric studies relatively early. Similarly, it may be appropriate to initiate pediatric studies relatively early for children with severe or life-threatening disease for whom all accepted therapies have failed.

When a pediatric disease has no close analogy in adults, as may be the case for some genetic/metabolic conditions that typically result in death before

TABLE 1 FDA Definitions of Phase 1, 2, and 3 Studies

Phase 1 clinical studies
Phase 1 includes the initial introduction of an investigational new drug into humans. These studies are closely monitored and may be conducted in patients but are usually conducted in healthy volunteer subjects. These studies are designed to determine the metabolic and pharmacologic actions of the drug in humans, the side effects associated with increasing doses, and, if possible, to gain early evidence on effectiveness. During Phase 1, sufficient information about the drug's pharmacokinetics and pharmacological effects should be obtained to permit the design of well-controlled, scientifically valid, Phase 2 studies.
Phase 1 studies also evaluate drug metabolism, structure-activity relationships, and the mechanism of action in humans. These studies also determine which investigational drugs are used as research tools to explore biological phenomena or disease processes. The total number of subjects included in Phase 1 studies varies with the drug but is generally in the range of 20 to 80.
In Phase 1 studies, the Center for Drug Evaluation and Research (CDER) can impose a clinical hold (ie, prohibit the study from proceeding or stop a trial that has started) for reasons of safety or because of a sponsor's failure to accurately disclose the risk of study to investigators. Although the CDER routinely provides advice in such cases, investigators may choose to ignore any advice regarding the design of Phase 1 studies in areas other than patient safety.
Phase 2 clinical studies
Phase 2 includes the early controlled clinical studies conducted to obtain some preliminary data on the effectiveness of the drug for a particular indication or indications in patients with the disease or condition. This phase of testing also helps determine the common short-term side effects and risks associated with the drug. Phase 2 studies are typically well-controlled, closely monitored, and conducted in a relatively small number of patients, usually involving several hundred people.
Phase 3 clinical studies
Phase 3 studies are expanded controlled and uncontrolled trials. They are performed after preliminary evidence suggesting effectiveness of the drug has been obtained in Phase 2, and are intended to gather the additional information about effectiveness and safety that is needed to evaluate the overall benefit-risk relationship of the drug. Phase 3 studies also provide an adequate basis for extrapolating the results to the general population and transmitting that information in the physician labeling. Phase 3 studies usually include several hundred to several thousand people.

www.fda.gov/Drugs/Development/ApprovalProcess/HowDrugsareDevelopedandApproved/ApprovalApplications/InvestigationalNewDrugINDApplication/ucm176522.htm.

adulthood, it may not be possible to obtain adult efficacy data before the initiation of pediatric testing. However, the possibility of adult testing in analogous, if not identical, patients, such as heterozygote carriers of a metabolic disorder, should be considered. Even when there is no analogous adult condition, it may still be reasonable to obtain initial safety data in adults before the initiation of any pediatric testing.

Registering and Reporting the Results of Clinical Trials in Children

It is unethical to unnecessarily repeat clinical drug trials in children. Therefore, all clinical trials should be registered before initiation (www.clinicaltrials.gov), and any results (including negative findings) should be published or otherwise made available to all researchers and the public.

THE INVESTIGATOR

The investigator's competence and ethical conduct are the most important safeguards for the protection of the child as a research subject. The investigator must:

- have the qualifications and expertise to carry out the study to completion;
- understand the developmental and ethical issues involved in research with children;
- have scientific uncertainty with regard to the research question being asked;
- understand the pathophysiologic features of pediatric illnesses and how they evolve with age;
- understand the adverse effects of drugs, drug interactions, and pediatric drug formulations;
- strive to prevent bias from affecting the design, conduct, or reporting of the results of the research study;
- ensure adequate disclosure of all conflicts of interest (COI) related to the research to the subjects and their families;
- be an effective communicator and present a balanced view of the risks and benefits of the research when seeking participation in the study;
- vigorously guard against scientific misconduct; and
- maintain complete records and comply with all regulatory, legal, and ethical standards for research in children.

If the investigator is a junior investigator, there should be evidence of appropriate mentorship and oversight by a more senior investigator or oversight committee.

INSTITUTIONAL REVIEW BOARDS

The primary responsibility of the institutional review board (IRB) is to protect the rights of the research subject. This responsibility includes interpreting the federal guidelines and determining whether each study is designed ethically in compliance with the federal regulations, local and state law, and local IRB directives. Any individual or institution under whose auspices clinical research is conducted must ensure that the research protocol is reviewed by an appropriately constituted IRB. The specific regulatory criteria for IRB approval of research are listed in Table 2.

All IRBs that review proposals for investigations in children must include members with pediatric expertise who are knowledgeable about the special medi-

TABLE 2 Criteria for IRB Approval of Research

1. Risks to subjects are minimized. Are procedures consistent with sound research design used? Do procedures not unnecessarily expose subjects to risk? Whenever possible, are procedures already being performed for diagnostic or treatment purposes? Note: consider only those risks and benefits that may result from the research (as distinguished from risks and benefits of therapies that participants would receive even if not participating in the research).
2. Risks to subjects are reasonable in relation to anticipated benefits, if any, to subjects and to the importance of the knowledge that may reasonably be expected to result. Consider only those risks and benefits that may result from the research and not possible long-range effects of the knowledge gained.
3. Selection of subjects is equitable. Consider the purposes and setting of the research, paying special attention to any vulnerable populations.
4. Informed consent will be prospectively obtained and documented (unless the IRB approves a waiver of this requirement).
5. Adequate provisions exist to monitor the data and ensure subject safety.
6, Adequate provisions exist to protect the privacy of subjects and maintain confidentiality of data.
7. The influence of payments on equitable selection and amount, method, and timing of compensation is not coercive or do not present undue influence to potential subjects. Also, consider whether completion bonuses are reasonable and do not unduly induce subjects to remain in the study when they otherwise would withdraw.
8. If some or all subjects are likely to be vulnerable to coercion or undue influence, additional safeguards exist to protect their rights and welfare.

cal, psychological, ethical, and social needs of child research subjects.[10] Members of the IRB are assumed to be reasonable individuals who act in the best interest of the prospective subjects.

The IRB should establish a mechanism to ensure that no child is enrolled in more studies than is consistent with his or her welfare. There may be reasons to enroll the same child in more than 1 study simultaneously. In most instances, this does not jeopardize the child's welfare or safety, but in some situations, the child's participation in more than 1 study may be detrimental to the child or may confound the scientific validity of the studies.

ETHICAL ISSUES OF PARTICULAR CONCERN IN DRUG INVESTIGATIONS IN PEDIATRIC POPULATIONS

Determination of Benefits and Risks

Federal law (Title 45, Protection of Human Subjects [21 CFR 50, Subpart D]) requires that IRBs review clinical investigations that involve children and approve only those that satisfy 1 of the following conditions[1]: clinical investigations involving no greater-than-minimal risk[7]; clinical investigations involving greater-than-minimal risk but presenting the prospect of direct benefit to clinical subjects[8]; or clinical investigations involving greater-than-minimal risk and no prospect of direct benefit to individual subjects but likely to yield generalizable knowledge about the subjects' disorder or condition.[7,8] If the proposed research does not satisfy 1 of these 3 conditions, there is a fourth condition of child research that includes research that is not otherwise approvable but presents opportunities to understand, prevent, or alleviate a serious problem that affects the health or welfare of children. Research that falls into this fourth category requires review and approval by the FDA and/or US Department of Health and Human Services (DHHS).[7,8]

The categories for approving research in children are presented in more detail in Table 3. Regulations stratify the levels of research risk for children into minimal and a minor increase over minimal. These risks include the known and predictable risks of the drug being studied as determined from previous animal and human studies in addition to the inherent risks of the research procedures themselves. In addition, there is always the risk of a heretofore unrecognized complication or adverse event from any drug being studied. Thus, all drug-study protocols in children must be scrutinized carefully for all potential risks, including those that are not necessarily a concern in adult studies. These risks include discomfort; inconvenience; fear; pain; separation from parents, family, or friends; effects on growth and development; and size and volume of biological samples being collected. The type and number of invasive tests must be minimized and scientifically sound, and creative methods to obtain needed information noninvasively must be sought.

With the growing number of pediatric drug studies, IRBs need to be familiar with the various research-design methods that minimize risk to the child. Examples include limiting research under some circumstances to pharmacokinetic and safety data, combining this approach with pharmacodynamic data, and minimizing the volume of blood withdrawn through the use of sensitive assays, pediatric-enabled laboratories, and population pharmacokinetic approaches.[11] The minimization of risk in pediatric studies also includes the requirement that those conducting the study be properly trained and experienced in studying the pediatric population, including in the evaluation and management of potential pediatric adverse events.[12] Minimizing risk requires careful design of pediatric studies. Every attempt should be made to minimize the number of subjects and procedures, consistent with good study design. Data-monitoring mechanisms should be in place for all drug studies in children to ensure that a study can be rapidly terminated should an unexpected hazard be identified.[10]

TABLE 3 Categories of Research

Category 1: Research not involving greater-than-minimal risk to children
- To approve this category of research, the IRB must make the following determinations:
  - the research presents no greater-than-minimal risk to the children; and
  - adequate provisions are made for soliciting the assent of the children and the permission of their parents or guardians

Category 2: Research involving greater-than-minimal risk but presenting the prospect of direct benefit to the individual child subjects involved in the research
- To approve research in this category, the IRB must make the following determinations:
  - the risk is justified by the anticipated benefits to the subjects;
  - the relation of the anticipated benefit to the risk presented by the study is at least as favorable to the subjects as that provided by available alternative approaches; and
  - adequate provisions are made for soliciting the assent of the children and the permission of their parents or guardians

Category 3: Research involving greater-than-minimal risk and no prospect of direct benefit to the individual child subjects involved in the research but likely to yield generalizable knowledge about the subject's disorder or condition
- To approve research in this category, the IRB must make the following determinations:
  - the risk of the research represents a minor increase over minimal risk;
  - the intervention or procedure presents experiences to the child subjects that are reasonably commensurate with those inherent in their actual, or expected, medical, dental, psychological, social, or educational situations;
  - the intervention or procedure is likely to yield generalizable knowledge about the subject's disorder or condition that is of vital importance for the understanding or amelioration of the disorder or condition; and
  - adequate provisions are made for soliciting the assent of the children and the permission of their parents or guardians

Category 4: Research that requires a special level of DHHS or FDA review beyond that provided by the IRB
- Research that the IRB believes does not meet the conditions of the above-listed categories but finds that the research presents a reasonable opportunity to further the understanding, prevention, or alleviation of a serious problem that affects the health or welfare of children
- If the IRB believes that the research does not meet the requirements of the categories listed above but finds that it presents a reasonable opportunity to further the understanding, prevention, or alleviation of a serious problem that affects the health or welfare of children, it may refer the protocol to DHHS or FDA for review; the research may proceed only if, after consulting with a panel of experts in pertinent disciplines (eg, science, medicine, education, ethics, law) and after an opportunity for public review and comment, it is determined that either (1) the research, in fact, satisfies the conditions of category 1, 2, or 3 or (2) the following:
  - the research presents a reasonable opportunity to further the understanding, prevention, or alleviation of a serious problem that affects the health or welfare of children;
  - the research will be conducted in accordance with sound ethical principles; and
  - adequate provisions are made for soliciting the assent of children and the permission of their parents or guardians

Data- and Safety-Monitoring Committees

Because children are a potentially fragile population, they deserve the highest standards for monitoring safety during a drug study. It is not possible to foresee all risks related to a drug study in children, and unexpected events can and do occur. Therefore, an independent data- and safety-monitoring committee (DSMC) should be created for all phase 3 drug trials conducted in children. A DSMC may also be necessary for some phase 1 and 2 trials as well, especially those that include blinding. In phase 1 and 2 studies without a DSMC, a robust data-monitoring plan must be in place.

Informed Permission/Consent/Assent

No drug research may be performed in humans without the informed permission/consent/assent of the subject and an individual who is legally qualified to act on behalf of the subject unless the need for permission/consent/assent is waived by the IRB. DHHS and FDA regulations are similar in their definition of parental permission. Subpart D of both regulations define permission as the agreement of parent(s) or guardian(s) to participation of their child or ward in research (DHHS) or a clinical investigation (FDA). A parent is defined as a child's biological or adoptive parent, and a guardian is defined as an individual who is authorized under applicable state or local law to consent on behalf of a child to general medical care. For a child to participate in a clinical study, parents or guardians must agree to (ie, permit) their child's participation in research.[11]

Permission Process

Parental permission is treated much the same as informed consent for adults, with the exception of some additional requirements.[7,8] All the general and required elements for adult consent apply to parental permission. Information provided to the subjects and/or parents must be written in language that is easily understood by the consenter, permission giver, and assenter. If the document is not written in an easily understood language, the information must be provided in a language that is understood, or an interpreter must be provided. The IRB must approve the procedure by which the prospective consenter, permission giver, or assenter is informed. Table 4 provides an outline of required content for written consent. In addition to obtaining permission from a parent or guardian, IRBs are required to determine that adequate provisions have been made for soliciting the assent of the child.[10] The requirement for permission is based on the premise of protecting a population whose mem-

TABLE 4 Required Contents of Written Consent Specified in DHHS Regulations

I. Basic elements of informed consent
- A. A statement that the study involves research, an explanation of the purposes of the research and the expected duration of the subject's participation, a description of the procedures to be followed, and identification of any procedures that are experimental
- B. A description of any reasonably foreseeable risks or discomforts to the subject
- C. A description of any benefits to the subject or to others that may reasonably be expected from the research
- D. A disclosure of appropriate alternative procedures or courses of treatment, if any, that might be advantageous to the subject
- E. A statement describing the extent, if any, to which confidentiality of records identifying the subject will be maintained and that notes the possibility that the FDA may inspect the records
- F. For research involving more-than-minimal risk, an explanation as to whether any compensation and any medical treatments are available if injury occurs and, if so, of what they consist or where further information may be obtained
- G. An explanation of whom to contact for answers to pertinent questions about the research and the rights of the research subjects and whom to contact in the event of a research-related injury to the subject
- H. A statement that participation is voluntary, that refusal to participate involves no penalty or loss of benefits to which the subject is otherwise entitled, and that the subject may discontinue participation at any time without penalty or loss of benefits to which the subject is otherwise entitled

II. Additional elements of informed consent: when appropriate, 1 or more of the following elements of information shall also be provided to each subject
- A. A statement that the particular treatment or procedure may involve risks to the subject (or the embryo or fetus, if the subject is pregnant or may become pregnant) that are currently unforeseeable
- B. Anticipated circumstances under which the subject's participation may be terminated by the investigator without regard to the subject's consent
- C. Any costs to the subject that may result from participation in the research
- D. The consequences of a subject's decision to withdraw from the research and procedures for orderly termination of participation by the subject
- E. A statement that significant new findings developed during the course of the research that may relate to the subject's willingness to continue participation will be provided to the subject
- F. The approximate number of subjects involved in the study

bers may not be capable of protecting themselves. Research that involves children that falls in categories 3 and 4 as described in Table 3 requires permission of both parents.[7,8] The regulations allow an exception to this requirement if 1 parent is deceased, unknown, incompetent, or not reasonably available or when only 1 parent has legal responsibility for the care and custody of the child.

Waiver of Permission

There are 2 situations in which parental permission may be modified or waived entirely under the federal regulations that do not involve an FDA-regulated product. The first waiver is for research that involves only minimal risk, does not negatively affect the welfare of the subjects, and cannot be practically performed without the waiver. The second waiver is applicable when getting permission will not function to protect the child. If a determination is made by the IRB that a research protocol is designed for conditions or for a subject population for which parental or guardian permission is not a reasonable requirement to protect the subjects (eg, neglected or abused children), it may waive the consent requirements. This situation is conditional, provided an appropriate mechanism for protecting the children who will participate is substituted, and the waiver is not inconsistent with federal, state, or local law. FDA regulations did not adopt this second waiver. The only waiver of parental permission that the FDA considers is for emergent and life-threatening situations (discussed in the next paragraph, "Emergency Research").[11]

Emergency Research

Federal regulations allow the conduct of research studies to test emergency treatments on patients with specific life-threatening medical conditions when patients cannot give informed consent because of their conditions and their family is not available to provide consent. Emergency research studies approved under this regulation must hold out the prospect of direct benefit to the subject. The exception for obtaining informed consent applies to emergency research that (1) involves human subjects who have life-threatening medical conditions for which available treatments are unproven or unsatisfactory, (2) involves subjects who, because of their conditions (eg, unconsciousness), cannot give informed consent, and (3) to be effective, must be initiated before consent can be obtained from the subject's legally authorized representative. An investigational new drug (IND) application or investigational device exemption (IDE) is required. Studies that involve an exception from the informed-consent requirements may proceed only after a sponsor has received previous written authorization from the FDA and the IRB has found and documented that the specific conditions have been met. Additional requirements for emergency research studies include developing and implementing a plan for community consultation and public disclosure before the start of the study and a mechanism for contacting and providing information to the subject's legally authorized representative or family member within the therapeutic window or at the earliest feasible opportunity. If subjects are

enrolled before consent is obtained, there must be an opportunity for family members to object to a subject's continued participation in the study.

Permission for Studies With Life-Threatening Illness

The study team and IRB need to carefully evaluate studies that require parents to make decisions when their child has a life-threatening illness. This situation creates dilemmas for parents when they are required to make emotionally charged decisions related to their child's health. It is important for the study team to acknowledge the parents' emotional state, lack of medical knowledge, and inexperience with clinical trials. During the initial consent process and throughout the study, clinical research staff who obtain consent from parents should educate them about their child's disease and how clinical trials work. They should clearly explain all potential risks and not overstate potential benefits. They should also outline in detail any potential financial costs that may be associated with the study.

Assent of the Child

Age of Assent

According to federal regulations, assent is defined as a child's affirmative agreement to participate in research, and further clarification is given that "mere failure to object should not, absent affirmative agreement, be construed as assent."[8] Federal regulations do not specify an age at which assent ought to be possible. The AAP recommends that active agreement by a minor (not qualified to give consent) to participate in a research study generally applies to children who have reached an intellectual age of at least 7 years. More recently, it was suggested that assent is generally applicable to developmentally normal children between 8 and 14 years of age.[12] It is up to the IRB to determine if children are capable of assent. Regulations state that adequate provisions are needed for soliciting assent when the child is capable, but little guidance exists to determine this capacity other than evaluating the child's age, maturity, and psychological state; as a practical matter, many IRBs require assent for children older than 7 years. The IRB can waive the requirement for child assent if the capability of some or all of the children is so limited that they cannot reasonably be consulted, if the intervention or procedure involved in the research holds out the prospect of direct benefit to the health or well-being of the children and is available only in the context of the research, or if the research meets the same conditions as those for waiver or alteration of informed consent in research involving adults.[11] For example, this waiver could be used in research with infants, children with illnesses that require mechanical ventilation, or children with severe developmental delay.

Delivery of Assent

The assent process for children requires ongoing discussion and evaluation throughout the trial. In situations in which children either do not give initial assent or withdraw assent for participation, researchers should not ignore a child's wishes.[13] If the IRB has determined that assent is required for a study and the child dissents from participating in research, the child's decision prevails even if his or her parents or guardian have granted permission.

The Consenting Minor

Generally, adolescents are considered to be between 12 and 18 years of age (dependent on region).[10] When obtaining assent from older adolescents, it is reasonable to assume that an adequate assent process would be viewed the same as the informed-consent process for adults, although parental permission is still required. The legal definition of adolescents groups them with children. Federal regulations define children as persons who have not attained the legal age for consent to treatments or procedures under the applicable law of jurisdiction in which the research will be conducted.[8] Under this definition, not all adolescents who are under the legal age of majority are defined as children. In common practice, the applicable law of the jurisdiction is state law, but it could include federal statutes. Childhood is not defined by age but by local laws that govern medical treatment, age of majority, and emancipation status.

Emancipated and Mature Minors

Because there is precedent that allows emancipated minors, and in some cases mature minors, to consent to clinical research, it is important that this group of youth be defined. Emancipation is governed by individual state law. Typical conditions that states use to establish the status of an emancipated minor are marriage, military service, parenthood, runaways who refuse to identify themselves, or court order. Therefore, for purposes of pediatric clinical research, emancipation, whatever the causal event, is taken to mean that the child becomes an adult in the eyes of the state; that is, all rules that govern parental custody or control are severed, which could include parental permission for research participation, to the extent that states follow a broader range of emancipation effects.[14] Investigators and IRBs considering recruitment of adolescents into research studies can obtain consent from only those adolescents considered adults, for all purposes under state law, as emancipated minors. Emancipated minors may give permission for their children. In research that involves an emancipated minor or a mature minor, the investigator and the

local IRB must be careful to protect the welfare of the minor subject. In cases in which minors are legally authorized to provide independent consent for particular treatments, parental permission is not required.

An emancipated minor is effectively an adult in the eyes of the law and is, therefore, capable of partaking in any medical research that would otherwise include adults. The capacity of the mature (but not emancipated) minor to partake in medical research depends on individual state laws, the type of research, and the risk/benefit ratio. The risk should be minimal, and answers to the scientific questions being asked must not be obtainable by using another group of adolescents whose parental permission and involvement are required. The research must be aimed at preventing or treating the medical condition for which the adolescent can legally give consent. For example, a researcher may investigate drug compliance in mature minors being treated for sexually transmitted diseases. Whether there are ethical reasons not to allow such research to proceed with adolescent consent would need to be addressed on a case-by-case basis. The investigator should determine if the parents can be informed by asking the minor's permission to involve the parents.

Withdrawal of Consent

The parent, emancipated minor, or mature minor has the right to revoke permission/consent at any time during the study. The child who gave assent also has the right to withdraw assent. If the investigator identifies reluctance in the parents or child about continued participation in a research protocol, the child's continuation in the study should be reevaluated. The same principles that govern permission/assent/consent also govern its withdrawal.

Institutionalized Children

Children who are institutionalized because of special care requirements or under the supervision of a court or social welfare agency acting in lieu of a court should rarely be considered for inclusion in research studies, because institutionalization may deprive them of some of the safeguards necessary for the conduct of ethical investigations. In general, these children should only be involved in studies of special conditions unique to them or to the type of institution in which they reside. They should have access to experimental drug therapy when the research therapy is the only treatment available for the illness that affects them. Access to experimental therapy may be allowed under a compassionate use protocol.

SPECIFIC ASPECTS OF PROTOCOL DESIGN

Advocate Group

Extra measures to protect the rights of special populations, such as institutionalized children or children with chronic progressive or lethal diseases, may involve special advocacy groups. Such groups may include parents of children in the institution at which the study is being conducted, health care professionals, lawyers, clergy, and other community representatives as appropriate. An advocacy group may assist in the overall design of the study as it relates to the rights, clinical condition, and needs of the targeted special population. Such a group could also facilitate communication with the subjects and their parents to help ensure that they understand the more complex or difficult aspects of the study, such as the implications of a randomized, controlled trial. The advocacy groups, however, must not act as a coercive influence on the subject or parents.

Distributive Justice

Insofar as possible, subjects enrolled in clinical investigations should represent a cross-section of society. A study should not rely exclusively or disproportionately on any socioeconomic, racial, gender, or ethnic group unless this type of selection is a necessary part of the investigation, such as in a study of sickle cell anemia. The distribution of risks, inconveniences, and benefits from research studies must be equitable throughout societal groups. This equity is important from both an ethical and scientific standpoint, because data obtained from 1 ethnic or socioeconomic group may not be applicable to other populations.

Recruitment

Payment of Providers

Recruitment of subjects to participate in a clinical research protocol often is vital to the successful completion of a study and involves identifying potential research subjects. Potential research subjects frequently are identified and recruited by health care workers who are providing their care. However, providing staff members or hospital personnel with a direct financial incentive for enrolling a research subject has the potential to add a strong element of undue influence or coercion to the recruitment and consent process. Therefore, a monetary "finder's fee" or other financial incentive for recruiting or referring children to clinical investigations should be prohibited.

Advertisements

Advertising for volunteers to enroll in a study may be necessary for recruitment. The content of an advertisement as well as the proposed distribution of the advertisement should be reviewed by the IRB before its dissemination. Advertisements should not explicitly or implicitly misconstrue the risks and benefits from participation in a study.

Payment for Participation of Children in Research

Compensation for participation in research is a common practice for research studies that involve both children and adults. A number of different types of compensation are used in clinical studies, including material or monetary compensation such as reimbursement for travel, parking, food expenses, overnight lodging, telephone calls, child care that a family might incur because of research participation, or inconvenience. IRBs are required to review proposals to pay research subjects with minimal guidance from federal regulations, which do not specifically address the issue of payment to research subjects. The amount paid to study subjects varies tremendously from site to site, even for the same multisite studies. It also varies from study to study, even at the same institution for similar tasks.[15]

Offering payment in studies that enroll children requires parents, investigators, and IRBs to weigh the importance of several competing values.[16] Incentive payments may be essential to the recruitment and retention of pediatric study subjects. In addition, prohibiting payments might jeopardize some important research. Finally, the obligation to treat all patients fairly might include compensating them for their time, effort, and discomfort and for their contribution to the social good. These objectives are all important and need to be balanced between the need to protect children from the potential harms of clinical research and to ensure that parents remain free from influences that might tempt them to enroll a child in a research protocol that is not consistent with the best interests of the child.[14,17] Payments to parents for their child's research participation could potentially sway parents to decide in favor of participation, because there is no personal risk to them.[18] This problem can be mitigated by keeping payments reasonable and minimal.[15] The investigators and the IRB must be certain that the compensation offered is fair and does not become an undue inducement for participation of the child subject.

When untoward medical events occur as a result of participating in a study, the institution and its investigators are obligated to provide emergency care. The extent to which emergency care and subsequent medical care will or will not be provided free of charge must be clearly stated in the consent form.

COI and Disclosure

Given the current efforts to increase the number of children in clinical research studies, it is critical that research be conducted ethically so that the outcomes provide adequate labeling of new medicines for children and that evidenced-based medicine will not be overshadowed by COI. The Office of Research Integrity (ORI) has provided a simple definition of COI: a situation in which financial or other personal considerations have the potential to compromise or bias professional judgment and objectivity.[19] These considerations include relationships with pharmaceutical companies or other entities that have an interest in the product (drug or device) under investigation.

Institutions that perform drug research in children should consider the appointment of COI committees that are independent of IRBs. These committees can require that clinical studies be reviewed for conflicts before submission to the IRB. COI committees govern a variety of activities at universities, including research. They are charged with reviewing conflicts in clinical studies and, if a conflict is present, determine how that conflict can be managed, reduced, or eliminated. Options include public disclosure of significant financial interests, independent monitoring of research, modification of the research plan, blinding of data or those who analyze the data, monitoring of the research by independent reviewers, conduct of all or part of the research by another nonconflicted member of the research team or by a third party, divestiture of financial interests that present COI, or severance of relationships that present COI.

Until recently, there has been little guidance available on how to appropriately disclose COI. The Conflict of Interest Notification Study (COINS), funded by the National Heart, Lung, and Blood Institute, was initiated to provide data to IRBs, COI committees, and other policy makers to assist them in deciding how, when, and what to disclose to potential research subjects. The study group developed disclosure language concerning different financial interests commonly found in clinical research.[20] The generic disclosure language states: "The person leading this medical research study might benefit financially from this study. The Institutional Review Board and a committee at ABC University have reviewed the possibility of a financial benefit. They believe that the possible financial benefit to the person leading the research is not likely to affect your safety and/or scientific quality of the study. If you would like more information, please ask the researchers or the study coordinator."

The new model language also includes specific language for situations in which there may be risks to the study subjects. The Conflict of Interest Notification Study team categorized this additional language by the 9 types of financial interests that are most commonly encountered in the clinical research setting: salary support; money received outside of the study; payment for each subject enrolled;

finder's fees restricted to research uses; unrestricted finders' fees; researchers holding a patent; university holding a patent; researchers owning equity; and university owning equity. Contractual agreements between sponsors and investigators should ensure that reports and publications of research results accurately and objectively represent the results and will not be constrained by any proprietary interests of the sponsor.

Placebo and Control Groups

Placebo and control groups can be used in pediatric studies if their use does not place children at increased risk. The conditions under which placebos may be ethically used in drug research in children include the following:

1. when there is no commonly accepted therapy for the condition and the agent under study is the first one that may modify the course of the disease process;
2. when the commonly used therapy for the condition is of questionable efficacy;
3. when the commonly used therapy for the condition carries with it a high frequency of undesirable adverse effects and the risks may be significantly greater than the benefits;
4. when the placebo is used to identify incidence and severity of adverse effects produced by adding a new treatment to an established regimen; or
5. when the disease process is characterized by frequent, spontaneous exacerbations and remissions and the efficacy of the therapy has not been demonstrated.

Long-term Prospective Studies of the Safety of a Drug

When investigational drugs are administered to children, the effects may be latent and may not be predicted from any previous studies. This concern is not unique to children; it also applies to studies of investigational drugs in adults. Thus, studies of certain drugs given to pediatric patients may require a mechanism for follow-up of the research subjects.

CONCLUSIONS

This report is intended to provide a format that allows for the participation and protection of child subjects in drug research. Research that involves children carries with it additional responsibilities for the investigator, IRB, and sponsor. The additional responsibilities should not be reasons for the pharmaceutical company or other sponsor, IRB, or the investigator to exclude children from drug research and its potential benefits.

The AAP believes it is unethical to deny children appropriate access to existing and new therapeutic agents. It is the combined responsibility of the pediatric community, pharmaceutical industry, and regulatory agencies to design, approve, and conduct high-quality studies in children. It is the responsibility of the general public to support the necessary research to ensure that all children have access to important medication and receive optimal therapy.

Abstract

Gastroesophageal reflux (GER), defined as passage of gastric contents into the esophagus, and GER disease (GERD), defined as symptoms or complications of GER, are common pediatric problems encountered by both primary and specialty medical providers. Clinical manifestations of GERD in children include vomiting, poor weight gain, dysphagia, abdominal or substernal pain, esophagitis and respiratory disorders. The GER Guideline Committee of the North American Society for Pediatric Gastroenterology and Nutrition has formulated a clinical practice guideline for the management of pediatric GER. The GER Guideline Committee, consisting of a primary care pediatrician, two clinical epidemiologists (who also practice primary care pediatrics) and five pediatric gastroenterologists, based its recommendations on an integration of a comprehensive and systematic review of the medical literature combined with expert opinion. Consensus was achieved through Nominal Group Technique, a structured quantitative method.

The Committee examined the value of diagnostic tests and treatment modalities commonly used for the management of GERD, and how those interventions can be applied to clinical situations in the infant and older child. The guideline provides recommendations for management by the primary care provider, including evaluation, initial treatment, follow-up management and indications for consultation by a specialist. The guideline also provides recommendations for management by the pediatric gastroenterologist.

This document represents the official recommendations of the North American Society for Pediatric Gastroenterology and Nutrition on the evaluation and treatment of gastroesophageal reflux in infants and children. The American Academy of Pediatrics has also endorsed these recommendations. The recommendations are summarized in a synopsis within the article. This review and recommendations are a general guideline and are not intended as a substitute for clinical judgment or as a protocol for the management of all patients with this problem.

SYNOPSIS

This clinical practice guideline was developed to assist the primary and specialist medical provider in the evaluation and management of gastroesophageal reflux in infants and children. Recommendations are based on an integration of a comprehensive and systematic review of the medical literature combined with expert opinion. The guideline is not intended for the management of neonates less than 72 hours old, premature infants or infants and children with either neurologic impairments or anatomic disorders of the upper gastrointestinal tract. The recommendations are a general guideline and are not intended as a substitute for clinical judgment or as a protocol for the management of all patients with this problem.

Gastroesophageal reflux (GER), defined as the passage of gastric contents into the esophagus, and GER disease (GERD), defined as symptoms or complications of GER, are common pediatric problems. Clinical manifestations of GERD in children include vomiting, poor weight gain, dysphagia, abdominal or substernal pain, esophagitis and respiratory disorders. The following section summarizes the conclusions and recommendations of the GER Guideline Committee of the North American Society for Pediatric Gastroenterology and Nutrition on the value of diagnostic tests and treatment modalities commonly used for the management of GERD, and how those interventions can be applied to clinical situations in the infant and older child.

Diagnostic Approaches

History and Physical Examination. In most infants with vomiting, and in most older children with regurgitation and heartburn, a history and physical examination are sufficient to reliably diagnose GER, recognize complications, and initiate management.

Upper GI Series. The upper gastrointestinal (GI) series is neither sensitive nor specific for the diagnosis of GER, but is useful for the evaluation of the presence of anatomic abnormalities, such as pyloric stenosis, malrotation and annular pancreas in the vomiting infant, as well as hiatal hernia and esophageal stricture in the older child.

Esophageal pH Monitoring. Esophageal pH monitoring is a valid and reliable measure of acid reflux. Esophageal pH monitoring is useful to establish the presence of abnormal acid reflux, to determine if there is a temporal association between acid reflux and frequently occurring symptoms, and to assess the adequacy of therapy in patients who do not respond to treatment with acid suppression. Esophageal pH monitoring may be normal in some patients with GERD, particularly those with respiratory complications.

Endoscopy and Biopsy. Endoscopy with biopsy can assess the presence and severity of esophagitis, strictures and Barrett's esophagus, as well as exclude other disorders, such as Crohn's disease and eosinophilic or infectious esophagitis. A normal appearance of the esophagus during endoscopy does not exclude histopathological esophagitis; subtle mucosal changes such as erythema and pallor may be observed in the absence of esophagitis. Esophageal biopsy is recommended when endoscopy is performed to detect microscopic esophagitis and to exclude causes of esophagitis other than GER.

Empiric Medical Therapy. A trial of time-limited medical therapy for GER is useful for determining if GER is causing a specific symptom.

Treatment Options

Diet Changes in the Infant. There is evidence to support a one- to two-week trial of a hypoallergenic formula in formula fed infants with vomiting. Milk-thickening agents do not improve reflux index scores but do decrease the number of episodes of vomiting.

Positioning in the Infant. Esophageal pH monitoring has demonstrated that infants have significantly less GER when placed in the prone position than in the supine position. However, prone positioning is associated with a higher rate of the sudden infant death syndrome (SIDS). In infants from birth to 12 months of age with GERD, the risk of SIDS generally outweighs the potential benefits of prone sleeping. Therefore, non-prone positioning during sleep is generally recommended. Supine positioning confers the lowest risk for SIDS and is preferred. Prone positioning during sleep is only considered in unusual cases where the risk of death from complications of GER outweighs the potential increased risk of SIDS. When prone positioning is necessary, it is particularly important that parents be advised not to use soft bedding, which increases the risk of SIDS in infants placed prone.

Positioning in the Child & Adolescent. In children older than one year it is likely that there is a benefit to left side positioning during sleep and elevation of the head of the bed.

Lifestyle Changes in the Child & Adolescent. It is recommended that children and adolescents with GERD avoid caffeine, chocolate and spicy foods that provoke symptoms. Obesity, exposure to tobacco smoke and alcohol are also associated with GER. It is not known whether lifestyle changes have an additive benefit in patients receiving pharmacological therapy.

Acid-suppressant Therapy. Histamine-$_2$ receptor antagonists (H_2RAs) produce relief of symptoms and mucosal healing. Proton pump inhibitors (PPIs), the most effective acid suppressant medications, are superior to H_2RAs in relieving symptoms and healing esophagitis. Chronic antacid therapy is generally not recommended since more convenient and safe alternatives (H_2RAs and PPIs) are available.

Prokinetic Therapy. Cisapride is available in the USA only through a limited-access program. Cisapride reduces the frequency of symptoms, including regurgitation and vomiting. However, because of concerns about the potential for serious cardiac arrhythmias in patients receiving cisapride, appropriate patient selection and monitoring as well as proper use, including correct dosage (0.2 mg/kg/dose QID) and avoidance of co-administration of contraindicated medications, are important. Other prokinetic agents have not been shown to be effective in the treatment of GERD in children.

Surgical Therapy. Case series indicate that surgical therapy generally results in favorable outcomes. The potential risks, benefits and costs of successful prolonged medical therapy versus fundoplication have not been well studied in infants or children in various symptom presentations.

Evaluation and Management of Infants and Children with Suspected GERD

The approach to the evaluation and management of infants and children with GERD depends upon the presenting symptoms or signs. Below is a summary of conclusions and recommendations derived from an integration of the research evidence with clinical experience for various clinical presentations. Where there are no

randomized studies, the recommendations are based on the consensus opinion of the GER Guideline Committee.

The Infant with Recurrent Vomiting. In the infant with recurrent vomiting, a thorough history and physical examination, with attention to warning signals, is generally sufficient to allow the clinician to establish a diagnosis of uncomplicated GER (the "happy spitter"). An upper GI series is not required unless there are signs of gastrointestinal obstruction. Other diagnostic tests may be indicated if there are symptoms of poor weight gain, excessive crying, irritability, disturbed sleep, feeding or respiratory problems. In the infant who has uncomplicated GER, parental education, reassurance and anticipatory guidance are recommended. Generally no other intervention is necessary. Thickening of formula and a brief trial of a hypoallergenic formula are other treatment options. If symptoms worsen or do not improve by 18 to 24 months of age, re-evaluation for complications of GER is recommended. Generally this includes an upper GI series and consultation with a pediatric gastroenterologist.

The Infant with Recurrent Vomiting and Poor Weight Gain. In the infant with vomiting and poor weight gain it is recommended that the adequacy of calories and the effectiveness of swallowing be assessed. If there is poor weight gain despite adequate caloric intake, a diagnostic evaluation to uncover other causes of vomiting or weight loss is generally indicated. Tests may include a complete blood count, electrolytes, bicarbonate, urea nitrogen, creatinine, alanine aminotransferase, ammonia, glucose, urinalysis, urine ketones and reducing substances, and a review of newborn screening tests. An upper GI series to evaluate anatomy is also recommended. Treatment options include thickening of formula, a trial of a hypoallergenic formula, increasing the caloric density of the formula, acid suppression therapy, prokinetic therapy and, in selected cases, prone positioning. Further management options include endoscopy with biopsy, hospitalization, tube feedings and rarely surgical therapy. Careful follow-up is necessary to assure adequate weight gain.

The Infant with Recurrent Vomiting and Irritability. Normal infants typically fuss or cry intermittently for an average of two hours daily, which may be perceived as excessive by some parents. A symptom diary may be useful to determine the extent to which the infant is irritable and has disturbed sleep. As in all infants with vomiting, other causes of vomiting need to be excluded. Expert opinion suggests two diagnostic and treatment strategies. Empiric treatment with either a sequential or simultaneous two-week trial of a hypoallergenic formula and acid suppression may be initiated. If there is no improvement, either esophageal pH monitoring to determine the adequacy of therapy or upper endoscopy with biopsy to diagnose esophagitis may be performed. If there is no response to therapy and these studies are normal, it is unlikely that GER is contributing to symptoms. Alternatively, evaluation could begin with esophageal pH monitoring to determine if episodes of irritability and sleep disturbance are temporally associated with acid reflux.

The Child or Adolescent with Recurrent Vomiting or Regurgitation. In otherwise normal children who have recurrent vomiting or regurgitation after the age of 2 years, management options include an upper GI series, upper endoscopy with biopsy, and prokinetic therapy.

Heartburn in the Child or Adolescent. For the treatment of heartburn in children or adolescents, lifestyle changes accompanied by a two- to four-week therapeutic trial of an H_2RA or PPI are recommended. If symptoms persist or recur, the child can be referred to a pediatric gastroenterologist for upper endoscopy with biopsy and in some cases long-term therapy.

Esophagitis. In the infant or child with esophagitis, initial treatment consists of lifestyle changes and H_2RA or PPI therapy. In patients with only histopathological esophagitis, the efficacy of therapy can be monitored by the degree of symptom relief. In patients with erosive esophagitis, repeat endoscopy is recommended to assure healing.

Dysphagia or Odynophagia. In the child with dysphagia (difficulty swallowing) or odynophagia (painful swallowing), a barium esophagram is recommended. If the initial history is suggestive of esophagitis, upper endoscopy may be performed as the initial diagnostic test. Treatment without prior diagnostic evaluation is not recommended. In the infant with feeding refusal, because a large variety of disorders may contribute to infant feeding difficulties, empiric therapy for GER is generally not recommended. However, if there are other signs or symptoms suggestive of GERD then a time-limited course of medical therapy can be considered.

Apnea or Apparent Life-threatening Events (ALTE). In patients with ALTEs recurrent regurgitation or emesis is common. However, investigations in unselected patients with ALTE have not demonstrated a convincing temporal relationship between esophageal acidification and apnea or bradycardia. There are no randomized studies to evaluate the usefulness of esophageal pH monitoring in infants with ALTE. In patients with frequent ALTE in which the role of GER is uncertain, esophageal pH monitoring may be useful to determine if there is a temporal association of acid reflux with ALTE. The evidence suggests that infants with ALTE and GER may be more likely to respond to anti-reflux therapy when there is gross emesis or oral regurgitation at the time of the ALTE, when episodes occur in the awake infant, and when the ALTE is characterized by obstructive apnea. Therapeutic options include thickened feedings and prokinetic and acid suppressant therapy. Since most infants improve with medical management, surgery is considered only in severe cases.

Asthma. In patients where symptoms of asthma and GER coexist, and in infants and toddlers with chronic vomiting or regurgitation and recurrent episodes of cough and wheezing, a three-month trial of vigorous acid suppressant therapy of GER is recommended. In patients with persistent asthma without symptoms of GER, esophageal pH monitoring is recommended in selected patients who are more likely to benefit from GER therapy. These include patients with radiographic evidence of recurrent pneumonia; patients with nocturnal asthma more than once a week; and patients requiring either continuous oral corticosteroids, high-dose inhaled corticosteroids, more than two bursts per year of oral corticosteroids or those with persistent asthma unable to wean medical management. If esophageal pH monitoring demonstrates an increased frequency or duration of esophageal acid exposure, a trial of prolonged medical therapy for GER is recommended.

Recurrent Pneumonia. GER can cause recurrent pneumonia in the absence of esophagitis or when esophageal pH monitoring is normal. There is insufficient evidence to provide recommendations for a uniform approach to diagnosis and treatment. Diagnostic evaluation may include flexible bronchoscopy with pulmonary lavage for lipid-laden macrophages, nuclear scintigraphy and assessment of airway protective mechanisms during swallowing.

Upper Airway Symptoms. Hoarseness, chronic cough, stridor and globus sensation can be associated with GER in infants and children. There is insufficient evidence to provide recommendations for diagnosis and treatment.

1. Background

Gastroesophageal reflux (GER), defined as passage of gastric contents into the esophagus, is a normal physiologic process that occurs throughout the day in healthy infants, children, and adults (1–4). Most episodes of reflux are brief and asymptomatic, not extending above the distal esophagus. Regurgitation is defined as passage of refluxed gastric contents into the oral pharynx. Vomiting is defined as expulsion of the refluxed gastric contents from the mouth. GER occurs during episodes of transient relaxation of the lower esophageal sphincter or inadequate adaptation of the sphincter tone to changes in abdominal pressure (5,6). The strength of the lower esophageal sphincter, the primary antireflux barrier, is normal in the vast majority of children with GER (5,6).

Gastroesophageal reflux disease (GERD) occurs when gastric contents reflux into the esophagus or oropharynx and produce symptoms (Table 1). The pathogenesis of GERD is multifactorial and complex, involving the frequency of reflux, gastric acidity, gastric emptying, esophageal clearing mechanisms, the esophageal mucosal barrier, visceral hypersensitivity, and airway responsiveness. To date no medical treatment targets the primary mechanism of GER, transient relaxation of the lower esophageal sphincter. The primary goals of therapy are to relieve the patient's symptoms, promote normal weight gain and growth, heal inflammation caused by refluxed gastric contents (esophagitis), and prevent respiratory and other complications associated with chronic reflux of gastric contents.

During infancy GER is common and is most often manifest as vomiting. Recurrent vomiting occurs in 50% of infants in the first three months of life, in 67% of four month old infants, and in 5% of 10 to 12 month old infants (7). Vomiting resolves spontaneously in nearly all of these infants (8). Parents do not usually perceive vomiting as a problem when it occurs no more often than once daily, but they are more likely to be concerned when vomiting is more frequent, the volume of vomitus is large, or when the infant cries frequently or with vomiting.

TABLE 1. *Complications of gastroesophageal reflux*

Symptoms
Recurrent vomiting
Weight loss or poor weight gain
Irritability in infants
Regurgitation
Heartburn or chest pain
Hematemesis
Dysphagia or feeding refusal
Apnea or ALTE
Wheezing or stridor
Hoarseness
Cough
Abnormal neck posturing (Sandifer syndrome)
Findings
Esophagitis
Esophageal stricture
Barrett's esophagus
Laryngitis
Recurrent pneumonia
Hypoproteinemia
Anemia

A small minority of infants develop GERD with symptoms including anorexia, dysphagia (difficulty swallowing), odynophagia (painful swallowing), arching of the back during feedings, irritability, hematemesis, anemia or failure to thrive. GER is one of the causes of apparent life-threatening events (ALTE) in infants and has been associated with chronic respiratory disorders including reactive airways disease, recurrent stridor, chronic cough and recurrent pneumonia in infants.

In preschool age children GER may manifest as intermittent vomiting. Older children are more likely to have the adult-type pattern of chronic heartburn or regurgitation with reswallowing. Esophagitis in older children may present as dysphagia or food impaction. Rarely, esophageal pain causes stereotypical, repetitive stretching and arching movements that are mistaken for atypical seizures or dystonia (Sandifer syndrome) (9,10). More severe inflammation may cause chronic blood loss with anemia, hematemesis, hypoproteinemia or melena (11). If the inflammation is untreated, circumferential scarring or strictures may form. Chronic inflammation may also result in replacement of distal esophageal mucosa with a metaplastic potentially malignant specialized epithelium known as a Barrett's mucosa (12). GER is common in children with asthma, but recurrent aspiration pneumonia due to GER is uncommon except in the neurologically impaired child. Hoarseness has also been associated with GER in children.

Little is known about the prevalence or natural history of GERD in children and adolescents. Numerous disorders can present with the same symptoms and signs as GER or GERD. Diagnostic and therapeutic approaches vary with the age of the patient and the presenting sign or symptom. Although GER is a common pediatric problem, no evidence-based guidelines for its evaluation and treatment currently exist. Therefore, the GER Guideline Committee was formed by the North American Society for Pediatric Gastroenterology and Nutrition (NASPGN) to develop a clinical practice guideline for the management of GER and GERD in infants and children.

The GER Guideline Committee consists of a primary care pediatrician, two clinical epidemiologists who are also primary care pediatricians and five pediatric gastroenterologists. This clinical practice guideline is designed to assist primary care providers, pediatric gastroenterologists, pediatric surgeons, pediatric pulmonologists and pediatric otolaryngologists in the management of children with GER in both inpatient and outpatient settings. The guideline is not intended for the management of neonates less than 72 hours old, premature infants or infants and children with either neurologic impairments

or anatomic disorders of the upper gastrointestinal tract. The management of infants less than two years of age was considered separately from the management of children and adolescents two to 18 years of age. The desirable outcome of optimal management was defined as improvement or resolution of the presenting symptoms and complications of GER, with interventions that have few or no adverse effects, and with resultant resumption of functional health. Cost effectiveness was not considered because of a lack of information in pediatric patients.

This document represents the official recommendations of the North American Society for Pediatric Gastroenterology and Nutrition on the evaluation and treatment of gastroesophageal reflux in infants and children. The American Academy of Pediatrics has also endorsed these recommendations. This review and recommendations are a general guideline and are not intended as a substitute for clinical judgment or as a protocol for the management of all patients with this problem.

2. Methods

In order to develop an evidence-based guideline the following search strategy was used. Articles on diagnosis, treatment, and complications were searched separately. Articles published in English between January 1966 and March 1999 on GER in children were searched using Ovid and PubMed. Letters, abstracts, editorials, case reports, reviews, and articles related to premature infants and children with neurological impairments were excluded. The search strategies for diagnosis yielded 169 articles, 129 articles after exclusion criteria were applied, while the search strategy for treatment yielded 770 articles. After exclusion criteria were applied, there were 23 articles related to non-pharmacological treatment (positioning and dietary changes), 42 to pharmacological treatment (prokinetics and acid-suppressants) and 70 to surgical treatment (fundoplication). Searches on specific complications of GER yielded the following: 140 before and 20 after application of exclusion criteria for apnea and apparent life-threatening events; 91 before and 27 after exclusion criteria for asthma; 18 before and 9 after exclusion criteria for eosinophilic esophagitis; and 83 before and 34 after exclusion criteria for pulmonary disease. Subsequently, additional articles were identified and reviewed. When the pediatric literature was insufficient, the adult literature was also considered.

Articles were evaluated using published criteria (13,14). To evaluate inter-rater reliability, both clinical epidemiologists independently reviewed twenty-nine of the therapy articles on respiratory complications. Concordance using the criteria was 48% with all differences attributable to case series (Level IIa) and descriptive studies (Level III) evidence. If case series and large case reports were considered equivalent, the concordance was 100%. The Committee based its recommendations on integration of the literature review with expert opinion. Consensus was achieved through Nominal Group Technique, a structured, quantitative method (15). Using the methods of the Canadian Preventive Services Task Force (16), the quality of evidence of each of the recommendations made by the GER Guideline Committee was determined and is summarized in the Appendix.

In the following sections we examine the effectiveness of diagnostic tests and treatment modalities commonly utilized for the management of GERD. Subsequent sections indicate how those interventions can be applied to various clinical situations in the infant and older child.

3. Diagnostic Approaches

Although many tests have been used for the diagnosis of GER, few objective studies compare the various diagnostic approaches. More importantly, it is not known whether tests can predict when an individual patient will improve with either medical or surgical therapy for GERD. A test may be useful to document the occurrence of GER, to detect complications of GER, to establish a causal relationship between GER and symptoms, to evaluate therapy or to exclude other causes of symptoms. Since each test is designed to answer a particular question, it is valuable only when used in the appropriate clinical situation.

3.1 History and Physical Examination

A review of the medical literature found no reports comparing the history and physical examination to diagnostic tests. In two pediatric studies of persistent GER there was no relationship between symptoms and the presence of esophagitis (17,18). Nonetheless, based upon expert opinion, in most infants with vomiting and most older children with regurgitation and heartburn, a history and physical examination are sufficient to reliably diagnose GER, recognize complications, and initiate management.

3.2 Barium Contrast Radiography

The upper gastrointestinal (GI) series is useful to detect anatomic abnormalities, such as pyloric stenosis, malrotation, hiatal hernia and esophageal stricture. When compared to esophageal pH monitoring, the upper GI series is neither sensitive nor specific for the diagnosis of GER. The sensitivity, specificity and positive predictive value of the upper GI series range from 31% to 86%, 21% to 83%, and 80% to 82% respectively when compared to esophageal pH monitoring (19–24). The brief duration of the upper GI series results in false negative results, while the frequent occurrence of non-pathological reflux results in false positive results. Thus, the upper GI series is not a useful test to reliably determine the presence or absence of GER.

3.3 Esophageal pH Monitoring

Esophageal pH monitoring, used widely as an index of esophageal acid exposure, measures the frequency and duration of episodes of acid reflux (25). The test is performed by the transnasal placement of a microelectrode into the lower esophagus, which measures and records intraesophageal pH. Most clinicians utilize computerized devices that record intraesophageal pH every 4 to 8 seconds (26,27). Computerized analysis calculates the number and duration of reflux episodes (28). An episode of acid reflux is usually defined as esophageal pH <4 for a specified minimum duration, usually 15 to 30 seconds (29).

The recording device, diet, position and activity during the study affect the measurement of esophageal pH. Location of the probe sensor also affects the results; the distal esophagus is normally exposed to more acid than the proximal esophagus. There is technical and biological variability on sequential 24-hour pH monitoring studies, but this variability appears to affect the interpretation of results in only a small number of patients (30–32). Abbreviated studies of fewer than 12 hours are less reproducible than longer studies (33,34).

Asymptomatic episodes of acid reflux occur in normal infants, children, adolescents and adults. In a study of 509 normal infants, 0 to 11 months of age, there were 31 ± 21 episodes of acid reflux per day; the upper limit of normal was 73 episodes daily (2). In three studies of 48 children, 0 to 9 years of age, the mean upper limit of normal was 25 daily (29,35,36) and in 50 normal adults it was 45 daily (37). The mean upper limit of normal for the number of episodes of acid reflux lasting 5 minutes or longer was 9.7 in infants, 6.8 in children and 3.2 in adults. The percentage of the total time that the esophageal pH is <4, also called the reflux index, is considered the most valid measure of reflux because it reflects the cumulative exposure of the esophagus to acid. The mean upper limit of normal of the reflux index was 11.7% in infants 0 to 11 months (2), 5.4% in children 0 to 9 years old (29,35,36), and approximately 6% in 432 normal adults (38). These studies indicate that acid reflux is a physiologic process that is more common in normal infants in the first year of life than it is in normal older children and adults. Based on the above studies, it is recommended that the upper limit of normal of the reflux index be defined as up to 12% in the first year of life and up to 6% thereafter.

The presence of endoscopic and histopathological esophagitis is strongly associated with abnormal esophageal pH monitoring. In pediatric patients with endoscopic esophagitis (ulcerations or erosions) or biopsy proven esophagitis, approximately 95% will have an abnormal reflux index (39–41). However, not all patients with GER have esophagitis. In the selected populations of patients reported, esophagitis is present in 50% of patients with positive esophageal pH monitoring studies (39–41) and the severity of esophagitis does not correlate with the reflux index (42). Proximal esophageal and pharyngeal pH monitoring have not been proven to be more useful than lower esophageal pH monitoring alone for determining which patients are at risk for upper airway complications of GER (3,43,44).

Esophageal pH monitoring can be used to detect abnormal acid reflux in selected clinical situations. Esophageal pH monitoring can determine if a patient's symptom is temporally associated with acid reflux by calculating the symptom index. The symptom index is the ratio of the number of episodes of a symptom (e.g., heartburn) that occur concurrent with acid reflux divided by the total number of episodes of that symptom. In adults, symptom index scores ≥ 0.5 suggest a relationship between heartburn and gastroesophageal reflux; in these cases, symptoms have successfully been controlled with acid suppression therapy (45). One study using the symptom index in infants compared behavior with episodes of acid reflux (46). Esophageal pH monitoring is also useful to assess the adequacy of the dosage of acid suppression therapy in children being treated with a proton pump inhibitor (47) and may be useful to determine if a patient may be at increased risk for airway complications of GER. For example, approximately 60% of children with asthma, poorly responsive to conventional treatment, had abnormal esophageal pH monitoring studies (48–50).

Esophageal pH monitoring does not detect non-acidic reflux episodes such as occur post-prandially in infants. In some patients, esophageal pH monitoring may be within the range of normal but brief episodes of GER may cause complications such as ALTE, cough or aspiration pneumonia.

In summary, esophageal pH monitoring is a valid and reliable measure of acid reflux. Esophageal pH monitoring establishes the presence of abnormal acid reflux, to determine if there is a temporal association between acid reflux and frequently occurring symptoms, and to assess the adequacy of therapy in patients who do not respond to treatment with acid suppressants

3.4 Endoscopy and Biopsy

Endoscopy enables both visualization and biopsy of the esophageal epithelium. Endoscopy and biopsy can determine the presence and severity of esophagitis, strictures and Barrett's esophagus, as well as exclude other disorders, such as Crohn's disease, webs and eosinophilic or infectious esophagitis. A normal appearance of the esophagus during endoscopy does not exclude histopathological esophagitis. The subtle mucosal changes of erythema and pallor may be observed in the absence of esophagitis (18,42,51). Endoscopic visualization of esophageal erosions or ulceration correlates with histopathological esophagitis, but the severity of endoscopic and histopathological changes may not correlate since the lesion can be patchy and biopsies sample only a small

portion of the mucosal surface. Endoscopic grading systems for the severity of erosive esophagitis, such as the Los Angeles criteria (52), have not yet been validated in pediatric patients but may provide more uniform definitions of severity, if applied. Other findings, such as the presence of vertical lines (53) also correlate with histopathological esophagitis in children. Because there is a poor correlation between endoscopic appearance and histopathology, esophageal biopsy is recommended when diagnostic endoscopy is performed.

In normal infants and children, eosinophils and neutrophils are not present in the esophageal epithelium (40,54). Basal zone hyperplasia (>20% to 25% of total epithelial thickness) and increased papillary length (>50% to 75% of epithelial thickness) have been found to correlate with increased acid exposure (40,55). The available pediatric data suggest that intraepithelial eosinophils or neutrophils as well as morphometric measures of basal cell layer thickness and papillary height are valid indicators of reflux esophagitis. It has been proposed that a high number of eosinophils in the esophageal epithelium (>7 to 24 per high power field) suggest the diagnosis of eosinophilic esophagitis (56,57).

3.5 Scintigraphy

A nuclear scintiscan is performed by the oral ingestion or instillation of technetium-labeled formula or food into the stomach. The areas of interest, the stomach, esophagus and lungs, are scanned for evidence of GER and aspiration. Unlike esophageal pH monitoring, the nuclear scan can demonstrate reflux of non-acidic gastric contents. Scintigraphy also provides information about gastric emptying, which may be delayed in children with GERD (58–60). However, a lack of standardized techniques and the absence of age-specific normative data limit the value of this test. Episodes of aspiration may be detected during a one-hour study or on images obtained up to 24 hours after the feeding is administered (61). A negative test does not exclude the possibility of infrequently occurring aspiration (62).

The reported sensitivity and specificity of the nuclear scan for the diagnosis of GER are 15% to 59% and 83% to 100%, respectively, when compared to esophageal pH monitoring (19,63–65). This lack of correlation most likely reflects the difference in techniques of the two tests. Scintigraphy measures both acid and non-acid reflux in the initial postprandial period, whereas esophageal pH monitoring measures acid reflux for prolonged periods up to 24 hours and protocols used for analysis often exclude the postprandial recording times (64,66). The role of nuclear scintigraphy in the diagnosis and management of GERD in infants and children is unclear.

3.6 Empiric Therapy

A trial of time-limited medical therapy for GER is useful for determining if GER is causing a specific symptom. Empiric therapy is widely used (67) but has not been validated for any symptom presentation in pediatric patients. Empiric treatment trials with omeprazole have been reported for cough (68,69), heartburn (70,71), non-cardiac chest pain (72) and dyspepsia (73) in adult patients.

4. Treatment Options

Treatment options are classified as lifestyle changes and pharmacological or surgical therapies. Lifestyle changes for infants include alterations in formula composition and sleep positioning. Lifestyle changes in adolescents include dietary modifications, altered sleep position, weight reduction and smoking cessation (74). Medications buffer gastric acid, reduce gastric acid secretion or alter gastrointestinal motility. Surgical therapy includes operative techniques that reduce or eliminate GER.

4.1 Lifestyle Changes

4.1.1 Feeding Changes in Infants. In most infants, symptoms of GER do not decrease when there is a change from one milk formula to another. However, a subset of infants with vomiting has cow's milk protein allergy (75). In these infants, elimination of cow's milk protein from the diet resulted in decreased vomiting within 24 hours. Two successive, blind challenges corroborated the diagnosis of cow's milk protein allergy-induced vomiting in infants (76,77). A similar study found that IgG anti-ß-lactoglobulin, a major antigenic determinant in cow's milk, was present in infants allergic to cow's milk protein with symptom reduction following the elimination of cow's milk (78,79). There is, therefore, evidence to support a one to two week trial of a hypoallergenic formula in formula fed infants with vomiting. There are no studies that evaluate the therapeutic value of a soy-protein formula for this indication, nor are there studies that evaluate whether sensitization to soy proteins causes vomiting. Similarly, there are no studies that examine whether sensitization to maternal dietary proteins passed into human breast milk leads to vomiting in breast fed infants. The role of breast feeding versus formula feeding in the treatment of GERD is uncertain. One study (80) measured esophageal acidification in breast-fed and formula-fed healthy term neonates aged 2 to 8 days during various sleep states. During active sleep, but not other sleep states, formula fed infants had an increased number of reflux episodes and increased esophageal acid exposure compared to breast fed infants.

Milk-thickening agents do not improve reflux index scores (81,82) but do decrease the number of episodes of vomiting (81–83). In the United States of America (USA), thickening is usually achieved with the addition of rice cereal to formula (83). When thickening an infant formula with a caloric density of 20 kcal per ounce, the

addition of one tablespoonful of rice cereal per ounce of formula increases the caloric density to approximately 34 kcal per ounce, whereas the addition of one tablespoonful of rice cereal per two ounces of formula increases the caloric density to approximately 27 kcal per ounce. When formula is thickened it is necessary to cross-cut the nipple to allow for adequate flow. Thickened formula may increase coughing during feedings (84). Newer formulas that contain carob flour or locust bean gum as thickening agents are now available in Europe. These formulas have been reported to decrease vomiting and esophageal acid exposure when compared with unthickened formula (85) and formula thickened with rice cereal (86). A formula with added rice starch is now available in the USA and Canada but there are no published studies regarding its efficacy for the treatment of GERD in infants.

Infants who are underweight due to GERD may gain weight when the caloric density of their feedings is increased. Some infants require more aggressive intervention such as overnight nasogastric tube feeding to promote weight gain (87). Rarely, patients require nasojejunal tube feeding to promote growth and prevent vomiting or aspiration. Although these approaches to therapy of GERD are widely utilized, there are no controlled studies comparing these treatment approaches to pharmacological or surgical treatments.

4.1.2 Positioning Therapy for Infants. Esophageal pH monitoring has demonstrated that infants have significantly less GER when placed in the prone position than in the supine position. In a study of 79 infants and children (11.6 ± 27 months old) with symptomatic GER, the reflux index during sleep was 24% in the supine position and 8% in the prone position (88). In a study of 60 asymptomatic newborns (1 to 10 days old) kept in one position for 17 hours, the reflux index was 5% when supine and 1% when prone (89). In a randomized crossover design study of 24 infants <5 months of age, each infant was evaluated in each of four positions (prone, supine, left, right) in both horizontal and 30 degree upright positions. The reflux index was significantly higher in the supine (15%) than in the prone (7%) position (90). There is conflicting evidence whether there is less reflux in infants placed prone at a 30-degree angle compared to prone flat (88–91). The amount of reflux is similar in the supine 30-degree angle and in the supine flat positions (88,90). The prone position is superior to semi-supine positioning in an infant seat, which exacerbates GER (92).

One sudy of 60 asymptomatic newborns showed similar reflux in the left, right and supine positions, which was more reflux than in the prone position (89). In contrast, in a study of 24 infants <5 months old, the left side position was similar to the prone position and led to less reflux than the right side and supine positions (90). In adults reflux occurs less often in the left lateral decubitus (left side down) than in the right lateral decubitus (right side down) position (93,94).

Prone positioning has been recommended for the treatment and prevention of GER in infants. However, this advice conflicts with the recent recognition that prone positioning is associated with a higher rate of the sudden infant death syndrome (SIDS). The Nordic epidemiological SIDS study demonstrated that the odds ratio of SIDS mortality was 13.9 for the prone position and 3.5 for the side position when compared to the supine position (95). Another study demonstrated that the SIDS mortality per 1000 live births was 4.4 in the prone position and <0.1 for the non-prone position (96). In California the SIDS rate declined from 1.2 to 0.7 per 1000 live births after a public health campaign to promote back sleeping (97). Evidence suggests that universal use of the supine position would likely markedly reduce SIDS (98). The side position appears to be unstable, because infants turn during sleep from side to prone. Prone sleeping results in longer uninterrupted sleep periods, and supine sleeping in more arousability, frequent awakening and crying during the night.

In view of the recent evidence describing the successful prevention of SIDS with supine positioning, it is now appropriate to modify the earlier advocacy of prone positioning for GERD. In infants from birth to 12 months with GERD, the risk of SIDS generally outweighs the potential benefits of prone sleeping. Therefore, consistent with the new recommendations of the American Academy of Pediatrics, non-prone positioning during sleep is recommended (99). Supine positioning confers the lowest risk for SIDS and is preferred. Prone positioning is acceptable while the infant is awake, particularly in the postprandial period. Prone positioning during sleep is only considered in unusual cases where the risk of death from complications of GER outweighs the potential increased risk of SIDS. When prone positioning is necessary, it is particularly important that parents be advised not to use soft bedding, which increases the risk of SIDS in infants placed prone (odds ratio 1.7) (100,101).

The efficacy of positioning therapy in children older than one year has not been studied. It is likely that there is a benefit to left side positioning and elevation of the head of the bed, as in adults (102–104).

4.1.3 Lifestyle Changes in Children and Adolescents. Lifestyle changes are often recommended to adults with gastroesophageal reflux. These include dietary modification, avoidance of alcohol, weight loss, and cessation of smoking. Most of the studies investigating these factors have been performed in adults; thus, their applicability to children remains indeterminate. A review of the pediatric and adult literature may be summarized as follows. The current evidence does not support a recommendation to decrease fat intake to treat GER (105–112). However, the limited evidence available supports the recommendation that children and adolescents with GERD avoid caffeine, chocolate and spicy

foods that provoke symptoms (113–124). Similarly there is evidence that obesity, exposure to tobacco smoke and alcohol are associated with GER (125–148). It is not known whether lifestyle changes have an additive benefit in patients receiving pharmacological therapy.

4.2 Pharmacological Therapies

The purpose of the two major pharmacological treatments for GERD, acid suppressants and prokinetic agents, is to reduce the amount of acid refluxate to which the esophagus or respiratory tract is exposed, thereby preventing symptoms and promoting healing. The aim of acid suppressants is to reduce esophageal acid exposure by either neutralizing gastric acid or decreasing secretion. The aim of prokinetic agents is to reduce the amount of refluxate by improving contractility of the body of the esophagus, increasing pressure in the lower esophageal sphincter, decreasing the frequency of transient lower esophageal sphincter relaxations and accelerating gastric emptying.

Studies of pharmacological therapies for the treatment of GERD in children are difficult to compare because of heterogeneous patient populations, variable drug doses and duration of therapy, and a lack of standard outcome variables. The majority of studies published to date have used two outcome assessments: symptom responses and change in results of esophageal pH monitoring. Many studies are confounded by multiple treatments including lifestyle changes and other drugs. For purposes of this guideline, double blind single drug studies or randomized comparison studies of pharmacological therapies were reviewed. When no such studies were available, other studies were considered. Recommended drug doses and the common adverse effects of these medications are listed in Table 2.

4.2.1 Acid Suppressants. Acid suppressants act to decrease esophageal acid exposure by reducing the quantity of gastric acid. The antisecretory agents, histamine-2 receptor antagonists (H_2RAs) and proton pump inhibitors (PPIs), reduce the secretion of gastric acid, whereas antacids neutralize gastric acid. Because of their superior efficacy and convenience, antisecretory agents have largely superceded antacids and surface agents in the treatment of GERD. Generally PPIs produce a greater reduction in acid secretion and have a longer duration of action than H_2RAs.

4.2.1.1 Histamine-2 Receptor Antagonists. H_2RAs act to decrease acid secretion by inhibiting the histamine-$_2$ receptor on the gastric parietal cell. In one study in infants ranitidine treatment, 2 mg per kg per dose BID, reduced by 44% the duration that gastric pH was <4, and with TID dosing the reduction was 90% (149). Ranitidine 5 mg/kg per dose orally has been shown to increase gastric pH for 9 to 10 hours in infants (150). Tolerance to intravenous ranitidine and escape from its acid inhibitory effect within six weeks has been observed (151).

Numerous randomized controlled trials in adults have demonstrated that cimetidine, ranitidine and famotidine

TABLE 2. *Drugs demonstrated to be effective in gastroesophageal reflux disease*

Type of medication	Recommended oral dosage	Adverse effects/precautions
Histamine$_2$ receptor antagonists		
Cimetidine	40mg/kg/day divided TID or QID (adult dose: 800–1200 mg/dose BID or TID)	rash, bradycardia, dizziness, nausea, vomiting, hypotension, gynecomastia, reduces hepatic metabolism of theophylline and other medications, neutropenia, thrombocytopenia, agranulocytosis, doses should be decreased with renal insufficiency
Nizatidine	10 mg/kg/day divided BID. (adult dose: 150 mg BID or 300 mg qhs)	headaches, dizziness, constipation, diarrhea, nausea, anemia, urticaria, doses should be decreased with renal insufficiency
Ranitidine	5 to 10 mg/kg/day divided TID (Adult dose: 300mg BID)	headache, dizziness, fatigue, irritability, rash, constipation, diarrhea, thrombocytopenia, elevated transaminases, doses should be decreased with renal insufficiency
Famotidine	1 mg/kg/day divided BID (adult dose: 20 mg BID)	headaches, dizziness, constipation, diarrhea, nausea, doses should be decreased with renal insufficiency
Proton pump inhibitors		
Omeprazole	1.0 mg/kg/day divided qd or BID (adult dose 20 mg qd)	headache, diarrhea, abdominal pain, nausea, rash, constipation, vitamin B12 deficiency
Lanzoprazole	No pediatric dose available (adult dose: 15–30 mg qd)	headache, diarrhea, abdominal pain, nausea, elevated transaminase, proteinuria, angina, hypotension
Pantoprazole	No pediatric dose available. (adult dose: 40 mg qd)	headache, diarrhea, abdominal pain, nausea
Rabeprazole	No pediatric dose available (adult dose: 20 mg qd)	headache, diarrhea, abdominal pain, nausea
Prokinetic
